One theory suggests that labor is initiated by a change in the estrogen-to-progesterone ratio. During the last trimester of pregnancy, estrogen levels increase and progesterone levels decrease. This change leads to an increase in the number of myometrium gap junctions. Gap junctions are proteins that connect cell membranes and facilitate coordination of uterine contractions and myometrial stretching (Norwitz et al., 2019).

Although physiologic evidence for the role of oxytocin in the initiation of labor is inconclusive, the number of oxytocin receptors in the uterus increases at the end of pregnancy. This creates an increased sensitivity to oxytocin. Estrogen, the levels of which are also rising, increases myometrial sensitivity to oxytocin. With the increasing levels of oxytocin in the maternal blood in conjunction with increasing fetal cortisol levels that synthesize prostaglandins, uterine contractions are initiated. Oxytocin also aids in stimulating prostaglandin synthesis through receptors in the decidua. Prostaglandins lead to additional contractions, cervical softening, gap junction induction, and myometrial sensitization, thereby leading to a progressive cervical **dilation** (the opening or enlargement of the external cervical os). Uterine contractions have two main functions: to dilate the cervix and to push the fetus through the birth canal (Blackburn, 2018).

PREMONITORY SIGNS OF LABOR

Before the onset of labor, a pregnant woman's body undergoes several changes in preparation for the birth of the newborn. The changes that occur often lead to characteristic signs and symptoms that suggest that labor is near. These premonitory signs and symptoms can vary, and not every woman experiences every one of them.

Cervical Changes

The rigid cervix of pregnancy must become distensible to expel the fetus. Before labor begins, cervical softening and possible cervical dilation with descent of the presenting part into the pelvis occur. These changes can occur 1 month to 1 hour before actual labor begins.

As labor approaches, the cervix changes from an elongated structure to a shortened, thinned segment. Cervical collagen fibers undergo enzymatic rearrangement into smaller, more flexible fibers that facilitate water absorption, leading to a softer, more stretchable cervix. These changes occur secondary to the effects of prostaglandins and pressure from Braxton Hicks contractions. The ripening and softening of the cervix are essential for effacement and dilation, which reflect the enhanced collagen breakdown that was previously inhibited by progesterone (Blackburn, 2018).

Lightening

Lightening occurs when the fetal presenting part begins to descend into the true pelvis. The uterus lowers and moves into a more anterior position. The shape of the abdomen changes as a result of the change in the uterus. With this descent, the woman usually notes that her breathing is much easier and that there is a decrease in gastric reflux. However, she may complain of increased pelvic pressure, leg cramping, dependent edema in the lower legs, and low back discomfort. She may notice an increase in vaginal discharge and more frequent urination. In primiparas, lightening can occur 2 weeks or more before labor begins; among multiparas, it may not occur until labor starts (King et al., 2019).

Increased Energy Level

Some women report a sudden increase in energy before labor. This is sometimes referred to as nesting, because many women will focus this energy toward childbirth preparation by cleaning, cooking,

preparing the nursery, and spending extra time with other children in the household. The increased energy level usually occurs 24 to 48 hours before the onset of labor. It is thought to be the result of an increase in epinephrine release caused by a decrease in progesterone (Jordan et al., 2019).

Bloody Show

At the onset of labor or before, the mucus plug that fills the cervical canal during pregnancy is expelled as a result of cervical softening and increased pressure of the presenting part. These ruptured cervical capillaries release a small amount of blood that mixes with mucus, resulting in the pink-tinged secretions known as bloody show.

Braxton Hicks Contractions

Braxton Hicks contractions, which the woman may have been experiencing throughout the pregnancy, may become stronger and more frequent. Braxton Hicks contractions are typically felt as a tightening or pulling sensation of the top of the uterus. They occur primarily in the abdomen and groin and gradually spread downward before relaxing. In contrast, true labor contractions are more commonly felt in the lower back. These contractions aid in moving the cervix from a posterior position to an anterior position. They also help in ripening and softening the cervix. However, the contractions are irregular and can be decreased by walking, voiding, eating, increasing fluid intake, or changing position.

Braxton Hicks contractions usually last about 30 seconds but can persist for as long as 2 minutes. As birth draws near and the uterus becomes more sensitive to oxytocin, the frequency and intensity of these contractions increase. However, if the contractions last longer than 30 seconds and occur more often than four to six times an hour, advise the woman to contact her health care provider so that she can be evaluated for possible preterm labor, especially if she is less than 38 weeks pregnant.

TAKE NOTE!

An infant born between 34 0/7 and 36 6/7 weeks' gestation is identified as "late preterm" and experiences many of the same health issues as other preterm birth infants (Martin & Rosenfeld, 2019).

Spontaneous Rupture of Membranes

Rupture of membranes with loss of amniotic fluid prior to the onset of labor is termed prelabor rupture of membranes (PROM). It occurs in 8% to 10% of women with term pregnancies, the majority of whom will begin labor spontaneously within 24 hours (King et al., 2019). The rupture of membranes can result in either a sudden gush or a steady leakage of amniotic fluid. Although much of the amniotic fluid is lost when the rupture occurs, a continuous supply is produced to ensure protection of the fetus until birth.

After the amniotic sac has ruptured, the barrier to infection is gone and an ascending infection is possible. In addition, there is a danger of cord prolapse if engagement has not occurred with the sudden release of fluid and pressure with rupture. Due to the possibility of these complications, advise women to notify their health care providers and go in for an evaluation.

CONSIDER THIS

I always pictured myself a dignified woman and behaved in ways to demonstrate that, because this was the way I was raised. My mother and grandmother always stressed that you should look polished, dress well, and do nothing to embarrass yourself in public. I did a fairly good job of living up to their expectations until an incident occurred at the end of my first pregnancy. I recall I was overdue according to my dates and was miserable in the summer heat. I decided to go to the store for some ice cream. As I waddled down the grocery aisles, all of a sudden my water broke and came pouring down my legs all over the floor. Not wanting to make a spectacle of myself and remembering what my mother always said about being dignified at all times in public, I quickly reached up onto the grocery shelf and "accidentally" knocked off a large jar of pickles right where my puddle was. As I walked hurriedly away from that mess without my ice cream, I heard on the store loudspeaker, "Cleanup on Aisle 13!"

Thoughts: We tend to live by what we are taught, and in this case, this woman felt the need to save face from her ruptured membranes. Many women experience ruptured membranes before the onset of labor, so it is not out of the ordinary for this to happen in public. What risks can occur when membranes do rupture? What action should this woman take now to minimize these risks? How can the nurse validate this woman's feelings?

TRUE VERSUS FALSE LABOR

Not all contractions indicate labor. False labor is a condition occurring during the latter weeks of some pregnancies when irregular uterine contractions are felt, but the cervix is not affected. In contrast, true labor is characterized by contractions occurring at regular intervals that increase in frequency, duration, and intensity. True labor contractions bring about progressive cervical dilation and effacement. Table 13.1 summarizes the differences between true and false labor. False labor, prodromal labor, and Braxton Hicks

contractions are all names for contractions that do not contribute in a measurable way toward the goal of birth. Distinguishing between true and false labor is an essential nursing assessment skill and one that develops with experience.

Many women fear being sent home from the hospital with false labor. All women feel anxious when they feel contractions, but they should be informed that labor could be a long process, especially if it is the first pregnancy. Encourage the woman to think of false labor or prelabor signs as positive, because they are part of the entire labor continuum. Describe her early contractions as a phase of preparatory activity by her body in advance of active labor. With first pregnancies, the cervix can take up to 20 hours to dilate completely (Cunningham et al., 2018).

TABLE 13.1 Differences Between True and False Labor

Parameters	True Labor	False Labor
Contraction timing	Regular, becoming closer together, usually 4–6 minutes apart, lasting 30–60 seconds	Irregular, not occurring close together
Contraction strength	Become stronger with time, vaginal pressure is usually felt	Frequently weak, not getting stronger with time or alternating (a strong one followed by weaker ones)
Contraction discomfort	Starts in the back and radiates around toward the front of the abdomen	Usually felt in the front of the abdomen
Any change in activity	Contractions continue no matter what positional change is made.	Contractions may stop or slow down with walking or making a position change.
Stay or go?	Stay home until contractions are 5 minutes apart, last 45–60 seconds, and are strong enough so that a conversation during one is not possible—then go to the hospital or birthing center.	Drink fluids and walk around to see if there is any change in the intensity of the contractions; if the contractions diminish in intensity after either or both, stay home.

Remember Kathy and Chuck, the anxious couple who came to the hospital too early? Kathy felt sure she was in labor and is now confused. What explanations and anticipatory guidance should be offered to this couple? What term describes her contractions?

FACTORS AFFECTING THE LABOR PROCESS

Traditionally, the critical factors that affect the process of labor and birth are outlined as the “five Ps:”

1. Passageway (birth canal)
2. Passenger (fetus and placenta)
3. Powers (contractions)
4. Position (maternal)
5. Psychological response

These critical factors are commonly accepted and discussed by health care providers. However, five additional “P’s” can also affect the labor process:

1. Philosophy (low-tech, high-touch)
2. Partners (support caregivers)
3. Patience (natural timing)
4. Patient (client) preparation (childbirth knowledge base)
5. Pain management (comfort measures)

These five additional Ps are helpful in planning care for the laboring family. These client-focused factors are an attempt to foster labor that can be managed through the use of high touch, patience, support, knowledge, and pain management.

Passageway

The birth passageway is the route through which the fetus must travel to be born vaginally. Compared to other primates, childbirth is remarkably difficult in humans because the head of the neonate is large relative to the birth-relevant dimensions of the maternal pelvis. The passageway consists of the maternal pelvis and soft tissues. Of the two, however, the maternal bony pelvis is more important because it is relatively unyielding (except for the coccyx). Typically, the pelvis is assessed and measured during the first trimester, often at the first visit to the health care provider, to identify any abnormalities that might hinder a successful vaginal birth. As the pregnancy progresses, the hormones relaxin and estrogen cause the

connective tissues to become more relaxed and elastic and cause the joints to become more flexible to prepare the mother's pelvis for birth. Additionally, the soft tissues usually yield to the forces of labor.

Bony Pelvis

The maternal bony pelvis can be divided into the true and false portions. The false (or greater) pelvis is composed of the upper flared parts of the two iliac bones with their concavities and the wings of the base of the sacrum. The false pelvis is divided from the true pelvis by an imaginary line drawn from the sacral prominence at the back to the superior aspect of the symphysis pubis at the front of the pelvis. This imaginary line is called the linea terminalis. The false pelvis lies above this imaginary line; the true pelvis lies below it (Fig. 13.1). The true pelvis is the bony passageway through which the fetus must travel. It is made up of three planes: the inlet, the mid-pelvis (cavity), and the outlet.

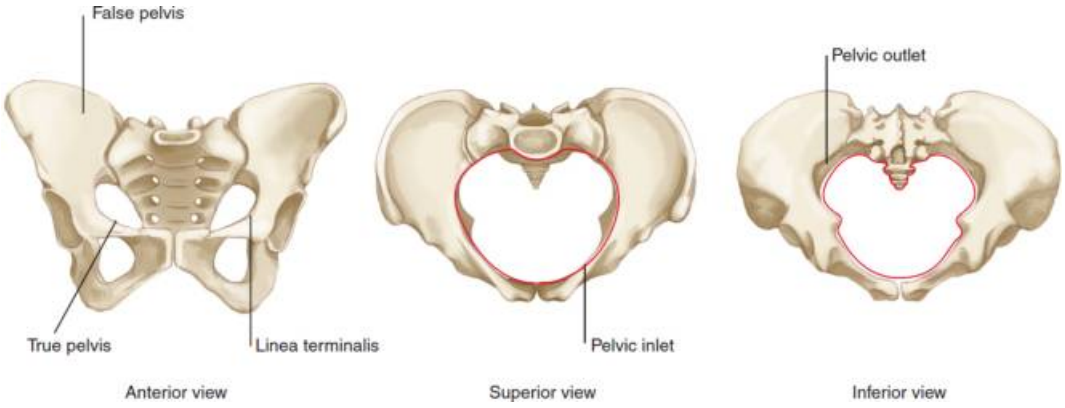

FIGURE 13.1. The bony pelvis.

PELVIC INLET

The pelvic inlet, or upper pelvic narrow, is the entrance toward the birth canal. It allows entrance to the true pelvis. It is bounded by the sacral prominence in the back, the ilium on the sides, and the superior aspect of the symphysis pubis in the front (Decherney et al., 2019). The pelvic inlet is wider in the transverse aspect (sideways) than it is from front to back.

MID-PELVIS

The mid-pelvis (cavity) occupies the space between the inlet and outlet. It is through this snug, curved space that the fetus must travel to reach the outside. As the fetus passes through this small area, their chest is compressed, causing lung fluid and mucus to be expelled. This expulsion removes the space-occupying fluid so that air can enter the lungs with the newborn's first breath.

PELVIC OUTLET

The pelvic outlet is bound by the ischial tuberosities, the lower rim of the symphysis pubis, and the tip of the coccyx. In comparison with the pelvic inlet, the outlet is wider from front to back. For the fetus to pass through the pelvis, the outlet must be large enough. To ensure the adequacy of the pelvic outlet for vaginal birth, the following pelvic measurements are assessed:

- Diagonal conjugate of the inlet (distance between the anterior surface of the sacral prominence and the anterior surface of the inferior margin of the symphysis pubis).
- Transverse or ischial tuberosity diameter of the outlet (distance at the medial and lowest aspect of the ischial tuberosities, at the level of the anus; a known hand span or clenched-fist measurement is generally used to obtain this measurement).
- True or obstetric conjugate (distance estimated from the measurement of the diagonal conjugate; 1.5 cm is subtracted from the diagonal conjugate measurement).

For more information about pelvic measurements, see Chapter 12.

If the diagonal conjugate measures at least 11.5 cm and the true or obstetric conjugate measures 10 cm or more (1.5 cm less than the diagonal conjugate, or about 10 cm), then the pelvis is large enough for a vaginal birth of what would be considered a normal-sized newborn.

Pelvic Shape

In addition to size, the shape of a woman's pelvis is a determining factor for a vaginal birth. Each plane of the pelvis has a shape, which is defined by the anterior–posterior and transverse diameters. The pelvis is divided into four main shapes: gynecoid, anthropoid, android, and platypelloid (Fig. 13.2).

GYNECOID PELVIS

The gynecoid pelvis is considered the true female pelvis, occurring in about 40% of all women; it is less common in men (Webster et al., 2018). Vaginal birth is most favorable with this type of pelvis because the inlet is round and the outlet is roomy. This shape offers the optimal diameters in all three planes of the pelvis. This type of pelvis allows early and complete fetal internal rotation during labor.

ANTHROPOID PELVIS

The anthropoid pelvis is common in men and is most common in non-White women. It occurs in approximately 25% of women (Deering, 2018). The pelvic inlet is oval and the sacrum is long, producing a deep pelvis (wider front to back [anterior to posterior] than side to side [transverse]). Vaginal birth is more favorable with this pelvic shape compared to the android or platypelloid shape (Jordan et al., 2019).

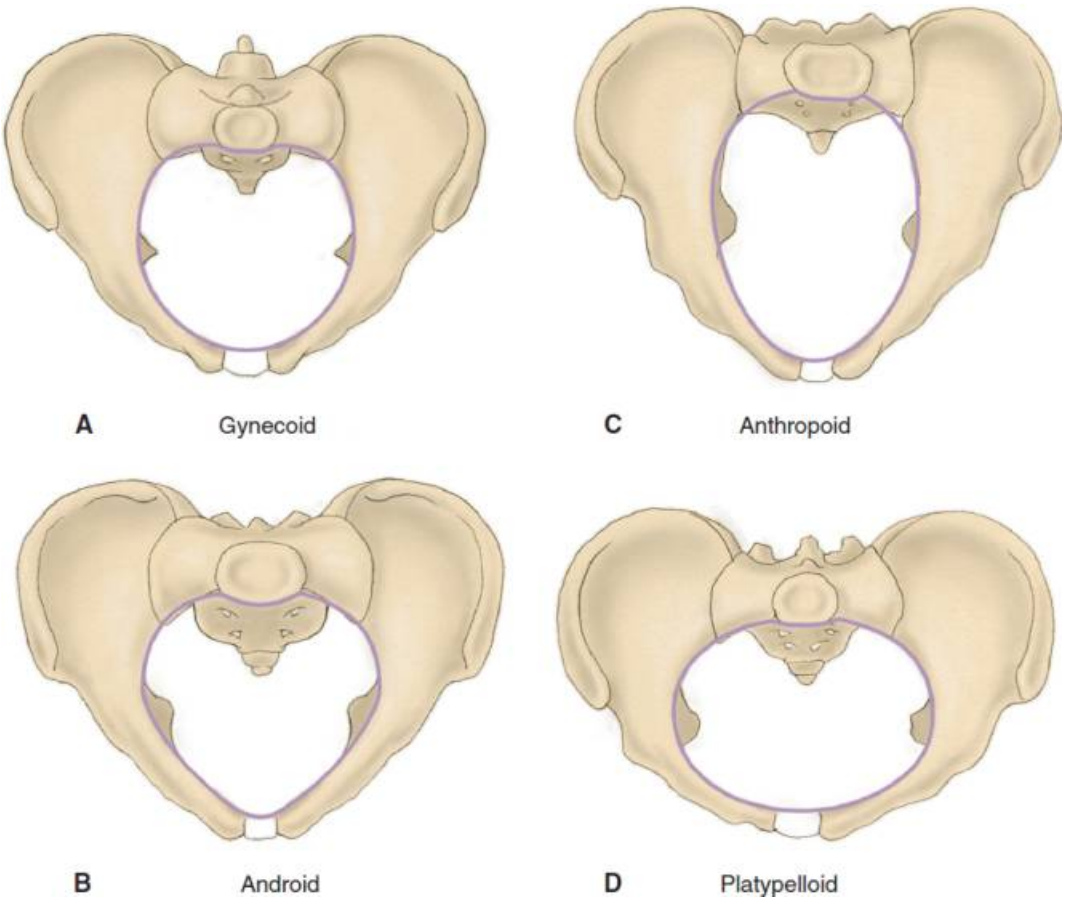

FIGURE 13.2. Pelvic shapes. **A.** Gynecoid. **B.** Android. **C.** Anthropoid. **D.** Platypelloid.

ANDROID PELVIS

The android pelvis is considered the male-shaped pelvis and is characterized by a funnel shape. It occurs in approximately 20% of women (Cunningham et al., 2018). The pelvic inlet is heart shaped and the posterior segments are reduced in all pelvic planes. Descent of the fetal head into the pelvis is slow, and failure of the fetus to rotate is common. The prognosis for labor is poor, subsequently leading to cesarean birth.

PLATYPELLOID (FLAT) PELVIS

The platypelloid or flat pelvis is the least common type of pelvic structure among men and women with an approximate incidence of 3% (King et al., 2019). The pelvic cavity is shallow but widens at the

pelvic outlet, making it difficult for the fetus to descend through the mid-pelvis. Labor prognosis is poor with arrest at the inlet occurring frequently. It is not favorable for a vaginal birth unless the fetal head can pass through the inlet. Women with this type of pelvis usually require cesarean birth.

An important principle is that most pelvises are not purely defined but occur in nature as mixed types. Many women have a combination of these four basic pelvis types, with no two pelvises shaped exactly the same. Regardless of the shape, the newborn can be born vaginally if size and positioning remain compatible. The narrowest part of the fetus attempts to align itself with the narrowest pelvic dimension (e.g., biparietal to interspinous diameters, which means the fetus generally tends to rotate to the most ample portion of the pelvis).

Soft Tissues

The soft tissues of the passageway consist of the cervix, the pelvic floor muscles, and the vagina. Through **effacement**, the cervix effaces (thins) to allow the presenting fetal part to descend into the vagina.

> *TAKE NOTE!*
>
> The process of cervical effacement and dilation is analogous to that of pulling a turtleneck sweater over your head.

The pelvic floor muscles help the fetus rotate anteriorly as it passes through the birth canal. The soft tissues of the vagina expand to accommodate the fetus during birth.

Passenger

The fetus (with placenta) is the passenger. The fetal head (size and presence of molding); fetal attitude (degree of body flexion); fetal lie (relationship of body parts); fetal presentation (first body part); fetal

position (relationship to maternal pelvis); fetal station; and fetal engagement are all important factors that have an impact on the ultimate outcome in the birthing process.

Fetal Head

The fetal head is the largest fetal structure, making it an important factor in labor and birth. There is considerable variation in the size and diameter of the fetal skull.

Compared with an adult's head, the fetal head is large in proportion to the rest of the body, usually about one third of the body length, compared to the adult ratio of one seventh (Hill, 2019). The bones that make up the face and cranial base are fused and essentially fixed. However, the five bones that make up the rest of the cranium (two frontal bones, two parietal bones, and the occipital bone) are not fused; rather, they are soft and pliable, with gaps between the plates of bone. These gaps, membranous spaces between the cranial bones, are called sutures, and the intersections of these sutures are called fontanelles. Sutures are important because they allow the cranial bones to overlap in order for the head to adjust in shape (elongate) when pressure is exerted on it by uterine contractions or the maternal bony pelvis. Some diameters shorten, while others lengthen as the head is molded during the labor and birthing process. This malleability of the fetal skull may decrease fetal skull dimensions by 0.5 to 1 cm (King et al., 2019). After birth, the sutures close as the bones grow and the brain reaches its full growth.

A newborn may occasionally endure minor physical injury during the childbirth process involving structural or tissue impairment. Most are temporary and self-limiting with full recovery. The changed (elongated) shape of the fetal skull at birth as a result of overlapping of the cranial bones is known as **molding**. Along with molding, fluid can also collect in the scalp (caput succedaneum) or blood can collect beneath the scalp (cephalohematoma), further distorting the shape and appearance of the fetal head. Caput succedaneum can be described as edema of the scalp at the presenting part. This

swelling crosses suture lines and disappears within 3 to 4 days. Cephalohematoma is a collection of blood between the periosteum and the bone that occurs several hours after birth. It does not cross suture lines and is generally reabsorbed over the next 6 to 8 weeks (Martin & Rosenfeld, 2019).

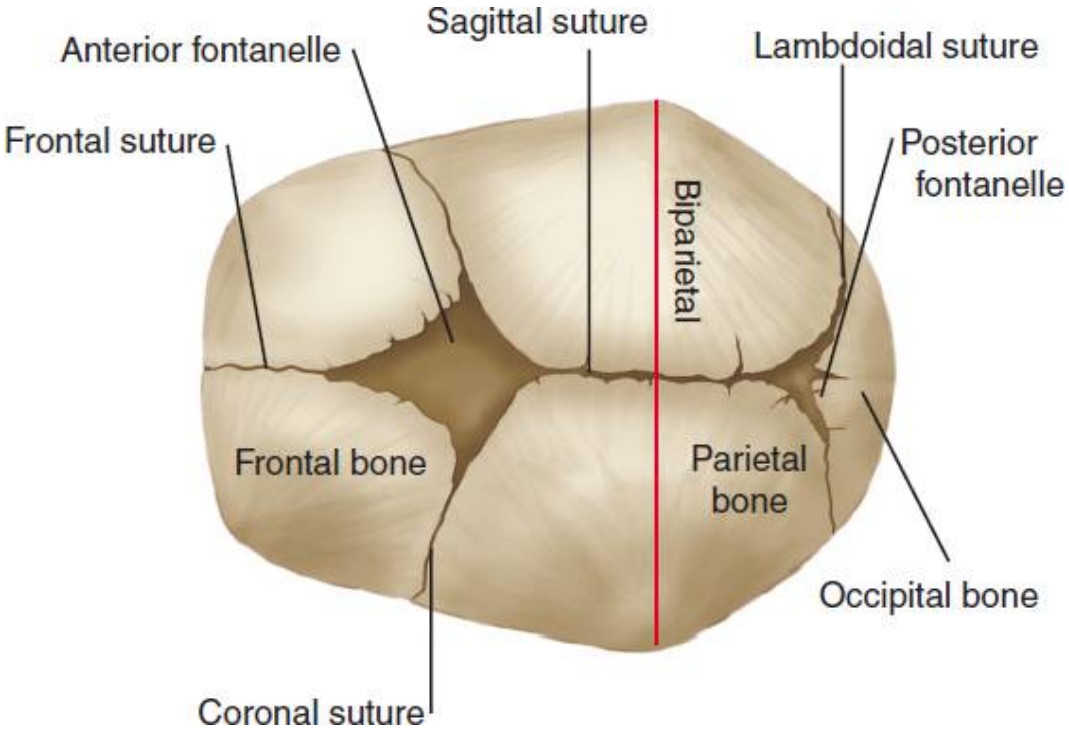

FIGURE 13.3. Fetal skull.

TAKE NOTE!

Parents may become concerned about the distortion of the newborn's head. However, reassurance that the oblong shape is only temporary is usually all that is needed to reduce their anxiety.

Sutures also play a role in helping to identify the position of the fetal head during a vaginal examination. Figure 13.3 shows a fetal skull. During a pelvic examination, palpation of these sutures by the examiner reveals the position of the fetal head and the degree of rotation that has occurred.

The anterior and posterior fontanelles are also useful in helping to identify the position of the fetal head. They allow for molding, and are important when evaluating the newborn. The anterior fontanelle is the famous “soft spot” of the newborn’s head. It is a diamond-shaped space that measures from 1 to 4 cm. It remains open for 12 to 18 months after birth to allow for growth of the brain (Webster et al., 2018). The posterior fontanelle corresponds to the anterior one but is located at the back of the fetal head; it is triangular. This one closes within 8 to 12 weeks after birth and on average, measures 1 to 2 cm at its widest diameter (Jarvis, 2020).

The diameter of the fetal skull is an important consideration during the labor and birth process. Fetal skull diameters are measured between the various landmarks of the skull. Diameters include occipitofrontal, occipitomental, suboccipitobregmatic, and biparietal (Fig. 13.4). The two most important diameters that can affect the birth process are the suboccipitobregmatic (approximately 9.5 cm at term) and the biparietal (approximately 9.25 cm at term) diameters. The suboccipitobregmatic diameter, measured from the base of the occiput to the center of the anterior fontanelle, identifies the smallest anteroposterior diameter of the fetal skull. The biparietal diameter measures the largest transverse diameter of the fetal skull—the distance between the two parietal bones. In a cephalic (head-first) presentation, which occurs in 95% of all term births, if the fetus presents in a flexed position in which the chin is resting on the chest, the optimal or smallest fetal skull dimensions for a vaginal birth are present. If the fetal head is not fully flexed at birth, the anteroposterior diameter increases. This increase in dimension might prevent the fetal skull from entering the maternal pelvis.

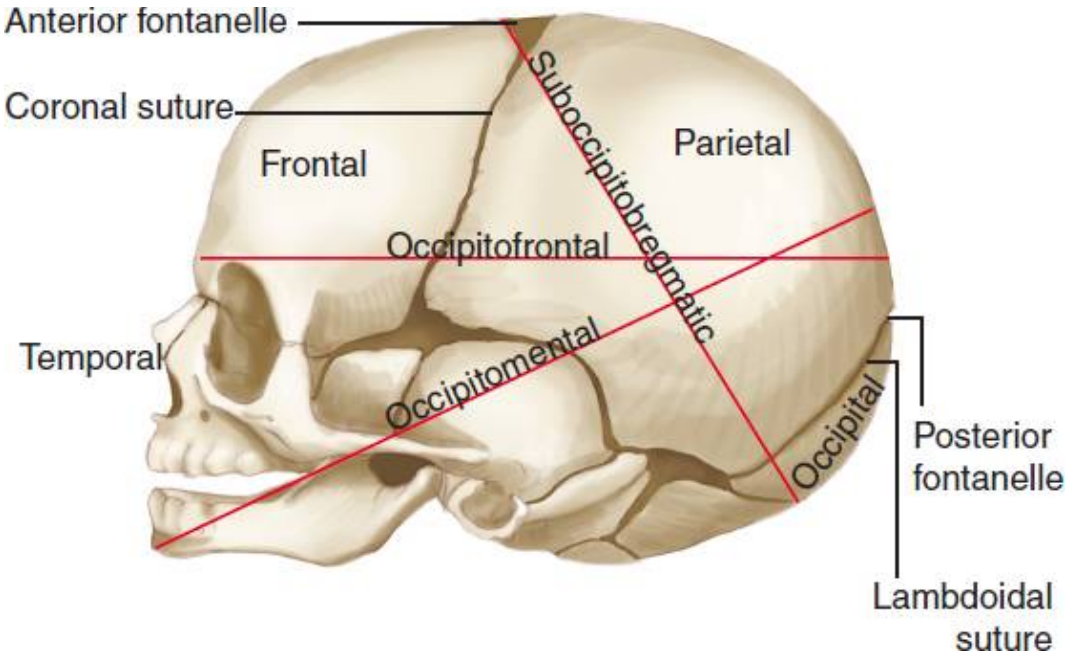

FIGURE 13.4. Fetal skull diameters.

Fetal Attitude

Fetal attitude is another important consideration related to the passenger. Fetal **attitude** refers to the posturing (flexion or extension) of the joints and the relationship of fetal parts to one another. The most common fetal attitude when labor begins is with all joints flexed—the fetal back is rounded, the chin is on the chest, the thighs are flexed on the abdomen, and the legs are flexed at the knees (Fig. 13.5). This normal fetal position is most favorable for vaginal birth, presenting the smallest fetal skull diameters to the pelvis.

When the fetus presents to the pelvis with abnormal attitudes (no flexion or extension), the nonflexed position can increase the diameter of the presenting part as it passes through the pelvis, increasing the difficulty of birth. An attitude of extension tends to present larger fetal skull diameters, which may make birth difficult.

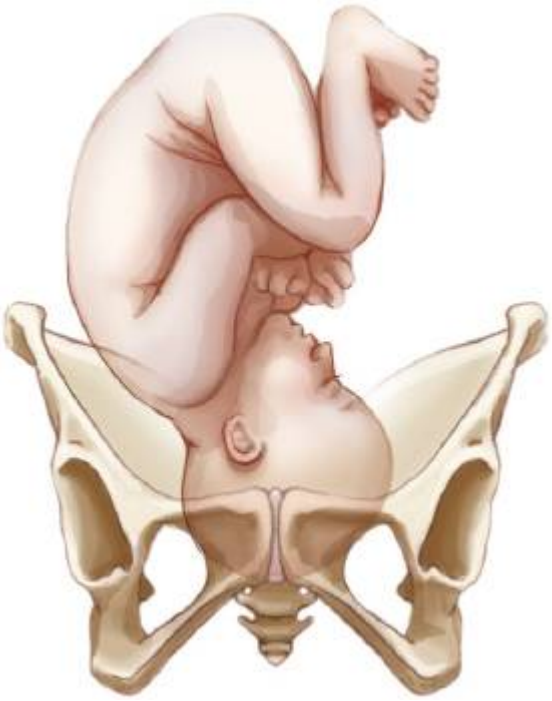

FIGURE 13.5. Fetal attitude: full flexion. Note that the smallest diameter presents to the pelvis.

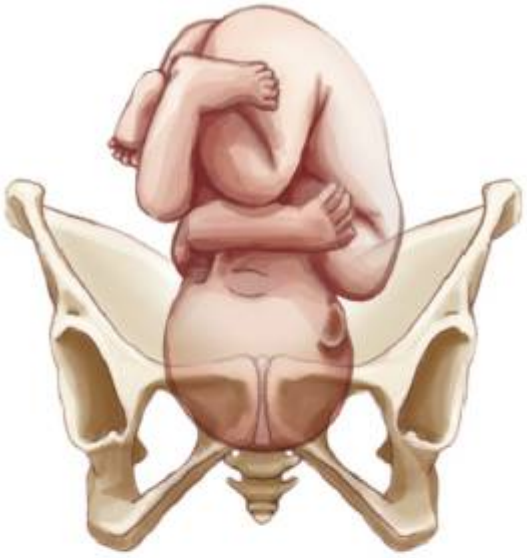
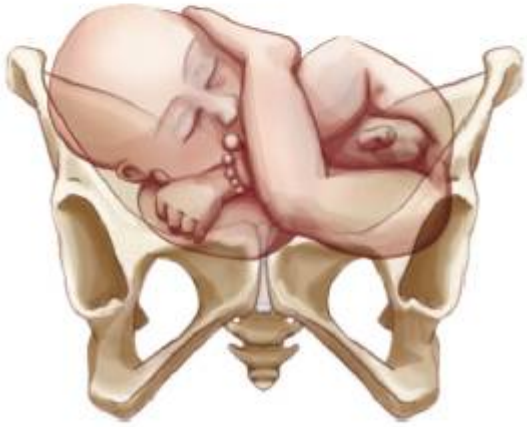


A. Longitudinal lie



B. Transverse lie

FIGURE 13.6. Fetal lie. **A.** Fetal long axis (spine) runs parallel to the mother's spine. **B.** Fetal long axis (spine) runs transverse or perpendicular to that of the mother's spine.

Fetal Lie

Fetal **lie** refers to the relationship of the long axis (spine) of the fetus to the long axis (spine) of the mother. There are three possible lies: longitudinal (the most common), transverse (Fig. 13.6), and oblique.

A longitudinal lie occurs when the long axis of the fetus is parallel to that of the mother (fetal spine to maternal spine side-by-side). A transverse lie occurs when the long axis of the fetus is perpendicular to the long axis of the mother (fetal spine lies across the maternal abdomen and crosses her spine). In an oblique lie, the fetal long axis is at an angle to the bony inlet, and no palpable fetal part is presenting. This lie is usually transitory and occurs during fetal conversion between other lies. A fetus in a transverse or oblique lie position cannot be delivered vaginally (Cunningham et al., 2018).

Fetal Presentation

Fetal **presentation** refers to the body part of the fetus that enters the pelvic inlet first (the "presenting part"). This is the fetal part that lies over the inlet of the pelvis or the cervical os. Knowing which fetal part is coming first at birth is critical for planning and initiating appropriate interventions.

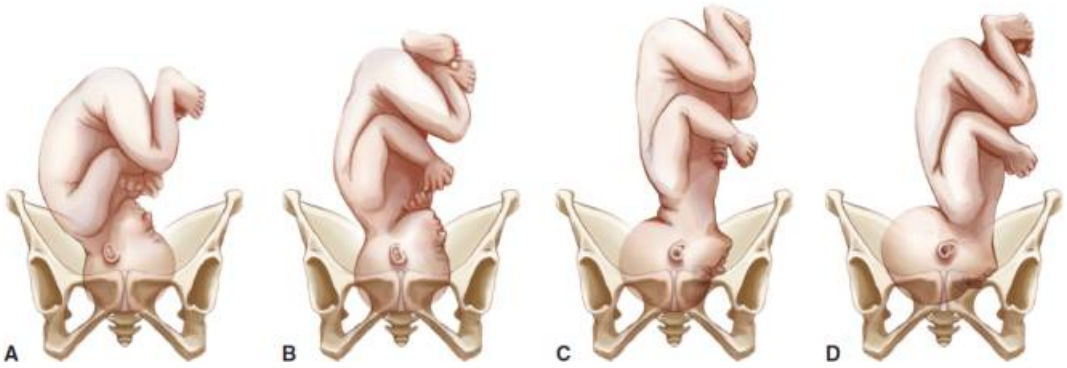


FIGURE 13.7. Fetal presentation: cephalic presentations. **A.** Vertex. **B.** Military. **C.** Brow. **D.** Face.

The three main fetal presentations are cephalic (head first), breech (pelvis first), and shoulder (scapula first). The majority of term newborns (95%) are born in a cephalic presentation; breech presentations account for 3% of term births and shoulder presentations for approximately 2% (Norwitz et al., 2019).

In a cephalic presentation, the presenting part is usually the occipital portion of the fetal head (Fig. 13.7). This presentation is

also referred to as a vertex presentation. Variations in a vertex presentation include the military, brow, and facial presentations.

BREECH PRESENTATION

In early pregnancy, fetuses have a variable lie within the uterus. As the pregnancy approaches the final weeks, the majority of singleton pregnancies have a longitudinal lie and the fetus enters the pelvis in a cephalic presentation. By term, approximately 97% of infants actively turn to a cephalic presentation. It can be determined by abdominal palpation (Cunningham et al., 2018). Breech presentation occurs when the fetal buttocks or feet enter the maternal pelvis first and the fetal skull enters last. This abnormal presentation poses several challenges at birth. Primarily, the largest part of the fetus (skull) is born last and may become stuck in the pelvis. In addition, the umbilical cord can become compressed between the fetal skull and the maternal pelvis after the fetal chest is born because the head is the last to exit. Moreover, unlike the hard fetal skull, the buttocks are soft and are not as effective as a cervical dilator during labor compared with a cephalic presentation. Finally, there is the possibility of trauma to the head as a result of the lack of opportunity for molding.

The types of breech presentations are determined by the positioning of the fetal legs (Fig. 13.8). In a frank breech (50% to 70%), the buttocks present first with both legs extended up toward the face. In a full or complete breech (5% to 10%), the fetus sits cross-legged above the cervix. In a footling or incomplete breech (10% to 30%), one or both legs are presenting. Breech presentations are associated with prematurity, placenta previa, multiparity, uterine abnormalities (fibroids), and some congenital anomalies such as hydrocephaly (Martin & Rosenfeld, 2019). A frank breech can result in a vaginal birth, but complete, footling, and incomplete breech presentations generally necessitate a cesarean birth.

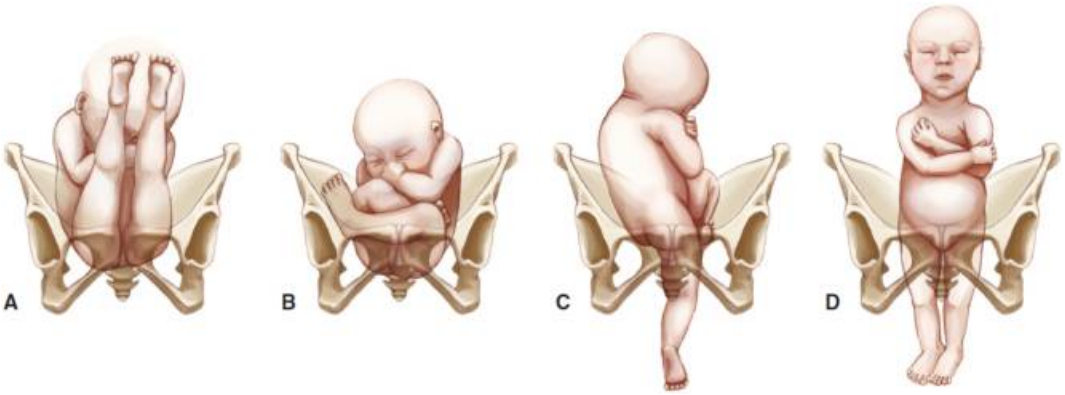

FIGURE 13.8. Breech presentations. **A.** Frank breech. **B.** Complete breech. **C.** Single footling breech. **D.** Double footling breech.

SHOULDER PRESENTATION

A shoulder presentation or shoulder dystocia occurs when the fetal shoulders present first with the head tucked inside. Clinically, signs of shoulder dystocia appear while the woman is pushing as the neonate's head slowly extends and emerges over the perineum but then retracts back into the vagina, commonly referred to as the "turtle sign." Odds of a shoulder presentation are one in 300 births (Cunningham et al., 2018). The fetus is in a transverse lie with the shoulder as the presenting part. Conditions associated with shoulder dystocia include placenta previa, prematurity, high parity, premature rupture of membranes, multiple gestation, or fetal anomalies. A cesarean birth is usually necessary if identified before labor begins but will be evaluated based on the length of gestation, the size of the fetus, the position of the placenta, and whether the membranes have ruptured (Vlasyuk, 2019).

Fetal Position

Fetal **position** describes the relationship of a given point on the presenting part of the fetus to a designated point of the maternal pelvis (King et al., 2019). The landmark fetal presenting parts include the occipital bone (O), which designates a vertex presentation; the chin (mentum [M]), which designates a face presentation; the buttocks (sacrum [S]), which designate a breech presentation; and

the scapula (acromion process [A]), which designates a shoulder presentation.

In addition, the maternal pelvis is divided into four quadrants: right anterior, left anterior, right posterior, and left posterior. These quadrants designate whether the presenting part is directed toward the front, back, left, or right side of the pelvis. Fetal position is determined first by identifying the presenting part and then the maternal quadrant the presenting part is facing (Fig. 13.9). Position is indicated by a three-letter abbreviation as follows:

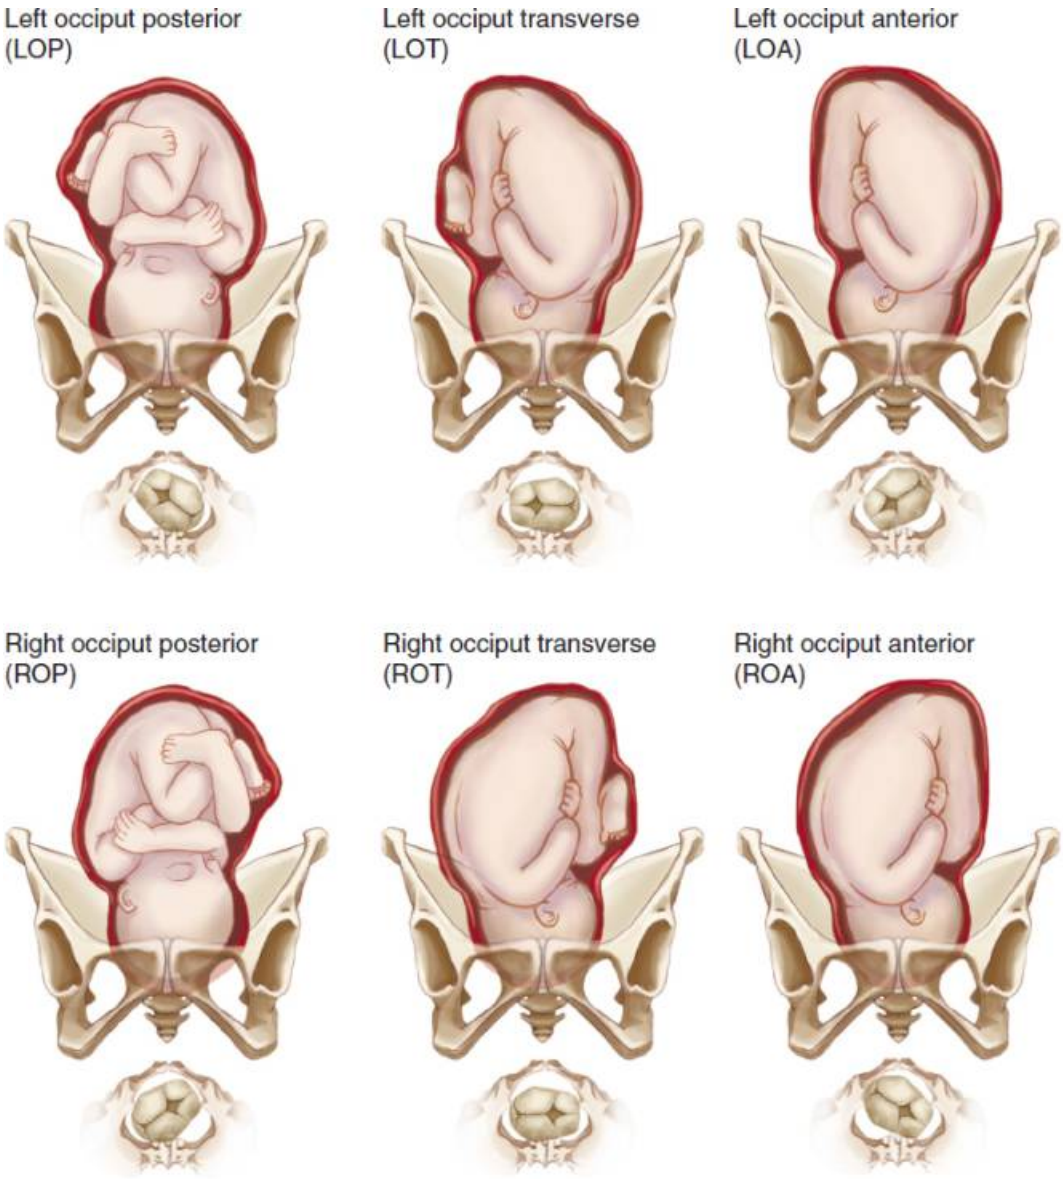

FIGURE 13.9. Examples of fetal positions in a vertex presentation. The lie is longitudinal for each illustration. The attitude is one of flexion. Notice that the view of the top illustration is seen when facing the pregnant woman. The bottom view is that seen with the woman in a dorsal recumbent position.

- The first letter defines whether the presenting part is tilted toward the left (L) or the right (R) side of the maternal pelvis.
- The second letter represents the particular presenting part of the fetus: O for occiput, S for sacrum, M for mentum, A for acromion process, and D for dorsal (refers to the fetal back) when denoting the fetal position in shoulder presentations (King et al., 2019).

- The third letter defines the location of the presenting part in relation to the anterior (A) portion of the maternal pelvis or the posterior (P) portion of the maternal pelvis. If the presenting part is directed to the side of the maternal pelvis, the fetal presentation is designated as transverse (T).

For example, if the occiput is facing the left anterior quadrant of the pelvis, then the position is termed left occiput anterior and is recorded as LOA.

TAKE NOTE!

LOA is currently the most common (and most favorable) fetal position for birthing, followed by right occiput anterior (ROA). The positioning of the fetus allows the fetal head to contour to the diameters of the maternal pelvis. LOA and ROA are optimal positions for vaginal birth.

An occiput posterior position may lead to a long and difficult birth, and other positions may or may not be compatible with vaginal birth.

Fetal Station

Fetal **station** refers to the relationship of the presenting part to the level of the maternal pelvic ischial spines. Fetal station is measured in centimeters and is referred to as a minus or plus, depending on its location above or below the ischial spines. Typically, the ischial spines are the narrowest part of the pelvis and are the natural measuring point for the birth progress.

Zero (0) station is designated when the presenting part is at the level of the maternal ischial spines. When the presenting part is above the ischial spines, the distance is recorded as minus stations. When the presenting part is below the ischial spines, the distance is recorded as plus stations. For instance, if the presenting part is above the ischial spines by 1 cm, it is documented as being a −1 station; if the presenting part is below the ischial spines by 1 cm, it is documented as being a +1 station.

An easy way to understand this concept is to think in terms of meeting the goal, which is birth. If the fetus is descending downward (past the ischial spines) and moving toward meeting the goal of birth, then the station is positive and the centimeter numbers grow bigger from +1 to +4. If the fetus is not descending past the ischial spines, then the station is negative and the centimeter numbers grow from −1 to −4. The farther away the presenting part from the outside, the larger the negative number (−4 cm). The closer the presenting part of the fetus is to the outside, the larger the positive number (+4 cm). Figure 13.10 shows stations of the presenting part.

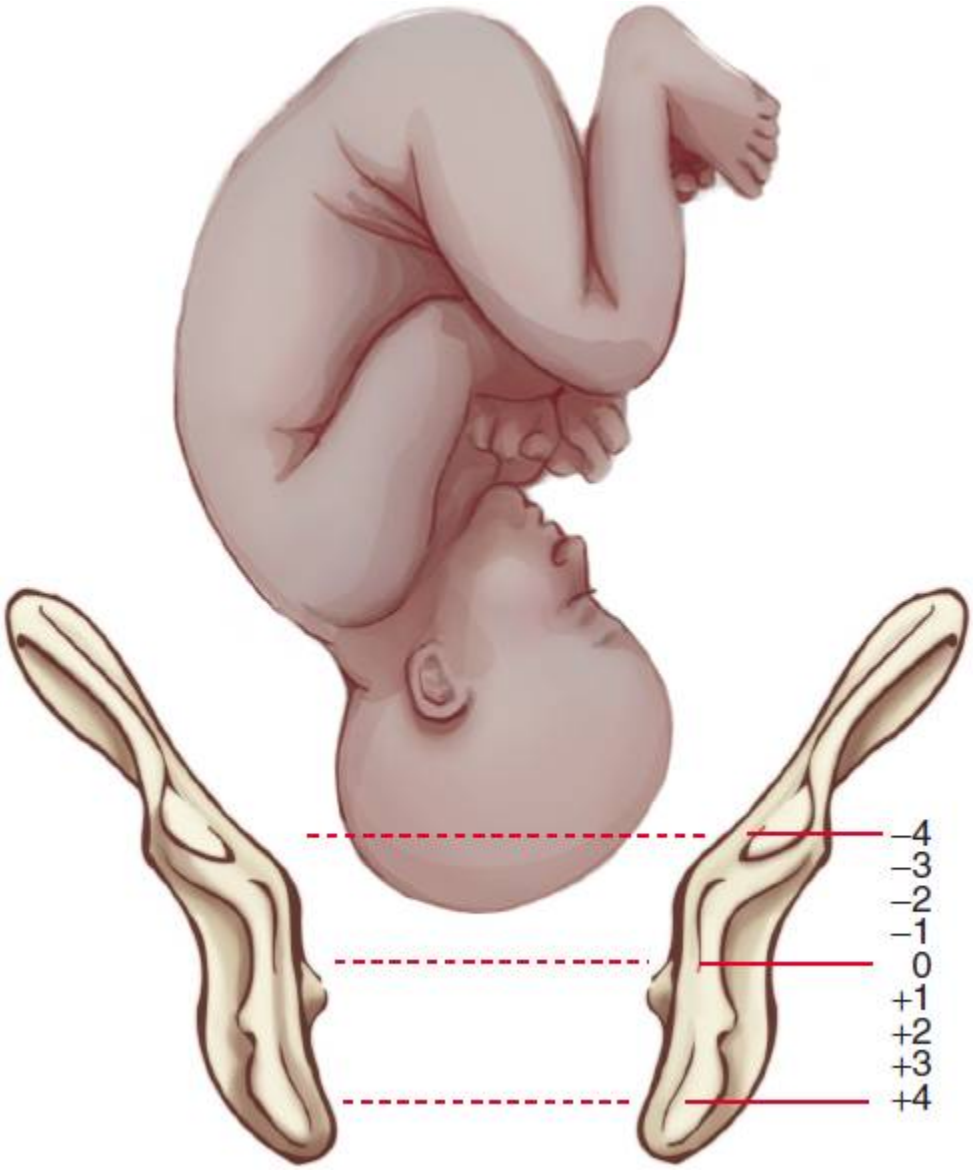

FIGURE 13.10. Fetal stations.

Fetal Engagement

Fetal **engagement** signifies the entrance of the largest diameter of the fetal presenting part (usually the fetal head) into the smallest diameter of the maternal pelvis (Deering, 2018). The fetus is said to be engaged in the pelvis when the presenting part reaches 0 station. Engagement is determined by pelvic examination.

The largest diameter of the fetal head is the biparietal diameter. It extends from one parietal prominence to the other. It is an important

factor in the navigation through the maternal pelvis. Engagement typically occurs in primigravidas 2 weeks before term, while multiparas may experience engagement several weeks before the onset of labor or not until labor begins.

TAKE NOTE!

The term *floating* is used when engagement has not occurred because the presenting part is freely movable above the pelvic inlet.

Cardinal Movements of Labor

The fetus goes through many positional changes as it travels through the passageway. These positional changes are known as the cardinal movements of labor. They are deliberate, specific, and precise movements that allow the smallest diameter of the fetal head to pass through a corresponding diameter of the mother's pelvic structure. Although cardinal movements are conceptualized as separate and sequential, the movements are typically concurrent (Fig. 13.11).

ENGAGEMENT

Engagement occurs when the greatest transverse diameter of the head in vertex (biparietal diameter) passes through the pelvic inlet (usually 0 station). The head usually enters the pelvis with the sagittal suture aligned in the transverse diameter.

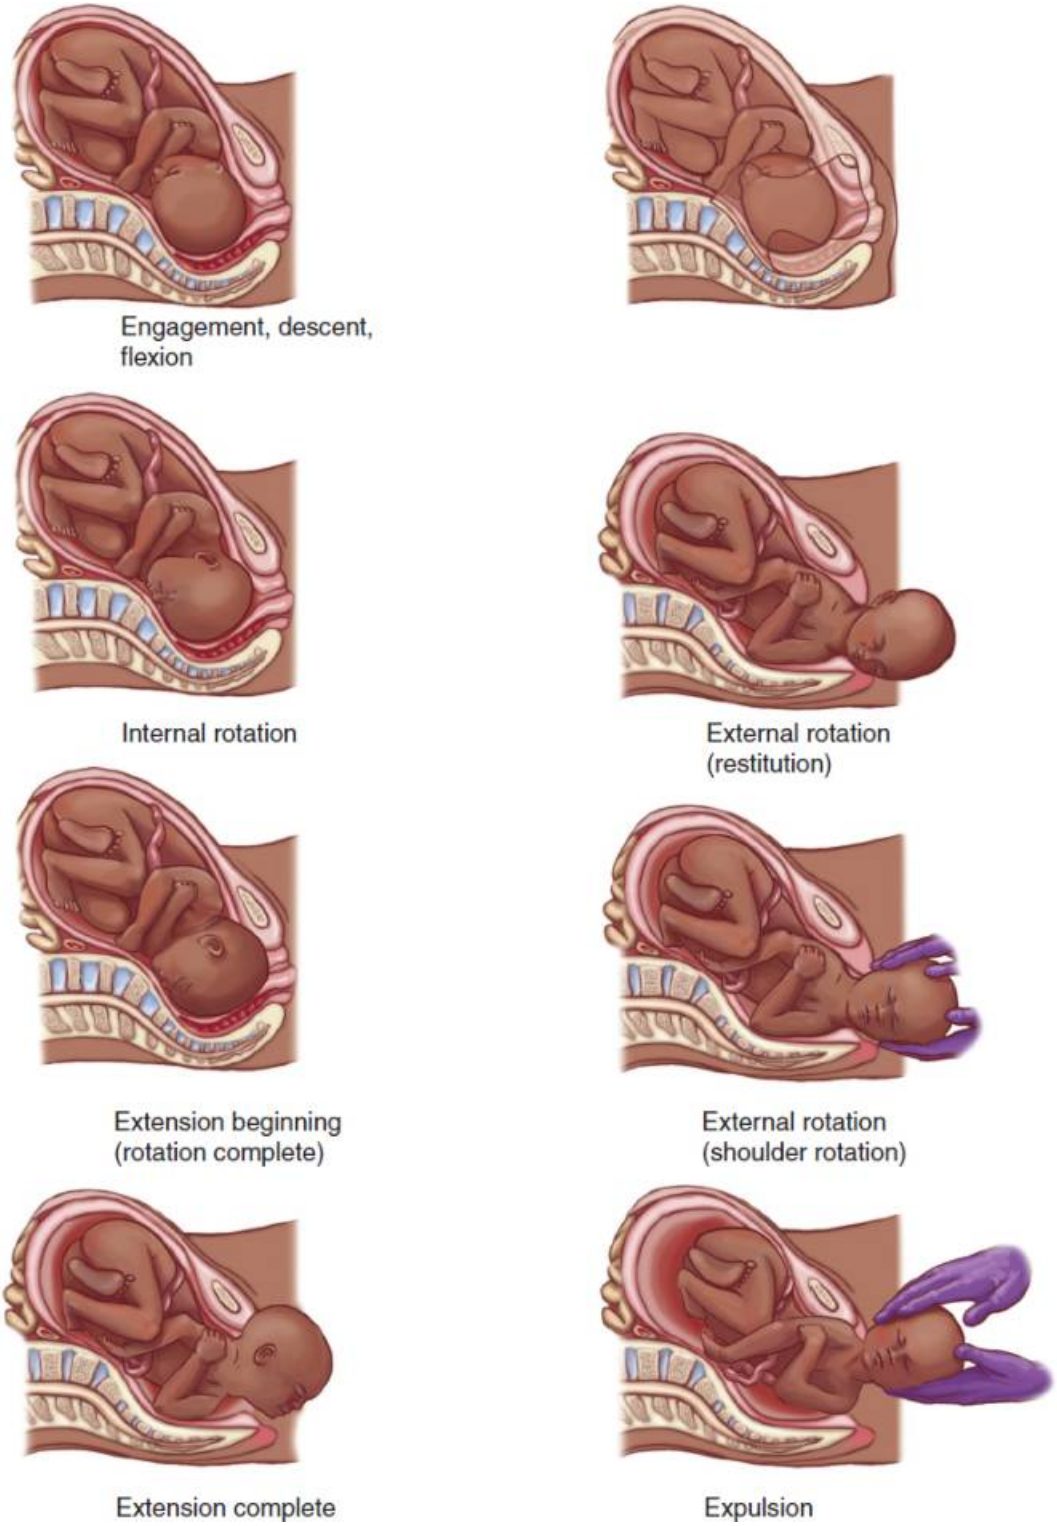

FIGURE 13.11. Cardinal movements of labor.

DESCENT

Descent is the downward movement of the fetal head until it is within the pelvic inlet. Descent occurs intermittently with contractions and is brought about by one or more of the following forces:

- Pressure of the amniotic fluid
- Direct pressure of the fundus on the fetus's buttocks or head (depending on which part is located in the top of the uterus)
- Contractions of the abdominal muscles (second stage)
- Extension and straightening of the fetal body

Descent occurs throughout labor, ending with birth. During this time, the mother experiences discomfort, but she is unable to isolate this particular fetal movement from her overall discomfort.

FLEXION

Flexion occurs as the vertex meets resistance from the cervix, the walls of the pelvis, or the pelvic floor. As a result, the chin is brought into contact with the fetal thorax and the presenting diameter is changed from occipitofrontal to suboccipitobregmatic (9.5 cm), which achieves the smallest fetal skull diameter presenting to the maternal pelvic dimensions.

INTERNAL ROTATION

After engagement, as the head descends, the lower portion of the head (usually the occiput) meets resistance from one side of the pelvic floor. As a result, the head rotates about 45 degrees anteriorly to the midline under the symphysis. This movement is known as *internal rotation*. Internal rotation brings the anteroposterior diameter of the head in line with the anteroposterior diameter of the pelvic outlet. It aligns the long axis of the fetal head with the long axis of the maternal pelvis. The widest portion of the maternal pelvis is the anteroposterior diameter, and thus the fetus must rotate to accommodate the pelvis.

EXTENSION

With further descent and full flexion of the head, the nucha (the base of the occiput) becomes impinged under the symphysis. Resistance from the pelvic floor causes the fetal head to extend so that it can pass under the pubic arch. *Extension* occurs after internal rotation is complete. The head emerges through extension under the symphysis pubis along with the shoulders. The anterior fontanlle, brow, nose, mouth, and chin are born successively.

EXTERNAL ROTATION (RESTITUTION)

After the head is born and is free of resistance, it untwists, causing the occiput to move about 45 degrees back to its original left or right position (restitution). The sagittal suture has now resumed its normal right-angle relationship to the transverse (bisacromial) diameter of the shoulders (i.e., the head realigns with the position of the back in the birth canal). *External rotation* of the fetal head allows the shoulders to rotate internally to fit the maternal pelvis.

EXPULSION

Expulsion of the rest of the body occurs more smoothly after the birth of the head and the anterior and posterior shoulders. Manual control of the fetus expulsion and perineal support by the health care provider reduces the risk of perineal injury to the mother (Riethmuller et al., 2018). See Figure 13.3 for an image of a fetal skull.

Powers

The primary stimulus powering labor is uterine contraction. Contractions cause complete dilation and effacement of the cervix during the first stage of labor. The secondary powers in labor involve the use of intra-abdominal pressure (voluntary muscle contractions) exerted by the woman as she pushes and bears down during the second stage of labor.

Uterine Contractions

Uterine contractions are involuntary and therefore cannot be controlled by the woman experiencing them, regardless of whether they are spontaneous or induced. Uterine contractions are rhythmic and intermittent, with a period of relaxation between contractions. This pause allows the woman and the uterine muscles to rest. In addition, this pause restores blood flow to the uterus and placenta, which is temporarily reduced during each uterine contraction.

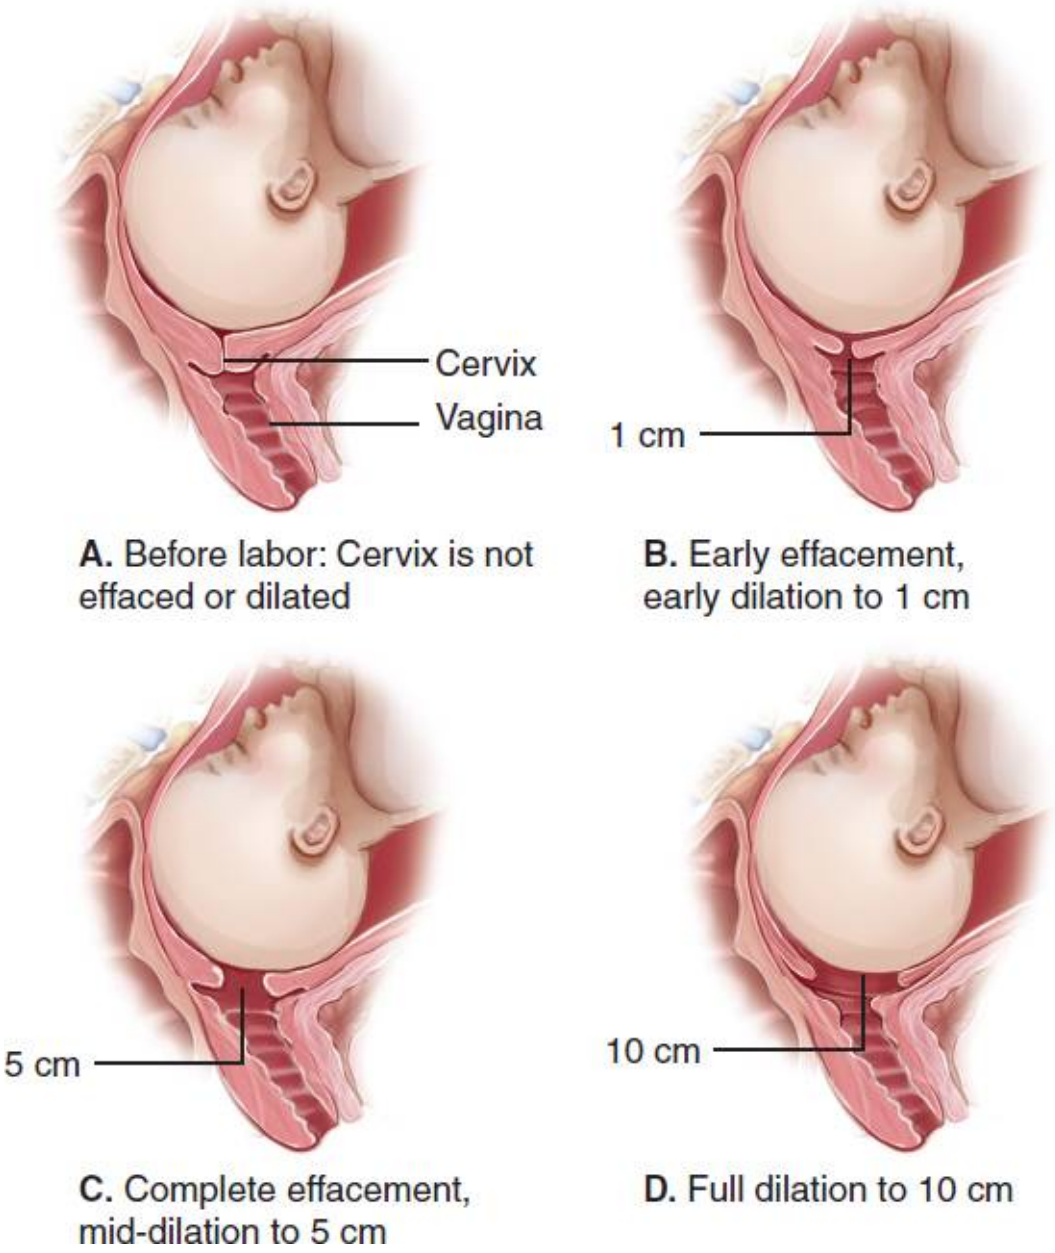

FIGURE 13.12. Cervical effacement and dilation. Cervical dilation is expressed in centimeters. **A.** Shows cervix not effaced or dilated. **B.** 50% effaced. **C.** 100% effaced. **D.** Fully dilated at 10 cm.

Uterine contractions are responsible for thinning and dilating the cervix, then thrusting the presenting part toward the lower uterine segment. The cervical canal reduces in length from 2 cm to a paper-thin entity and is described in terms of percentages from 0% to 100%. In primigravidas, effacement typically starts before the onset

of labor and usually begins before dilation; in multiparas, however, neither effacement nor dilation may start until labor ensues (Fig. 13.12). On clinical examination, the following may be assessed:

- Cervical canal 2 cm in length would be described as 0% effaced.
- Cervical canal 1 cm in length would be described as 50% effaced.
- Cervical canal 0 cm in length would be described as 100% effaced.

Dilation is dependent on the pressure of the presenting part and the contraction and retraction of the uterus. The diameter of the cervical os increases from less than 1 cm to approximately 10 cm to allow for birth. When the cervix is fully dilated, it is no longer palpable on vaginal examination. Descriptions may include:

- External cervical os closed: 0 cm dilated
- External cervical os half open: 5 cm dilated
- External cervical os fully open: 10 cm dilated

During early labor, uterine contractions are described as mild, they last about 30 seconds, and they occur about every 5 to 7 minutes. As labor progresses, contractions last longer (60 seconds), occur more frequently (2 to 3 minutes apart), and are described as being moderate to high in intensity. Each contraction has three phases: increment (buildup of the contraction), acme (peak or highest intensity), and decrement (descent or relaxation of the uterine muscle fibers). See Figure 13.13.

Uterine contractions are monitored and assessed according to three parameters: frequency, duration, and intensity.

1. **Frequency** refers to how often the contractions occur and is measured from the beginning of one contraction to the beginning of the next contraction.
2. **Duration** refers to how long a contraction lasts and is measured from the beginning of one contraction to the end of that same contraction.
3. **Intensity** refers to the strength of the contraction determined by manual palpation or measured by an internal intrauterine pressure catheter. The catheter is positioned in the uterine cavity through the cervix after the membranes have ruptured. It reports intensity by measuring the pressure of the amniotic fluid inside the uterus in

millimeters of mercury. It is not recommended for routine use in low-risk laboring women due to the potential risk of infection and injury to the placenta or fetus. In a recent study using noninvasive technology, it was found that using a multichannel electromyogram that acquires a uterine signal and maternal and fetal electrocardiograms was more accurate than that of an external Doppler and fetal scalp electrode monitor (Ashwal et al., 2019).

Intra-Abdominal Pressure

Increased intra-abdominal pressure (voluntary muscle contractions) compresses the uterus and adds to the power of the expulsion forces of the uterine contractions (King et al., 2019). Coordination of these forces in unison promotes birth of the fetus and expulsion of the fetal membranes and placenta from the uterus. Interference with these forces (such as when a woman is highly sedated or extremely anxious) can compromise the effectiveness of these powers.

Position (Maternal)

Positioning for normal labor and birth has evolved. Until about 250 years ago, women were depicted in art and described in essays as sitting upright with flexed hips, squatting, or less commonly standing or kneeling during the childbirth process. These positions maintain flexion at the hip joint and somewhat straighten the pelvis (Norwitz et al., 2019). In the past 250 years, dorsal and dorsal lithotomy positions evolved for unclear reasons ascribed to Western medicine. Childbirth medicalization has reduced laboring women's opportunity in a spontaneous position of choice to a recumbent one. Medical historians posit the evolution was to facilitate forceps usage, to promote men's power over women, and for convenience after administration of anesthesia (Jordan et al., 2019).

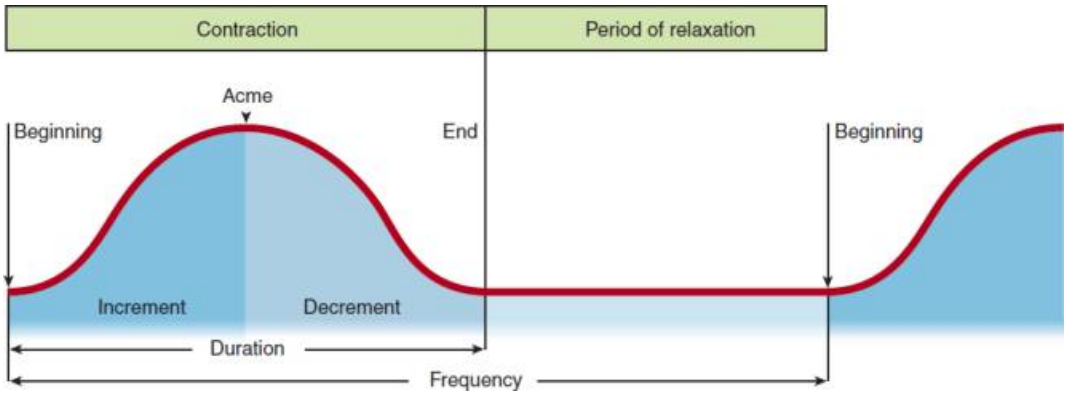

FIGURE 13.13. The three phases of a uterine contraction.

Maternal positioning during labor has only recently been the subject of well-controlled research. Scientific evidence has shown that nonmoving, back-lying positions during labor are not healthy (Dekker, 2019). In an upright position, gravity can help in bringing the fetus down, and there is less risk of compressing the maternal aorta which supplies oxygen to the fetus. However, despite this evidence to the contrary, many women continue to lie flat on their backs during labor. Some of the reasons why this practice continues include the beliefs that:

- laboring women need to conserve their energy and not tire themselves.
- nurses cannot keep track of the whereabouts of ambulating women.
- it is the preference of the health care provider.
- the fetus can be monitored better in this position.
- the supine position facilitates vaginal examinations and external belt adjustment.
- a bed is “where one is supposed to be” in a hospital setting.
- the position is more convenient for the delivering health care provider.
- laboring women are connected to medical equipment that impedes movement (Blackburn, 2018).

Although many labor and birthing facilities claim that all women are allowed to adopt any position of comfort during their laboring experience, many women spend their time on their backs during

labor and birth. Women should be encouraged to assume any position of comfort for them. In a recent randomized controlled study, the use of a peanut-shaped ball that is placed between the woman's legs during labor decreased the length of labor and increased the rate of vaginal births. The peanut ball was associated with a significantly lower incidence of cesarean births. The peanut ball can be a potentially successful nursing intervention to help progress labor and support vaginal birth, along with position changes, for women laboring under epidural analgesia (Hickey & Savage, 2019).

TAKE NOTE!

If the only furniture provided is a bed, this is what the woman will use. Furnishing rooms with comfortable chairs, beanbag chairs, and other birth props allows a woman to choose from a variety of positions and to be free to move around during labor.

Changing positions and moving around during labor and birth offer several benefits. Maternal position can influence pelvic size and contours. Changing position and walking affect the pelvis joints, which may facilitate fetal descent and rotation. Squatting enlarges the pelvic inlet and outlet diameters, and a kneeling position removes pressure on the maternal vena cava and helps rotate the fetus from a posterior position to an anterior one to facilitate birth (Blackburn, 2018). The use of any upright or lateral position compared to supine or lithotomy positions may:

- reduce the length of the first stage of labor.
- reduce the duration of the second stage of labor.
- reduce the number of assisted deliveries (vacuum and forceps).
- reduce episiotomies and perineal tears.
- contribute to fewer abnormal fetal heart rate patterns.
- increase comfort and reduce requests for pain medication.
- enhance a sense of control by the mother.
- alter the shape and size of the pelvis, which assists in descent.
- assist gravity to move the fetus downward (Dekker, 2019).

Using the research available can promote better outcomes, heightened professionalism, and evidence-based practice to childbearing practices. The National Institute for Health and Care Excellence (NICE) guidelines recommend discouraging women from lying supine or semisupine during labor and encourage them to adapt to any other position that they find comfortable since lying on the back is associated with longer labor, increase in surgical births, increased pain, and a higher incidence of fetal heart rate abnormalities. See Evidence-Based Practice 13.1.

Psychological Response

Childbearing can be one of the most life-altering experiences for a woman. The experience of childbirth goes beyond the physiologic aspects: it can influence a woman's self-confidence, self-esteem, and view of life, relationships, and children. Her state of mind (psyche) throughout the entire process is critical to bringing about a positive outcome for her and her family. Factors promoting a positive birth experience include:

- Clear information about procedures
- Support; not being alone
- Sense of mastery, self-confidence
- Trust in staff caring for her
- Positive reaction to the pregnancy
- Personal control over breathing
- Preparation for the childbirth experience

Having a strong sense of self and meaningful support from others can often help women manage labor well. Feeling safe and secure typically promotes a sense of control and ability to withstand the challenges of the childbearing experience. Anxiety and fear, however, decrease a woman's ability to cope with the discomfort of labor. Maternal catecholamines secreted in response to anxiety and fear can inhibit uterine blood flow and placental perfusion. In contrast, relaxation can augment the natural process of labor (Brooks & Wilson, 2019). Preparing mentally for childbirth is

important so that the woman can work with, rather than against, the natural forces of labor.

EVIDENCE-BASED PRACTICE 13.1 Upright Versus Recumbent Position during First Stage of Labor among Primipara Women on Labor Outcomes

STUDY

The process of birth occurs in several stages lasting from several hours to days. The first stage of labor is longer and the most painful, lasting 12 to 16 hours for primiparas and 6 to 8 hours for multiparas. Generally, laboring women recline in a recumbent position to make it easier for nurses to monitor fetal progress and perform vaginal exams. However, recumbent positions result in supine hypotension, diminishing uterine activity and reducing the dimensions of the pelvic outlet. The purpose of this study was to assess the effect of upright versus recumbent position during the active phase of the first stage of labor in terms of progress, duration of labor, method of birth, neonatal outcome, and maternal satisfaction with the specific position.

Findings

A quasiexperimental research design was utilized for this study. A total of 100 primiparas were recruited to participate in this study equally divided into the recumbent group or the upright group. Based on the findings of this study, women that assumed the upright position during the first stage of labor experienced significant improvement in the progress of labor, faster fetal head descent, significant reduction of pain, and a good Apgar score. There was also a high statistically significant difference regarding maternal satisfaction and preference of the upright position for the next labor.

Nursing Implications

Based on the results of this study, nurses should actively encourage laboring women to walk around, stand, sit, kneel, or squat to allow gravity to speed the cervix to dilate. Ambulation can reduce the duration of labor, need for analgesia, and improve maternal comfort. Encouraging an upright position improves frequency, strength and length of contractions, decreases the use of oxytocin to augment labor, and improves oxygen supply to the fetus. Nurses can inform all low-risk laboring women about the benefits of assuming upright positions during the first stage of labor and support them in their endeavors.

Adapted from Emam, A. M. M., & Al-Zahrani, A. E. (2018). Upright versus recumbent position during the first stage of labor among primipara women on labor outcomes. Journal of Nursing Education and Practice. 8(7), 113–124. https://doi.org/10.5430/jnep.v8n7p113

Philosophy

Not everyone views childbirth in the same way. A philosophical continuum exists that extends from viewing labor as a disease process to a normal process. One end of the spectrum assumes women cannot manage the birth experience adequately and therefore need constant expert monitoring and management. The other philosophy assumes that women are capable and reasonable individuals who can actively participate in their birth experience.

The health care system in the United States today appears to lean toward the former philosophy, applying technologic interventions to most mothers who enter the hospital system. Giving birth in a hospital in the 21st century for many women has become “intervention-intensive.” It is designed to start, continue, and end labor with extensive medical management, rather than allowing the normal process of birth to unfold. Advances in medical care have improved the safety for women with high-risk pregnancies. However, the routine use of intravenous therapy, electronic fetal monitoring, augmentation, and epidural anesthesia has not necessarily improved birth outcomes for all women (American Council on Science and

Health, 2019). Perhaps supporting a physiologic approach to childbirth using fewer unnecessary medical interventions is the way to improve birth outcomes in the United States.

During the 1970s, family-centered maternity care was developed in response to the consumer reaction to the depersonalization of birth. The hope was to shift the philosophy from “medicalization” to physiologic childbirth. The term “physiologic” is more appropriate today to denote the low-tech, high-touch approach requested by many childbearing women, who view childbirth as a normal process. Physiologic childbirth is an approach to care that supports the body’s ability to perform processes during childbirth while considering the woman’s philosophy, values, and preferences during this life event.

Certified nurse midwives (CNMs) are champions of physiologic birthing, and their participation in the childbirth process is associated with fewer unnecessary interventions when compared to obstetricians. CNMs subscribe to a normal birth process during which the woman uses her own instincts and bodily signs during labor. In short, midwives empower women within the birthing environment (Thompson et al., 2019).

No matter what philosophy is held, it is ideal if everyone involved in the particular birth process—from the health care provider to the mother—shares the same philosophy toward the birth process.

Partners

Women desire support and attentive care during labor and birth. Caregivers can convey emotional support by offering their continued presence and words of encouragement. Throughout the world, few women are left to labor totally alone; emotional, physical, and/or spiritual support during labor is the norm for most cultures. A caring partner can use massage, light touch, acupressure, hand-holding, stroking, and relaxation; can help the woman communicate her wishes to the staff; and can provide a continuous, reassuring presence, all of which bring some degree of comfort to the laboring woman (Salmon & Brunner, 2019). Although the presence of the mother’s significant other at the birth provides special emotional

support, a partner can be anyone who is present to support the woman throughout the experience. For many women, the essential ingredients for a safe and satisfying birth include a sense of empowerment and success in coping with or transcending the experience in addition to having solid, positive encouragement from a support companion.

Worldwide, women usually support other women in childbirth. **Doula** is a Greek word meaning woman servant or caregiver. It now commonly refers to a woman who offers emotional and practical support to a mother or couple before, during, and after childbirth. A doula believes in "mothering the mother," and clinical support remains the job of the midwife or medical staff (International Doula Institute, 2020). The continuous presence of a trained female support person reduces the need for medication for pain relief, the use of vacuum or forceps delivery, and the need for cesarean births. Continuous support has also been associated with a slight reduction in the length of labor. The doula, who is an experienced labor companion, provides the woman and her partner with emotional and physical support and information throughout the entire labor and birth experience.

Research finds that nursing care decreases the likelihood of negative evaluations of the childbirth experience, feelings of tenseness during labor, and finding labor worse than expected. Evidence also notes less perineal trauma, reduced difficulty in mothering, and reduced likelihood of early cessation of breastfeeding. Continuous support by nurses includes reassurance, encouragement, praise, and explanation (Aparecida Piler et al., 2019).

Nursing care of women during labor should incorporate finding a way to connect with her and to understand what she is experiencing (knowing); spending time with her (presence); protecting her and preserving her dignity (doing for); providing information and explanations in a clear methodical manner (enabling); and ensuring a safe childbirth experience. Given the many benefits of intrapartum support, laboring women should always have the option to receive partner support, whether from nurses, doulas, significant others, or

family. Whoever the support partner is, they should provide the mother with continuous presence and hands-on comfort and encouragement. The overall objective of providing support for women during childbirth is to create a positive experience for her while preserving her physical and psychological health.

Patience

The birth process takes time. If more time were allowed for women to labor naturally without intervention, the cesarean birth rate would most likely be reduced. In one study, continuous support provided by midwives during labor reduced the duration of labor and the number of cesarean births; this model of support should be available to all women (Kline, 2019). The literature suggests that delaying interventions can give a woman enough time to progress in labor and reduce the need for surgical intervention (American College of Obstetricians and Gynecologists [ACOG], 2019a).

Healthy People 2030 includes one goal related to cesarean births in the United States, “MICH-2030-06 Reduce cesarean births among low-risk women with no prior births.”

We are a long way from achieving this and other goals; the current cesarean birth rate in the United States at 32% (approximately one in three births) is the highest since these data first became available from birth certificates in 1989. Cesarean birth rate is associated with increased morbidity and mortality for both mother and infant as well as increased inpatient length of stay and health care costs (Centers for Disease Control and Prevention [CDC], 2019a).

It is difficult to predict how labor will progress and therefore equally difficult to determine how long an individual woman’s labor will last. There is no way to estimate the likely strength and frequency of uterine contractions, the extent to which the cervix will soften and dilate, and how much the fetal head will mold to fit the birth canal. We cannot know beforehand whether the complex fetal rotations needed for an efficient labor will properly take place. All of these factors are unknown when a woman starts labor.

Induction of Labor

Timing of birth is a vital component of a healthy pregnancy. An increase in morbidity and mortality exists at both ends of the gestational-age-at-birth spectrum. There is a trend in health care to attempt to manipulate and speed up the process of labor through medical means such as artificial rupture of membranes (amniotomy) and augmentation of labor with oxytocin (Grobman, 2019). The labor induction rate has declined slightly in the United States when compared to the 1990s (CDC, 2019b).

Approximately one in four women (24%) are induced or have labor augmented with uterine-stimulating drugs or artificial rupture of membranes to accelerate progress and early-term (in the 37th and 38th week) inductions (CDC, 2019b). An amniotomy may be performed to augment or induce labor when the membranes have not ruptured spontaneously. Doing so allows the fetal head to have more direct contact with the cervix to dilate it. This procedure is performed with the fetal head at −2 station or lower, with the cervix dilated to at least 3 cm. Synthetic oxytocin (Pitocin) is also used to induce or augment labor by stimulating uterine contractions. It is administered piggybacked into the primary intravenous line with an infusion pump titrated to uterine activity.

Elective induction of labor occurs in approximately 20% of all pregnancies in the United States despite known associated risks (Kim et al., 2019). It can lead to birth of an infant too early, a long labor, exposure to a high-alert medication with its potential side effects, unnecessary cesarean birth, and maternal and neonatal morbidity. Elective induction has a cascade of related interventions, such as an intravenous line, continuous electronic fetal monitoring, confinement to bed, amniotomy, pharmacologic labor-stimulating agents, parental pain medications, and regional anesthesia, each with its own set of potential complications and risks. These risks apply to all women having the procedure; however, for nulliparous women before 41 weeks' gestation with an unfavorable cervix, the main risk is cesarean birth after unsuccessful labor induction with the potential for maternal and neonatal morbidity and increased health

care costs. When cesarean occurs, subsequent births are likely to be via cesarean as well (Kawakita et al., 2019). Compelling evidence indicates that elective induction of labor may increase the risk of cesarean birth, especially for nulliparous women (Kellerman & Rakel, 2019). Elective induction of labor in nulliparas is associated with increased rates of cesarean, postpartum hemorrhage, neonatal resuscitation, and longer hospitalizations without improvement in neonatal outcomes (Lee et al., 2019). The belief is that many cesarean births could be avoided if women are allowed to labor longer and if the natural labor process is allowed to complete the job. The longer wait (using the intervention of patience) usually results in less intervention.

ACOG attributes the dramatic increase in inductions in part to pressure from women, convenience for physicians, and liability concerns. Other reasons for the increase in inductions include the availability of better cervical ripening agents and a more relaxed attitude toward marginal indications for inductions. ACOG recommends a cautious approach regarding elective induction until clinical trials can validate a more liberal use of labor inductions (2019b). Current medical indications for inducing labor include:

- Spontaneous rupture of membranes and labor does not start
- Large size fetus not expected to navigate the maternal pelvis
- Fetal growth restriction (FGR) with which external intervention is needed
- Fetal health in jeopardy if remaining in utero
- A pregnancy of more than 42 weeks' gestation
- Maternal hypertension, diabetes, or lung disease
- Uterine infection (March of Dimes, 2019)

When the laboring woman feels the urge to bear down, pushing begins. Most women respond extremely well to messages from their bodies without being directed by the nurse. A more natural, undirected approach allows the woman to wait and bear down when she feels the urge to push. Having patience and letting nature take its course will reduce the incidence of physiologic stress in the mother, resulting in less trauma to her perineal tissue.

Patient (Client) Preparation: Prenatal Education

Basic prenatal education can help women manage the labor process and feel in control of the birthing experience. The literature indicates that if a woman is prepared before the labor and birth experience, the labor is more likely to remain natural without the need for medical intervention (Yikar & Nazik, 2019). An increasing body of evidence also indicates that the well-prepared woman with good labor support is less likely to need analgesia or anesthesia and is less likely to require cesarean birth (Mamaghani et al., 2019).

Prenatal education teaches the woman about the childbirth experience and increases her sense of control. She is then able to work as an active participant during the labor and birth experience (Jordan et al., 2019). The research also suggests that prenatal preparation may affect intra- and postpartum psychosocial outcomes (Pan et al., 2019). For example, prenatal education covering parenting communication classes had a significant effect on postpartum anxiety and postpartum adjustment. Special consideration of each woman's culture, age, cognitive skills, access to health information, and health literacy all impact her understanding of the content presented. Nurses play an essential role in providing evidence-based education throughout the prenatal period.

TAKE NOTE!

Learning about labor and birth allows women and couples to express their needs and preferences ahead of time, enhance their confidence, and improve communication between themselves and the staff.

Pain Management

The perception of pain can be influenced by a number of factors—past experiences of pain, culture and beliefs, stoicism, and anxiety and depression. To manage a client's plan, nurses need to understand what it is and provide support to the laboring client to

enable her to deal with the pain and challenges of labor. Labor and birth, though a normal physiologic process, can produce significant pain. Pain during labor is a nearly universal experience. Controlling the uterine discomfort without harm to the fetus or labor process is the major focus of pain management during childbirth. Pain is a subjective experience involving a complex interaction of physiologic, spiritual, psychosocial, cultural, and environmental influences (Lennon, 2018). Cultural values and learned behaviors influence perception and response to pain, as do anxiety and fear, both of which tend to heighten the sense of pain (Deering, 2018). The challenge for care providers is to find the right combination of pain management methods to keep the discomfort manageable while minimizing the negative effect on the fetus, the normal physiology of labor, maternal–infant bonding, breastfeeding, and a woman's perception of the labor itself (King et al., 2019). Chapter 14 presents a full discussion of pain management during labor and birth.

PHYSIOLOGIC RESPONSES TO LABOR

Labor is the process by which the birth canal is prepared to allow the fetus to pass from the uterine cavity to the outside world. During pregnancy, progesterone secreted from the placenta suppresses the spontaneous contractions of a typical uterus, keeping the fetus within the uterus. In addition, the cervix remains firm and noncompliant. At term, however, changes occur in the cervix that make it softer. In addition, uterine contractions become more frequent and regular, signaling the onset of labor.

The labor process involves a series of rhythmic, involuntary, often uncomfortable uterine muscle contractions. The contractions bring about a shortening that causes effacement and dilation of the cervix and a bursting of the fetal membranes. Uterine contractions of an intensity of 30 mm Hg or greater promote cervical dilation. Then, accompanied by both reflex and voluntary contractions of the abdominal muscles (pushing), the uterine contractions result in the

birth of the baby (Blackburn, 2018). During labor, the mother and fetus make several physiologic adaptations.

Maternal Responses

As the woman progresses through childbirth, numerous physiologic responses occur that assist her to adapt to the labor process. The labor process stresses several of the woman's body systems, which react through numerous compensatory mechanisms. Maternal physiologic responses include:

- Heart rate increases by 10 to 20 bpm.
- Cardiac output increases by 12% to 31% during the first stage of labor and by 50% during the second stage of labor.
- Blood pressure increases by up to 35 mm Hg during uterine contractions in all labor stages.
- The white blood cell count increases to 25,000 to 30,000 cells/mm^3 perhaps as a result of tissue trauma.
- Respiratory rate increases and more oxygen is consumed related to the increase in metabolism.
- Gastric motility and food absorption decrease, which may increase the risk of nausea and vomiting during the transition stage of labor.
- Gastric emptying and gastric pH decrease, increasing the risk of vomiting with aspiration.
- Temperature rises slightly, possibly due to an increase in muscle activity.
- Muscular aches and cramps occur as a result of stress on the musculoskeletal system.
- Basal metabolic rate increases and blood glucose levels decrease because of the stress of labor (Funai & Norwitz, 2019).

A woman's ability to adapt to the stress of labor is influenced by her psychological and physical state. Among the many factors that affect her coping ability are:

- Previous birth experiences and their outcomes (complications and previous birth outcomes)
- Current pregnancy experience (planned versus unplanned, discomforts experienced, age, risk status of pregnancy, chronic

illness, weight gain)
- Cultural considerations (values and beliefs about health status)
- Support system (presence and support of a valued partner during labor)
- Childbirth preparation (attended childbirth classes and has practiced paced breathing techniques)
- Exercise during pregnancy (muscles toned; ability to assist with intra-abdominal pushing)
- Expectations of the birthing experience (viewed as a meaningful or stressful event)
- Anxiety level (excessive anxiety may interfere with labor progress)
- Fear of labor and loss of control (fear may enhance pain perception, augmenting fear)
- Fatigue and weariness (not feeling adequately energized for the challenge and duration of labor) (King et al., 2019)

Fetal Responses

Although the focus during labor may be on assessing the mother's adaptations, several physiologic adaptations occur in the fetus as well. The fetus is experiencing labor along with the mother. If the fetus is healthy, the stress of labor usually has no adverse effects. The nurse needs to be alert to any abnormalities in the fetus's adaptation to labor. Fetal responses to labor include:

- Periodic fetal heart rate accelerations and slight decelerations related to fetal movement, fundal pressure, and uterine contractions
- Decrease in circulation and perfusion to the fetus secondary to uterine contractions (a healthy fetus is able to compensate for this drop)
- Increase in arterial carbon dioxide pressure (PCO2)
- Decrease in fetal breathing movements throughout labor
- Decrease in fetal oxygen pressure with a decrease in the partial pressure of oxygen (PO2) (Decherney et al., 2019)

TAKE NOTE!

Respiratory changes during labor help prepare the fetus for extrauterine respiration immediately after birth.

STAGES OF LABOR

Labor is typically divided into four stages: dilation, expulsive, placental, and restorative. Table 13.2 summarizes the major events of each stage.

The first stage is the longest; it begins with the first true contraction and ends with full dilation (opening) of the cervix. Because this stage lasts so long, it is divided into two phases, latent and active, each corresponding to the progressive dilation of the cervix.

The second stage, the expulsive stage, begins when the cervix is completely dilated and ends with the birth of the newborn. The expulsive stage can last from minutes to hours. The contractions typically occur every 2 to 3 minutes, lasting 60 to 90 seconds and are strong by palpation. The woman is usually intent on the work of pushing during this stage.

The third stage, placental expulsion, starts after the newborn is born and ends with the separation and birth of the placenta. Continued uterine contractions typically cause the placenta to be expelled within 5 to 30 minutes. If the newborn is stable, bonding of infant and mother takes place during this stage through touching, holding, and skin-to-skin contact.

The fourth stage, the restorative stage or immediate postpartum period, lasts from 1 to 4 hours after birth. This period is when the mother's body begins to stabilize after the hard work of labor and the loss of the products of conception. The fourth stage is often not recognized as a true stage of labor, but it is a critical period for maternal physiologic transition as well as new family attachment. Close monitoring of both the mother and her newborn are done during this stage (King et al., 2019).

TABLE 13.2 Stages and Phases of Labor

	First Stage	Second Stage	Third Stage	Fourth Stage
Description	From 0–10 cm dilation; consists of three phases	From complete dilation (10 cm) to birth of the newborn; may last up to 3 hours	Separation and delivery of the placenta; usually takes 5–10 minutes, but may take up to 30 minutes	1–4 hours after the birth of the newborn; time of maternal physiologic adjustment
Phases	**Latent phase** (0–6 cm dilation) • Cervical dilation from 0 to 6 cm • Cervical effacement from 0% to 40% • Nullipara, lasts up to 20 hours; multipara, lasts up to 14 hours • Contraction frequency every 5–10 minutes • Contraction duration 30–45 seconds • Contraction intensity mild to palpation **Active phase** (6–10 cm dilation) • Cervical dilation from 6 to 10 cm • Cervical effacement from 40% to 100% • Nullipara, lasts up to 6 hours; multipara, lasts up to 4 hours • Contraction frequency every 2–5 minutes • Contraction duration 45–60 seconds • Contraction intensity moderate to palpation	**Pelvic phase** (period of fetal descent) **Perineal phase** (period of active pushing) • Nullipara, lasts up to 3 hours; multipara, lasts up to 2 hours • Contraction frequency every 2–3 minutes or less • Contraction duration 60–90 seconds • Contraction intensity strong by palpation • Strong urge to push during the later perineal phase	**Placental separation:** detaching from uterine wall **Placental expulsion:** coming outside the vaginal opening

(2019). *Evidence-based obstetrics and gynecology*. Wiley Blackwell.

First Stage

During the first stage of labor, the fundamental change underlying the process is progressive dilation of the cervix. Cervical dilation is gauged subjectively by vaginal examination and is expressed in centimeters. The first stage ends when the cervix is dilated to 10 cm in diameter and is large enough to permit the passage of a fetal head of average size. The fetal membranes usually rupture during the first stage, but they may have burst earlier or may even remain intact until birth. For the primigravida, the first stage of labor can last up to 20 hours without being considered prolonged. However, this time can vary widely; for the multiparous woman, it can last up to 14 hours (ACOG & SMFM, 2016).

During the first stage of labor, women usually perceive the visceral pain of diffuse abdominal cramping and uterine contractions. Pain during the first stage of labor is primarily a result of the dilation of the

cervix and lower uterine segment, and the distention (stretching) of these structures during contractions. The first stage is divided into two phases: latent and active.

Latent Phase

The latent phase gives rise to the familiar signs and symptoms of labor. This phase begins with the start of regular contractions and ends when rapid cervical dilation begins. During the latent phase, the cervix dilates slowly to approximately 6 cm. Sedation can increase the duration of this phase.

Contractions usually occur every 5 to 10 minutes, last 30 to 45 seconds, and are described as mild by palpation by the nurse. Assessment of intensity is evaluated by pressing down on the fundus during a contraction to see if it can be dented with the nurse's fingers. The ability to indent the fundus at the peak of the contraction would typically indicate a mild contraction. Effacement of the cervix is from 0% to 40%. Many women remain talkative during this period, perceiving their contractions to be similar to menstrual cramps. Women may remain at home during this phase, contacting their health care provider about the onset of labor.

During this phase, women are apprehensive but excited about the start of labor after the long gestational period.

Think back to the couple who were sent home from the hospital birthing center. Three days later, Kathy awakens with a wet sensation and intense discomfort in her back spreading around to her abdomen. She decides to go for a walk, but her contractions don't diminish. Instead, her contractions continue to occur every few minutes and grow stronger in intensity. She and Chuck decide to go back to the hospital birthing center. Was there a difference in the location of Kathy's discomfort this time? What changes will the admission nurse find in Kathy if this is true labor?

Active Phase

The active phase of labor encompasses the time from an increase in the rate of cervical dilation (end of latent phase of labor) until completion of cervical dilation. Cervical dilation begins to occur more

rapidly and predictably until it reaches 10 cm and cervical dilation and effacement are complete. Active labor with more rapid cervical dilation generally dilates at a rate of 1.2 to 1.5 cm per hour (ACOG & SMFM, 2016). The fetus descends farther in the pelvis. Contractions become more frequent (every 2 to 5 minutes) and increase in duration (45 to 60 seconds). The woman's discomfort intensifies (moderate to strong by palpation). She becomes more intense and inwardly focused, absorbed in the serious work of her labor. She limits interactions with those in the room. If she and her partner have attended childbirth education classes, she will begin to use the relaxation and paced breathing techniques that they learned to cope with the contractions.

In assessing Kathy, the nurse finds she is 4 cm dilated and 50% effaced with ruptured membranes. In what stage and phase of labor would this assessment finding place Kathy?

Second Stage

The second stage of labor begins with complete cervical dilation (10 cm) and effacement and ends with the birth of the newborn. Although the previous stage of labor primarily involved the thinning and opening of the cervix, this stage involves moving the fetus through the birth canal and out of the body. The cardinal movements of labor occur during the early phase of passive descent in the second stage of labor.

Contractions occur every 2 to 3 minutes, last 60 to 90 seconds, and are described as strong by palpation. Parity, delayed pushing, use of epidural analgesia, maternal body mass index, birth weight, pelvis shape, occiput posterior position, and fetal station at complete dilation all have been shown to affect the length of the second stage of labor. A longer duration of the second stage of labor is associated with adverse maternal outcomes, such as higher rates of puerperal infection, third- and fourth-degree perineal lacerations, and postpartum hemorrhage (Hutchison et al., 2019). During this expulsive stage, the mother usually feels more in control and less

irritable and agitated. She is focused on the work of pushing. The maternal urge to push is generally felt when there is direct contact of the fetus to the pelvic floor. Stretch receptors in the wall of the vagina, rectum, and perineum communicate the pressure of the fetus descending in the birth canal that, along with increased abdominal pressure, causes the overwhelming urge to push described by laboring women (Deering, 2018).

Pushing

During the second stage of labor, active pushing is the time in which the laboring mother is feeling rectal pressure by the fetal presenting part and physiologically feels the urge to push. If the mother has an epidural in place, this sensation to push is dulled (Funai & Norwitz, 2020).

In the second stage of labor, the perineum bulges, and there is an increase in bloody show. The fetal head becomes apparent at the vaginal opening but disappears between contractions. When the top of the head no longer regresses between contractions, it is said to have crowned. The fetus rotates as it maneuvers out. Evidence now shows that labor actually progresses slower than was previously thought. Many women might need a little more time to labor and give birth vaginally instead of moving to a surgical birth (Zipori et al., 2019). The second stage may last up to 3 hours in a first labor and up to 2 hours in subsequent ones (Fig. 13.14).

SPONTANEOUS PUSHING VERSUS DIRECTED PUSHING

There are two ways of conducting the second stage of labor: *spontaneous pushing* (following the mother's spontaneous urge) and *directed pushing* (pushing directed by the caregiver). Spontaneous pushing represents a natural way of managing the second stage of labor. However, as a result of epidural analgesia, health care providers frequently resort to directed pushing without taking into account the negative repercussions it has on the woman and her

fetus. The physiologic approach focuses on spontaneous pushing as the mother feels the need rather than when she is directed, which can reduce fetal oxygenation (Blackburn, 2018).

Evidence is mounting that the management of the second stage, particularly pushing, is a modifiable risk factor in long-term perinatal outcomes (Kadour-Peero et al., 2019). Research supports spontaneous physiologic approaches to second-stage labor care; however, many women in hospital settings continue to receive direction from nurses to use prolonged Valsalva bearing-down efforts as soon as the cervix is completely dilated. Traditionally, women have been taught to hold their breath to the count of 10, inhale again, push again, and repeat the process several times during a contraction. This sustained, strenuous style of pushing is linked to hemodynamic changes in the mother and interferes with oxygen exchange between the mother and the fetus. In addition, it is associated with pelvic floor damage; the longer the push, the more damage to the pelvic floor. See Evidence-Based Practice 13.2.

In clinical practice, health care providers sometimes resist delaying the onset of pushing after the second stage of labor has begun because of a belief that it will increase labor time. Delaying maternal bearing-down efforts during the second stage until the woman feels the urge to push (laboring down) allows for optimal use of maternal energy, has no detrimental maternal effects, and results in improved fetal oxygenation (Norwitz et al., 2019). Research shows that delaying pushing for up to 90 minutes after complete cervical dilation resulted in a significant decrease in the time mothers spend pushing without a significant increase in total time in second stage of labor (King et al., 2019). Because research is inconclusive, does not support a policy of directed pushing, and some evidence suggests it may be harmful, the practice of directed pushing should be abandoned (Blackburn, 2018). The World Health Organization (WHO) has recommended that during the second stage of labor, nurses should encourage and support women to follow their own urge to push and not direct it (2018a). Using an open-glottis method (involuntary pushing with expiratory grunting and vocalization) to push supports the mother's involuntary bearing-down efforts

(Garpiel, 2018). The adoption of a physiologic, woman-directed approach to bearing down is advocated (King et al., 2019).

Behaviors demonstrated by laboring women during this time include pushing at the onset of the urge to bear down; using their own patterns and techniques of bearing down in response to sensations they experience; using open-glottis bearing down with contractions; pushing with variations in strength and duration; pushing down with progressive intensity; and using multiple positions to increase progress and comfort. This approach is in stark contrast to management by arbitrary time limits and the directed bearing-down efforts seen in practice today. Labor nurses need to develop an evidence-based approach that acknowledges and reinforces women's innate ability to give birth and refrain from trying to direct women's pushing behaviors (Dekker, 2019).

Laboring down (promotion of passive descent) is an alternative strategy for second-stage management in women with epidurals. Using this approach, the fetus descends and is born without coached maternal pushing.

Third Stage

The third stage of labor begins with the birth of the newborn and ends with the separation and birth of the placenta. The ideal placement for the newborn immediately following the birth is on the mother's abdomen, in skin-to-skin contact which promotes a positive transition from intrauterine to extrauterine life. The third stage of labor consists of two phases: placental separation and placental expulsion. Worldwide, approximately 800 women die each day from preventable causes related to childbirth. The single most common cause is severe bleeding, which can kill a woman within hours if care is delayed. Postpartum hemorrhage occurs mostly during the third stage of labor, and active management of it can prevent its occurrence. Active management includes administration of a uterotonic agent after the birth, expulsion of the placenta with controlled traction of the cord, and uterine fundal message after placental expulsion (WHO, 2018b). Prompt and effective

management is paramount to saving the lives of these women, and prevention measures can be initiated in the third stage of labor. Controversy continues about active versus expectant management of the third stage of labor.

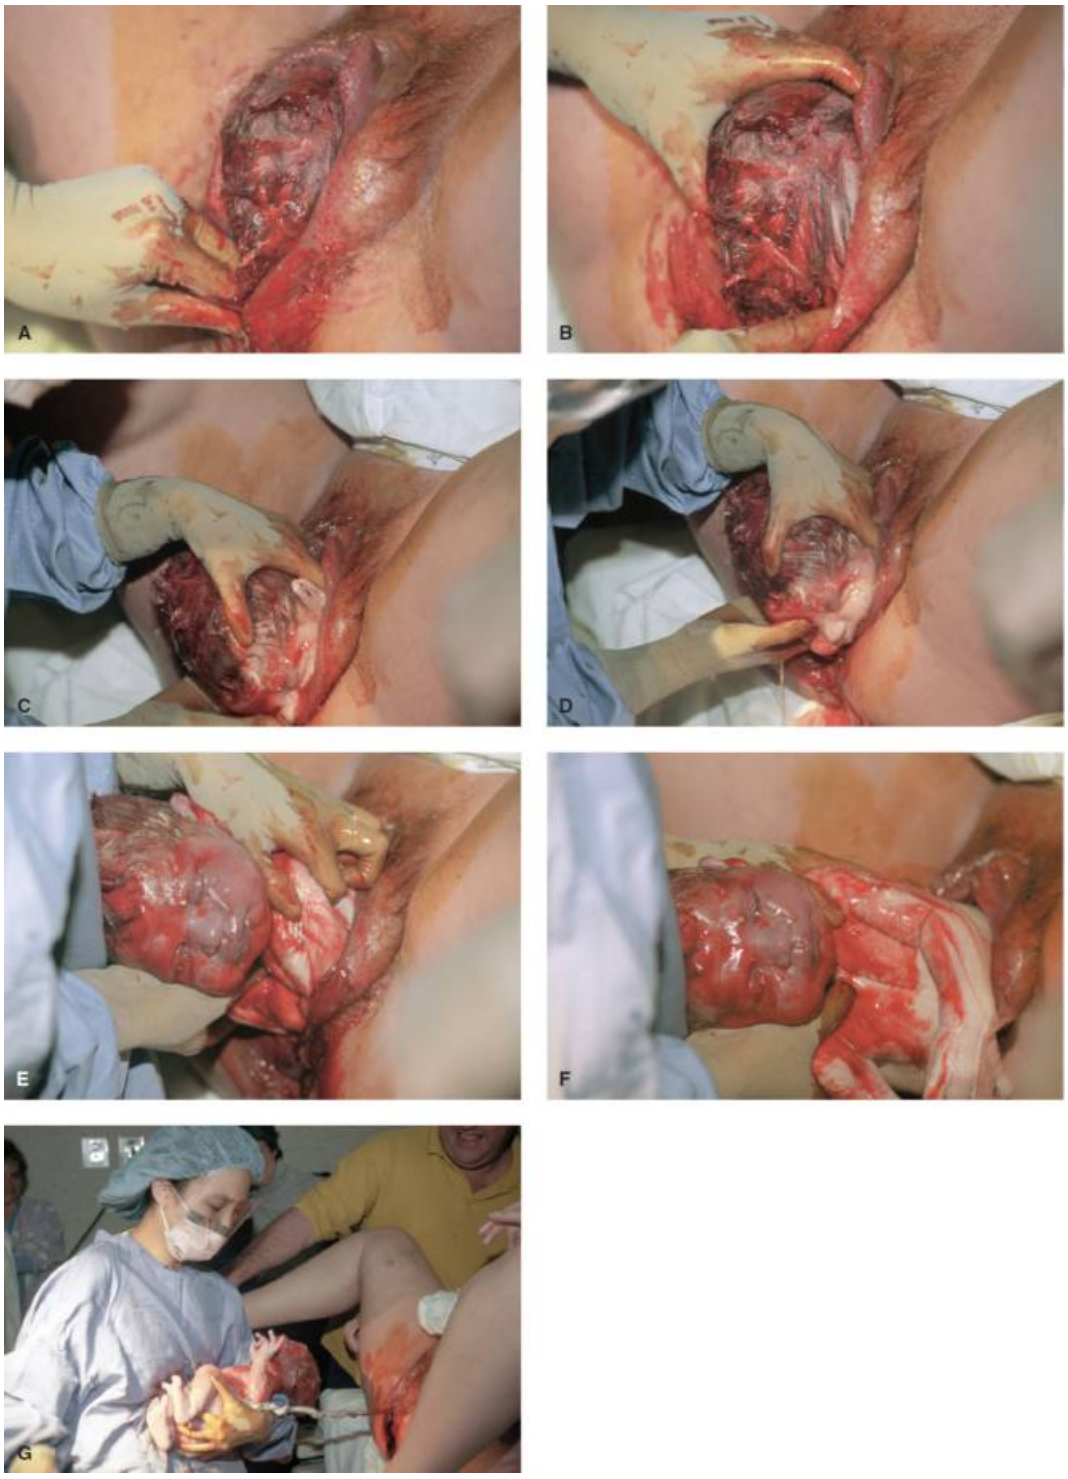

FIGURE 13.14. Birth sequence from crowning through birth of the newborn. **A.** Early crowning of the fetal head. Notice the bulging of the perineum. **B.** Late crowning. Notice that the fetal head is appearing face down. This is the normal OA position. **C.** As the head extends, you can see that the occiput is to the mother's right side–ROA position. **D.** The

cardinal movement of extension. **E.** The shoulders are born. Notice how the head has turned to line up with the shoulders—the cardinal movement of external rotation. **F.** The body easily follows the shoulders. **G.** The newborn is held for the first time. (Photo by B. Proud.)

EVIDENCE-BASED PRACTICE 13.2 Maternal and Neonatal Outcomes from a Comparison of Spontaneous and Directed Pushing in the Second Stage

STUDY

During the second stage of labor, a common technique is to encourage women to take a deep breath at the start of a contraction and bear down throughout the contraction (known as "directed pushing"). Spontaneous pushing is a response to a natural urge to push that comes with pushing three to five times per contraction. Women are free to follow their own instincts and urges. The purpose of this study was to compare the effect of directed to spontaneous maternal pushing efforts on duration of the second stage of labor, perineal injury, and neonatal condition at birth.

Findings

A retrospective cross-sectional design included 19,212 women with singleton, cephalic presentations using multivariate analysis. Women were grouped based on spontaneous or directed pushing. It was found that directed pushing was associated with a longer duration of second-stage labor for multiparous women (8 minutes) and nulliparous women (14 minutes) as well as an increased risk for prolonged second stage of labor in multiparous women. The use of episiotomy in the directed pushing group was significantly higher than that of the spontaneous pushing group. Directed pushing was also associated with a significantly increased risk of neonatal resuscitation and nursery admission versus the spontaneous group. There was no difference of Apgar scores between the groups at 5 minutes.

Nursing Implications

Based on this study's findings, nurses should discourage directed pushing when mothers don't feel a natural urge to do push and support women to follow their own expulsive urges for better perinatal outcomes.

Adapted from Lee, N., Gao, Y., Lotz, L., & Kildea, S. (2019). Maternal and neonatal outcomes from a comparison of spontaneous and directed pushing in the second stage. Women and Birth, 32(4), e433–e440.

Placental Separation

After the infant is born, the uterus continues to contract strongly and can now retract, decreasing markedly in size. These contractions cause the placenta to pull away from the uterine wall. The following signs of separation indicate that the placenta is ready to deliver:

- The uterus rises upward.
- The umbilical cord lengthens.
- A sudden trickle of blood is released from the vaginal opening.
- The uterus changes its shape to globular.

Spontaneous birth of the placenta occurs in one of two ways: the fetal side (shiny gray side) presenting first (called Schultz mechanism or more commonly called "shiny Schultz") or the maternal side (red raw side) presenting first (termed Duncan mechanism or "dirty Duncan").

Placental Expulsion

After separation of the placenta from the uterine wall, continued uterine contractions cause the placenta to be expelled within 2 to 30 minutes unless there is gentle external traction to assist. After the placenta is expelled, the uterus is massaged briefly by the attending physician or midwife until it is firm so that uterine blood vessels constrict, minimizing the possibility of hemorrhage. Normal blood loss is approximately 500 mL for a vaginal birth and up to 1,000 mL

for a cesarean birth. Blood loss of over 1,000 mL is considered severe (Kellerman & Rakel, 2019).

If the placenta does not spontaneously deliver, the health care provider assists with its removal by manual extraction. On expulsion, the placenta is inspected for its intactness by the health care provider and the nurse to make sure all sections are present. If any piece is still attached to the uterine wall, it places the woman at risk for postpartum hemorrhage because it becomes a space-occupying object that interferes with the ability of the uterus to contract fully and effectively.

Fourth Stage

The fourth stage begins with completion of the expulsion of the placenta and membranes and ends with the initial physiologic adjustment and stabilization of the mother (1 to 4 hours after birth). This stage initiates the postpartum period. The mother usually feels a sense of peace and excitement, is wide awake, and is initially talkative. The attachment process begins with her inspecting her newborn and desiring to cuddle and breastfeed them. The mother's fundus should be firm and well contracted. Typically it is located at the midline between the umbilicus and the symphysis, but it then slowly rises to the level of the umbilicus during the first hour after birth (Jordan et al., 2019). If the uterus becomes boggy, it is massaged to keep it firm. The lochia (vaginal discharge) is red, mixed with small clots, and of moderate flow. If the woman has had an episiotomy during the second stage of labor, it should be intact with the edges approximated and clean and no redness or edema present.

The focus during this stage is to monitor the mother closely to prevent hemorrhage, bladder distention, and venous thrombosis. Usually the mother is thirsty and hungry during this time and may request food and drink. Her bladder is hypotonic, and thus she has limited sensation to acknowledge a full bladder or to void. Vital signs, the amount and consistency of the lochia, and the uterine fundus are usually monitored every 15 minutes for at least 1 hour. The woman

will be feeling cramp-like discomfort during this time due to the contracting uterus.

KEY CONCEPTS

- Labor is a complex, multifaceted interaction between the mother and fetus. Thus, it is difficult to determine exactly why labor begins and what initiates it.
- Before the onset of labor, a pregnant woman's body undergoes several changes in preparation for the birth of the newborn, often leading to characteristic signs and symptoms that suggest labor is near. These changes include cervical changes, lightening, increased energy level, bloody show, Braxton Hicks contractions, and spontaneous rupture of membranes.
- False labor is a condition seen during the latter weeks of some pregnancies in which irregular uterine contractions are felt, but the cervix is not affected.
- The critical factors in labor and birth are designated as the 10 Ps: passageway (birth canal), passenger (fetus and placenta), powers (contractions), position (maternal), psychological response, philosophy (low-tech, high-touch), partners (support caregivers), patience (natural timing), patient (client) preparation (childbirth knowledge base), and pain management (comfort measures).
- The size and shape of a woman's pelvis are determining factors for a vaginal birth. The female pelvis is classified according to four main shapes: gynecoid, anthropoid, android, and platypelloid.
- The labor process is comprised of a series of rhythmic, involuntary, usually quite uncomfortable uterine muscle contractions that bring about a shortening (effacement) and opening (dilation) of the cervix, and a bursting of the fetal membranes. Important parameters of uterine contractions are frequency, duration, and intensity.
- The diameters of the fetal skull vary considerably, with some diameters shortening and others lengthening as the head is molded during the labor and birth process.
- Pain during labor is a nearly universal experience for childbearing women. Having a strong sense of self and meaningful support from others can often help women manage labor well and reduce the sensation of pain.
- Mentally preparing for childbirth is important for women to enable them to work with the natural forces of labor and not against

them.
- As the woman experiences and progresses through childbirth, numerous physiologic responses occur that assist her adaptation to the laboring process.
- Labor is typically divided into four stages that are unequal in length.
- During the first stage, the fundamental change underlying the process is progressive dilation of the cervix. It is further divided into two phases: latent phase and active phase.
- The second stage of labor is from complete cervical dilation (10 cm) and effacement through the birth of the infant.
- The third stage is that of separation and birth of the placenta. It consists of two phases: placental separation and placental expulsion.
- The fourth stage begins after the birth of the placenta and membranes and ends with the initial physiologic adjustment and stabilization of the mother (1 to 4 hours).

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. When determining the frequency of contractions, the nurse would measure which period of time?
   a. Start of one contraction to the start of the next contraction
   b. Beginning of one contraction to the end of the same contraction
   c. Peak of one contraction to the peak of the next contraction
   d. End of one contraction to the beginning of the next contraction

2. Which fetal lie is most conducive to a spontaneous vaginal birth?
   a. Transverse
   b. Longitudinal
   c. Perpendicular
   d. Oblique

3. Which observation would suggest that placental separation is occurring?
   a. Uterus stops contracting altogether.
   b. Umbilical cord pulsations stop.
   c. Uterine shape changes to globular.
   d. Maternal blood pressure drops.

4. As the nurse is explaining the difference between true versus false labor to her childbirth class, she states that the major difference between them is
   a. discomfort level is greater with false labor.

b. progressive cervical changes occur in true labor.
c. there is a feeling of nausea with false labor.
d. there is more fetal movement with true labor.

5. The most intense time during labor is during the

a. latent phase.
b. active phase.
c. membranes breaking.
d. placental expulsion phase.

6. A laboring woman is admitted to the labor and birth suite at 4-cm dilation. She would be in which phase of labor?

a. Latent
b. Active
c. Late
d. Early

7. Which assessment would indicate that a woman is in true labor?

a. Membranes are ruptured and fluid is clear.
b. Presenting part is engaged and not floating.
c. Cervix is 4 cm dilated, 90% effaced.
d. Contractions last 30 seconds every 5 to 10 minutes.

8. Which interventions are underutilized in promoting a normal birth? Select all that apply.

a. Oral nutrition and fluids in labor
b. Open-glottis pushing in the second stage of labor
c. Skin-to-skin contact after birth for infant bonding
d. Routine artificial rupture of membranes (amniotomy)
e. Labor induction with intravenous Pitocin
f. Routine episiotomy to shorten labor length

9. Physiologic preparation for labor would be demonstrated by

a. a decrease in Braxton Hicks contractions felt by mother.
b. weight gain and an increase in appetite by mother.
c. lightening, when the fetus drops into true pelvis.
d. fetal heart rate accelerations and increased movements.

10. Evidence-based practice applied to the clinical setting improves

a. communication between health care professionals.
b. client care and overall better outcomes.
c. cost-effectiveness of therapeutic treatments.
d. ability to carry out a research study by nurses.

CRITICAL THINKING EXERCISES

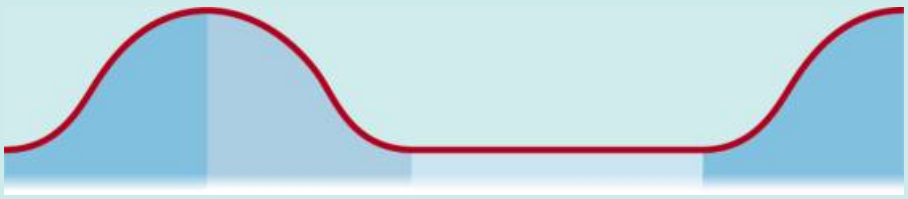
1. Cindy, a 20-year-old primipara, calls the birthing center where you work as a nurse and reports that she thinks she is in labor because she feels labor pains. Her due date is this week. The midwives have been giving her prenatal care throughout this pregnancy.

a. What additional information do you need to respond appropriately?
b. What suggestions and recommendations would you make to her?
c. What instructions need to be given to guide her decision-making process?
d. About what other premonitory signs of labor might the nurse ask?
e. What manifestations would be found if Cindy is experiencing true labor?

2. You are assigned to lead a community education class for women in the third trimester of pregnancy to prepare them for upcoming birth. Prepare an outline of topics that should be addressed.

STUDY ACTIVITIES

1. During clinical post-conference, share with the other nursing students how the critical forces of labor influenced the length of labor and the birthing process for a laboring woman assigned to you.
2. Which are cardinal movements of labor include? Select all that apply.
   a. Extension and rotation
   b. Descent and engagement
   c. Presentation and position
   d. Attitude and lie
   e. Flexion and expulsion
3. Interview a woman on the mother–baby unit who has given birth within the past few hours. Ask her to describe her experience and examine psychological factors that may have influenced her laboring process.
4. On the following illustration, identify the parameters of uterine contractions by marking an “X” where the nurse would measure the duration of the contraction.



BRINGING IT ALL TOGETHER: A CASE STUDY

Moritza is a 20-year-old pregnant female who comes to the prenatal clinic with her boyfriend for her prenatal visit at 39 weeks’ gestation. This is her first pregnancy and she has missed several of her previous prenatal office visits. Her pregnancy has been uneventful thus far, but she is concerned today about impending labor and how she will know when to go to the hospital. She feels unprepared for

labor and admits she is afraid of the pain since she has heard “horror” stories about others’ experiences. She admits she is scared about having an IV in her arm at the hospital. She wants a normal physiologic childbirth.

ASSESSMENT

Moritza has taken good care of herself during this pregnancy, having only gained 22 lb. She didn’t attend any of the prepared childbirth classes offered free through the health department, so she has numerous questions about her upcoming labor and birth. Fetal heart rate is 140 bpm, fetus active upon palpation, and there is no dependent edema in the extremities. Urine specimen was negative for glucose or protein. Today’s weight is 138 lb.

Go to thePoint to find questions to consider about this case.

Nursing Management During Labor and Birth

WOW

WORDS OF WISDOM

Wise nurses are not always silent, but they know when to be during the miracle of birth.

KEY TERMS

accelerations

artifact

baseline fetal heart rate

baseline variability

crowning

deceleration

electronic fetal monitoring (EFM)

episiotomy (e-piz´ē-ot´ŏ-mē)

Leopold maneuvers

neuraxial analgesia/anesthesia

periodic baseline changes

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Examine the measures used to evaluate maternal status during labor and birth.
2. Discuss the advantages and disadvantages of external and internal fetal monitoring, including the appropriate use for each.
3. Choose appropriate nursing interventions to address the categories of fetal heart rate patterns.
4. Outline the nurse's role in fetal assessment.
5. Appraise the various comfort promotion and pain relief strategies used during labor and birth.
6. Summarize the assessment data collected upon admission to the perinatal unit.
7. Relate the ongoing assessments involved in each stage of labor and birth.
8. Analyze the nurse's role throughout the labor and birth process.

Sheila was admitted in active labor to the labor and birth unit. She has progressed to dilated 8 cm and is becoming increasingly more uncomfortable. She is using a patterned-paced breathing pattern now, but is thrashing around in the hospital bed.

INTRODUCTION

The laboring and birthing process is a life-changing event. Childbirth is the culmination of a human pregnancy with the emergence of a newborn from the mother's uterus. Nurses need to be respectful, available, encouraging, supportive, and professional in dealing with all women. Nursing management for labor and birth involves assessment, comfort measures, emotional support, information and instruction, advocacy, and support for the partner. Providing the highest quality in maternity care is dependent on nurses valuing the childbirth experience and recognizing it as a life-changing experience for women and their families; caring nurse practice encompasses technical skills and caring behaviors; giving care that protects, promotes, and supports physiologic childbirth; providing optimal, evidence-based care; and recognizing health disparity and cultural diversity in all women cared for to improve their childbirth experience across time, settings, and disciplines. One of the components for evidence-based care and woman-centered care is a woman's preferences to guide care for herself during the birthing process. In a recent study, women's needs and expectations during labor and birth were assessed. Eight themes emerged—physiologic needs (nutrition, room environment, hygiene, comfort, and privacy); psychological needs (empathy and advocacy, constant emotional support and encouragement); informational needs (about labor process and hospital policies); communication needs (health care provider and familiar attendant); esteem needs (sense of value, confidence, involvement in decisions); security needs (calming fears); medical needs (pain relief and prevention of unnecessary interventions during labor and birth); and autonomy needs

(Siguroardottir et al., 2019). It is important that nurses identify the expectations and needs of women in their care so as to empower them to fully participate in their childbirth experience.

The health of mothers and their infants is of critical importance, both as a reflection of the current health status of a large segment of our population and as a predictor of the health of the next generation. The U.S. Department of Health and Human Services (USDHHS, 2019) addresses maternal health with objectives: reducing maternal deaths and reducing maternal illness and complications due to pregnancy (complications during hospitalized labor and delivery). In addition, more objectives address increasing the proportion of pregnant women who receive early and adequate prenatal care. (See Chapter 12 for more information on these objectives.)

This chapter provides information about nursing management during labor and birth. First, the essentials for in-depth assessment of maternal and fetal status during labor and birth are discussed. This is followed by a thorough description of the major methods of promoting comfort and providing pain management during the labor and birth process. The chapter concludes by putting all the information together with a discussion of the nursing care specific to each stage of labor, including the necessary data to be obtained with the admission assessment, methods to evaluate labor progress during the first stage of labor, and key nursing measures that focus on maternal and fetal assessments and pain relief for all stages of labor.

MATERNAL ASSESSMENT DURING LABOR AND BIRTH

During labor and birth, various techniques are used to assess maternal status. These techniques provide an ongoing source of data to determine the woman's response and her progress during labor:

- Assess maternal vital signs, including temperature, blood pressure, pulse, respiration, and pain, which are primary components of the physical examination and ongoing assessment.
- Also review the prenatal record to identify risk factors that may contribute to a decrease in uteroplacental circulation during labor.
- If there is no vaginal bleeding upon admission, a vaginal examination or ultrasound assessment is performed to assess cervical dilation, after which it is monitored periodically as necessary to identify progress.
- Evaluate maternal pain and the effectiveness of pain management strategies at regular intervals during labor and birth.

Vaginal Examination

Vaginal examinations form a part of the care for women in labor as a means to assess the progress of labor. However, these examinations are highly invasive and can be distressing and/or painful for many women. Nurses need to ensure that there is a clear indication to perform them and that the exam will provide information that will aid in the woman's care. Prior to performing a vaginal exam, a full explanation should be given to the woman and her birth partner. The woman's privacy and dignity should be maintained during the exam. A full explanation of the nurse's findings should be given to the woman and her birth partner with details of how the findings may impact the plan of care for her labor (Lindsay et al., 2018).

TAKE NOTE!

A vaginal examination is an assessment skill that takes time and experience to develop; only by doing it frequently in clinical practice can the practitioner's skill level improve.

The purpose of performing a vaginal examination is to assess the amount of cervical dilation, the percentage of cervical effacement, and the fetal membrane status and to gather information on presentation, position, station, degree of fetal head flexion, and

presence of fetal skull swelling or molding (Fig. 14.1). Prepare the woman by informing her about the procedure, what information will be obtained from it, how she can assist with the procedure, how it will be performed, and who will be performing it.

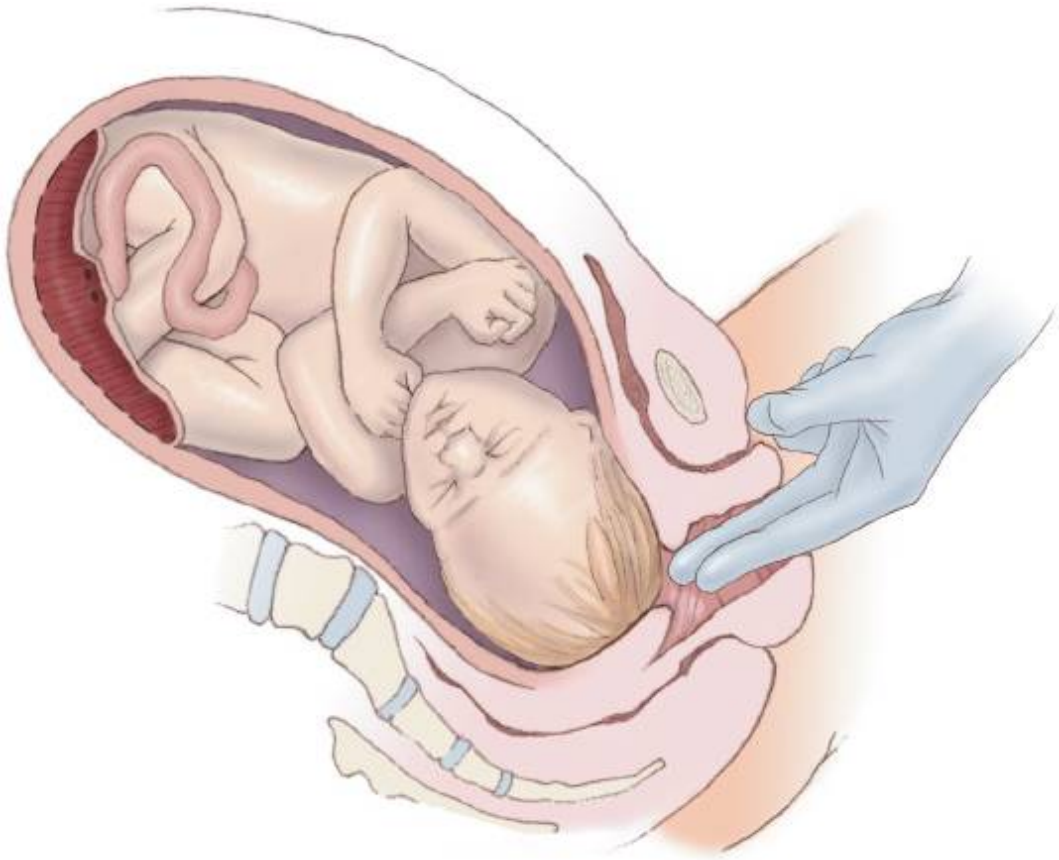

FIGURE 14.1. Vaginal examination to determine cervical dilation and effacement.

The woman is typically on her back during the vaginal examination. The vaginal examination is performed gently with concern for the woman's comfort. If it is the initial vaginal examination to check for membrane status, water is used as a lubricant.

After donning sterile gloves, the examiner inserts their index and middle fingers into the vaginal introitus. Next, the cervix is palpated to assess dilation, effacement, and position (e.g., posterior or anterior). If the cervix is open to any degree, the presenting fetal

part, fetal position, station, and presence of molding can be assessed. In addition, the membranes can be evaluated and described as intact, bulging, or ruptured.

At the conclusion of the vaginal examination, the findings are discussed with the woman and her partner to bring them up to date about labor progress. In addition, the findings are documented either electronically or in writing and reported to the primary health care provider in charge of the woman's care.

Cervical Dilation and Effacement

During the first stage of labor, the cervix opens and thins to allow descent of the fetus into the birth canal. The amount of cervical dilation (opening) and the degree of cervical effacement (thinning) are key areas assessed during the vaginal examination as the cervix is palpated with the gloved index finger. Although this finding is somewhat subjective, experienced examiners typically come up with similar findings. The width of the cervical opening determines dilation, and the length of the cervix assesses effacement. Effacement and dilation are used to assess cervical changes as follows:

- Effacement:
  - 0%: cervical canal is 2 cm long
  - 50%: cervical canal is 1 cm long
  - 100%: cervical canal is obliterated
- Dilation:
  - 0 cm: external cervical os is closed
  - 5 cm: external cervical os is halfway dilated
  - 10 cm: external os is fully dilated and ready for birth passage

The information yielded by this examination serves as a basis for determining which stage of labor the woman is in and what her ongoing care should be.

Fetal Descent and Presenting Part

In addition to cervical dilation and effacement findings, the vaginal examination or ultrasound can also determine fetal descent (station)

and presenting part. During the vaginal examination, the gloved index finger is used to palpate the fetal skull (if vertex presentation) through the opened cervix or the buttocks in the case of a breech presentation. Station is assessed in relation to the maternal ischial spines and the presenting fetal part. These spines are not sharp protrusions but rather blunted prominences at the midpelvis. The ischial spines serve as landmarks and have been designated as zero station. If the presenting part is palpated higher than the maternal ischial spines, a negative number is assigned; if the presenting fetal part is felt below the maternal ischial spines, a positive number is assigned, denoting how many centimeters below zero station (see Chapter 13 for a more detailed discussion).

Progressive fetal descent (−5 to +4) is the expected norm during labor—moving downward from the negative stations to zero station to the positive stations in a timely manner. If progressive fetal descent does not occur, a disproportion between the maternal pelvis and the fetus might exist and needs to be investigated.

Rupture of Membranes

The integrity of the membranes can be determined during the vaginal examination. Typically, if intact, the membranes will be felt as a soft bulge that is more prominent during a contraction. If the membranes have ruptured, the woman may have reported a sudden gush of fluid. Membrane rupture may also occur as a slow trickle of fluid. When membranes rupture, the priority focus should be on assessing fetal heart rate (FHR) first to identify a deceleration, which might indicate cord compression secondary to cord prolapse. If the membranes are ruptured when the woman comes to the hospital, the health care provider should ascertain when this occurred. Prolonged ruptured membranes increase the risk of infection as a result of ascending vaginal pathologic organisms for both mother and fetus. Signs of intrauterine infection to be alert for include maternal fever, fetal and maternal tachycardia, foul odor of vaginal discharge, and an increase in white blood cell count.

The fetal membranes usually rupture during the first stage of labor. To confirm if they have ruptured, a sample of fluid is taken from the vagina via a nitrazine yellow dye swab to determine the fluid's pH. Vaginal fluid is acidic, while amniotic fluid is alkaline and turns a nitrazine swab blue. Sometimes, however, false-positive results can occur, especially in women experiencing a large amount of bloody show because blood is alkaline. The membranes are most likely intact if the nitrazine swab remains yellow to olive green with pH between 5 and 6. The membranes are probably ruptured if the nitrazine swab turns a blue-green to deep blue with pH ranging from 6.5 to 7.5 (Jordan et al., 2019). Many bedside tests are available to determine a change in vaginal pH or the presence of amniotic components insulin-like growth factor–binding protein 1 (a gene that may predict placental dysfunction, gestational diabetes, and preterm labor) or alpha-fetoprotein (AFP) in the vaginal fluid. These tests should be part of an overall clinical assessment and not rely exclusively on one test (FDA, 2019).

Assessing Uterine Contractions

The primary power of labor is uterine contractions, which are involuntary. Uterine contractions increase intrauterine pressure, causing tension on the cervix. This tension leads to cervical dilation and thinning, which in turn eventually forces the fetus through the birth canal. Normal uterine contractions have a contraction (systole) and a relaxation (diastole) phase. The contraction resembles a wave, moving downward to the cervix and upward to the fundus of the uterus. Each contraction starts with a building up (increment), gradually reaching an acme (peak intensity), and then a letting down (decrement). Each contraction is followed by an interval of rest, which ends when the next contraction begins. At the acme (peak) of the contraction, the entire uterus is contracting with the greatest intensity in the fundal area. The relaxation phase follows and occurs simultaneously throughout the uterus.

Uterine contractions during labor are monitored by palpation of the uterine fundus and by electronic monitoring. Assessment of the

contractions includes frequency, duration, intensity, and uterine resting tone (see Chapter 13 for a more detailed discussion). Uterine contractions with an intensity of 30 mm Hg or greater initiate cervical dilation. During active labor, the intensity usually reaches 50 to 80 mm Hg. Resting tone is normally between 5 and 10 mm Hg in early labor and between 12 and 18 mm Hg in active labor (Milton, 2019).

To palpate the fundus for contraction intensity, place the pads of your fingers on the fundus and describe how it feels: like the tip of the nose (mild), like the chin (moderate), or like the forehead (strong). Palpation of intensity is a subjective judgment of the indentability of the uterine wall; a descriptive term is assigned (mild, moderate, or strong) (Fig. 14.2).

FIGURE 14.2. Nurse palpating the woman's fundus during a contraction.

TAKE NOTE!

Frequent clinical experience is needed to gain accuracy in assessing the intensity of uterine contractions.

The second method used to assess the intensity of uterine contractions is electronic monitoring, either external or internal. Both methods provide a reasonable measurement of the intensity of uterine contractions. Although the external fetal monitor is sometimes used to estimate the intensity of uterine contractions, it is not as accurate an assessment tool.

Performing Leopold Maneuvers

Leopold maneuvers are a method for determining the presentation, position, and lie of the fetus through the use of four specific steps. This method involves inspection and palpation of the maternal abdomen as a screening assessment for malpresentation. The flat palmar surfaces of the nurse's hands with the fingers together palpate the uterus. A longitudinal lie is expected, and the presentation can be cephalic, breech, or shoulder. Each maneuver answers a question:

- *Maneuver 1*: What fetal part (head or buttocks) is located in the fundus (top of the uterus)?
- *Maneuver 2*: On which maternal side is the fetal back located? (Fetal heart tones are best auscultated through the back of the fetus.)
- *Maneuver 3*: What is the presenting part?
- *Maneuver 4*: Is the fetal head flexed and engaged in the pelvis?

Leopold maneuvers are described in Nursing Procedure 14.1. Also see Chapter 12.

NURSING PROCEDURE 14.1 Performing Leopold Maneuvers

Purpose: To Determine Fetal Presentation, Position, and Lie

1. Place the woman in the supine position and stand beside her.
2. Perform the first maneuver to determine presentation.
   a. Facing the woman's head, place both hands on the abdomen to determine fetal position in the uterine fundus.
   b. Feel for the buttocks, which will feel soft and irregular (indicates vertex presentation); feel for the head, which will feel hard, smooth, and round (indicates a breech presentation).

3. Complete the second maneuver to determine position.
   a. While still facing the woman, move hands down the lateral sides of the abdomen to palpate on which side the back is located (feels hard and smooth).
   b. Continue to palpate to determine on which side the limbs are located (irregular nodules with kicking and movement).

4. Perform the third maneuver to confirm presentation.
    a. Move hands down the sides of the abdomen to grasp the lower uterine segment and palpate the area just above the symphysis pubis.
    b. Place thumb and fingers of one hand apart and grasp the presenting part by bringing fingers together.
    c. Feel for the presenting part. If the presenting part is the head, it will be round, firm, and ballottable; if it is the buttocks, it will feel soft and irregular.

5. Perform the fourth maneuver to determine attitude.
   a. Turn to face the client's feet and use the tips of the first three fingers of each hand to palpate the abdomen.
   b. Move fingers toward each other while applying downward pressure in the direction of the symphysis pubis. If you palpate a hard area on the side opposite the fetal back, the fetus is in flexion, because you have palpated the chin. If the hard area is on the same side as the back, the fetus is in extension, because the area palpated is the occiput.

Also, note how your hands move. If the hands move together easily, the fetal head is not descended into the woman's pelvic inlet. If the hands do not move together and stop because of resistance, the fetal head is engaged into the woman's pelvic inlet (Lindsay et al., 2018).

FETAL ASSESSMENT DURING LABOR AND BIRTH

A fetal assessment identifies well-being or signs that indicate compromise. The character of the amniotic fluid is assessed, but the fetal assessment focuses primarily on determining the FHR pattern. Umbilical cord blood analysis and fetal scalp stimulation are additional assessments performed as necessary in the case of questionable FHR patterns.

Analysis of Amniotic Fluid

Amniotic fluid should be clear when the membranes rupture. Rupturing of membranes is either spontaneous or artificial by means of an amniotomy, during which a disposable plastic hook (an Amnihook) is used to perforate the amniotic sac. Cloudy or foul-smelling amniotic fluid indicates infection. Green fluid may indicate that the fetus has passed meconium secondary to transient hypoxia, prolonged pregnancy, cord compression, intrauterine growth restriction (IUGR), maternal hypertension, diabetes, or chorioamnionitis; however, it is considered a normal occurrence if the fetus is in a breech presentation. If it is determined that meconium-stained amniotic fluid is due to fetal hypoxia, the maternity and pediatric teams work together to prevent meconium aspiration syndrome, which can lead to respiratory distress. This would necessitate suctioning after the head is born before the infant takes a breath and perhaps direct tracheal suctioning after birth if the Apgar score is low. In some cases, an amnioinfusion (introduction of warmed, sterile normal saline or Ringer's lactate solution into the uterus) is used to dilute moderate to heavy meconium released in utero to assist in preventing meconium aspiration syndrome.

Analysis of the FHR

Monitoring of the FHR throughout labor and birth is essential to assure fetal well-being to optimize neonatal outcomes. Analysis of the FHR is one of the primary evaluation tools used to determine fetal oxygen status indirectly. FHR assessment can be done intermittently using a fetoscope (a modified stethoscope attached to a headpiece) or a Doppler (ultrasound) device, or continuously with an electronic fetal monitor applied externally or internally. The object of FHR monitoring is to reduce mortality and morbidity by ensuring that all fetal hypoxic insults are identified in time to allow removal or alteration of the reason for them, or to enable a safe birth of the fetus before irreversible asphyxia damage occurs (Murray et al., 2019).

Intermittent FHR Monitoring

Intermittent auscultation is a primary method of fetal surveillance in labor. It is the practice of using a handheld Doppler or fetoscope for periodic assessment of the FHR. The handheld Doppler device uses ultrasound waves that bounce off the fetal heart, producing echoes or clicks that reflect the rate of the fetal heart (Fig. 14.3). Intermittent auscultation of the FHR is an acceptable option for low-risk laboring women, yet it is underutilized in the hospital setting. Recently several professional organizations have proposed the use of intermittent auscultation as a means of promoting physiologic births (AWHONN, 2018); thus, at present, it is used in some clinical settings. See Evidence-Based Practice 14.1 for more information.

FIGURE 14.3. Nurse using a handheld Doppler to obtain a fetal heart rate.

TAKE NOTE!

Doppler devices to detect FHRs are relatively low in cost and are used in hospitals and in home births and birthing centers routinely. Many nurses use them in their work settings.

The nurse listens to FHR for short periods of time at regular intervals. Intermittent FHR monitoring allows the woman to be mobile during the first stage of labor. She is free to move around and change position at will since she is not attached to a stationary electronic fetal monitor. However, intermittent monitoring does not provide a continuous FHR recording and does not document how the fetus responds to the stress of labor (unless listening is done during the contraction). The best way to assess fetal well-being would be to start listening to the FHR at the end of the contraction (not after one) so that late decelerations could be detected. However, the pressure of the device during a contraction is uncomfortable and can distract the woman from using her paced-breathing patterns.

Intermittent FHR auscultation can be used to detect FHR baseline and rhythm and changes from baseline. However, it cannot detect variability and types of decelerations, as electronic fetal monitoring (EFM) can. Research finds no differences between continuous fetal monitoring versus intermittent fetal monitoring as they relate to Apgar scores, cord blood gases, rates of low-oxygen brain damage, admission to the neonatal intensive care unit (NICU), or perinatal death rates (Dekker, 2019a). During intermittent auscultation to establish a baseline, the FHR is assessed for a full minute after a contraction. From then on, unless there is a problem, listening for 30 seconds and multiplying the value by two is sufficient. If the woman experiences a change in condition during labor, auscultation assessments should be more frequent. Changes in condition include ruptured membranes or the onset of bleeding. In addition, more frequent assessments occur after periods of ambulation, a vaginal examination, administration of pain medications, or other clinically important events (King et al., 2019).

EVIDENCE-BASED PRACTICE 14.1

Effectiveness of a Novel Continuous Doppler (Mayo) versus Intermittent Doppler in Intrapartum Detection of Abnormal FHR: A Randomized Controlled Study

STUDY

Intrapartum FHR monitoring is an important strategy in providing a targeted and appropriate management of fetal well-being. Monitoring of fetal well-being is essential for identification of hypoxic fetuses, and it provides subsequent interventions. The objective of this study was to compare the effectiveness of continuous monitoring versus intermittent handheld Doppler in the intrapartum detection of abnormal FHR. An unmasked randomized controlled study was conducted using a total of 2,973 low-risk singleton pregnant women in the first stage of labor. They were divided into two groups, intermittently monitored every 30 minutes in the first stage and 5 to 15 minutes in the second stage versus continuously monitored.

Findings

Use of the continuous Mayo device identified 46% more abnormal FHRs compared to the intermittent Doppler assessments; however, the cesarean section rates were 26% higher in the Mayo continuous monitoring group versus the intermittent group. There were no differences in perinatal outcomes between the two groups. The higher rates of surgical births with continuous FHR monitoring compared to intermittent monitoring are consistent with previous studies and systematic reviews.

Nursing Implications

An abnormal FHR was detected more frequently and earlier when using continuous monitoring as compared to intermittent assessments; there were no differences in adverse perinatal outcomes. Despite the lack of scientific evidence to support routinely using continuous EFM to reduce adverse perinatal outcomes, its use is almost universal in the hospital setting and likely has contributed to the rise in cesarean birth rates. Nurses are uniquely positioned to influence the monitoring method used in labor by offering intermittent auscultation to low-risk women and requesting orders from the health care providers that include it as an option. The high-touch nature of intermittent auscultation may help nurses reconnect to their clients and to the essence of nursing practice.

Adapted from Kamala, B., Kidanto, H., Dalen, I., Ngarina, M., Abeid, M., Perlman, J., & Ersdal, H. (2019). Effectiveness of a novel continuous Doppler (Mayo) verses intermittent Doppler in intrapartum detection of abnormal FHR: A randomized controlled study. International Journal of Environmental Research and Public Health, 16, 315. https://doi.org/10.3390/ijerph16030315.

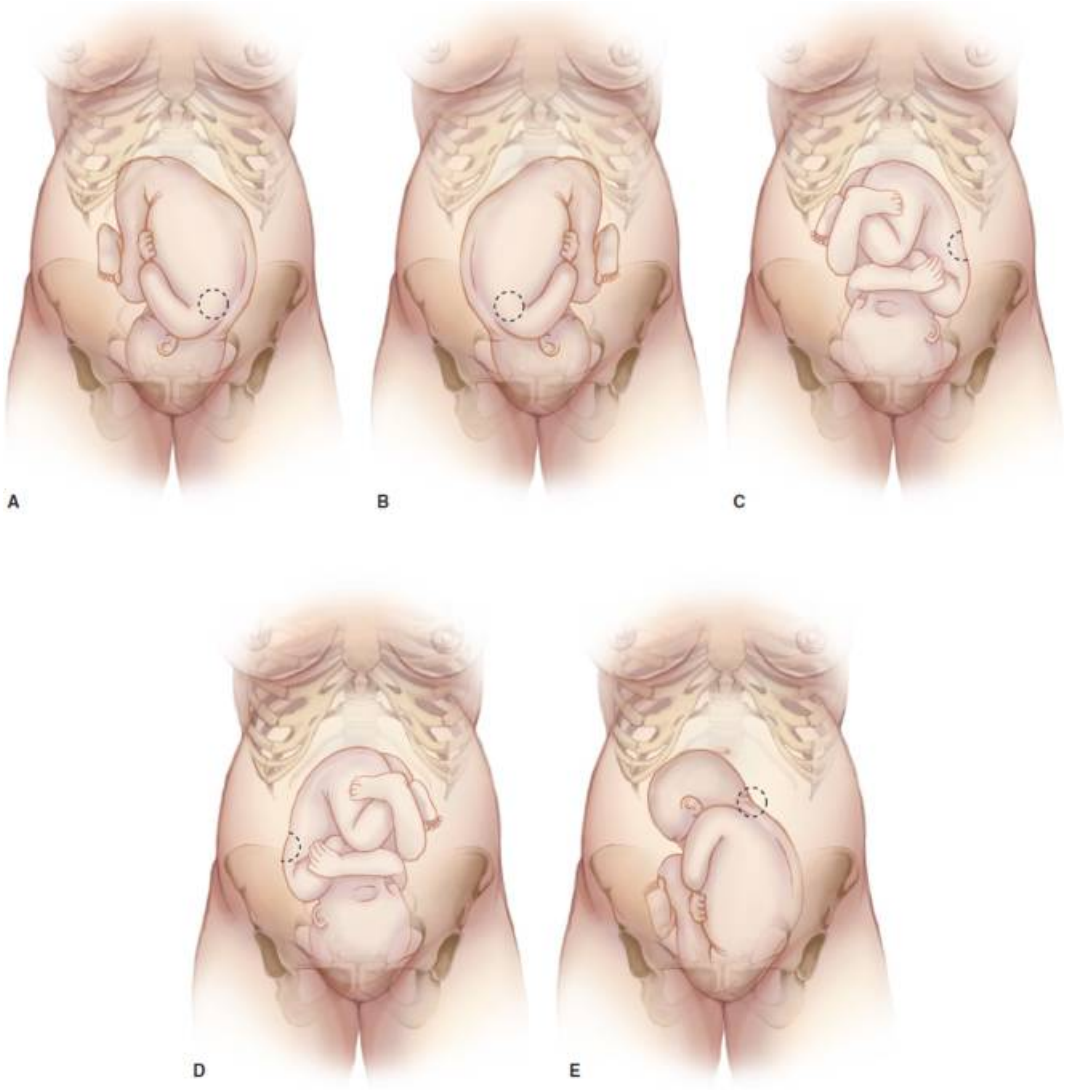

FIGURE 14.4. Locations for auscultating fetal heart rate based on fetal position. **A.** Left occiput anterior (LOA). **B.** Right occiput anterior (ROA). **C.** Left occiput posterior (LOP). **D.** Right occiput posterior (ROP). **E.** Left sacral anterior (LSA).

The FHR is heard most clearly at the fetal back. In a cephalic presentation, the FHR is best heard in the lower quadrant of the maternal abdomen. In a breech presentation, it is heard at or above the level of the maternal umbilicus (Fig. 14.4). As labor progresses, the FHR location will change accordingly as the fetus descends into the maternal pelvis for the birthing process. To ensure that the maternal heart rate is not confused with the FHR, palpate the client's

radial pulse simultaneously while the FHR is being auscultated through the abdomen.

For low-risk women, the FHR and contraction characteristics should be assessed every 15 to 30 minutes in active labor and every 5 to 15 minutes while pushing, as well as before and after any digital vaginal examinations, membrane rupture, medication administered, and ambulation to the restroom (Lindsay et al., 2018).

Nursing Procedure 12.1 lists detailed steps for using a Doppler device to assess FHR. In brief, a small amount of water-soluble gel is applied to the woman's abdomen or ultrasound device before auscultation with the Doppler device to promote sound wave transmission. Usually the FHR is best heard in the woman's lower abdominal quadrants; if the FHR is not found quickly, it may help locate the fetal back by performing Leopold maneuvers.

Although the intermittent method of FHR assessment allows the client to move during labor, the information obtained doesn't provide a complete picture of the well-being of the fetus from moment to moment. This leads to the question of what the fetal status is during the times that are not assessed. For women who are considered at low risk for complications, these periods without assessment is not a problem. However, for the undiagnosed high-risk woman, it might prove ominous.

GUIDELINES FOR ASSESSING FHR

National professional organizations have provided general guidelines for the frequency of assessments based on existing evidence. The American College of Obstetricians and Gynecologists (ACOG), the World Health Organization (WHO), and the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) have published guidelines designed to assist clinicians in caring for laboring clients. Their recommendations are supported by large controlled studies. They recommend the following guidelines for assessing FHR:

- Initial 10- to 20-minute continuous FHR assessment upon entry into labor and birth area
- Completion of a prenatal and labor risk assessment on all clients

- Intermittent auscultation every 30 minutes during active labor for a low-risk woman and every 15 minutes for a high-risk woman
- During the second stage of labor, every 15 minutes for the low-risk woman and every 5 minutes for the high-risk woman and during the pushing stage (ACOG, 2019; AWHONN, 2018; WHO, 2018)

EVIDENCE-BASED RESULTS: INTERMITTENT VERSUS ELECTRONIC MONITORING

In several randomized controlled studies comparing intermittent auscultation with electronic monitoring in both low- and high-risk clients, no difference in intrapartum fetal death was found, but an increase in surgical births occurred with electronic monitoring when compared to intermittent Doppler monitoring (Bayes & Whitehead, 2018). There is insufficient evidence to indicate specific situations in which continuous electronic FHR monitoring might result in better outcomes when compared to intermittent assessment. However, in pregnancies involving an increased risk of perinatal death, cerebral palsy, or neonatal encephalopathy, and when oxytocin is used for induction or augmentation, it is recommended that continuous EFM be used rather than intermittent fetal auscultation (Society of Obstetricians and Gynecologists of Canada, 2018).

Continuous Electronic Fetal Monitoring

Continuous fetal monitoring was brought into labor rooms in the 1970s, despite the fact that there was no evidence from research to support its safety or effectiveness. Randomized trials have found that EFM has contributed to an increase in cesarean birth rates without improving rates of occurrences of cerebral palsy, Apgar scores, cord blood gases, rates of NICU admissions, or perinatal death rates (Dekker, 2019a). **Electronic fetal monitoring (EFM)** detects the fetal pulse by sensing and analyzing tissue movements via Doppler ultrasound. The machine uses a transducer that is capable of both sending and receiving ultrasound waves. The waves travel through the ultrasound gel, then body tissues, and are

eventually reflected by any tissue. The fast reflections are analyzed and software in the machine determines the FHR. EFM is the recommended method of intrapartum fetal surveillance for high-risk pregnancies. Despite the questions about its efficacy and controversy regarding increased rates of surgical births associated with its use, continuous cardiotocography (CTG) remains the predominant method of fetal monitoring today (Milton, 2019).

EFM is not a substitute for appropriate, professional nursing care and support of women in labor. The indications for offering women continuous fetal monitoring in labor are documented in the National Institute for Health and Care Excellence (NICE) guidelines. These include women receiving oxytocin infusing; women who have epidural analgesia; and when there are a variety of problems related to a compromise in either fetal or maternal health like prolonged rupture of membranes (longer than 24 hours), moderate hypertension (higher than 150/100 mm Hg), confirmed delay in the first or second stage of labor, and the presence of meconium (NICE, 2019).

EFM uses a machine to produce a continuous tracing of the FHR. When the monitoring device is in place, a sound is produced with each heartbeat. In addition, a graphic record of the FHR pattern is produced. The primary objective of EFM is to provide information about fetal oxygenation and prevent fetal injury that could result from impaired fetal oxygenation during labor. The purpose of EFM is to detect FHR changes early before they are prolonged and profound. Fetal hypoxia is demonstrated in a heart rate pattern change and is by far the most common etiology of fetal injury and death that can be prevented with optimal fetal surveillance during labor and early interventions (Murray et al., 2019).

Current methods of continuous EFM were introduced in the United States, specifically for use in clients considered to be at high risk. However, the use of these methods gradually increased and they eventually came to be used for women beyond those at high risk. This increased use has become controversial because it is suspected of being associated with the steadily increasing rates of cesarean births with no decrease in the rate of cerebral palsy

(Ehsanipoor & Satin, 2019). Many studies suggest that when compared with standardized intermittent auscultation, the use of intrapartum continuous EFM seems to increase the number of preterm and surgical births but has no significant effect on reducing the incidence of intrapartum death or long-term neurologic injury. When a woman is admitted to the labor unit, a fetal monitor is applied and the FHR is monitored continuously. EFM has been given excessive importance in legal cases. Using EFM during labor helps determine whether the fetus is well oxygenated, thereby reducing the risks of neonatal seizures or fetal death. It enables practitioners to detect fetal acidemia earlier and intervene to prevent injury. Before assigning fault on events at birth, a better understanding of developmental neurobiology and limitations of the present biomarkers is warranted (Reiter & Thomas, 2018).

With EFM, there is a continuous record of the FHR; no gaps exist, as they do with intermittent auscultation. The concept of hearing and evaluating every beat of the fetus's heart to allow for early intervention seems logical. However, using continuous monitoring can limit maternal movement and encourages the woman to lie in the supine position, which reduces placental perfusion. Despite the criticisms, EFM remains an accurate method for determining fetal health status by providing a moment-to-moment printout of FHR status.

Various groups within the medical community have criticized the use of continuous fetal monitoring for all pregnant clients, especially those at low risk. Concerns about the efficiency and safety of routine EFM in labor have led expert panels in the United States to recommend that such monitoring be limited to high-risk pregnancies. However, its use in low-risk pregnancies continues globally. The clinical goal of EFM is to identify fetuses with increased risk of hypoxic injury so that intervention can avoid adverse outcomes (Norwitz et al., 2019). This remains an important research issue.

Continuous EFM can be performed externally (indirectly) with the equipment attached to the maternal abdominal wall or internally (directly) with the equipment attached to the fetus. Both methods provide a continuous printout of the FHR, but they differ in their

specificity. The efficacy of EFM depends on the accurate interpretation of the tracings, not necessarily which method (external or internal) is used.

CONTINUOUS EXTERNAL MONITORING

In external or indirect monitoring, two ultrasound transducers, each of which is attached to a belt, are applied around the woman's abdomen. They are similar to the handheld Doppler device. One transducer is called a tocotransducer, a pressure-sensitive device that is applied against the uterine fundus. It detects changes in uterine pressure and converts the pressure registered into an electronic signal that is recorded on graph paper (Lindsay et al., 2018). The tocotransducer is placed over the uterine fundus in the area of greatest contractility to monitor uterine contractions. The other ultrasound transducer records the baseline FHR, long-term variability, accelerations, and decelerations. It is positioned on the maternal abdomen in the midline between the umbilicus and the symphysis pubis. The diaphragm of the ultrasound transducer is moved to either side of the abdomen to obtain a stronger sound and is then attached to the second elastic belt. This transducer converts the fetal heart movements into beeping sounds and records them on graph paper (Fig. 14.5).

Good continuous data are provided on the FHR. External monitoring can be used while the membranes are still intact and the cervix is not yet dilated but also can be used with ruptured membranes and a dilating cervix. It is noninvasive and can detect relative changes in abdominal pressure between uterine resting tone and contractions. External monitoring also measures the approximate duration and frequency of contractions, providing a permanent record of FHR (King et al., 2019).

However, external monitoring can restrict the mother's movements. It also cannot detect short-term variability. Signal disruptions can occur due to maternal obesity, fetal malpresentation, and fetal movement as well as by artifact. The term **artifact** is used to describe irregular variations or absence of the FHR on the fetal

monitor record that result from mechanical limitations of the monitor or electrical interference. For instance, the monitor may pick up transmissions from radios used by drivers on nearby roads and translate them into a signal. Additionally, gaps in the monitor strip can occur periodically without explanation.

FIGURE 14.5. Continuous external electronic fetal monitoring device applied to the woman in labor.

CONTINUOUS INTERNAL MONITORING

Continuous internal monitoring is usually indicated for women or fetuses considered to be at high risk. Possible conditions might include multiple gestation, decreased fetal movement, abnormal FHR on auscultation, IUGR, maternal fever, preeclampsia, dysfunctional labor, preterm birth, or medical conditions such as diabetes or hypertension. It involves the placement of a spiral electrode into the fetal presenting part, usually the parietal bone on the head, to assess FHR, and a pressure transducer placed

internally within the uterus to record uterine contractions (Fig. 14.6). The fetal spiral electrode is considered the most accurate method of detecting fetal heart characteristics and patterns because it involves receiving a signal directly from the fetus (Cunningham et al., 2018). Specially trained labor and birth nurses are permitted to place the spiral electrode on the fetal head when the membranes rupture to assess the FHR in some health care facilities, but they do not place the intrauterine pressure catheter in the uterus. Internal monitoring does not have to include both an intrauterine pressure catheter and a scalp electrode. A fetal scalp electrode can be used to monitor the fetal heartbeat without monitoring the maternal intrauterine pressure.

Both the FHR and the duration and interval of uterine contractions are recorded on the graph paper. This method permits evaluation of baseline heart rate and changes in rate and pattern.

Four specific criteria must be met for this type of monitoring to be used:

- Ruptured membranes
- Cervical dilation of at least 2 cm

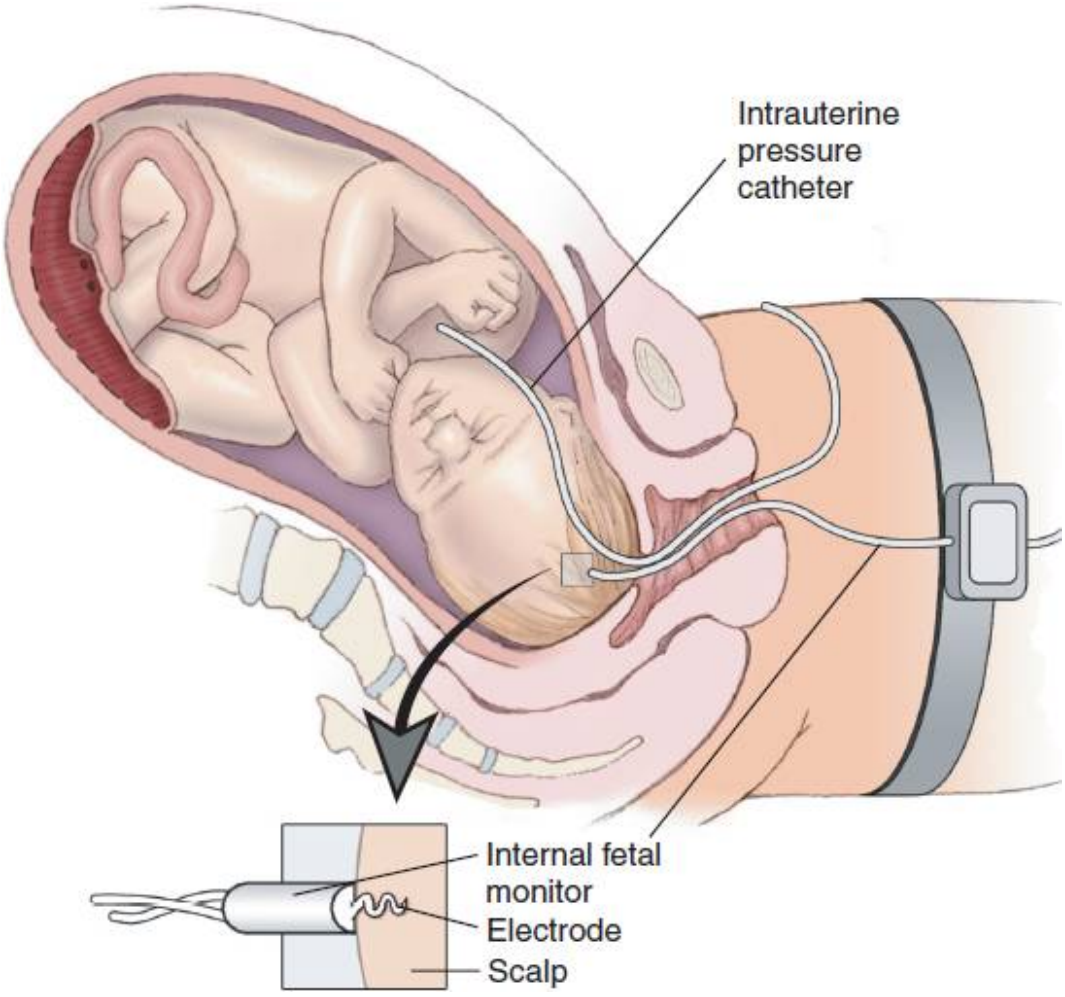

FIGURE 14.6. Continuous internal electronic fetal monitoring.

- Presenting fetal part low enough to allow placement of the scalp electrode
- Skilled practitioner available to insert spiral electrode (Murray et al., 2019)

Compared with external monitoring, continuous internal monitoring can accurately detect both short-term (moment-to-moment) changes and variability (fluctuations within the baseline) and FHR dysrhythmias. In addition, maternal position changes and movement do not interfere with the quality of the tracing.

Determining FHR Patterns

Due to the rising costs of litigation related to birth asphyxia of the newborn and increasing complexity of obstetric populations, it has become absolutely mandatory that all nurses responsible for the care of women in labor are trained adequately in interpretation and documentation of electronic tracings, as well as the guidelines for interventions based on the assessment of the tracing and overall clinical situation. Assessment parameters of the FHR include baseline FHR and variability, presence of accelerations, periodic or episodic decelerations, and changes or trends of FHR patterns over time. The nurse must be able to interpret the various parameters to determine if the FHR pattern is a *category I*, strongly predictive of normal fetal acid–base status at the time of observation and needs no intervention; a *category II*, not predictive of abnormal fetal acid–base status but does require evaluation and continued monitoring; or a *category III*, predictive of abnormal fetal acid–base status at the time of observation and requires prompt evaluation and interventions, such as giving maternal oxygen, changing maternal position, discontinuing labor augmentation medication, and/or treating maternal hypotension (AWHONN, 2018). Table 14.1 summarizes these categories.

BASELINE FHR

Baseline fetal heart rate refers to the average FHR that occurs during a 10-minute segment that excludes periodic or episodic rate changes, such as tachycardia or bradycardia. It is assessed when the woman has no contractions and the fetus is not experiencing episodic FHR changes. The normal baseline FHR ranges between 110 and 160 beats per minute (bpm) (Deering, 2018). The normal baseline FHR can be obtained by auscultation, ultrasound, or Doppler, or by a continuous internal direct fetal electrode.

Fetal bradycardia occurs when the FHR is below 110 bpm and lasts 10 minutes or longer (Blackburn, 2018). Causes of fetal bradycardia might include fetal hypoxia, prolonged maternal hypoglycemia, fetal acidosis, administration of analgesic drugs to the mother, hypothermia, anesthetic agents (epidural), maternal

hypotension, fetal hypothermia, prolonged umbilical cord compression, and fetal congenital heart block (Carvalho, 2019). Bradycardia may be benign if it is an isolated event, but it is considered an ominous sign when accompanied by a decrease in baseline variability and late decelerations.

TABLE 14.1 Interpreting Fetal Heart Rate Patterns

Category I: normal	Predictive of normal fetal acid–base status and do not require intervention • Baseline rate (110–160 bpm) • Baseline variability moderate • Present or absent accelerations • Present or absent early decelerations • No late or variable decelerations • Can be monitored with intermittent auscultation during labor
Category II: indeterminate	Not predictive of abnormal fetal acid–base status, but require evaluation and continued surveillance • Fetal tachycardia (>160 bpm) present • Bradycardia (<110 bpm) not accompanied by absent baseline variability • Absent baseline variability not accompanied by recurrent decelerations • Minimal or marked variability • Recurrent late decelerations with moderate baseline variability • Recurrent variable decelerations accompanied by minimal or moderate baseline variability; overshoots, or shoulders • Prolonged decelerations >2 minutes but <10 minutes
Category III: abnormal	Predictive of abnormal fetus acid–base status and require intervention • Fetal bradycardia (<110 bpm) • Recurrent late decelerations • Recurrent variable decelerations—declining or absent • Sinusoidal pattern (smooth, undulating baseline)

Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN). (2018). Fetal heart monitoring. *Nursing for Women's Health*, *22*(6), 506–509; Dekker, R. (2019a). *The evidence on: Fetal monitoring*. Retrieved May 21, 2018, from https://evidencebasedbirth.com/fetal-monitoring/; and Murray, M. L., Huelsmann, G., & Koperski, N. (2019). *Essentials of fetal and uterine monitoring* (5th ed.). Springer Publishing Company.

Fetal tachycardia is a baseline FHR greater than 160 bpm that lasts for 10 minutes or longer (Murray et al., 2019). It can represent an early compensatory response to asphyxia. Other causes of fetal tachycardia include fetal hypoxia, maternal fever, maternal dehydration, amnionitis, drugs (e.g., cocaine, amphetamines, nicotine), maternal hyperthyroidism, maternal anxiety, fetal anemia, prematurity, fetal infection, chronic hypoxemia, congenital anomalies, fetal heart failure, and fetal arrhythmias. Fetal tachycardia is considered an ominous sign if it is accompanied by a decrease in variability and late decelerations (Carvalho, 2019).

BASELINE VARIABILITY

Baseline variability is defined as irregular fluctuations in the baseline FHR, which is measured as the amplitude of the peak to trough in beats per minute (De Cherney et al., 2019). It represents the interplay between the parasympathetic and sympathetic nervous systems. The constant interplay (push-and-pull effect) on the FHR from the parasympathetic and sympathetic systems produces a moment-to-moment change in the FHR. Because variability is in essence the combined result of autonomic nervous system branch function, its presence implies that both branches are working and receiving adequate oxygen (Blackburn, 2018). Thus, variability is one of the most important characteristics of the FHR. Variability is described in four categories as follows:

- Fluctuation range undetectable
- Fluctuation range observed at fewer than 5 bpm
- Fluctuation range from 6 to 25 bpm
- Fluctuation range more than 25 bpm

Absent or minimal variability is typically caused by fetal acidemia secondary to uteroplacental insufficiency, cord compression, a preterm fetus, maternal hypotension, uterine hyperstimulation, abruptio placenta, or a fetal dysrhythmia. Interventions to improve uteroplacental blood flow and perfusion through the umbilical cord include lateral positioning of the mother, increasing the intravenous (IV) fluid rate to improve maternal circulation, administering oxygen at 8 to 10 L/min by mask, considering internal fetal monitoring, documenting findings, and reporting to the health care provider. Preparation for a surgical birth may be necessary if no changes occur after attempting the interventions.

Moderate viability indicates that the autonomic and central nervous systems (CNSs) of the fetus are well developed and well oxygenated. It is considered a good sign of fetal well-being and correlates with the absence of significant metabolic acidosis (Fig. 14.7).

Marked variability occurs when there are more than 25 beats of fluctuation in the FHR baseline. Causes of this include cord prolapse or compression, maternal hypotension, uterine hyperstimulation, and abruptio placenta. Interventions include determining the cause if possible, lateral positioning, increasing IV fluid rate, administering oxygen at 8 to 10 L/min by mask, discontinuing oxytocin infusion, observing for changes in tracing, considering internal fetal monitoring, communicating an abnormal pattern to the health care provider, and preparing for a surgical birth if no change in pattern is noted (Kellerman & Rakel, 2019).

FHR variability is an important clinical indicator that is predictive of fetal acid–base balance and cerebral tissue perfusion. It is influenced by fetal oxygenation status, cardiac output, and drug effects (King et al., 2019). As the CNS is desensitized by hypoxia and acidosis, FHR decreases until a smooth baseline pattern appears. Loss of variability may be associated with a poor outcome.

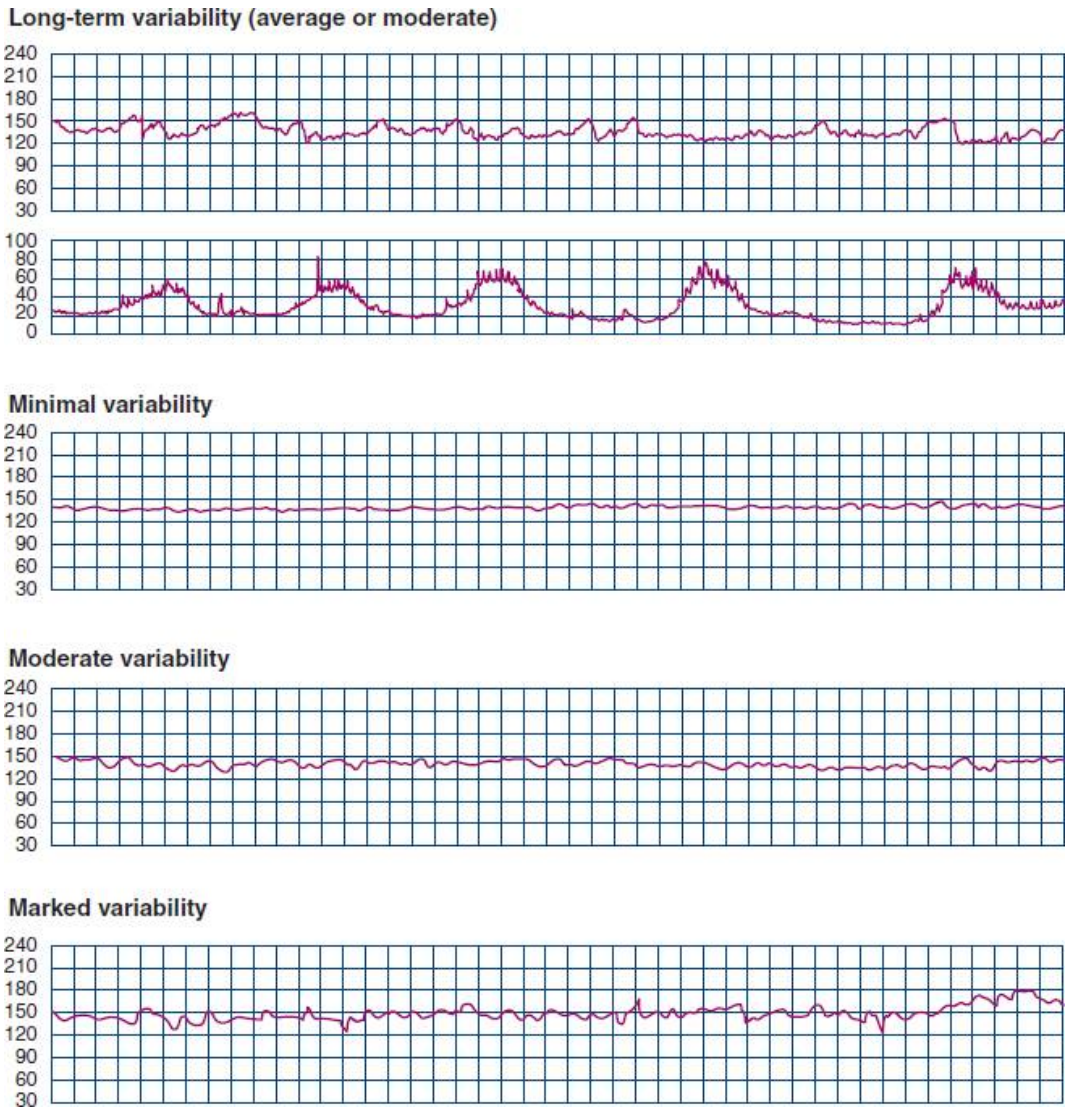

FIGURE 14.7. Examples of fetal monitoring strips.

TAKE NOTE!

External electronic fetal monitoring cannot assess variability accurately. Therefore, if external monitoring shows a baseline that is smoothing out, use of an internal spiral electrode should be considered to gain a more accurate picture of the fetal health status.

PERIODIC BASELINE CHANGES

Periodic baseline changes are temporary, recurrent changes made in response to a stimulus such as a contraction. The FHR can

demonstrate patterns of acceleration or deceleration in response to most stimuli. Fetal **accelerations** are transitory abrupt increases in the FHR above the baseline that last less than 30 seconds from onset to peak. They are associated with sympathetic nervous stimulation. They are visually apparent, with elevations of FHR of more than 15 bpm above the baseline, and their duration is longer than 15 seconds but less than 2 minutes (Funai & Norwitz, 2019). They are generally considered reassuring and require no interventions. Accelerations denote fetal movement and fetal well-being and are the basis for nonstress testing.

Concept Mastery Alert

Responding to Fetal Heart Rate Distress during Labor

During possible fetal distress that involves lack of variability, late decelerations, and fetal tachycardia, simply changing the woman's position is inadequate. The nurse should notify the health care provider immediately regarding the situation.

A **deceleration** is a transient fall in FHR caused by stimulation of the parasympathetic nervous system. Decelerations are described by their shape and association to a uterine contraction. They are classified as early, late, and variable only (Fig. 14.8).

Early decelerations are visually apparent, usually symmetrical, and characterized by a gradual decrease in the FHR in which the nadir (lowest point) occurs at the peak of the contraction. They rarely decrease more than 30 to 40 bpm below the baseline. Typically, the onset, nadir, and recovery of the deceleration occur at the same time as the onset, peak, and recovery of the contraction. They are most often seen during the active stage of any normal labor, during pushing, crowning, or vacuum extraction. They are thought to be a result of fetal head compression that results in a reflex vagal response with a resultant slowing of the FHR during uterine contractions. Early decelerations are not indicative of fetal distress and do not require intervention.

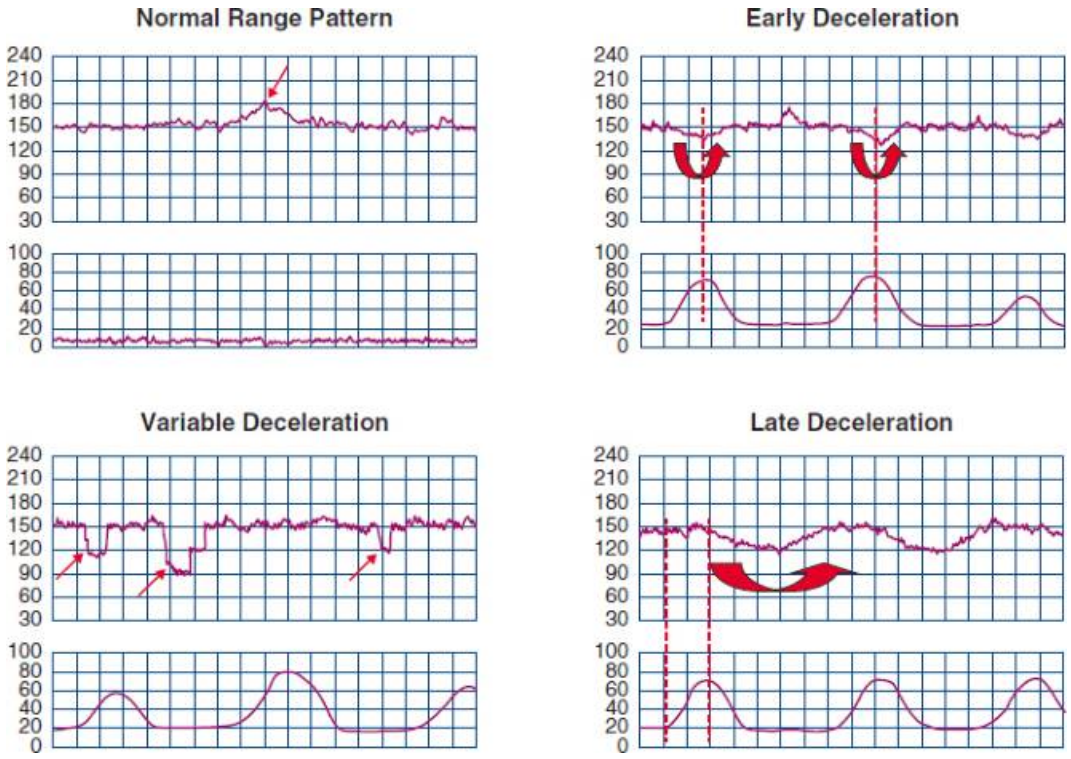

FIGURE 14.8. Decelerations.

Late decelerations are visually apparent, usually symmetrical, transitory decreases in FHR that occur after the peak of the contraction. They have a gradual waveform and can be recurrent, occurring with each contraction over a period of time. The FHR does not return to baseline levels until well after the contraction has ended. Delayed timing of the deceleration occurs with the nadir of the uterine contraction. Late decelerations are associated with uteroplacental insufficiency, which occurs when blood flow within the intervillous space is decreased to the extent that fetal hypoxia or myocardial depression exists (Blackburn, 2018). Conditions that may decrease uteroplacental perfusion with resultant decelerations include maternal hypotension, gestational hypertension, placental aging secondary to diabetes and postmaturity, hyperstimulation via oxytocin infusion, maternal smoking, anemia, and cardiac disease. They imply some degree of fetal hypoxia. Recurrent or intermittent late decelerations are always category II (indeterminate) or category III (abnormal) regardless of depth of deceleration. Acute episodes with moderate variability are more likely to be correctable, while

chronic episodes with loss of variability are less likely to be correctable (SOGC, 2018). Box 14.1 highlights interventions for category III decelerations.

Variable decelerations present as visually apparent abrupt decreases in FHR below baseline and have an unpredictable shape on the FHR baseline, possibly demonstrating no consistent relationship to uterine contractions. The shape of variable decelerations may be of a U, V, or W, or they may not resemble other patterns (Norwitz et al., 2019). Variable decelerations usually occur abruptly with quick deceleration. They are the most common deceleration pattern found in the laboring woman and are usually transient and correctable (Cunningham et al., 2018). Variable decelerations are associated with cord compression. However, they are classified either as category II or III depending on the accompanying change in baseline variability (Murray et al., 2019). The pattern of variable deceleration consistently related to the contractions with a slow return to FHR baseline warrants further monitoring and evaluation.

Prolonged decelerations are abrupt FHR declines of at least 15 bpm that last longer than 2 minutes but less than 10 minutes (Carvalho, 2019). The rate usually drops to less than 90 bpm. Many factors are associated with this pattern, including prolonged cord compression, abruptio placenta, cord prolapse, supine maternal position, vaginal examination, fetal blood sampling, maternal seizures, regional anesthesia, or uterine rupture (AWHONN, 2018). Prolonged decelerations can be remedied by identifying the underlying cause and correcting it.

BOX 14.1 Interventions for Category III Patterns

- Notify the health care provider about the pattern and obtain further orders, making sure to document all interventions and their effects on the FHR pattern.
- Discontinue oxytocin or other uterotonic agent as dictated by the facility's protocol if it is being administered.
- Turn the client on her left or right lateral, knee-chest, or hands and knees to increase placental perfusion or relieve cord compression.
- Administer oxygen via nonrebreather face mask to increase fetal oxygenation.
- Increase the IV fluid rate to improve intravascular volume and correct maternal hypotension.
- Assess the client for any underlying contributing causes.
- Provide reassurance that interventions are to effect pattern change.
- Modify pushing in the second stage of labor to improve fetal oxygenation.
- Document any and all interventions and any changes in FHR patterns.
- Prepare for an expeditious surgical birth if the pattern is not corrected in 30 minutes.

King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning; Murray, M. L., Huelsmann, G., & Koperski, N. (2019). *Essentials of fetal and uterine monitoring* (5th ed.). Springer Publishing Company; and Resnik, R., Lockwood, C. J., Moore, T. R., Greene, M. F., Copel, J. A., & Silver, R. M. (2019). *Creasy & Resnik's Maternal-fetal Medicine: Principles and practice* (8th ed.). Elsevier.

A *sinusoidal pattern* is described as having a visually apparent smooth, sinewave-like undulating pattern in the FHR baseline with a cycle frequency of 3 to 5 bpm that persists for more than 20 minutes. A true sinusoidal FHR pattern is rare. It is attributed to a derangement of CNS control of FHR and occurs when a severe degree of hypoxia secondary to fetal anemia and hypovolemia is present. It is always considered a category III pattern, and to correct it, a fetal intrauterine transfusion would be needed. It indicates the fetus is in marked jeopardy (Blackburn, 2018).

Combinations of FHR patterns obtained by EFM during labor are not infrequent. Category II and III patterns are more significant if they are mixed, persist for long periods, or have frequent prolonged late decelerations, absent or minimal variability, bradycardia or

tachycardia, and prolonged variable decelerations lower than 60 bpm. The likelihood of fetal compromise is increased if category II and III patterns are associated with decreased baseline variability or abnormal contraction patterns (Murray et al., 2019).

Other Fetal Assessment Methods

In situations suggesting the possibility of fetal compromise, such as category II or III FHR patterns, further ancillary testing such as umbilical cord blood analysis and fetal scalp stimulation may be used to validate the FHR findings and assist in planning interventions.

TAKE NOTE!

In recent years, the use of fetal scalp sampling has decreased, being replaced by techniques that yield similar information. It has been shown to have a poor positive predictive value for intrapartum hypoxia, and recent systematic reviews have reported no evidence of benefit in reducing cesarean section rates (Young & Ryce, 2018).

Umbilical Cord Blood Analysis

Neonatal and childhood mortality and morbidity, including cerebral palsy, are often attributed to fetal acidosis as indicated by a low cord pH at birth. Umbilical cord blood acid–base analysis drawn at birth provides an objective method of evaluating a newborn's condition, identifying the presence of intrapartum hypoxia and acidemia. This test is considered a good indicator of fetal oxygenation and acid–base condition at birth (Saneh et al., 2020). The normal mean pH value range is 7.2 to 7.3. The pH values are useful for planning interventions for the newborn born with low 5-minute Apgar scores, severe fetal growth restriction (FGR), category II and III patterns during labor, umbilical cord prolapse, uterine rupture, maternal fever, placental abruption, meconium-stained amniotic fluid, and post-term births (Jordan et al., 2019). The interventions needed for the compromised newborn might include providing an optimal

extrauterine environment, fluids, oxygen, medications, and other treatments.

Fetal Scalp Stimulation

An indirect method used to evaluate fetal oxygenation and acid–base balance to identify fetal hypoxia is fetal scalp stimulation or vibroacoustic stimulation. If the fetus does not have adequate oxygen reserves, carbon dioxide builds up, leading to acidemia and hypoxemia. These metabolic states are reflected in abnormal FHR patterns as well as fetal inactivity. Fetal stimulation is performed to promote fetal movement with the hope that FHR accelerations will accompany the movement.

Fetal movement can be stimulated with a vibroacoustic stimulator (artificial larynx) applied to the woman's lower abdomen and turned on for 3 to 5 seconds to produce sound and vibration or by placing a gloved finger on the fetal scalp and applying firm pressure. A well-oxygenated fetus will respond when stimulated (tactile or by noise) by moving in conjunction with an acceleration of 15 bpm above the baseline heart rate that lasts at least 15 seconds. This FHR acceleration reflects a pH of more than 7 and a fetus with an intact CNS. Fetal scalp stimulation is not done if the fetus is preterm, or if the woman has an intrauterine infection, a diagnosis of placenta previa (which could lead to hemorrhage), or a fever (which increases the risk of an ascending infection) (King et al., 2019). If no acceleratory response by the fetus is exhibited with either scalp stimulation or vibroacoustic stimulation, further evaluation of the fetus is warranted.

Nurses play an essential role in the evaluation of maternal and fetal status during labor, continued surveillance, initiation of corrective measures when indicated, and reevaluation. A vital attribute of nursing surveillance is that it is a systematic process for assessment, intervention, and evaluation.

PROMOTING COMFORT AND PROVIDING PAIN MANAGEMENT DURING LABOR

Pain during labor is a universal experience, though the intensity of the pain may vary. Labor pain is unique to every woman based on various contributing physiologic, emotional, social, and cultural factors. Although labor and childbirth are viewed as natural processes, both can produce significant pain and discomfort. The physical causes of pain during labor include cervical stretching, hypoxia of the uterine muscle due to a decrease in perfusion during contractions, pressure on the urethra, bladder, and rectum, and distention of the muscles of the pelvic floor (Milton, 2019).

Pain during labor is a physiologic phenomenon. The etiology of pain during the first stage of labor is associated with ischemia of the uterus during contractions. In the second stage, pain is caused by the stretching of the vagina and perineum and compression of the pelvic structures. A woman's pain perception can be influenced by her previous experiences with pain, fatigue, pain anticipation, genetics, positive or negative support system, health care provider's presence and encouragement, labor and birth environment, cultural expectations, and level of emotional stress and anxiety. Pain perception during labor changes in intensity and nature as labor progresses, and this is associated with behavioral changes in the laboring woman (King et al., 2019).

The techniques used to manage the pain of labor vary according to geography and culture. For example, some Appalachian women believe that placing a hatchet or knife under the bed of a laboring woman may help "cut the pain of childbirth," and a woman from this background may wish to do so in the hospital setting (Andrews & Boyle, 2019). Asian, Latino, and Orthodox Jewish women may request that their own mothers, not their husbands, attend their births; partners do not actively participate in the birthing process. Cherokee, Hmong, and Japanese women may remain quiet during labor and birth and not complain of pain because outwardly expressing pain is not appropriate in their cultures. Never interpret quietness as freedom from pain. The concept of pain and pain

expression during labor has different meanings for women of different cultures. Several points for the nurse to consider when caring for diverse cultural clients include using a qualified interpreter to communicate about pain as needed, offer and support culturally acceptable forms of pain relief, and assess for pain frequently (Giger, 2019).

Immigrating to a new country is a stressful process of readjustment and change. Effective verbal communication and understanding nonverbal social cues are invaluable when providing care to diverse cultures. Culturally diverse childbearing families present to the labor and birth suites with the same needs and desires of all families. Give them the same respect and sense of welcome shown to all families. Make sure they have a high-quality birth experience; uphold their religious, ethnic, and cultural values and integrate them into their own care.

Today, women have many safe nonpharmacologic and pharmacologic choices for the management of pain during labor and birth, which may be used separately or in combination with one another. Pharmacologic approaches are directed at eliminating the physical sensation of labor pain, while nonpharmacologic approaches are largely directed at prevention of suffering.

Nurses are in an ideal position to provide childbearing women with balanced, clear, concise information about effective nonpharmacologic and pharmacologic measures to relieve pain. Pain management standards issued by The Joint Commission mandate that pain be assessed in all clients admitted to a health care facility. Attention to the pain that occurs during labor and childbirth should be a priority of care for all nurses (King et al., 2019). A pain assessment tool named the “Coping with Labor Algorithm” uses the FOCUS (find, organize, clarify, understand, and select) format, “plan, do, check, and act” cycle in laboring women. This tool provides a mechanism for pain documentation and links it to nursing care interventions (Chance et al., 2018). Thus, it is important for nurses to be knowledgeable about the most recent scientific research on labor pain relief modalities, to make sure that accurate and unbiased information about effective pain relief measures is

available to laboring women, to be sure that the woman determines what is an acceptable labor pain level for her, and to allow the woman the choice of pain relief method.

Nonpharmacologic Measures

Nonpharmacologic measures may include continuous labor support, hydrotherapy, hypnosis, ambulation and maternal position changes, transcutaneous electrical nerve stimulation (TENS), acupuncture and acupressure, attention focusing and imagery, therapeutic touch and massage, breathing techniques, and effleurage. Most of these methods are based on the *gate control theory of pain*, which proposes that local physical stimulation can interfere with pain stimuli by closing a hypothetical gate in the spinal cord, thus blocking pain signals from reaching the brain (Delgado et al., 2019). It has long been a standard of care for labor nurses to first provide or encourage a variety of nonpharmacologic measures before moving to the pharmacologic interventions. Educating women on what to expect with labor pain can help reduce their anxiety and their sense of loss of control.

Nonpharmacologic measures are usually simple, safe, and inexpensive to use. Many of these measures are taught in childbirth classes, and women should be encouraged to try a variety of methods prior to the real labor. Many of the measures need to be practiced for best results and coordinated with the partner or coach. The nurse provides support and encouragement for the woman and her partner using nonpharmacologic methods. Although women cannot consciously direct the labor contractions, they can control how they respond to them, thereby enhancing their feelings of control. See Evidence-Based Practice 14.2 for more information.

EVIDENCE-BASED PRACTICE 14.2

Acupuncture or Acupressure for Pain Management during Labor

STUDY

The pain women experience during labor can be intense with body tension, anxiety, and fear increasing it. Many women would like to avoid pharmacologic or invasive methods of pain management in labor, and this may contribute to the popularity of complementary methods of pain management. Acupuncture and acupressure have a long history in China, Korea, and Japan and have become popular in the United States. The purpose of this review was to examine the effects of acupuncture and acupressure for pain management in labor. Twenty-eight trials with data reporting on 3,960 women were included. Pain intensity was measured on a scale of 0 to 10 or 0 to 100 with low scores indicating less pain.

Findings

When compared to a variety of other pain controls (placebo, no treatment, or usual care), acupuncture and acupressure increased satisfaction with pain management and reduced the use of pharmacologic analgesia. Acupressure did seem to reduce pain intensity when used and reduced the need for cesarean section in comparison to other pain reduction methods.

Nursing Implications

Although effective, satisfactory pain management needs to be individualized for each laboring woman, offering this nonpharmacologic modality is one more measure to offer women who want to go through labor without using drugs. Laboring women want to use strategies to break the fear-tension-pain cycle

and work effectively with the pain. Nurses working with laboring mothers can offer acupuncture and acupressure methods along with support and encouragement, finding comfortable positions, immersion in water, and self-help techniques to assist each woman through her labor process.

Adapted from Smith, C. A., Collins, C. T., Levett, K. M., Armour, M., Dahlen, H. G., Tan, A. L., & Mesgarpour, B. (2020). Acupuncture or acupressure for pain management during labor. Cochrane Database of Systematic Reviews, 2, CD009232. https://doi.org/10.1002/14651858.CD009232.pub2

Continuous Labor Support

Childbirth is a life-changing experience and can create lifelong memories. Nurses need to be familiar with women's diverse needs during childbirth, which includes emotional, physical, and informational needs. Continuous labor support involves offering a sustained presence to the laboring woman by providing emotional support, comfort measures, advocacy, information and advice, and support for the partner. It is a nonpharmacologic, evidence-based strategy associated with reduced cesarean rates. There is strong evidence that having a companion present throughout the childbirth process reduces the need for pain relief measures (Webster et al., 2018). A woman's family, a midwife, a nurse, a doula, or anyone else close to the woman can provide this continuous presence. A support person can assist the woman with ambulating, repositioning herself, and using breathing techniques. A support person can also aid with the use of acupressure, massage, music therapy, or therapeutic touch. During the natural course of childbirth, a laboring woman's functional ability is limited secondary to pain, and she often has trouble making decisions. The support person can help make them based on their knowledge of the woman's birth plan and personal wishes. Good interpersonal relationships can reduce fear associated with childbirth and subsequently contribute to a satisfactory birth experience.

Research has supported the value of continuous labor support versus intermittent support in terms of fewer operative deliveries, cesarean births, and requests for pain medication. Continuous labor support has been shown to have beneficial effects on the mother and the newborn primarily due to the reduction in anxiety during the laboring experience. Most women expressed greater satisfaction with their childbirth experience (King et al., 2019).

TAKE NOTE!

The human presence is of immeasurable value to make the laboring woman feel secure.

Hydrotherapy

Hydrotherapy is the external use of any form of water for health promotion. It is a nonpharmacologic measure that may involve showering or soaking in a regular tub or whirlpool bath. When showering is the selected method of hydrotherapy, the woman stands or sits in a shower chair in a warm shower and allows the water to gently glide over her abdomen and back. If a tub or whirlpool is chosen, the woman immerses herself in warm water for relaxation and relief of discomfort. When the woman enters the warm water, the warmth and buoyancy help release muscle tension and can impart a sense of well-being (De Cherney et al., 2019). Warm water provides soothing stimulation of nerves in the skin, promoting vasodilation, reversal of sympathetic nervous response, and a reduction in catecholamines (Norwitz et al., 2019). Contractions are usually less painful in warm water because the warmth and buoyancy of the water have a relaxing effect. Recent research findings reported that women who used hydrotherapy had significantly reduced surgical birth rates, a shorter second stage of labor, reduced analgesic requirements, and a lower incidence of perineal trauma. The research concluded that hydrotherapy during labor significantly aids the labor process, minimizes the use of analgesic medications, offers fast- and short-acting pain and anxiety

relief, and should be considered a safe and effective birthing aid (Yadav et al., 2019).

A wide range of hydrotherapy options are available, from ordinary bathtubs to whirlpool baths and showers, combined with low lighting and music. Many hospitals provide showers and whirlpool baths for laboring women for pain relief. However, hydrotherapy is more commonly practiced in birthing centers managed by midwives. The recommendation for initiating hydrotherapy is that the woman be in active labor (more than 6 cm dilated) to prevent the slowing of labor contractions secondary to muscular relaxation. The woman's membranes can be intact or ruptured. Women are encouraged to stay in the bath or shower as long as they feel they are comfortable. The water temperature should not exceed body temperature.

Hydrotherapy is an effective pain management option for many women. Women who are experiencing a healthy pregnancy can be offered this option. The potential risks associated with hydrotherapy including hyperthermia, hypothermia, changes in maternal heart rate, fetal tachycardia, and unplanned underwater birth. The benefits include reducing pain, relieving anxiety, and promoting a sense of control during labor (Deering, 2018).

Ambulation and Position Changes

Positioning during labor is influenced by cultural factors, obstetric practices, place of childbirth, technology, and the preferences of the mother and health care providers. Ambulation and position changes during labor are another extremely useful comfort measure. Historically, women adopted a variety of positions during labor, rarely using the recumbent position until during the first half of the 20th century. The medical profession has favored recumbent positions during labor but without evidence to demonstrate their appropriateness. A recent Cochrane database systematic review reported there is evidence that walking and upright positions in the first stage of labor reduce the length of labor and do not seem to be associated with increased intervention or negative effects on mothers' and babies' well-being. In an upright posture, gravity directs

the weight of the fetus and amniotic fluid downward, successively dilating the cervix and the birth canal. Uterine contractions have been shown to be better spaced, stronger, and more efficient in dilating the cervix when the mother is in an upright position than when she is supine (Huang et al., 2019). Women should be encouraged to use whatever position they find most comfortable in the first stage of labor (Blackburn, 2018).

Changing position frequently (every 30 minutes or so)—sitting, walking, kneeling, standing, lying down, getting on hands and knees, and using a birthing ball—helps relieve pain (Fig. 14.9). Position changes may also help speed labor by adding the benefits of gravity and changing the shape of the pelvis. Research has found that the position that the woman assumes and the frequency of position changes have a profound effect on uterine activity and efficiency. Allowing the woman to obtain a position of comfort frequently facilitates a favorable fetal rotation by altering the alignment of the presenting part with the pelvis. As the mother continues to change position based on comfort, the optimal presentation is afforded. An upright position during the second stage has been associated with a decrease in surgical births and a reduction in labor duration (King et al., 2019). Supine positions should be avoided, since they may interfere with labor progress and can cause compression of the vena cava and decrease blood return to the heart.

Swaying from side to side, rocking, or other rhythmic movements may also be comforting. If labor is progressing slowly, ambulating may speed it up again. Upright positions such as walking, kneeling forward, or doing a lunge on the birthing ball give most women a greater sense of control and active movement than just lying down. Table 14.2 highlights some of the more common positions that can be used during labor and birth.

Acupuncture and Acupressure

Acupuncture and acupressure can be used to relieve pain during labor. Although controlled research studies of these methods are limited, there is adequate evidence that both are useful in relieving

pain associated with labor and birth. However, both methods require a trained, certified clinician, and such a person is not available in many birth facilities (Xiao et al., 2019).

Acupuncture involves stimulating key trigger points with needles. This form of Chinese medicine has been practiced for approximately 3,000 years. Classical Chinese teaching holds that throughout the body there are meridians or channels of energy (*qi*) that when in balance, regulate body functions. Pain reflects an imbalance or obstruction of the flow of energy. The purpose of acupuncture is to restore balance, thus diminishing pain (Betts, 2019). Stimulating the trigger points causes the release of endorphins, reducing the perception of pain.

Acupressure involves the application of a firm finger, thumb, knuckles, or massage used on similar points to those used in acupuncture to reduce the pain sensation. The amount of pressure is important. The intensity of the pressure is determined by the needs of the woman. Holding and squeezing the hand of a woman in labor may trigger the point most commonly used for both techniques. Some acupressure points are found along the spine, neck, shoulder, toes, and soles of the feet. Pressure along the side of the spine can help relieve back pain during labor (Fig. 14.10) (Dekker, 2019b). A Cochrane collaboration review found that acupuncture and acupressure may indeed reduce labor pain, increasing satisfaction with pain management and reducing use of pharmacologic management. However, there is a need for further research (Smith et al., 2020).

FIGURE 14.9. Various positions for use during labor. **A.** Ambulation. **B.** Leaning forward. **C.** Sitting in a chair. **D.** Using a birthing ball.

TABLE 14.2 Common Positions for Use during Labor and Birth

Standing	• Takes advantage of gravity during and between contractions • Makes contractions feel less painful and be more productive • Helps fetus line up with angle of maternal pelvis • Helps increase urge to push in second stage of labor
Walking	• Has the same advantages as standing • Causes changes in the pelvic joints, helping the fetus move through the birth canal
Standing and leaning forward on partner, bed, or birthing ball	• Has the same advantages as standing • Is a good position for a backrub • May feel more restful than standing • Can be used with electronic fetal monitor
Slow dancing (standing with woman's arms around partner's neck, head resting on his chest or shoulder, with his hands rubbing woman's lower back; sway to music and breathe in rhythm if it helps)	• Has the same advantages as walking • Back pressure helps relieve back pain • Rhythm and music help woman relax and provide comfort
The lunge (standing facing a straight chair with one foot on the seat with knee and foot to the side; bending raised knee and hip, and lunging sideways repeatedly during a contraction, holding each lunge for 5 seconds; partner holds chair and helps with balance)	• Widens one side of the pelvis (the side toward lunge) • Encourages rotation of the baby • Can also be done in a kneeling position
Sitting upright	• Helps promote rest • Has more gravity advantage than lying down • Can be used with electronic fetal monitor
Semi-sitting (setting the head of the bed at a 45-degree	• Has the same advantages as sitting upright • Is an easy position if on a bed

angle with pillows used for support)	
Sitting on toilet or commode	• Has the same advantages as sitting upright • May help relax the perineum for effective bearing down
Rocking in a chair	• Has the same advantages as sitting upright • May help speed labor (rocking movement)
Sitting, leaning forward with support	• Has the same advantages as sitting upright • Is a good position for a backrub
On all fours, on hands and knees	• Helps relieve backache • Assists rotation of baby in posterior position • Allows for pelvic rocking and body movement • Relieves pressure on hemorrhoids • Allows for vaginal examinations • Is sometimes preferred as a pushing position by women with back labor
Kneeling, leaning forward with support on a chair seat, the raised head of the bed, or on a birthing ball	• Has the same advantages as all-fours position • Puts less strain on wrists and hands
Side-lying	• Is a good position for resting and convenient for many kinds of medical interventions • Helps lower elevated blood pressure • May promote progress of labor when alternated with walking • Is useful in slowing a rapid second stage • Avoids vena cava syndrome • May offer increased control of pushing efforts • Takes pressure off hemorrhoids • Facilitates relaxation between contractions
Squatting	• May relieve backache • Takes advantage of gravity • Requires less bearing-down effort • Widens pelvic outlet by approximately 28% • Pressure is evenly distributed to the perineum, reducing the need for episiotomy • May help fetus turn and move down in a difficult birth

	• Helps if the woman feels no urge to push • Allows freedom to shift weight for comfort • Offers an advantage when pushing, since upper trunk presses on the top of the uterus
Supported squat (leaning back against partner, who supports woman under the arms and takes the entire woman's weight; standing up between contractions)	• Requires great strength in partner • Lengthens trunk, allowing more room for fetus to maneuver into position • Lets gravity help
Dangle (partner sitting high on bed or counter with feet supported on chairs or footrests and thighs spread; woman leaning back between partner's legs, placing flexed arms over partner's thighs; partner gripping sides with his thighs; woman lowering herself and allowing partner to support her full weight; standing up between contractions)	• Has the same advantages of a supported squat • Requires less physical strength from the partner

Application of Heat and Cold

Superficial applications of heat and/or cold in various forms are popular with laboring women. They are easy to use, inexpensive, require no prior practice, and have minimal negative side effects when used properly. Heat is typically applied to the woman's back, lower abdomen, groin, and/or perineum. Heat sources include a hot

water bottle, heated rice-filled sock, warm compress (washcloth soaked in warm water and wrung out), electric heating pad, warm blanket, and warm bath or shower. In addition to being used for pain relief, heat is used to relieve chills or trembling, decrease joint stiffness, reduce muscle spasm, and increase connective tissue extensibility (Cunningham et al., 2018).

Cold therapy, or cryotherapy, is usually applied on the woman's back, chest, and/or face during labor. Forms of cold include a bag or surgical glove filled with ice, a frozen gel pack, camper's "ice," a hollow, plastic rolling pin or bottle filled with ice, a washcloth dipped in cold water, soda cans chilled in ice, and even a frozen bag of vegetables. "Instant" cold packs, often available in hospitals, usually are not cold enough to effectively relieve labor pain. Women who feel cold usually need to feel warm before they can comfortably tolerate using a cold pack. Chilled soda cans and rolling pins filled with ice give the added benefit of mechanical pressure when rolled on the low back. Cold has the additional effects of relieving muscle spasms and reducing inflammation and edema (Jordan et al., 2019).

To date, no randomized controlled studies have evaluated the use of heat and cold, so further study is needed to determine if either approach is effective. With appropriate safety precautions, heat and cold offer comfort and relief, and their use should be dictated by the desires and responses of the laboring woman.

Attention Focusing and Imagery

Visualization or guided imagery uses many of the senses and the mind to focus on stimuli. The woman can focus on tactile stimuli such as touch, massage, or stroking. She may focus on auditory stimuli such as music, humming, or verbal encouragement. Visual stimuli might be any object in the room, or the woman can imagine the beach, a mountaintop, a happy memory, or even the contractions of the uterine muscle pulling the cervix open and the fetus pressing downward to open the cervix. Some women focus on a particular mental activity such as a song, a chant, counting backward, or a religious verse. Breathing, relaxation, positive thinking, and positive

visualization work well for mothers in labor. The use of these techniques keeps the sensory input perceived during the contraction from reaching the pain center in the cortex of the brain (Hart, 2019).

Effleurage and Massage

Effleurage is a light, stroking, superficial touch of the abdomen, in rhythm with breathing during contractions. It is used as a relaxation and distraction technique from discomfort. External fetal monitor belts may interfere with the ability to accomplish this.

Effleurage and massage use the sense of touch to promote relaxation and pain relief. Massage works as a form of pain relief by increasing the production of endorphins in the body. Endorphins reduce the transmission of signals between nerve cells and thus lower the perception of pain. Because touch receptors go to the brain faster than pain receptors, massage—anywhere on the body—can block the pain message to the brain. In addition, light touch has been found to release endorphins and induce a relaxed state. In addition, touching and massage distract the woman from discomfort. Massage involves manipulation of the body's soft tissues. It is commonly used to help relax tense muscles and to soothe and calm the individual. Massage may help relieve pain by assisting with relaxation, inhibiting sensory transmission in the pain pathways, or improving blood flow and oxygenation of tissues. Research indicates the duration of labor is shorter and Apgar scores were higher when massage techniques were used during labor to promote maternal relaxation (Field, 2019).

Breathing Techniques

Conscious use of breath by the woman has the power to profoundly influence her labor and how she engages with it. The first action anyone takes in any situation is a breath. The breath affects the lungs, immediately cueing the nervous system. The nervous system responds by sending messages, which impact the entire psycho-physiologic system. Messages sent from the nervous system affect us physically, emotionally, and mentally. If we alter how we breathe,

we alter the constellation of messages and reactions in our entire mind–body experience (King et al., 2019).

Breathing techniques are effective in producing relaxation and pain relief through the use of distraction. If the woman is concentrating on slow-paced rhythmic breathing, she is not likely to fully focus on contraction pain. Breathing techniques are often taught in childbirth education classes (see Chapter 12 for additional information).

Controlled breathing helps reduce the pain experienced by using stimulus–response conditioning. The woman selects a focal point within her environment to stare at during the first sign of a contraction. This focus creates a visual stimulus that goes directly to her brain. The woman takes a deep cleansing breath, which is followed by rhythmic breathing. Verbal commands from her partner supply an ongoing auditory stimulus to her brain. Benefits of practicing patterned breathing include breathing that:

- becomes an automatic response to pain.
- increases relaxation and can be used to deal with life's everyday stresses.
- is calming during labor.
- provides a sense of well-being and a measure of control.
- brings purpose to each contraction, making them more productive.
- provides more oxygen for the mother and fetus (American Pregnancy Association, 2019).

Many couples learn patterned-paced breathing during their childbirth education classes. Three levels may be taught, each beginning and ending with a cleansing breath or sigh after each contraction. In the first pattern, also known as slow-paced breathing, the woman inhales slowly through her nose and exhales through pursed lips. The breathing rate is typically six to nine breaths per minute. In the second pattern, the woman inhales and exhales through her mouth at a rate of four breaths every 5 seconds. The rate can be accelerated to two breaths per second to assist her to relax. The third pattern is similar to the second pattern except that the breathing is punctuated every few breaths by a forceful

exhalation through pursed lips. All breaths are kept equal and rhythmic and can increase as contractions increase in intensity (Deering, 2018).

Many childbirth educators do not recommend specific breathing techniques or try to teach parents to breathe the “right” way during labor and birth. Women are encouraged to find breathing styles that enhance their relaxation and use them. There are numerous benefits to controlled and rhythmic breathing in childbirth (outlined previously), and many women choose these techniques to manage discomfort during labor.

Pharmacologic Measures

The goal for all laboring mothers is the provision of adequate comfort and analgesia in labor and safety for her and her newborn. With varying degrees of success, generations of women have sought ways to relieve the pain of childbirth. Childbirth is a natural phenomenon, but it is painful. Pharmacologic pain relief during labor includes systemic analgesia and regional or local anesthesia. Women have seen dramatic changes in pharmacologic pain management options over the years. Methods have evolved from biting down on a stick to cope with pain, experiencing “twilight sleep” and not remembering what happened, to a more complex pharmacologic approach such as epidural/intrathecal analgesia. Systemic analgesia and regional analgesia/anesthesia have become less common, while newer neuraxial analgesia/anesthesia techniques involving minimal motor blockade have become more popular. **Neuraxial analgesia/anesthesia** is the administration of analgesic (opioids) or anesthetic (capable of producing a loss of sensation in an area of the body) agents, either continuously or intermittently, into the epidural or intrathecal space to relieve pain. Low-dose and ultra–low-dose epidural analgesia, spinal analgesia, and combined spinal–epidural analgesia have replaced the traditional epidural for labor. Neuraxial analgesia does not interfere with the progress or outcome of labor. There is no need to withhold neuraxial analgesia until the active stage of labor (Bateman, 2019).

This shift in pain management techniques allows a woman to be an active participant in labor.

TAKE NOTE!

Regardless of which approach is used during labor, the woman has the right to choose the methods of pain control that will best suit her and meet her needs.

Systemic Analgesia

Systemic analgesia involves the use of one or more drugs administered orally, intramuscularly, or intravenously; they become distributed throughout the body via the circulatory system. Depending on which administration method is used, the therapeutic effect of pain relief can occur within minutes and last for several hours. The most important complication associated with the use of this class of drugs is respiratory depression. Therefore, women given these drugs require careful monitoring. Opioids given close to the time of birth can cause CNS depression in the newborn, necessitating the administration of naloxone (Narcan) to reverse the depressant effects of the opioids.

DRUG GUIDE 14.1 Common Agents Used for Systemic Analgesia

Type	Drug	Comments
Opioids	Morphine 2–5 mg IV	May be given IV or epidurally Rapidly crosses the placenta, causes a decrease in FHR variability Can cause maternal and neonatal CNS depression Decreases uterine contractions
	Meperidine (Demerol) 25–75 mg IV	May be given IV, intrathecally, or epidurally with maximal fetal uptake 2–3 hr after administration Can cause CNS depression Decreases fetal variability
	Butorphanol (Stadol) 1–2 mg IV	Is given IV
	Q 2–4 hr	Is rapidly transferred across the placenta Causes neonatal respiratory depression
	Nalbuphine (Nubain) 10–20 mg IV	Is given IV Causes less maternal nausea and vomiting Causes decreased FHR variability, fetal bradycardia, and respiratory depression
	Fentanyl (Sublimaze) 50–100 mcg IV	Is given IV or epidurally Can cause maternal hypotension, maternal and fetal respiratory depression Rapidly crosses placenta

Antiemetics	Hydroxyzine (Vistaril) 50–100 mg IM	Does not relieve pain but reduces anxiety and potentiates opioid analgesic effects; cannot be given IV Is used to decrease nausea and vomiting
	Promethazine (Phenergan) 25–50 mg IV or IM	Is used for antiemetic effect when combined with opioids Causes sedation and reduces apprehension May contribute to maternal hypotension and neonatal depression
	Prochlorperazine (Compazine) 5–10 mg IV or IM	Frequently given with morphine sulfate for sleep during prolonged latent phase; counteracts the nausea that opioids can produce
Benzodiazepines	Diazepam (Valium) 2–5 mg IV	Is given to enhance pain relief of opioid and cause sedation May be used to stop eclamptic seizures Decreases nausea and vomiting Can cause newborn depression; therefore, lowest possible dose should be used
	Midazolam (Versed) 1–5 mg	Is not used for analgesic but amnesia effect

	IV	Is used as adjunct for anesthesia Is excreted in breast milk

Deering, S. (2018). *A practical manual to labor and delivery* (2nd ed.). Cambridge University Press; Resnik, R., Lockwood, C. J., Moore, T. R., Greene, M. F., Copel, J. A., & Silver, R. M. (2019). *Creasy & Resnik's Maternal-fetal Medicine: Principles and practice* (8th ed.). Elsevier; and Skidmore-Roth, L. (2020). *Mosby's 2020 nursing drug reference* (3rd ed.). Elsevier.

Several drug categories may be used for systemic analgesia:

- *Opioids*, such as butorphanol (Stadol), nalbuphine (Nubain), meperidine (Demerol), morphine, or fentanyl (Sublimaze)
- *Ataractics*, such as hydroxyzine (Vistaril), promethazine (Phenergan), or prochlorperazine (Compazine)
- *Benzodiazepines*, such as diazepam (Valium) or midazolam (Versed)

Drug Guide 14.1 highlights some of the major drugs used for systemic analgesia.

Systemic analgesics are typically administered parenterally, usually through an existing IV line. Nearly all medications given during labor cross the placenta and have a depressant effect on the fetus; therefore, it is important for the woman to receive the least amount of systemic medication that relieves her discomfort so that it does not cause any harm to the fetus (Hemmings & Egan, 2019). Historically opioids have been administered by nurses, but currently there has been increasing use of client-controlled IV analgesia. With this system, the woman is given a button connected to a computerized pump on the IV line. When the woman desires analgesia, she presses the button and the pump delivers a preset amount of medication. This system provides the woman with a sense of control over her own pain management and active participation in the childbirth process.

OPIOIDS

Opioids are morphine-like medications that are most effective for the relief of moderate to severe pain. Opioids typically are administered

IV. All opioids are lipophilic and cross the placental barrier but do not affect labor progress in the active phase. Opioids are associated with newborn respiratory depression, decreased alertness, inhibited sucking, and a delay in effective feeding (King et al., 2019).

Opioids decrease the transmission of pain impulses by binding to receptor site pathways that transmit the pain signals to the brain. The effect is increased tolerance to pain and respiratory depression related to a decrease in sensitivity to carbon dioxide (Skidmore-Roth, 2021). All opioids are considered good analgesics. However, respiratory depression can occur in the mother and fetus depending on the dose given. They may also cause a decrease in FHR variability identified on the fetal monitor strip. This FHR pattern change is usually transient. Other systemic side effects include nausea, vomiting, pruritus, delayed gastric emptying, drowsiness, hypoventilation, and newborn depression. To reduce the incidence of newborn depression, birth should occur within 1 hour or after 4 hours of administration to prevent the fetus from receiving the peak concentration (Funai & Norwitz, 2019).

A recent study reported that parenteral opioids provide some relief from pain in labor but are associated with neonatal respiratory distress. Maternal satisfaction with opioid analgesia appeared moderate at best (Hemmings & Egan, 2019).

Opioid antagonists such as naloxone (Narcan) are given to reverse the effects of the CNS depression, including respiratory depression, caused by opioids. Opioid antagonists also are used to reverse the side effects of neuraxial opioids, such as pruritus, urinary retention, nausea, and vomiting, without significantly decreasing analgesia (Skidmore-Roth, 2021). Consult a current drug guide for more specifics on these drug categories.

ANTIEMETICS

The antiemetic group of medications is used in combination with an opioid to decrease nausea and vomiting and lessen anxiety. These adjunct drugs potentiate the effectiveness of the opioid so that a lesser dose can be given. They may also be used to increase

sedation. Promethazine (Phenergan) can be given IV, but hydroxyzine (Vistaril) must be given by mouth or by intramuscular injection into a large muscle mass. Neither drug affects the progress of labor, but either may cause a decrease in FHR variability and possible newborn depression (Skidmore-Roth, 2021). Prochlorperazine (Compazine) is typically given IV or intramuscularly with morphine sulfate for sleep during a prolonged latent phase. It counteracts the nausea associated with opioids (King et al., 2019).

BENZODIAZEPINES

Benzodiazepines are used for minor tranquilizing and sedative effects. Diazepam (Valium) is also given IV to stop seizures resulting from eclampsia. It can be administered to calm a woman who feels out of control, thereby enabling her to relax enough so that she can participate effectively during her labor process rather than fighting against it. Lorazepam (Ativan) can also be used for its tranquilizing effect, but increased sedation is experienced with this medication (Skidmore-Roth, 2021). Midazolam (Versed), also given IV, produces good amnesia but no analgesia. It is most commonly used as an adjunct for anesthesia. Diazepam and midazolam cause CNS depression for both the woman and the newborn.

Inhaled Analgesics

Inhaled nitrous oxide offers a safe and effective means of labor analgesia for many laboring women. Nitrous oxide is known by most people as “laughing gas.” For labor pain, half nitrous oxide gas (50%) is mixed with half oxygen (50%) and breathed through a mask or mouthpiece. It has been gaining popularity in the United States since it was approved by the FDA in 2012 (Vallejo & Zakowski, 2019) but has been in widespread use in Europe and Canada for many years. Women have generally reported satisfaction with the use of nitrous oxide for pain relief in labor. An additional factor that may contribute to the decreased perception of pain is maternal control—it is self-administered. Self-administration is not only empowering for women, but it also acts as a safety mechanism because it is almost

impossible to overdose when it is self-administered (Milton, 2019). Potential side effects of N2O/O2 include nausea and vomiting, dizziness, and dysphoria, although these are rare. No FHR abnormalities have been attributed to its use (Baysinger, 2019).

Regional Analgesia/Anesthesia

Regional analgesia/anesthesia provides pain relief without loss of consciousness. It involves the use of local anesthetic agents with or without added opioids to bring about pain relief or numbness through the drug's effects on the spinal cord and nerve roots. Obstetric regional analgesia generally refers to a partial or complete loss of pain sensation below the T8 to T10 level of the spinal cord (Hemmings & Egan, 2019).

The routes for regional pain relief include epidural block, combined spinal–epidural, local infiltration, pudendal block, and intrathecal (spinal) analgesia/anesthesia. Local and pudendal routes are used during birth for episiotomies (surgical incisions into the perineum to facilitate birth); epidural and intrathecal routes are used for pain relief during active labor and birth. The major advantage of regional pain management techniques is that the woman can participate in the birthing process and still have good pain control.

EPIDURAL ANALGESIA

Women requesting epidural analgesia in labor will do so when they feel they need pain relief, and for some, it might be quite early in their labor. Epidural analgesia for labor and birth involves the injection of a local anesthetic agent (e.g., lidocaine or bupivacaine) and an opioid analgesic agent (e.g., morphine or fentanyl) into the lumbar epidural space. A small catheter is then passed through the epidural needle to provide continuous access to the epidural space for maintenance of analgesia throughout labor and birth (Fig. 14.11). Epidural analgesia does increase the duration of the second stage of labor and may increase the rate of instrument-assisted vaginal deliveries as well as that of oxytocin administration (Cunningham et al., 2018). Approximately 70% of laboring women in the United

States receive an epidural for pain relief during labor (White, 2018). In urban areas, many hospitals approach 90% use of epidurals (Kellerman & Rakel, 2019).

An epidural involves the injection of a drug into the epidural space, which is located outside the dura mater between the dura and the spinal canal. The epidural space is typically entered through the third and fourth lumbar vertebrae with a needle, and a catheter is threaded into the epidural space. An epidural can be used for both vaginal and cesarean births. It has evolved from a regional block producing total loss of sensation to analgesia with minimal blockade. The effectiveness of epidural analgesia depends on the technique and medications used. Theoretically, epidural local anesthetics could block all labor pain if used in large volumes and high concentrations. However, pain relief is balanced against other goals such as walking during the first stage of labor, pushing effectively in the second stage, and minimizing maternal and fetal side effects.

An epidural is contraindicated for women with a previous history of spinal surgery or spinal abnormalities, coagulation defects, cardiac disease, obesity, infections, and hypovolemia. It is also contraindicated for the woman who is receiving anticoagulation therapy.

Complications include nausea and vomiting, hypotension, fever, pruritus, intravascular injection, maternal fever, allergic reaction, and respiratory depression. Effects on the fetus during labor include fetal distress secondary to maternal hypotension (Milton, 2019). Ensuring that the woman avoids a supine position after an epidural catheter has been placed will help minimize hypotension.

The addition of opioids, such as fentanyl or morphine, to the local anesthetic helps decrease the amount of motor block obtained. Continuous infusion pumps can be used to administer the epidural analgesia, allowing the woman to be in control and administer a bolus dose on demand (Hemmings & Egan, 2019).

COMBINED SPINAL–EPIDURAL ANALGESIA

Another epidural technique is combined spinal–epidural (CSE) analgesia. This technique involves inserting the epidural needle into the epidural space and subsequently inserting a small-gauge spinal needle through the epidural needle into the subarachnoid space. An opioid without a local anesthetic is injected into this space. The spinal needle is then removed and an epidural catheter is inserted for later use.

FIGURE 14.11. Epidural catheter insertion. **A.** A needle is inserted into the epidural space. **B.** A catheter is threaded into the epidural space; the needle is then removed. The catheter allows medication to be administered intermittently or continuously to relieve pain during labor and childbirth.

CSE is advantageous because of its rapid onset of pain relief (within 3 to 5 minutes) that can last up to 3 hours. It also allows the woman's motor function to remain active. Her ability to bear down during the second stage of labor is preserved because the pushing reflex is not lost, and her motor power remains intact. The CSE technique provides greater flexibility and reliability for labor than either spinal or epidural analgesia alone (Hemmings & Egan, 2019). When compared with traditional epidural or spinal analgesia, which often keeps the woman lying in bed, CSE allows her to ambulate ("walking epidural"). A recent study contrasting the CSE analgesia approach with traditional and low-dose epidural analgesia in labor

identified that CSE analgesia was associated with a greater incidence of pruritus but a lower incidence of urinary retention and need for rescue analgesia than epidural alone. In addition, CSE analgesia had a faster onset of pain relief, and there were no differences in labor outcomes (Xiao et al., 2019). Ambulating during labor provides several benefits; it may help control pain better, shorten the first stage of labor, increase the intensity of the contractions, and decrease the possibility of an operative vaginal or cesarean birth.

CONSIDER THIS

When I was expecting my first child, I was determined to put my best foot forward and do everything right. I was an experienced OB nurse, and in my mind doing everything right was expected behavior. I was already 2 weeks past my calculated due date and I was becoming increasingly worried. That particular day I went to work with a backache but felt no contractions.

I managed to finish my shift but felt completely wiped out. As I walked to my car outside the hospital, my water broke and I felt the warm fluid run down my legs. I went back inside to be admitted for this much-awaited event.

Although I had helped so many women go through their childbirth experiences, I was now the one in the bed and not standing alongside it. My husband and I had practiced our breathing techniques to cope with the discomfort of labor, but this "discomfort" in my mind was more than I could tolerate. So, despite my best intentions of doing everything "right," within an hour, I begged for a painkiller to ease the pain. While the medication took the edge off my pain, I still felt every contraction and truly now appreciate the meaning of the word "labor." Although I wanted to use natural childbirth without any medication, I know that I was a full participant in my son's birthing experience, and that is what "doing everything right" was for me!

Thoughts: Doing what is "right" varies for each individual, and as nurses, we need to support whatever that is. Having a positive outcome from the childbirth experience is the goal; the means it takes to achieve it is less important. How can nurses support women in making their personal choices to achieve a healthy outcome? Are any women "failures" if they ask for pain medication to tolerate labor? How can nurses help women overcome any stigma of using pharmacologic analgesia?

Although women can walk with CSE, they often choose not to because of sedation and fatigue. Often health care providers do not encourage or assist women with ambulating for fear of injury. Nurses

need to evaluate for ambulation safety that includes no postural hypotension and normal leg strength by demonstrating a partial knee bend while standing; they also need to assist with ambulation at all times (Jordan et al., 2019). Currently, anesthesiologists are performing walking epidurals using continuous infusion techniques as well as CSE and client-controlled epidural analgesia (Hemmings & Egan, 2019).

Complications include maternal hypotension, intravascular injection, accidental intrathecal blockade, postdural puncture headache, pruritus, inadequate or failed block, maternal fever, and pruritus. Hypotension and associated FHR changes are managed with maternal positioning (semi-Fowler position), IV hydration, and supplemental oxygen (Daily & Ortiz, 2019).

PATIENT-CONTROLLED EPIDURAL ANALGESIA

Patient-controlled epidural analgesia (PCEA) involves the use of an indwelling epidural catheter with an infusion of medication and a programmed pump that allows the woman to control the dosing. This method allows the woman to have a sense of control over her pain and reach her own individually acceptable analgesia level. When compared with traditional epidural analgesia, PCEA provides equivalent analgesia with lower anesthetic use, lower rates of supplementation, and higher client satisfaction (Bateman, 2019).

With PCEA, the woman uses a handheld device connected to an analgesic agent that is attached to an epidural catheter. When she pushes the button, a bolus dose of agent is administered via the catheter to reduce her pain. This method allows her to manage her pain at will without having to ask a staff member to provide pain relief. Evidence supports the use of PCEA which appears to result in greater maternal satisfaction and lower overall medication use (Sugur et al., 2020).

LOCAL INFILTRATION

Local infiltration involves the injection of a local anesthetic, such as lidocaine, into the superficial perineal nerves to numb the perineal area. This technique is done by the physician or midwife just before performing an episiotomy or before suturing a laceration. Local infiltration does not alter the pain of uterine contractions, but it does numb the immediate area of the episiotomy or laceration. Local infiltration does not cause side effects for the woman or her newborn.

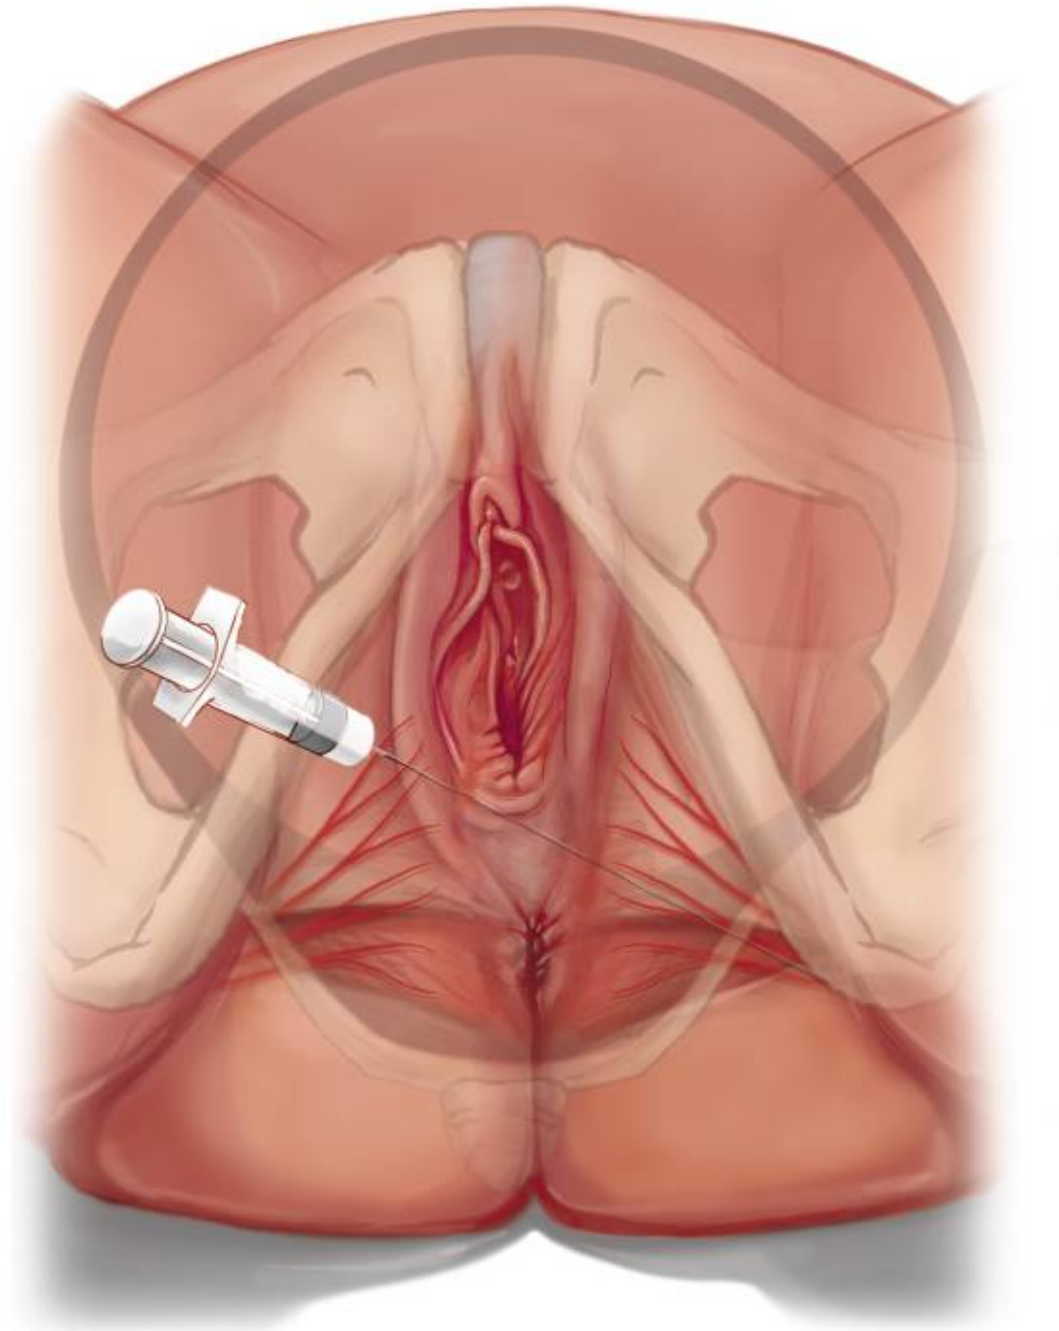

FIGURE 14.12. Pudendal nerve block.

PUDENDAL NERVE BLOCK

The pudendal nerve block provides long-lasting perineal analgesia. A pudendal nerve block refers to the injection of a local anesthetic agent (e.g., bupivacaine, ropivacaine) into the pudendal nerves near

each ischial spine. It provides pain relief in the lower vagina, vulva, and perineum (Fig. 14.12).

A pudendal block is used for the second stage of labor, an episiotomy, or an operative vaginal birth with outlet forceps or vacuum extractor. It must be administered about 15 minutes before it would be needed to ensure its full effect. A transvaginal approach is generally used to inject an anesthetic agent at or near the pudendal nerve branch. Neither maternal nor fetal complications are common.

SPINAL (INTRATHECAL) ANALGESIA/ANESTHESIA

The spinal (intrathecal) pain management technique involves injection of an anesthetic "caine" agent with or without opioids into the subarachnoid space to provide pain relief during labor or cesarean birth. The subarachnoid space is a fluid-filled area located between the dura mater and the spinal cord. Spinal anesthesia is frequently used for elective and emergent cesarean births. The contraindications are similar to those for an epidural block. Adverse reactions for the woman include hypotension and spinal headache.

The subarachnoid injection of opioids alone or in combination, a technique termed "intrathecal narcotics," has been used for laboring women successfully for decades. A narcotic is injected into the subarachnoid space, providing rapid pain relief while still maintaining motor function and sensation (Layera et al., 2019). An intrathecal narcotic is given during the active phase (more than 5 cm of dilation) of labor. Compared with epidural blocks, intrathecal narcotics are easy to administer, require a smaller volume of medication, produce excellent muscular relaxation, provide rapid-onset pain relief, are less likely to cause newborn respiratory depression, and do not cause motor blockade (Hemmings & Egan, 2019). Although pain relief is rapid with this technique, it is limited by the narcotic's duration of action, which may be only a few hours and not last through the labor. Adding dexmedetomidine to the morphine or fentanyl prolonged the analgesia considerably during many labors in a recent study (Khaled & Sabry, 2020).

General Anesthesia

Obstetric guidelines recommend neuraxial anesthesia for cesarean births in most women. General anesthesia is typically reserved for emergency cesarean births when there is not enough time to provide spinal or epidural anesthesia or if the woman has a contraindication to the use of regional anesthesia. It can be started quickly and causes a rapid loss of consciousness. General anesthesia can be administered by IV injection, inhalation of anesthetic agents, or both. Commonly, thiopental, a short-acting barbiturate, or propofol is given IV to produce unconsciousness. This is followed by administration of a muscle relaxant. After the woman is intubated, nitrous oxide and oxygen are administered. A volatile halogenated agent may also be administered to produce amnesia (Cobb et al., 2019).

All anesthetic agents cross the placenta and affect the fetus. The primary complication with general anesthesia is fetal depression, along with uterine relaxation and potential maternal vomiting and aspiration. General anesthesia complications are usually due to maternal aspiration or the inability to intubate the woman. The incidence of these complications has decreased greatly as a result of improved techniques (Cobb et al., 2019).

Although the anesthesiologist or nurse anesthetist administers the various general anesthesia agents, the nurse needs to be knowledgeable about the pharmacologic aspects of the drugs used and must be aware of airway management. Ensure that the woman is not taking anything by mouth (NPO) and has a patent IV line. In addition, administer a nonparticulate (clear) oral antacid (e.g., Bicitra or sodium citrate) or a proton pump inhibitor (Protonix) as ordered to reduce gastric acidity. Assist with placement of a wedge under the woman's right hip to displace the gravid uterus and prevent vena cava compression in the supine position. Once the newborn has been removed from the uterus, assist the perinatal team in providing supportive care.

NURSING CARE DURING LABOR AND BIRTH

Childbirth, a physiologic process that is fundamental to human existence, can be one of the most significant cultural, psychological, spiritual, and behavioral events in a childbearing woman's life. Although the act of giving birth is a universal phenomenon, it is a unique experience for each woman. Continuous evaluation and appropriate intervention for women during labor are essential to promoting a positive outcome for the family.

Care will vary at the different stages of labor, but what is essential is that an effective partnership with the woman is established, built upon successful communication and mutual trust. The nurse's role in childbirth is to ensure a safe environment for the mother and her newborn. Nurses begin evaluating the mother and fetus during the admission procedures at the health care agency and continue to do so throughout labor. It is critical to provide anticipatory guidance and explain each procedure (fetal monitoring, IV therapy, and medications given and their expected reactions) and what will happen next. This will prepare the woman for the upcoming physical and emotional challenges, thereby helping reduce her anxiety. Acknowledging members of her support system (family or partner) helps allay their fears and concerns, thereby assisting them in carrying out their supportive role. Knowing how and when to evaluate a woman during the various stages of labor is essential for all labor and birth nurses to ensure a positive maternal experience and a healthy newborn.

A major focus of care for the woman during labor and birth is assisting her with maintaining control over her pain, emotions, and actions while being an active participant. Nurses can help and support women's active involvement in their childbirth experience by allowing time for discussion, offering companionship, listening to worries and concerns, paying attention to emotional needs, and offering information to explain what is happening in each stage of labor.

Nursing Management during the First Stage of Labor

Depending on how far advanced the woman's labor is when she arrives at the facility; the nurse will determine assessment parameters of maternal–fetal status and plan care accordingly. The nurse will provide high-touch, low-tech supportive nursing care during the first stage of labor when admitting the woman and orienting her to the labor and birth suite. The nurse is usually the primary gatekeeper of observations, interventions, treatments, and often the management of labor in the inpatient perinatal setting. Nursing care during this stage will include taking an admission history (reviewing the prenatal record); checking the results of routine laboratory tests and any special tests such as chorionic villi sampling, amniocentesis, genetic studies, and biophysical profile done during pregnancy; asking the woman about her childbirth preparation (birth plan, classes taken, coping skills); and completing a physical assessment of the woman to establish baseline values for future comparison.

Key nursing interventions include:

- Identifying the estimated date of birth from the client and the prenatal chart
- Validating the client's prenatal history to determine fetal risk status
- Determining fundal height to validate dates and fetal growth
- Performing Leopold maneuvers to determine fetal position, lie, and presentation
- Checking FHR
- Performing a vaginal examination as appropriate to evaluate effacement and dilation progress
- Instructing the client and her partner about monitoring techniques and equipment
- Assessing fetal response and FHR to contractions and recovery time
- Interpreting fetal monitoring strips
- Checking FHR baseline for accelerations, variability, and decelerations
- Repositioning the client to obtain an optimal FHR pattern
- Recognizing FHR problems and initiating corrective measures
- Checking amniotic fluid for meconium staining, odor, and amount

- Comforting the client throughout the testing period and labor
- Documenting times of notification for team members if problems arise
- Knowing appropriate interventions when abnormal FHR patterns present
- Supporting the client's decisions regarding intervention or avoidance of intervention
- Assessing the client's support system and coping status frequently

In addition to these interventions to promote optimal outcomes for the mother and fetus, the nurse must document care accurately and in a timely fashion. Accurate and timely documentation helps decrease professional liability exposure, minimize the risk of preventable injuries to women and infants during labor and birth, and preserve families (King et al., 2019). Guidelines for recording care include documenting:

- All care rendered to prove standards were met
- Conversations with all providers including notification times
- Nursing interventions before and after notifying the provider
- Use of the chain of command and response at each level
- All flow sheets and forms to validate care given
- All education given to the client and the response to it
- Facts, not personal opinions
- Detailed descriptions of any adverse outcome
- Initial nursing assessment, all encounters, and discharge plan
- All telephone conversations (Jordan et al., 2019)

This standard of documentation is needed to prevent or defend against litigation, which is prevalent in the childbirth arena.

Assessing the Woman upon Admission

The nurse usually first comes in contact with the woman either by phone or in person. The nurse should ascertain whether the woman is in true or false labor and whether she should be admitted or sent home. Upon admission to the labor and birth suite, the highest priorities include assessing FHR, assessing cervical dilation and effacement, and determining whether membranes have ruptured or

are intact. These assessment data will guide the critical thinking in planning care for the client.

If the initial contact is by phone, establish a therapeutic relationship with the woman. Speaking in a calm caring tone facilitates this. Nurses providing a telephone triage service need to have sufficient clinical experience and have clear lines of responsibility to enable sound decision-making. When completing a phone assessment, include questions about:

- Estimated date of birth to determine if term or preterm
- Fetal movement (frequency in the past few days)
- Other premonitory signs of labor experienced
- Parity, gravida, and previous childbirth experiences
- Time from start of labor to birth in previous labors
- Characteristics of contractions, including frequency, duration, and intensity
- Appearance of any vaginal bloody show
- Membrane status (ruptured or intact)
- Presence of supportive adult in household or if she is alone

When speaking with the woman over the telephone, review the signs and symptoms that denote true versus false labor, and suggest various positions she can assume to provide comfort and increase placental perfusion. Also suggest walking, massage, and taking a warm shower to promote relaxation. Outline what foods and fluids are appropriate for oral intake in early labor. Throughout the phone call, listen to the woman's concerns and answer any questions clearly.

Reducing the risk of liability exposure and avoiding preventable injuries to mothers and fetuses during labor and birth can be accomplished by adhering to two basic tenets of clinical practice: (1) use applicable evidence and/or published standards and guidelines as the foundation of care, and (2) whenever a clinical choice is presented, choose client safety (Gams et al., 2019). With these two tenets in mind, advise the woman on the phone to contact her health care provider for further instructions or to come to the facility to be evaluated, since ruling out true labor and possible maternal–fetal

complications cannot be done accurately over the phone. Additional nursing responsibilities associated with a phone assessment include:

- Consulting the woman's prenatal record for parity status, estimated date of birth, and untoward events
- Calling the health care provider to inform them of the woman's status
- Preparing for admission to the perinatal unit to ensure adequate staff assignment
- Notifying the admissions office of a pending admission

If the nurse's first encounter with the woman is in person, an assessment is completed to determine whether she should be admitted to the perinatal unit or sent home until her labor advances. Recent research findings suggest that women admitted before active labor are approximately twice as likely to be augmented with oxytocin and give birth via cesarean when compared with women admitted in active labor (Iobst et al., 2019). Nurses need to make careful assessment of labor progression *prior* to labor admission to decrease early admissions and to improve labor safety and birth outcomes.

Entering a facility is often an intimidating and stressful event for women since it is an unfamiliar environment. Giving birth for the first time is a pivotal event in the lives of most women. Therefore, demonstrate respect when addressing the client; listen carefully and express interest and concern. Nurses must value and respect women and promote their self-worth and sense of control by allowing them to participate in making decisions. Allowing them a fair amount of autonomy in their childbirth decisions, supporting their personal worth, knowing them holistically, and using caring communication will increase client satisfaction (King et al., 2019).

An admission assessment includes maternal health history, physical assessment, fetal assessment, laboratory studies, and assessment of psychological status. Usually the facility has a form that can be used throughout labor and birth to document assessment findings (Fig. 14.13).

MATERNAL HEALTH HISTORY AND CULTURAL ASSESSMENT

A maternal health history should include typical biographical data such as the woman's name and age and the name of the delivering health care provider. Other information that is collected includes reason for admission, such as labor, cesarean birth, or observation for a complication; the prenatal record data, including the estimated date of birth, a history of the current pregnancy, and the results of any laboratory and diagnostic tests, such as blood type, Rh status, and group B streptococcal status; past pregnancy and obstetric history; past health history and family history; prenatal education; list of medications; risk factors such as diabetes, hypertension, and use of tobacco, alcohol, or illicit drugs; pain management plan; history of potential domestic violence; history of previous preterm births; allergies; time of last food ingestion; method chosen for infant feeding; and name of birth attendants and pediatrician.

Ascertaining this information is important so that an individualized plan of care can be developed for the woman. If, for example, the woman's due date is still 2 months away, it is important to establish this information so interventions can be initiated to arrest the labor immediately or notify the intensive perinatal team to be available. In addition, if the woman has diabetes, it is critical to monitor her glucose levels during labor, to prepare for a surgical birth if dystocia of labor occurs, and to alert the newborn nursery of potential hypoglycemia in the newborn after birth. By collecting important information about each woman they care for, nurses can help improve the outcomes for all concerned.

Be sure to observe the woman's emotions, support system, verbal interaction, cultural background and language spoken, body language and posture, perceptual acuity, and energy level. This psychosocial information provides cues about the woman's emotional state, culture, and communication systems. For example, if the woman arrives at the labor and birth suite extremely anxious, alone, and unable to communicate in English, how can the nurse meet her needs and plan her care appropriately? It is only by

assessing each woman physically and psychosocially that the nurse can make astute decisions regarding proper care. In this case, an interpreter would be needed to assist in the communication process between the staff and the woman to initiate proper care.

It is important to acknowledge and try to understand the cultural differences in women with cultural backgrounds different from that of the nurse. Attitudes toward childbirth are heavily influenced by the culture in which the woman has been raised. As a result, within every society, specific attitudes and values shape the woman's childbearing behaviors. Be aware of what these are. When carrying out a cultural assessment during the admission process, ask questions (Box 14.2) to help plan culturally competent care during labor and birth.

BOX 14.2 Questions for Providing Culturally Competent Care during Labor and Birth

- Where were you born? How long have you lived in the United States?
- What languages do you speak and read?
- Who are your major support people?
- What are your religious practices?
- How do you view childbearing?
- Are there any special precautions or restrictions that are important?
- Is birth considered a private or a social experience?
- How would you like to manage your labor discomfort?
- Who will provide your labor support?

Giger, J. N. (2019). *Transcultural nursing: Assessment and intervention* (8th ed.). Elsevier; McFarland, M. R., & Wehbe-Alamah, H. B. (2018). *Leininger's transcultural nursing: Concepts, theories, research & practice* (4th ed.). McGraw-Hill Professional.

PHYSICAL EXAMINATION

The physical examination typically includes a generalized assessment of the woman's body systems, including hydration status, vital signs, auscultation of heart and lung sounds, and measurement of height and weight. The physical examination also includes the following assessments:

1. Pain level and coping behaviors demonstrated
2. Uterine activity, including contraction frequency, duration, and intensity
3. Fetal status, including heart rate, position, and station
4. Cervical dilation and degree of effacement
5. Status of membranes (intact or ruptured)
6. Assess vital signs: temperature, pulse, respirations, and blood pressure
7. Perform Leopold maneuvers to determine fetal lie
8. Fundal height measurement
9. Ability to ambulate safely

These assessment parameters form a baseline against which the nurse can compare all future values throughout labor. The findings should be similar to those of the woman's prepregnancy and pregnancy findings with the exception of her pulse rate, which might be elevated secondary to her anxious state with beginning labor.

LABORATORY STUDIES

Upon admission, laboratory studies are typically done to establish a baseline. Although the exact tests may vary among facilities, they usually include a urinalysis via clean-catch urine specimen and complete blood count. Blood typing and Rh factor analysis may be necessary if the results of these are unknown or unavailable. In addition, if the following test results are not included in the maternal prenatal history, it may be necessary to perform them at this time. They include syphilis screening, hepatitis B (HbsAg) screening, group B streptococcus, human immune deficiency virus (HIV) testing (if the woman gives consent), and possible drug screening if the history is positive.

Group B streptococcus (GBS) is a Gram-positive organism that colonizes in the female genital tract and rectum and is present in 10% to 30% of all healthy women (King et al., 2019). These women are asymptomatic carriers but can cause GBS disease of the newborn through vertical transmission during labor and horizontal

transmission after birth. The mortality rate of infected newborns varies according to time of onset (early or late). Risk factors for GBS include maternal intrapartum fever, prolonged ruptured membranes (longer than 12 to 18 hours), previous birth of an infected newborn, and GBS bacteriuria in the present pregnancy.

The Centers for Disease Control and Prevention (CDC), ACOG, and the American Academy of Pediatrics (AAP) have guidelines that advise universal screening of pregnant women at 35 to 37 weeks' gestation for GBS and intrapartum antibiotic therapy for GBS carriers (2019). These guidelines reaffirm the major prevention strategy—universal antenatal GBS screening and intrapartum antibiotic prophylaxis for culture-positive and high-risk women. Also included are new recommendations for laboratory methods for identification of GBS colonization during pregnancy, algorithms for screening and intrapartum prophylaxis for women with preterm labor and premature rupture of membranes, updated prophylaxis recommendations for women with a penicillin allergy, and a revised algorithm for the care of newborn infants (CDC, 2019a). Maternal infections associated with GBS include acute chorioamnionitis, endometritis, and urinary tract infection. Neonatal clinical manifestations include pneumonia and sepsis. Identified GBS carriers receive IV antibiotic prophylaxis (penicillin G or ampicillin) at the onset of labor or ruptured membranes.

The ACOG, CDC, AWHONN, and the U.S. Preventive Services Task Force recommend that all pregnant women be offered a screening test for HIV antibodies on their first prenatal visit, again during the third trimester if engaging in high-risk behaviors, and upon admission to the labor and birth area. The CDC estimates that approximately 50,000 individuals contract HIV in the United States each year, and 250,000 individuals have undiagnosed HIV infections (CDC, 2019b).

If her HIV status is not documented, the woman being admitted to the labor and birth suite should have rapid HIV testing done. To reduce perinatal transmission, women who are HIV-positive are given a combination of antiretroviral drugs. To further reduce the risk of perinatal transmission, ACOG and the U.S. Public Health Service

recommend that women who are infected with HIV and have plasma viral loads of more than 1,000 copies/mL be counseled regarding the benefits of elective cesarean birth. In the absence of any medical intervention, the rate of vertical transmission of HIV to the fetus can range from 15% to 45%. However, with the use of antiretroviral regimens, the transmission rate is reduced to less than 2% (Jordan et al., 2019).

Additional interventions to reduce the transmission risk would include avoiding use of a scalp electrode for fetal monitoring or doing a scalp blood sampling for fetal pH, delaying amniotomy, encouraging formula feeding after birth, and avoiding invasive procedures such as forceps- or vacuum-assisted devices. The nurse stresses the importance of all interventions and the goal to reduce transmission of HIV to the newborn.

Continuous Assessment during the First Stage of Labor

After the admission assessment is complete and the woman and her support person have been oriented to the room, equipment, and procedures, assessment continues for changes that would indicate that labor is progressing as expected. Assess the woman's knowledge, experience, and expectations of labor. Typically, blood pressure, pulse, and respirations are assessed every hour during the latent phase of labor unless the clinical situation dictates that vital signs be taken more frequently. During the active phase of labor, vital signs are assessed every 30 minutes. Temperature is taken every 4 hours throughout the first stage of labor and every 2 hours after membranes have ruptured to detect an elevation indicating an ascending infection.

Vaginal examinations are performed periodically to track labor progress. This assessment information is shared with the woman to reinforce that she is making progress toward the goal of birth. Uterine contractions are monitored for frequency, duration, and intensity every 30 to 60 minutes during the latent phase, and every 15 to 30 minutes during the active phase. Note the changes in the character of the contractions as labor progresses, and inform the

woman of her progress. Continually determine the woman's level of pain and her ability to cope and use relaxation techniques effectively.

When the fetal membranes rupture, spontaneously or artificially, assess the FHR and check the amniotic fluid for color, odor, and amount. Assess the FHR intermittently or continuously via electronic monitoring. During the latent phase of labor, assess the FHR every 30 to 60 minutes; in the active phase, assess the FHR at least every 15 to 30 minutes. Also, be sure to assess the FHR before ambulation, before any procedure, and before administering analgesia or anesthesia to the mother. Table 14.3 summarizes assessments for the first stage of labor.

Remember Sheila from the chapter-opening scenario? What is the nurse's role with Sheila in active labor? What additional comfort measures can the labor nurse offer Sheila?

TABLE 14.3 Summary of Assessments during the First Stage of Labor

Assessments[a]	Latent Phase (0–6 cm)	Active Phase (6–10 cm)
Vital signs (BP, pulse, respirations)	Every 30–60 min	Every 15–30 minutes
Temperature	Every 4 hours; more frequently if membranes are ruptured	Every 4 hours; more frequently if membranes are ruptured
Contractions (frequency, duration, intensity)	Every 30–60 minutes by palpation or continuously if EFM	Every 15–30 minutes by palpation or continuously if EFM
Fetal heart rate	Every hour by Doppler or continuously by EFM	Every 15–30 minutes by Doppler or continuously by EFM
Vaginal examination	Initially on admission to determine phase and as needed based on maternal cues to document labor progression	As needed to monitor labor progression
Behavior/psychosocial	With every client encounter: talkative, excited, anxious	With every client encounter: self-absorbed in labor; intense and quiet now

[a]The frequency of assessments is dictated by the health status of the woman and fetus and can be altered if either one of their conditions changes.

King, T. L., Brucker, M.C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning; Hutchison, J., Mahdy, H., & Hutchison, J. (2019). Stages of labor. *StatPearls*. Retrieved March 27, 2020, from https://www.ncbi.nlm.nih.gov/books/NBK544290/

Nursing Interventions

Nursing interventions during the admission process should include:

- Asking about the client's expectations of the birthing process

- Providing information about labor, birth, pain management options, and relaxation techniques
- Presenting information about fetal monitoring equipment and the procedures needed
- Monitoring FHR and identifying patterns that need further intervention
- Monitoring the mother's vital signs to obtain a baseline for later comparison
- Reassuring the client that her labor progress will be monitored closely and nursing care will focus on ensuring fetal and maternal well-being throughout

As the woman progresses through the first stage of labor, nursing interventions include:

- Encouraging the woman's partner to participate
- Keeping the woman and her partner up to date on the progress of the labor
- Orienting the woman and her partner to the labor and birth unit and explaining all of the birthing procedures
- Providing clear fluids (e.g., ice chips) as needed or requested
- Maintaining the woman's parenteral fluid intake at the prescribed rate if she has an IV
- Initiating or encouraging comfort measures, such as backrubs, cool cloths to the forehead, frequent position changes, ambulation, showers, slow dancing, leaning over a birth ball, side-lying, or counterpressure on lower back (Teaching Guidelines 14.1)
- Encouraging the partner's involvement with breathing techniques
- Assisting the woman and her partner with focusing on breathing techniques
- Informing the woman that the discomfort will be intermittent and of limited duration; urging her to rest between contractions to preserve her strength; and encouraging her to use distracting activities to lessen the focus on contractions
- Changing bed linens and gown as needed
- Keeping the perineal area clean and dry
- Supporting the woman's decisions about pain management
- Monitoring maternal vital signs frequently and reporting any abnormal values

- Ensuring that the woman takes deep cleansing breaths before and after each contraction to enhance gas exchange and oxygen to the fetus
- Educating the woman and her partner about the need for rest and helping them plan strategies to conserve strength
- Monitoring FHR for baseline, accelerations, variability, and decelerations
- Checking on bladder status and encouraging voiding at least every 2 hours to facilitate birth
- Repositioning the woman as needed to obtain optimal heart rate pattern
- Communicating requests from the woman to appropriate personnel
- Respecting the woman's sense of privacy by covering her when appropriate
- Offering human presence by being present with the woman, not leaving her alone for long periods
- Being patient with the natural labor pattern to allow time for change
- Encouraging maternal movement throughout labor to increase the woman's level of comfort
- Dimming the lights in the room when pushing and requesting softened voices be used to maintain a calm and centered ambiance
- Reporting any deviations from normal to the health care professional so that interventions can be initiated early to be effective (Escobar et al., 2019; Gams et al., 2019; Jordan et al., 2019).

See Nursing Care Plan 14.1.

TEACHING GUIDELINES 14.1
Positioning during the First Stage of Labor

- Walking with support from the partner (adds the force of gravity to contractions to promote fetal descent)
- Slow-dancing position with the partner holding the woman (adds the force of gravity to contractions and promotes support from and active participation of your partner)
- Side-lying with pillows between the knees for comfort (offers a restful position and improves oxygen flow to the uterus)
- Semi-sitting in bed or on a couch leaning against the partner (reduces back pain because fetus falls forward, away from the sacrum)
- Sitting in a chair with one foot on the floor and one on the chair (changes pelvic shape)
- Leaning forward by straddling a chair, a table, or a bed or kneeling over a birth ball (reduces back pain, adds the force of gravity to promote descent; possible pain relief if partner can apply sacral pressure)
- Encourage any position of comfort the woman chooses to labor in and give birth.
- Sitting in a rocking chair or on a birth ball and shifting weight back and forth (provides comfort because rocking motion is soothing; uses the force of gravity to help fetal descent)
- Lunge by rocking weight back and forth with foot up on chair during contraction (uses force of gravity by being upright; enhances rotation of fetus through rocking)
- Women should be allowed to position themselves in whatever position they find most comfortable.
- Open knee–chest position (helps relieve back discomfort) (King et al., 2019; Watkins 2019)

Nursing Management during the Second Stage of Labor

Management of the second stage of labor often follows tradition-based routines rather than evidence-based practices. Current evidence for management of the second stage of labor supports the practices of delayed pushing, spontaneous (nondirected) pushing, and maternal choice positions (Polnaszek & Cahill, 2020). To be able to help women through the second stage of labor requires the nurse to have a comprehensive understanding of physiology and be aware of the latest evidence-based research and apply it to practice (Blackburn, 2018).

Nursing care during the second stage of labor focuses on supporting the woman and her partner in making active decisions about her care and labor management, implementing strategies to prolong the early passive phase of fetal descent, supporting involuntary bearing-down efforts, providing instruction and assistance, and using maternal positions that can enhance descent and reduce pain (King et al., 2019). Women in the past gave birth unaided by following their bodies' signals to birth their babies, so the role of the nurse should be to support the woman in her choice of pushing method and to encourage confidence in her instinct of when and how to push.

In the absence of any complications, nurses should not be controlling this stage of labor but rather empowering women to achieve a satisfying experience. The primary rationale for directing women to push is to shorten the second stage of labor. Common practice in many labor units is still to coach women to use closed glottis pushing with every contraction, starting at 10 cm of dilation, a practice that is not supported by research. Research suggests that directed pushing during the second stage may be accompanied by a significant decline in fetal pH and may cause maternal muscle and nerve damage if done too early (Norwitz et al., 2019). Shortening the phase of active pushing and lengthening the early phase of passive descent can be achieved by encouraging the woman not to push until she has a strong desire to do so and until the descent and rotation of the fetal head are well advanced. Effective pushing can be achieved by assisting the woman with assuming a more upright or squatting position. Supporting spontaneous pushing and

encouraging women to choose their own method of pushing should be accepted as best clinical practice.

Perineal lacerations or tears can occur during the second stage when the fetal head emerges through the vaginal introitus. The extent of the laceration is defined by depth: a first-degree laceration extends through the skin; a second-degree laceration extends through the muscles of the perineal body; a third-degree laceration continues through the anal sphincter muscle; and a fourth-degree laceration also involves the anterior rectal wall. Special attention needs to be paid to third- and fourth-degree lacerations to prevent fecal incontinence. Risks for third- or fourth-degree lacerations include nulliparity, being of Asian or Pacific Islander descent, increased birth weight of the newborn, operative vaginal birth, episiotomy, and longer second stage of labor. Increasing body mass index was associated with fewer lacerations (Waldman, 2019). The primary care provider should repair any lacerations during the third stage of labor.

NURSING CARE PLAN 14.1 Overview of a Woman in the Active Phase of the First Stage of Labor

Candice, a 23-year-old gravida 1, para 0 (G1P0), is admitted to the labor and birth suite at 39 weeks' gestation having contractions of moderate intensity every 5 to 6 minutes. A vaginal examination reveals that her cervix is 80% effaced and 5 cm dilated. The presenting part (vertex) is at 0 station and her membranes ruptured spontaneously 4 hours ago at home. She is admitted and an IV line is started for hydration and vascular access. An external fetal monitor is applied. FHR is 140 bpm and regular. Her partner is present at her bedside. Candice is now in the active phase of the first stage of labor, and her assessment findings are as follows: cervix dilated 7 cm, 80% effaced; moderate to strong contractions occurring regularly every 3 to 5 minutes lasting 45 to 60 seconds; at 0 station on pelvic examination; FHR auscultated loudest below umbilicus at 140 bpm; vaginal show—pink or bloody vaginal mucus; currently apprehensive, inwardly focused, with increased dependency; voicing concern about ability to cope with pain; limited ability to follow directions.

NURSING ANALYSIS: Anxiety related to labor and birth process and fear of the unknown related to client's first experience

OUTCOME IDENTIFICATION AND EVALUATION

The client will remain calm and in control as evidenced by ability to make decisions and use positive coping strategies.

INTERVENTIONS: *Promoting Positive Coping Strategies*

- Provide instruction regarding the labor process *to allay anxiety*.
- Orient the woman to the physical environment and equipment as necessary *to keep her informed of events*.
- Encourage verbalization of feelings and concerns *to reduce anxiety*.
- Listen attentively to the woman and her partner *to demonstrate interest and concern*.
- Inform the woman and her partner of standard procedures and processes *to ensure adequate understanding of events and procedures*.
- Frequently update woman of progress and labor status *to provide positive reinforcement for actions*.
- Reinforce relaxation techniques and provide instruction if needed *to aid in coping*.

- Encourage participation of the partner in the coaching role; role model *to facilitate partner participation in labor process to provide support and encouragement to the client*.
- Provide a presence and remain with the client as much as possible *to provide comfort and support*.

NURSING ANALYSIS: Acute pain related to uterine contractions and stretching of the cervix and birth canal

OUTCOME IDENTIFICATION AND EVALUATION

The client will maintain a tolerable level of pain and discomfort as evidenced by statements of pain relief, pain rating of 2 or less on pain rating scale, and absence of adverse effects in client and fetus from analgesia or anesthesia.

INTERVENTIONS: *Providing Pain Relief*

- Monitor vital signs, observe for signs of pain, and have client rate pain on a scale of 0 to 10 *to provide baseline for comparison*.
- Encourage client to void every 1 to 2 hours *to decrease pressure from a full bladder*.
- Assist woman in changing positions frequently *to increase comfort and promote labor progress*.
- Encourage use of distraction *to reduce focus on contraction pain*.
- Suggest pelvic rocking, massage, or back counter pressure *to reduce pain*.
- Assist with use of relaxation and breathing techniques *to promote relaxation*.
- Use touch appropriately (backrub) when desired by the woman *to promote comfort*.
- Integrate use of nonpharmacologic measures for pain relief, such as warm water, birthing ball, or other techniques *to facilitate pain relief*.
- Administer pharmacologic agents as ordered when requested *to control pain*.
- Provide reassurance and encouragement between contractions *to foster self-esteem and continued participation in labor process*.

NURSING ANALYSIS: Infection risk related to multiple vaginal examinations following rupture of membranes and tissue trauma

OUTCOME IDENTIFICATION AND EVALUATION

The client will remain free of infection as evidenced by the absence of signs and symptoms of infection, vital signs and FHR within acceptable parameters, lab test results within normal limits, and clear amniotic fluid without odor.

INTERVENTIONS: *Preventing Infection*

- Monitor vital signs (every 2 hours after rupture of membranes) and FHR frequently as per protocol *to allow for early detection of problems*; report fetal tachycardia (early sign of maternal infection) *to ensure prompt treatment*.
- Provide frequent perineal care and pad changes *to maintain good perineal hygiene*.
- Change linens and woman's gown as needed *to maintain cleanliness*.
- Ensure that vaginal examinations are performed only when needed *to prevent introducing pathogens into the vaginal vault*.
- Monitor lab test results such as white blood cell count *to assess for elevations indicating infection*.
- Encourage emptying of her bladder at least every 2 hours *to not impede fetal descent.*
- Use aseptic technique for all invasive procedures *to prevent infection transmission*.
- Carry out good hand washing techniques before and after procedures and use standard precautions as appropriate *to minimize risk of infection transmission*.
- Document amniotic fluid characteristics like color and odor *to establish baseline for comparison*.

An **episiotomy** is an incision made in the perineum to enlarge the vaginal outlet and theoretically to shorten the second stage of labor. Alternative measures such as warm compresses and continual massage with oil have been successful in stretching the perineal area to prevent cutting it. Certified nurse midwives can cut and repair episiotomies, but they frequently use alternative measures if possible.

TAKE NOTE!

Restrictive use of episiotomy has been recommended by ACOG given the risks of the procedure and unclear benefits of routine use (Waldman, 2019).

The midline episiotomy has been the most commonly used one in the United States because it can be easily repaired and causes the least amount of pain. The application of warmed compresses and/or intrapartum perineal massage is associated with a decrease in

trauma to the perineal area and reduced need for an episiotomy (Waldman, 2019). Routine episiotomy has declined since liberal usage has been discouraged by ACOG except to avoid several maternal lacerations or to expedite difficult births. Anal sphincter laceration rates with spontaneous vaginal delivery have decreased, likely reflecting the decreased usage of episiotomy. The decline in operative vaginal delivery corresponds with a sharp increase in cesarean births, which may indicate that health care providers are favoring cesarean births for difficult births (Cunningham et al., 2018). Figure 14.14 shows episiotomy locations.

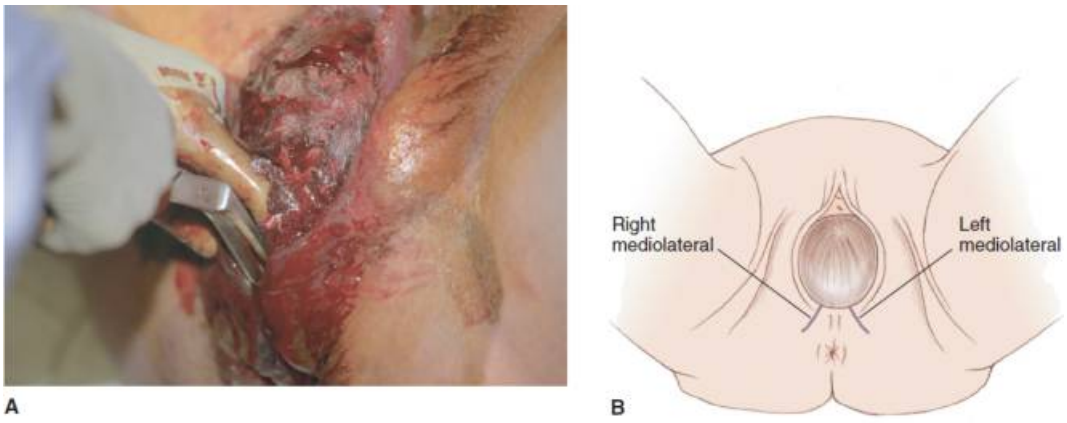

FIGURE 14.14. Location of an episiotomy. **A.** Midline episiotomy. **B.** Right and left mediolateral episiotomies.

Continuous Assessment during the Second Stage of Labor

Assessment is continuous during the second stage of labor. Hospital policies dictate the specific type and timing of assessments, as well as the way in which they are documented. Assessment involves identifying the signs typical of the second stage of labor, including:

- Increase in apprehension or irritability
- Spontaneous rupture of membranes
- Sudden appearance of sweat on upper lip
- Increase in blood-tinged show
- Low grunting sounds from the woman
- Complaints of rectal and perineal pressure

- Beginning of involuntary bearing-down efforts

Other ongoing assessments include the contraction frequency, duration, and intensity; maternal vital signs every 5 to 15 minutes; fetal response to labor as indicated by FHR monitor strips; amniotic fluid for color, odor, and amount when membranes are ruptured; and the coping status of the woman and her partner (Table 14.4).

Assessment also focuses on determining the progress of labor. Associated signs include bulging of the perineum, labial separation, advancing and retreating of the newborn's head during and between bearing-down efforts, and **crowning** (fetal head is visible at vaginal opening; Fig. 14.15).

A vaginal examination is completed to determine if it is appropriate for the woman to push. Pushing is appropriate if the cervix has fully dilated to 10 cm and the woman feels the urge to do so.

Nursing Interventions

Nursing interventions during this stage focus on motivating the woman, assisting her with positioning, encouraging her to put all her efforts to pushing this newborn to the outside world, and giving her feedback on her progress. If the woman is pushing without progress, suggest that she keep her eyes open during the contractions and look toward where the newborn is coming out. Changing positions frequently will also help her make progress. Positioning a mirror so the woman can visualize the birthing process and how successful her pushing efforts are can help motivate her.

TABLE 14.4 Summary of Assessments during the Second, Third, and Fourth Stages of Labor

Assessments[a]	Second Stage of Labor (Birth of Neonate)	Third Stage of Labor (Placenta Expulsion)	Fourth Stage of Labor (Recovery)
Vital signs (BP, pulse, respirations)	Every 5–15 minutes	Every 15 minutes	Every 15 minutes
Fetal heart rate	Every 5–15 minutes by Doppler or continuously by EFM	Apgar scoring at 1 and 5 minutes	Newborn—complete head-to-toe assessment; vital signs every 15 minutes until stable
Contractions/uterus	Palpate every one	Observe for placental separation	Palpating for firmness and position every 15 minutes for first hour
Bearing down/pushing	Assist with every effort	None	None
Vaginal discharge	Observe for signs of descent—bulging of perineum, crowning	Assess bleeding after expulsion	Assess every 15 minutes with fundus firmness
Behavior/psychosocial	Observe every 15 minutes: cooperative, focus is on work of pushing newborn out	Observe every 15 minutes: often feelings of relief after hearing newborn crying; calmer	Observe every 15 minutes: usually excited, talkative, awake; needs to hold newborn, be close, and inspect body

[a]The frequency of assessments is dictated by the health status of the woman and fetus and can be altered if either one of their condition's changes.

(2019). *All-in-one nursing care planning resource book*. Elsevier.

FIGURE 14.15. Crowning.

During the second stage of labor, an ideal position would be one that opens the pelvic outlet as wide as possible, provides a smooth pathway for the fetus to descend through the birth canal, takes advantage of gravity to assist the fetus to descend, and gives the

mother a sense of being safe and in control of the labor process (Berta et al., 2019). Some suggestions for positions in the second stage include:

- Lithotomy with feet up in stirrups: most convenient position for caregivers, though evidence does not support this position physiologically
- Semi-sitting with pillows underneath knees, arms, and back
- Lateral/side-lying with curved back and upper leg supported by partner
- Sitting on birthing stool: opens pelvis, enhances the pull of gravity, and helps with pushing
- Squatting/supported squatting: gives the woman a sense of control
- Using a peanut ball between the legs to widen the pelvic diameter
- Kneeling with hands on bed and knees comfortably apart

Other important nursing interventions during the second stage include:

- Providing continuous comfort measures such as mouth care, encouraging position changes, changing bed linen and underpads, and providing a quiet, focused environment
- Instructing the woman on the following bearing-down positions and techniques:
  - Pushing only when she feels an urge to do so
  - Delaying pushing for up to 90 minutes after complete dilation
  - Using abdominal muscles when bearing down
  - Using short pushes of 6 to 7 seconds
  - Focusing attention on the perineal area to visualize the newborn
  - Relaxing and conserving energy between contractions
  - Pushing several times with each contraction
  - Pushing with an open glottis and slight exhalation (Jordan et al., 2019)
- Continuing to monitor contraction and FHR patterns to identify problems
- Providing brief, explicit directions throughout this stage
- Continuing to provide psychosocial support by reassuring and coaching
- Facilitating the upright position to encourage the fetus to descend

- Continuing to assess blood pressure, pulse, respirations, uterine contractions, bearing-down efforts, FHR, and coping status of the client and her partner
- Providing pain management if needed
- Providing a continuous nursing presence
- Offering praise for the client's efforts
- Preparing for and assisting with delivery by:
  - Notifying the health care provider of the estimated time frame for birth
  - Preparing the delivery bed and positioning the client
  - Preparing the perineal area according to the facility's protocol
  - Offering a mirror and adjusting it so the woman can watch the birth
  - Explaining all procedures and equipment to the client and her partner
  - Setting up delivery instruments needed while maintaining sterility
  - Using standard precautions during the birthing process to avoid body fluid splashes
  - Recording the time of birth, time of placenta, and type of birth
  - Receiving newborn and transporting them to a warming environment, or covering the newborn with a warmed blanket on the woman's abdomen
  - Providing initial care and assessment of the newborn (see the "Birth" section that follows)

Sheila is completely dilated now and experiencing the urge to push. How can the nurse help Sheila with her pushing efforts? What additional interventions can the labor nurse offer Sheila now? In addition to encouraging Sheila to rest between pushing and offering praise for her efforts, what is the nurse's role during the birthing process?

BIRTH

The second stage of labor ends with the birth of the newborn. The maternal position for birth varies from the standard lithotomy position to side-lying to squatting to standing or kneeling depending on the birthing location, the woman's preference, and standard protocols. Once the woman is positioned for birth, cleanse the vulva and

perineal areas. The primary health care provider then takes charge after donning protective eyewear, masks, gowns, and gloves and performing hand hygiene.

Once the fetal head has emerged, the primary care provider explores the fetal neck to see if the umbilical cord is wrapped around it. If it is, the cord is slipped over the head to facilitate delivery. As soon as the head emerges, the health care provider suctions the newborn's mouth first (because the newborn is an obligate nose breather) and then the nares with a bulb syringe to prevent aspiration of mucus, amniotic fluid, or meconium (Fig. 14.16). The umbilical cord is double-clamped and cut between the clamps by the birth attendant or the woman's partner if desired. With the first cries of the newborn, the second stage of labor ends. For care of the woman undergoing a surgical birth, see Chapter 21.

In addition to encouraging Sheila to rest between pushing and offering praise for her efforts, what is the nurse's role during the birthing process?

FIGURE 14.16. Suctioning the newborn immediately after birth.

IMMEDIATE CARE OF THE NEWBORN

Once birth takes place, the newborn is placed under a radiant warmer, dried, assessed, wrapped in warmed blankets, and placed on the woman's abdomen for warmth and closeness. In some health

care facilities, the newborn is placed on the woman's abdomen immediately after birth and covered with a warmed blanket without being dried or assessed. In either scenario, the stability of the newborn dictates the location of aftercare. The nurse can also assist the mother with breastfeeding her newborn for the first time.

Assessment of the newborn begins at the moment of birth and continues until the newborn is discharged. Drying the newborn and providing warmth to prevent heat loss by evaporation is essential to help support thermoregulation and provide stimulation. Placing the newborn under a radiant heat source and putting on a cap will further reduce heat loss after drying.

Assess the newborn by assigning an Apgar (appearance, pulse, grimace, activity, and respiration) score at 1 and 5 minutes. The Apgar score assesses five parameters—(1) heart rate (absent, slow, or fast), (2) respiratory effort (absent, weak cry, or good strong yell), (3) muscle tone (limp, or lively and active), (4) response to irritation stimulus, and (5) color—that evaluate a newborn's cardiorespiratory adaptation after birth. The parameters are arranged from the most important (heart rate) to the least important (color). The newborn is assigned a score of 0 to 2 in each of the five parameters. The purpose of the Apgar assessment is to evaluate the physiologic status of the newborn; see Chapter 18 for additional information on Apgar scoring.

Secure two identification bands on the newborn's wrist and ankle that match the band on the mother's wrist to ensure the newborn's identity. This identification process is completed in the birthing suite before anyone leaves the room. Some health care agencies also take an early photo of the newborn for identification in the event of abduction (National Center for Missing and Exploited Children [NCMEC], 2020).

Other types of newborn security systems can also be used to prevent abduction. Some systems have sensors that are attached to the newborn's identification bracelet or cord clamp. An alarm is set off if the bracelet or clamp activates receivers near exits. Others have an alarm that is activated when the sensor is removed from the newborn (Fig. 14.17). Even with the use of electronic sensors, the

parents, nursing staff, and security personnel are responsible for prevention strategies and ensuring the safety and protection of all newborns (NCMEC, 2020). Nurses can help prevent newborn abduction by educating parents about abduction risks, using identically numbered bands on the baby and parents, by instructing parents to keep their newborn in their direct line of vision within their hospital room at all times, taking color photographs of the infant, wearing color photograph ID badges themselves, discouraging parents and families from publishing birth notices in the public media with mother's name and address, controlling access to the nursery or postpartum unit with locked doors, and utilizing infant security tags or abduction alarm systems (NCMEC, 2019).

FIGURE 14.17. An example of a security sensor applied to a newborn's arm.

Sheila gave birth to a healthy 7-lb, 7-oz baby girl. She is eager to hold and nurse her newborn. What is the initial care of the newborn? How can the nurse meet the needs of both the newborn and Sheila, who is exhausted but eager to bond with her newborn?

Nursing Management during the Third Stage of Labor

During the third stage of labor, strong uterine contractions continue at regular intervals under the continuing influence of oxytocin. The uterine muscle fibers shorten, or retract, with each contraction, leading to a gradual decrease in the size of the uterus, which helps shear the placenta away from its attachment site. The third stage is complete when the placenta is delivered. Nursing care during the third stage of labor primarily focuses on immediate newborn care and assessment and observing for signs of placental separation, being available to assist with the delivery of the placenta, recording the time of expulsion, and inspecting the placenta for intactness. The nurse should also be assessing the mother by palpating the uterus before and after placental expulsion.

Three hormones play important roles in the third stage. During this stage, the woman experiences peak levels of oxytocin and endorphins, while the high adrenaline levels that occurred during the second stage of labor to aid with pushing begin falling. The hormone oxytocin causes uterine contractions and helps the woman enact instinctive mothering behaviors such as holding the newborn close to her body and cuddling the baby.

Skin-to-skin contact immediately after birth and the newborn's first attempt at breastfeeding further augment maternal oxytocin levels, strengthening the uterine contractions that will help the placenta separate and the uterus contract to prevent hemorrhage. Endorphins, the body's natural opiates, produce an altered state of consciousness and aid in blocking out pain. In addition, the drop in adrenaline level from the second stage, which had kept the mother

and baby alert at first contact, causes most women to shiver and feel cold shortly after giving birth.

TAKE NOTE!

A crucial role for nurses during the third stage of labor is to protect the natural hormonal process by ensuring unhurried and uninterrupted contact between mother and newborn after birth, providing warmed blankets to prevent shivering and allowing skin-to-skin contact with initial breastfeeding.

Continuing Assessment during the Third Stage of Labor

Assessment during the third stage of labor includes:

- Monitoring placental separation by looking for the following signs:
  - Firmly contracting uterus
  - Change in uterine shape from discoid to globular ovoid
  - Sudden gush of dark blood from vaginal opening
  - Lengthening of umbilical cord protruding from vagina
  - Examining placenta and fetal membranes for intactness the second time (the health care provider assesses the placenta for intactness the first time) (Fig. 14.18)
- Assessing for any perineal trauma, such as the following, before allowing the birth attendant to leave:
  - Firm fundus with bright red blood trickling: laceration
  - Boggy fundus with red blood flowing: uterine atony
  - Boggy fundus with dark blood and clots: retained placenta
  - Inspecting the perineum for condition of episiotomy if performed
  - Assessing for perineal lacerations and ensuring repair by birth attendant

Nursing Interventions

Interventions during the third stage of labor include:

- Describing the process of placental separation to the couple
- Instructing the woman to push when signs of separation are apparent
- Administering an oxytocic agent if ordered and indicated after placental expulsion

- Providing support and information about episiotomy and/or laceration if applicable
- Cleaning and assisting the client into a comfortable position after birth, making sure to lift both legs out of stirrups (if used) simultaneously to prevent strain
- Assessing the woman's knowledge of breastfeeding to determine educational needs
- Educating the woman about latching on, positioning, infant sucking and swallowing
- Repositioning the birthing bed to serve as a recovery bed if applicable
- Assisting with transfer to the recovery area if applicable
- Providing warmth by replacing warmed blankets over the woman
- Applying an ice pack to the perineal area to provide comfort to episiotomy if indicated
- Explaining what assessments will be carried out over the next hour and offering positive reinforcement for actions

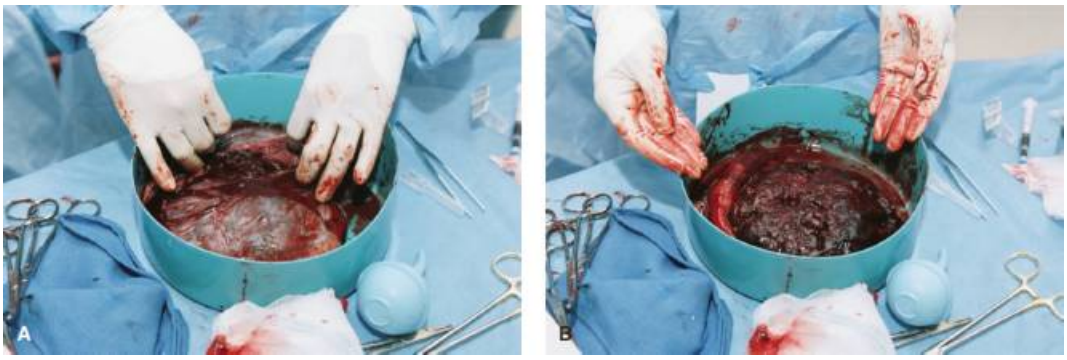

FIGURE 14.18. Placenta. **A.** Fetal side. **B.** Maternal side.

- Ascertaining any needs
- Monitoring maternal physical status by assessing:
  - Vaginal bleeding: amount, consistency, and color
  - Vital signs: blood pressure, pulse, and respirations taken every 15 minutes
  - Uterine fundus, which should be firm, in the midline, and at the level of the umbilicus
- Recording all birthing statistics and securing primary caregiver's signature

- Documenting birthing event in the birth book (official record of the facility that outlines every birth event), detailing any deviations

Nursing Management during the Fourth Stage of Labor

The fourth stage of labor begins after the placenta is expelled and lasts up to 4 hours after birth, during which time recovery takes place. This recovery period may take place in the same room where the woman gave birth, in a separate recovery area, or in the postpartum room. During this stage, the woman's body is beginning to undergo the many physiologic and psychological changes that occur after birth. The focus of nursing management during the fourth stage of labor involves frequent close observation for hemorrhage, provision of comfort measures, and promotion of family attachment.

Assessment

Assessments during the fourth stage center on the woman's vital signs, status of the uterine fundus and perineal area, comfort level, lochia amount, and bladder status. During the first hour after birth, vital signs are taken every 15 minutes, then every 30 minutes for the next hour if needed. The woman's blood pressure should remain stable and within normal range after giving birth. A decrease may indicate uterine hemorrhage; an elevation might suggest preeclampsia.

The pulse is usually typically slower (60 to 70 bpm) than during labor. This may be associated with a decrease in blood volume following placental separation. An elevated pulse rate may be an early sign of blood loss. The blood pressure usually returns to its prepregnancy level and therefore is not a reliable early indicator of shock. Fever is indicative of dehydration (less than 100.4°F or 38°C) or infection (above 101°F), which may involve the genitourinary tract. Respiratory rate is usually between 16 and 24 breaths per minute and regular. Respirations should be unlabored unless there is an underlying preexisting respiratory condition.

Assess fundal height, position, and firmness every 15 minutes during the first hour following birth. The fundus needs to remain firm to prevent excessive postpartum bleeding. The fundus should be firm (feels like the size and consistency of a grapefruit), located in the midline and below the umbilicus. If it is not firm (boggy), gently massage it until it is firm (see Nursing Procedure 22.1 for more information). Once firmness is obtained, stop massaging.

TAKE NOTE!

If the fundus is displaced to the right of the midline, suspect a full bladder as the cause.

The vagina and perineal areas are quite stretched and edematous following a vaginal birth. Assess the perineum including the episiotomy if present for possible hematoma formation. Suspect a hematoma if the woman reports excruciating pain or cannot void or if a mass is noted in the perineal area. Also assess for hemorrhoids, which can cause discomfort.

Assess the woman's comfort level frequently to determine the need for analgesia. Ask the woman to rate her pain on a scale of 1 to 10; it should be less than 3. If it is higher, further evaluation is needed to make sure there aren't any deviations contributing to her discomfort.

Assess vaginal discharge (lochia) every 15 minutes for the first hour and every 30 minutes for the next hour. Palpate the fundus at the same time to ascertain its firmness and help estimate the amount of vaginal discharge. In addition, palpate the bladder for fullness, since many women receiving an epidural block experience limited sensation in the bladder region. Voiding should produce large amounts of urine (diuresis) each time. Palpating the woman's bladder after each voiding helps in assessing it and ensuring complete emptying. A full bladder will displace the uterus to either side of the midline and potentiate uterine hemorrhage secondary to bogginess.

Nursing Interventions

Nursing interventions during the fourth stage might include:

- Providing support and information to the woman regarding episiotomy repair and related pain relief and self-care measures
- Applying an ice pack to the perineum to promote comfort and reduce swelling
- Assisting with hygiene and perineal care; teaching the woman how to use the perineal bottle after each pad change and voiding; helping the woman into a new gown
- Monitoring for return of sensation and ability to void (if regional anesthesia was used)
- Encouraging the woman to void by ambulating to the bathroom, listening to running water, or pouring warm water over the perineal area with the peribottle
- Monitoring vital signs and fundal and lochia status every 15 minutes and documenting them
- Assessing for postpartum hemorrhage and urinary retention via uterine palpation
- Promoting comfort by offering analgesia for afterpains and warm blankets to reduce chilling
- Offering fluids and nourishment if desired
- Encouraging parent–infant attachment by providing privacy for the family
- Being knowledgeable about and sensitive to typical cultural practices after birth
- Assisting and encouraging the mother to nurse, if she chooses, during the recovery period to promote uterine firmness (the release of oxytocin from the posterior pituitary gland stimulates uterine contractions)
- Teaching the woman how to assess her fundus for firmness periodically and to massage it if it is boggy
- Describing the lochia flow and normal parameters to observe for postpartum
- Teaching safety techniques to prevent newborn abduction
- Demonstrating the use of the portable sitz bath as a comfort measure for her perineum if she had a laceration or an episiotomy repair

- Explaining comfort and hygiene measures and when to use them
- Assisting with ambulation when getting out of bed for the first time
- Providing information about the routine on the mother–baby unit or nursery during the stay
- Observing for signs of early parent–infant attachment: fingertip touch to palm touch to enfolding of the infant (Jordan et al., 2019; King et al., 2019)

The nurse's role in labor and birth is a privileged one, supporting women during one of their most vulnerable times—childbirth. The nurse's focus during this time should be on supporting, protecting, advocating for, and empowering women. The nurse should also provide informational support, which allows the woman to realize her aspirations and goals by making decisions through informed choice. Nurses make a long-term difference in the lives of childbearing women with small things they do for their clients that can make a big difference.

KEY CONCEPTS

- A nurse provides physical and emotional support during the labor and birth process to assist a woman in achieving her goals.
- When a woman is admitted to the labor and birth area, the admitting nurse must assess and evaluate the risk status of the pregnancy and initiate appropriate interventions to provide optimal care for the client.
- Completing an admission assessment includes taking a maternal health history; performing a physical assessment on the woman and fetus, including her emotional and psychosocial status; and obtaining the necessary laboratory studies.
- The nurse's role in fetal assessment for labor and birth includes determining fetal well-being and interpreting signs and symptoms of possible compromise. Determining the FHR pattern and assessing amniotic fluid characteristics are key.
- FHR can be assessed intermittently or continuously. Although the intermittent method allows the client to move around during labor, the information obtained intermittently does not provide a complete picture of fetal well-being from moment to moment.
- Assessment parameters of the FHR are classified as baseline rate, baseline variability, and periodic changes in the rate (accelerations and decelerations).
- The nurse monitoring the laboring client needs to be knowledgeable about which category the FHR pattern is in so that appropriate interventions can be instituted.
- For a category III FHR pattern, the nurse should notify the health care provider about the pattern and obtain further orders, making sure to document all interventions and their effects on the FHR pattern.
- In addition to interpreting assessment findings and initiating appropriate inventions for the laboring client, accurate and timely documentation must be carried out continuously.
- Today's women have many safe nonpharmacologic and pharmacologic choices for the management of pain during childbirth. They may be used individually or in combination to complement one another.
- Nursing management for the woman during labor and birth includes comfort measures, emotional support, information and

instruction, advocacy, and support for the partner.

- Nursing care during the first stage of labor includes taking an admission history (reviewing the prenatal record), checking the results of routine laboratory work and special tests done during pregnancy, asking the woman about her childbirth preparation (birth plan, classes taken, coping skills), and completing a physical assessment of the woman to establish baseline values for future comparison.
- Nursing care during the second stage of labor focuses on supporting the woman and her partner in making decisions about her care and labor management, implementing strategies to prolong the early passive phase of fetal descent, supporting involuntary bearing-down efforts, providing support and assistance, and encouraging the use of maternal positions that can enhance descent and reduce the pain.
- Nursing care during the third stage of labor primarily focuses on immediate newborn care and assessment and being available to assist with the delivery of the placenta and inspecting it for intactness.
- The focus of nursing management during the fourth stage of labor involves frequently observing the mother for hemorrhage, providing comfort measures, and promoting family attachment.

Unfolding Patient Stories: Fatime Sanago • Part 2

Recall Fatime Sanogo, the primiparous 23-year-old you met in Chapter 2. Fatime is now at 41 4/7 weeks' gestation and admitted to the hospital for induction of labor. What physical findings should be present before labor is induced? What nursing assessments are performed and what nursing interventions are implemented to safely manage induction of labor with an oxytocin infusion? What assessment data should be documented when artificial rupture of membranes is performed?

Care for Fatime and other patients in a realistic virtual environment: (**thepoint.lww.com/vSimMaternity**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

Unfolding Patient Stories: Carla Hernandez • Part 2

Recall Carla Hernandez from Chapter 4. She is at 39 5/7 weeks' gestation when her husband brings her to the hospital. How does the nurse determine that she is in active labor? If she is in active labor, how will the nurse monitor the progress of labor? What nursing assessments are done to identify the signs of potential complications during labor? What questions would the nurse ask Carla to identify symptoms of potential complications of labor? What nursing interventions can assist the couple's ability to cope with pain and stress experienced during labor?

Care for Carla and other patients in a realistic virtual environment: (**thepoint.lww.com/vSimMaternity**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. When a client in labor is fully dilated, which instruction would be most effective to assist her in encouraging effective pushing?
   a. Hold your breath and push through the entire contraction.
   b. Use chest breathing with the contraction.
   c. Pant and blow during each contraction.
   d. Wait until you feel the urge to push.

2. During the fourth stage of labor, the nurse assesses the woman at frequent intervals after giving childbirth. What assessment data would cause the nurse the most concern?
   a. Moderate amount of dark red lochia drainage on peripad
   b. Uterine fundus palpated to the right of the umbilicus
   c. An oral temperature reading of 100.6°F
   d. Perineal area bruised and edematous beneath her ice pack

3. When managing a client's pain during labor, nurses should
   a. make sure the agents given do not prolong labor.
   b. know that all pain relief measures are similar.
   c. support the client's decisions and requests.
   d. not recommend nonpharmacologic methods.

4. When caring for a client during the active phase of labor without continuous electronic fetal monitoring, the nurse

would intermittently assess FHR every

a. 15 to 30 minutes.
b. 5 to 10 minutes.
c. 45 to 60 minutes.
d. 60 to 75 minutes.

5. The nurse notes the presence of transient fetal accelerations on the fetal monitoring strip. Which intervention would be most appropriate?

a. Reposition the client on the left side.
b. Begin 100% oxygen via face mask.
c. Document this as indicating a normal pattern.
d. Call the health care provider immediately.

6. By the end of the second stage of labor, the nurse would expect which of the following events?

a. The cervix is fully dilated and effaced.
b. The placenta is detached and expelled.
c. The fetus is born and on mother's chest.
d. The woman may request pain medication.

7. Which practice would not be included in a physiologic birth?

a. Early induction of labor before 39 weeks' gestation
b. Freedom of movement for the laboring woman
c. Continuous presence and support throughout labor
d. Encouraging spontaneous pushing when urge is felt

CRITICAL THINKING EXERCISES

1. A 20-year-old primigravida at term comes to the birthing center in active labor (dilation 7 cm and 80% effaced, –1 station) with ruptured membranes. She states she wants an "all-natural" birth without medication. Her partner is with her and appears anxious but supportive. Upon the

admission assessment, this client's prenatal history is unremarkable; vital signs are within normal limits; FHR via Doppler ranges between 140 and 144 bpm and is regular.

   a. Based on your assessment data and the woman's request not to have medication, what nonpharmacologic interventions could you offer her?
   b. What positions might be suggested to facilitate fetal descent?

2. Several hours later, the client complains of nausea and turns to her partner and angrily tells him to not touch her and to go away.

   a. What assessment needs to be done to determine what is happening?
   b. What explanation can you offer the client's partner regarding the client's change in behavior?

STUDY ACTIVITIES

1. Share experiences within a postclinical conference group regarding the pain management interventions of the clients to which you were assigned. Compare and evaluate the effectiveness of different methods used, maternal behavior observed, and neonatal outcome in terms of Apgar scores.
2. On the fetal heart monitor, the nurse notices an elevation of the fetal baseline with the onset of contractions. This elevation would describe _____.
3. Compare and contrast a local birthing center to a community hospital's birthing suite in terms of the pain management techniques and fetal monitoring used.
4. Select a childbirth website for expectant parents and critique the information provided in terms of its educational level and amount of advertising.

BRINGING IT ALL TOGETHER: A CASE STUDY

A 30-year-old woman at term presents to the emergency room with abdominal pain. This is her first pregnancy and she is accompanied by her partner and her anxious sister. She is 40 weeks and 6 days' gestation based on her last ultrasound. All pregnancy blood tests have been normal. Earlier in the day, she had a mucus-like dark red discharge followed by the onset of irregular menstrual-like cramps. Two hours ago, she felt a gush of clear fluid from her vagina and since then she says she has felt miserable. She took two Tylenol at home for the pain, but she is now in distress and came to the hospital for assessment.

ASSESSMENT

Upon examination, she is comfortable between pains. Her blood pressure is 130/80 mm Hg and pulse is 100 bpm. Fetal movement is felt by the nurse. FHR is 142 bpm. Fundal height upon palpation is 37 cm and in a cephalic presentation. Speculum exam shows clear fluid pooled in the posterior vaginal fornix. A ferning pattern is present when fluid is placed on a glass slide. The vaginal exam reveals the cervix to be fully effaced and 4 cm dilated. The fetal head is 2 cm above the ischial spines. There is no fetal caput or molding felt during the vaginal exam.

Go to thePoint to find questions to consider about this case.

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Examine the systemic physiologic changes occurring in the woman after childbirth.
2. Integrate dimensions of postpartum care for the multicultural family.
3. Determine the psychological changes that occur in women in the postpartum period.
4. Plan postpartum nursing care with interventions to foster maternal–infant bonding.
5. Assess the phases of maternal role adjustment and accompanying behaviors.
6. Analyze the psychological adaptations occurring in the mother's partner after childbirth.

Betsy had been home 3 days when she called the obstetrics unit where she had given birth and asked to speak to the lactation consultant. She reported pain in both breasts. Her nipples were tender due to frequent breastfeeding, and she described her breasts as heavy, hard, and swollen.

INTRODUCTION

The postpartum period is a critical transitional time for a woman, her newborn, and her family on physiologic and psychological levels. The **puerperium** period begins after the delivery of the placenta and lasts approximately 6 weeks. It is frequently called the "fourth trimester." During this period, the woman's body begins to return to its prepregnant state, and these changes generally resolve by the 6th week after giving birth. However, the postpartum period can also be defined to include the changes in all aspects of the mother's life that occur during the first year after a child is born. Some believe that the postpartum adjustment period lasts well into the first year, making the fourth trimester the longest. Keeping this in mind, the true postpartum period may last between 9 and 12 months as the mother's body returns to its prepregnant state, adjusts as she psychologically to the changes in her life, and as she takes on the new role of mother.

Nurses caring for childbearing families should consider all aspects of culture, including communication, space, and family roles. Beliefs, traditions, values, and culture are all reflected in practices transferred from one society to another. Communication encompasses an understanding of not only a person's language and loudness of speech, but also the meaning of touch and gestures. The concept of personal space and the dimensions of comfort zones differ from culture to culture. Touching, placing clients in proximity to others, and taking away personal possessions can reduce a client's personal security and heighten her anxiety. Nurses must be sensitive to how people respond when being touched and should refrain from touching if the client's response indicates it is unwelcome. Cultural norms also have an impact on family roles, expectations, and behaviors associated with a member's position in the family. For example, culture may influence whether a male partner actively participates in the woman's pregnancy and childbirth. Maternity health care professionals in the United States expect partners to be involved, but this role expectation may conflict with that of many of the diverse groups now living in the United States. Some groups of

Mexican Americans, Arab Americans, Asian Americans, and Orthodox Jewish Americans, for example, may view the birthing experience as a woman's affair (Andrews & Boyle, 2019).

Our major role as nurses is to provide safe and evidence-based care to promote optimal birth outcomes for all women, regardless of their backgrounds. Nurses need to remember that there is more than one way to provide this care. Traditional postpartum practices are still dominant in many cultural groups. Nurses must educate women and provide strategies to help them integrate their beliefs into contemporary practices. Nurses are important cultural brokers as they welcome women and their families into obstetrical units, where nurses share with those families one of the most intimate experiences of their lives (Ozturk et al., 2019).

This chapter describes the major physiologic and psychological changes that occur in a woman after childbirth. Various systemic adaptations take place throughout the woman's body. In addition, the mother and the family adjust to the new addition psychologically. The birth of a child changes the family structure and the roles of the family members. The adaptations are dynamic and continue to evolve as physical changes occur and new roles emerge.

MATERNAL PHYSIOLOGIC ADAPTATIONS

During pregnancy, the woman's entire body changes to accommodate the needs of the growing fetus. After birth, the woman's body once again undergoes significant changes as all body systems return to the prepregnant state.

Reproductive System Adaptations

The reproductive system goes through tremendous adaptations to return to the prepregnancy state. All organs and tissues of the reproductive system are involved. The female reproductive system is unique in its capacity to remodel itself throughout the woman's reproductive life. The events after birth, with the shedding of the

placenta and subsequent uterine involution, involve substantial tissue destruction and subsequent repair and remodeling. For example, the woman's menstrual cycle, interrupted during pregnancy, will begin to return several weeks after childbirth if the woman is not breastfeeding. Ovulation can return any time, so breastfeeding should not be considered a safe contraceptive and other methods should be used to prevent pregnancy. The uterus, which has undergone tremendous expansion during pregnancy to accommodate progressive fetal growth, will return to its prepregnant size over several weeks. The mother's breasts have grown to prepare for lactation and do not return to their prepregnant size as the uterus does.

Uterine Involution

The uterus returns to its normal size through a gradual process of **involution**, which involves retrogressive changes that return it to its nonpregnant size and condition. Involution involves three retrogressive processes:

1. Contraction of muscle fibers to reduce those previously stretched during pregnancy
2. Catabolism, which shrinks enlarged individual myometrial cells
3. Regeneration of uterine epithelium from the lower layer of the decidua after the upper layers have been sloughed off and shed during lochial discharge (Jordan et al., 2019)

The uterus, which weighs approximately 1,000 g (2.2 lb) soon after birth, undergoes physiologic involution as it returns to its nonpregnant state. Approximately 1 week after birth, the uterus shrinks in size by 50% and weighs about 500 g (1 lb); at the end of 6 weeks, it weighs approximately 60 g (2 oz), about the weight it was before the pregnancy (Jordan et al., 2019) (Fig. 15.1). During the first 12 hours postpartum, the fundus of the uterus is located at the level of the umbilicus. Over the first few days after birth, the uterus typically descends from the level of the umbilicus at a rate of 1 cm (one fingerbreadth) per day. By 3 days, the fundus lies two to three fingerbreadths below the umbilicus (or slightly higher in multiparous

women). By the end of 10 days, the fundus usually cannot be palpated because it has descended into the true pelvis.

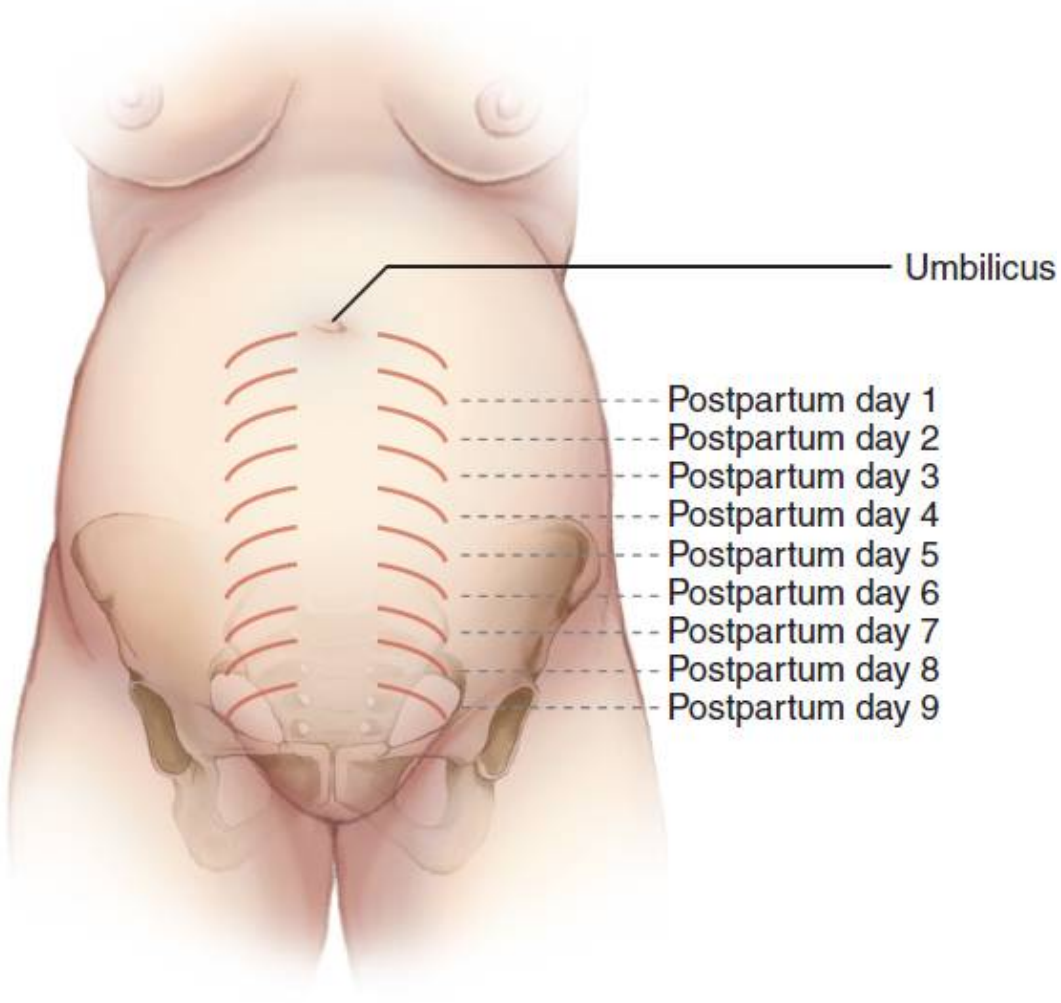

FIGURE 15.1. Uterine involution.

If these retrogressive changes do not occur as a result of retained placental fragments or infection, then subinvolution of the uterus typically results (delayed or absent involution). Subinvolution is generally responsive to early diagnosis and treatment. Factors that facilitate uterine involution include complete expulsion of amniotic membranes and placenta at birth, a complication-free labor and birth process, breastfeeding, and early ambulation. Factors that inhibit involution include a prolonged labor and difficult birth, incomplete

expulsion of amniotic membranes and placenta, uterine infection, overdistention of uterine muscles (such as by multiple gestation, hydramnios, or a large singleton fetus), a full bladder (which displaces the uterus and interferes with contractions), anesthesia (which relaxes uterine muscles), and close childbirth spacing (frequent and repeated distention decreases tone and causes muscular relaxation).

LOCHIA

The process of involution and restoration of the endometrium is reflected in the characteristics of the lochia. **Lochia** is the vaginal discharge that occurs after birth and continues for approximately 4 to 8 weeks. It results from involution, during which the superficial layer of the decidua basalis becomes necrotic and is sloughed off. Immediately after childbirth, lochia is bright red and consists mainly of blood, fibrinous products, decidual cells, and red and white blood cells. The lochia from the uterus is alkaline but becomes acidic as it passes through the vagina. Patterns of lochia flow vary in amount and duration among women and pregnancies. Each day, the amount of bleeding should be less and the color lighter. The color changes result from the changing composition of the tissue that is sloughed and expelled during the endometrial restoration process (Berens, 2020).

Women who have had cesarean births tend to have less flow because the uterine debris is removed manually along with delivery of the placenta by the physician. Lochia is present after a surgical birth with most women experiencing it up to 6 weeks.

Lochia passes through three stages:

- *Lochia rubra* is a deep-red mixture of mucus, tissue debris, and blood that occurs for the first 3 to 4 days after birth. As uterine bleeding subsides, it becomes paler and more serous.
- *Lochia serosa* is the second stage. It is pinkish brown and is expelled 3 to 10 days postpartum. Lochia serosa primarily contains leukocytes, decidual tissue, red blood cells, and serous fluid.

- *Lochia alba* is the final stage. The discharge is creamy white or light brown and consists of leukocytes, decidual tissue, and reduced fluid content. It occurs from days 10 to 14 but can last 3 to 6 weeks postpartum in some women and still be considered normal.

Lochia at any stage should have a fleshy smell; an offensive odor usually indicates an infection, such as endometritis.

TAKE NOTE!

A danger sign is the reappearance of bright-red blood after lochia rubra has stopped. Reevaluation by a health care provider is essential if this occurs.

AFTERPAINS

Part of the involution process involves uterine contractions. Immediately after birth and delivery of the placenta, the uterus begins to contract constricting the intramyometrial vessels and impeding blood flow; this is the primary mechanism preventing hemorrhage from the placental site. Inadequate myometrial contractions will result in atony which will result in an early postpartum hemorrhage (Berens, 2020). These painful uterine contractions are often called *afterpains*. All women experience afterpains, but they are more acute in multiparous and breastfeeding women secondary to repeated stretching of the uterine muscles from multiple pregnancies or stimulation during breastfeeding with oxytocin released from the pituitary gland. Primiparous women typically experience mild afterpains because the uterus is able to maintain a contracted state. Breastfeeding and administration of exogenous oxytocin both cause powerful and painful uterine contractions. Afterpains usually respond to oral analgesics.

TAKE NOTE!

Afterpains are usually stronger during breastfeeding because oxytocin released by the sucking reflex strengthens the contractions. Mild analgesics can reduce this discomfort.

Cervix

Immediately after a vaginal birth, the cervix extends into the vagina and remains partly dilated, bruised, and edematous. The cervix typically returns to its prepregnant state by week 6 of the postpartum period. The cervix gradually closes but never regains its prepregnant appearance. Immediately after childbirth, the cervix is shapeless and edematous and is easily distensible for several days. The internal cervical os gradually closes and returns to normal by 2 weeks, while the external os widens and never appears the same after childbirth. The external cervical os is no longer shaped like a circle, but instead appears as a jagged slit-like opening, often described as looking like a fish mouth (Fig. 15.2).

Vagina

Shortly after birth, the vaginal mucosa is edematous, relaxed, and thin with few rugae. As ovarian function returns and estrogen production resumes, the mucosa thickens and rugae return in approximately 3 weeks. The vagina gapes at the opening and is generally lax. It returns to its approximate prepregnant size by 6 to 8 weeks postpartum but will always remain a bit larger than it had been before pregnancy.

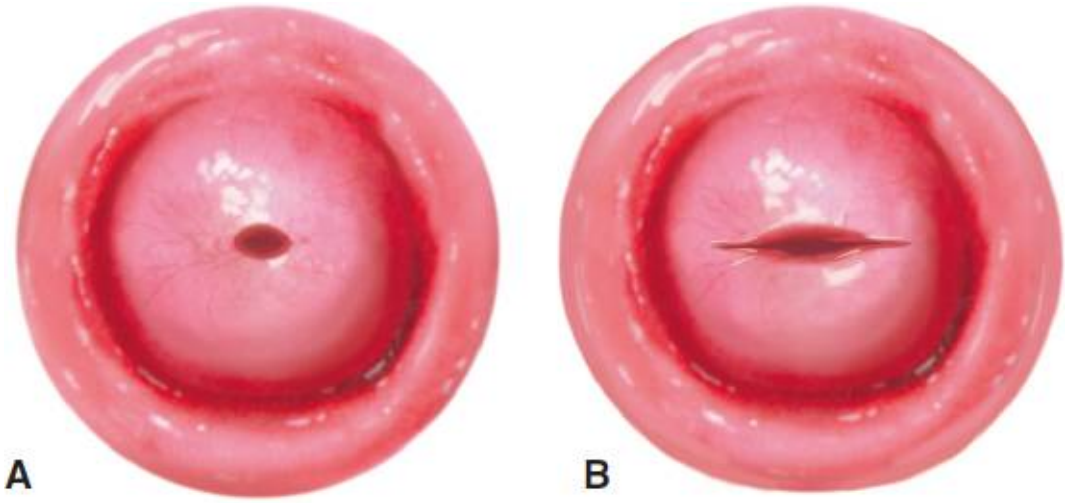

FIGURE 15.2. Appearance of the cervical os. **A.** Before the first pregnancy. **B.** After pregnancy.

Normal mucus production and thickening of the vaginal mucosa usually return with ovulation. The vagina gradually decreases in size and regains tone over several weeks. By 3 to 4 weeks, the edema and vascularity have decreased. The vaginal epithelium is generally restored by 6 to 8 weeks postpartum (Blackburn, 2018). Localized dryness and coital discomfort (dyspareunia) plague many women until menstruation returns. Water-soluble lubricants can reduce discomfort during intercourse.

Perineum

The perineum stretches during childbirth to allow passage of the newborn, but the majority of women sustain some degree of perineal trauma during childbirth, which can be painful postpartum. The perineum is often edematous and bruised for the first day or two after birth. If the birth involved an episiotomy or laceration, complete healing may take as long as 4 to 6 months in the absence of complications at the site, such as hematoma or infection. The muscle tone may or may not return to normal, depending on the extent of injury to muscle, nerve, and connecting tissues (Begley et al., 2019). Perineal lacerations may extend into the anus and cause considerable discomfort for the mother when she is attempting to

defecate or ambulate. The presence of swollen hemorrhoids may also heighten discomfort. Local comfort measures such as ice packs, pouring warm water over the area via a peribottle, witch hazel pads, anesthetic sprays, and sitz baths can relieve pain.

Supportive tissues of the pelvic floor are stretched during the childbirth process, and restoring their tone may take up to 6 months. Pelvic relaxation can occur in any woman experiencing a vaginal birth. Pelvic floor dysfunction is one of the most common complications of childbirth following a vaginal birth, and it can have a significant impact on the woman's quality of life as she ages. Nurses should encourage all women to practice pelvic floor muscle training exercises (PFMT) to improve pelvic floor tone, strengthen the perineal muscles, and promote healing. See Evidence-Based Practice 15.1

TAKE NOTE!

Failure to maintain and restore perineal muscular tone can lead to urinary incontinence later in life for many women.

Cardiovascular System Adaptations

Childbirth alters maternal hemodynamics and can lead to cardiovascular instability during the immediate postpartum period. The cardiovascular system undergoes dramatic changes after birth. During pregnancy, the heart is displaced slightly upward and to the left. This reverses as the uterus undergoes involution. Cardiac output remains high for the first few days postpartum and then gradually declines to nonpregnant values within 3 months of birth.

EVIDENCE-BASED PRACTICE 15.1 Effects of Electromyographic (EMG) Biofeedback-Guided Pelvic Floor Muscle Training on Postpartum Stress Incontinence

STUDY

Postpartum stress urinary incontinence refers to an acute increase in intraperitoneal pressure, causing unconscious urination due to the loss of contraction of the detrusor muscle. Damaged muscles and nerves of the pelvic floor during childbirth may result in the loss of control over the bladder. Subsequently, any increase in intraperitoneal pressure causes leakage of urine. Postpartum urinary incontinence is a common condition that worsens with age. The purpose of this study was to explore the efficacy of electromyographic (EMG) feedback-guided pelvic floor muscle training on postpartum stress urinary incontinence verses regular Kegel exercises.

Findings

One hundred women with postpartum urinary incontinence were chosen and divided equally into two groups; one received EMG and the other group underwent regular Kegel exercises. Follow-ups occurred at 1 and 6 months. Both groups went through training of the specific techniques to be used. The EMG group had a probe inserted into the vagina and an electric shock was administered to induce contractions of the pelvic floor muscles, thus building strength in the muscle fibers. Following treatment, it was determined that when compared to the Kegel-only group, the EMG group had enhanced contractions of pelvic floor muscles with significant improvement in symptoms of urinary incontinence.

Nursing Implications

The accumulation of evidence based on this and other studies showed that the pelvic floor muscle rehabilitation apparatus works better for treatment of postpartum urinary incontinence than the simple application of Kegel exercises. Nurses can address this potential condition with their postpartum women to encourage use of this method to improve symptoms of urinary incontinence and quality of life as they age.

Adapted from Liu, Z., & Sun, Z. (2019). Effects of electromyographic (EMG) biofeedback-guided pelvic floor muscle training on postpartum stress urinary incontinence. International Journal of Clinical and Experimental Medicine, 12(4), 3743–3749.

Blood volume, which increases substantially during pregnancy, drops rapidly after birth and returns to normal within 4 weeks postpartum. The decrease in both cardiac output and blood volume reflects the birth-related blood loss (an average of 500 mL with a vaginal birth and 1,000 mL with a cesarean birth). The cardiac output deceases to prelabor values 24 to 72 hours postpartum, rapidly falls over the next 2 weeks and usually returns to nonpregnant levels within 6 to 8 weeks postpartum. Blood plasma volume is further reduced through diuresis, which occurs between days 2 and 5 (Blackburn, 2018). Despite the decrease in blood volume, the hematocrit level remains relatively stable and may even increase, reflecting the predominant loss of plasma. Thus, an acute decrease in hematocrit is not an expected finding and may indicate hemorrhage.

Concept Mastery Alert

Prioritizing Postpartum Vital Signs

It is not uncommon for women to have a temperature elevation up to 100.4°F in the first 24 hours postpartum due to mild dehydration. There may also be a slight decrease in blood pressure. The nurse should be most concerned about a blood pressure elevation because preeclampsia may occur during the early postpartum period.

Pulse and Blood Pressure

The increase in cardiac output and stroke volume during pregnancy begins to diminish after birth once the placenta has been delivered. This decrease in cardiac output is reflected in bradycardia (40 to 60 bpm) for up to the first 2 weeks postpartum. This slowing of the heart rate is related to the increased blood that flows back to the heart and to central circulation after it is no longer perfusing the placenta. This increase in central circulation brings about an increased stroke volume and allows a slower heart rate to provide ample maternal circulation. Gradually, cardiac output returns to prepregnant levels by 3 months after childbirth (Cunningham et al., 2019).

Tachycardia (heart rate above 100 bpm) in the postpartum woman warrants further investigation. It may indicate hypovolemia, dehydration, or hemorrhage. However, because of the increased blood volume during pregnancy, a considerable loss of blood may be well tolerated and not cause a compensatory cardiovascular response such as tachycardia. In most instances of postpartum hemorrhage, blood pressure and cardiac output remain increased because of the compensatory increase in heart rate. Thus, a decrease in blood pressure and cardiac output are not expected changes during the postpartum period. Early identification is essential to ensure prompt intervention.

Blood pressure falls mostly in the first 2 days, then increases 3 to 7 days after childbirth, and returns to prepregnancy levels by 6 weeks (Jordan et al., 2019). A significant increase accompanied by headache might indicate preeclampsia and requires further investigation. Decreased blood pressure may suggest an infection or a uterine hemorrhage.

Coagulation

Normal physiologic changes of pregnancy, including alterations in hemostasis that favor coagulation, reduced fibrinolysis, and pooling and stasis of blood in the lower limbs, place women at risk for blood clots. These changes, which usually return to prepregnant levels after 3 weeks postpartum, are important for minimizing blood loss at

childbirth. Smoking, obesity, immobility, and postpartum factors such as infection, bleeding, and emergency surgery (including emergency cesarean section) also increase the risk of coagulation disorders (Resnik et al., 2019).

Clotting factors that increased during pregnancy tend to remain elevated during the early postpartum period. Giving birth stimulates this hypercoagulability state further. As a result, these coagulation factors remain elevated for 2 to 3 weeks postpartum (King et al., 2019). This hypercoagulable state, combined with vessel damage during birth and immobility, places the woman at risk for thromboembolism (blood clots) in the lower extremities and the lungs.

Blood Cellular Components

Red blood cell production ceases early in the puerperium, causing mean hemoglobin and hematocrit levels to decrease slightly in the first 24 hours. During the next 2 weeks, both levels rise slowly. The white blood count, which increases in labor, remains elevated for first 4 to 6 days after birth but then falls to 6,000 to 10,000/mm^3. This white blood cell elevation can complicate a diagnosis of infection in the immediate postpartum period.

Urinary System Adaptations

Pregnancy and birth can have profound effects on the urinary system. During pregnancy, the glomerular filtration rate and renal plasma flow increase significantly. Both usually return to normal by 6 weeks after birth. There is a gradual return of bladder tone and normal size and function of the bladder, ureters, and renal pelvis, all of which were dilated during pregnancy.

Many women have difficulty feeling the sensation to void after giving birth if they received an anesthetic block during labor (which inhibits neural functioning of the bladder) or if they received oxytocin to induce or augment labor (antidiuretic effect). These women will be

at risk for incomplete emptying, bladder distention, difficulty voiding, and urinary retention. In addition, urination may be impeded by:

- perineal lacerations.
- generalized swelling and bruising of the perineum and tissues surrounding the urinary meatus.
- hematomas.
- decreased bladder tone as a result of regional anesthesia.
- diminished sensation of bladder pressure as a result of swelling, poor bladder tone, and numbing effects of regional anesthesia used during labor (Kellerman & Rakel, 2019).

Difficulty voiding can lead to urinary retention, bladder distention, and ultimately urinary tract infection. Urinary retention and bladder distention can cause displacement of the uterus from the midline to the right and can inhibit the uterus from contracting properly, which increases the risk of postpartum hemorrhage. Urinary retention is a major cause of **uterine atony**, which allows excessive bleeding. Frequent voiding of small amounts (less than 150 mL) suggests urinary retention with overflow, and catheterization may be necessary to empty the bladder to restore tone.

Postpartum diuresis occurs as a result of several mechanisms: the large amounts of intravenous fluids given during labor; a decreasing antidiuretic effect of oxytocin as its level declines; the buildup and retention of extra fluids during pregnancy; and a decreasing production of aldosterone, the hormone that decreases sodium retention and increases urine production (Berens, 2020). All of these factors contribute to rapid filling of the bladder within 12 hours of birth. Diuresis begins within 12 hours after childbirth and continues throughout the first week postpartum. Normal function returns within a month after birth (Cunningham et al., 2018).

CONSIDER THIS

Have you ever felt like a real idiot by not being able to complete a simple task in life? I had a beautiful baby boy after only 6 hours of labor. My epidural worked well and I actually felt very little discomfort throughout my labor. Because it was in the middle of the night when they brought me to my postpartum room, I felt a few hours of sleep would be all I needed to be back to normal. During an assessment early the next morning, the nurse found my uterus had shifted to the right from my midline, and I was instructed to empty my bladder. I didn't understand why the nurse was concerned about where my uterus was located, and besides, I didn't feel any sensation of a full bladder. But I did get up anyway and tried to comply. Despite all the nurse's tricks of running the faucet for sound effects, in addition to having warm water poured over my thighs via the peribottle, I was unable to urinate. How could I not accomplish one of life's simplest tasks?

Thoughts: Women who receive regional anesthesia frequently experience reduced sensation to their perineal area and do not feel a full bladder. The nursing assessment revealed a displaced uterus secondary to a full bladder. What additional "tricks" can be used to assist this woman in voiding? What explanation should be offered to her regarding why she is having difficulty urinating?

Gastrointestinal System Adaptations

The gastrointestinal system quickly returns to normal after birth because the gravid uterus is no longer filling the abdominal cavity and producing pressure on the abdominal organs. Progesterone levels, which caused relaxation of smooth muscle during pregnancy and diminished bowel tone, are also declining.

Regardless of the type of delivery, most women experience decreased bowel tone and sluggish bowels for several days after birth. Decreased peristalsis occurs in response to analgesics, surgery, diminished intra-abdominal pressure, a low-fiber diet, insufficient fluid intake, and diminished muscle tone. In addition,

women with episiotomies, perineal lacerations, or hemorrhoids may fear pain or damage to the perineum with the first bowel movement and may attempt to delay it. Subsequently, constipation is a common problem during the postpartum period. A stool softener can be prescribed for this reason.

Most women are hungry and thirsty after childbirth, commonly related to nothing-by-mouth (NPO) restrictions and the energy expended during labor. Their appetite returns to normal immediately after giving birth.

TAKE NOTE!

Anticipate the woman's need to replenish her body with food and fluids, and provide both soon after she gives birth.

Musculoskeletal System Adaptations

The effects of pregnancy on the muscles and joints vary widely. Musculoskeletal changes associated with pregnancy, such as increased ligament laxity, weight gain, change in the center of gravity, and carpal tunnel syndrome, revert back during the postpartum period. During pregnancy, the hormones relaxin, estrogen, and progesterone relax the joints. After birth, levels of these hormones decline, resulting in a return of all joints to their prepregnant state, with the exception of the woman's feet. Parous women may note a permanent increase in shoe size (Jordan et al., 2019).

Women commonly experience fatigue and activity intolerance and have a distorted body image for weeks after birth secondary to declining relaxin and progesterone levels, which cause hip and joint pain that interferes with ambulation and exercise. Good body mechanics and correct positioning are important during this time to prevent low back pain and injury to the joints. Within 6 to 8 weeks after delivery, joints are completely stabilized and return to normal.

During pregnancy, stretching of the abdominal wall muscles occurs to accommodate the enlarging uterus. This stretching leads to a loss in muscle tone and possibly separation of the longitudinal muscles (rectus abdominis muscles) of the abdomen. Separation of the rectus abdominis muscles, called diastasis recti, is more common in women who have poor abdominal muscle tone before pregnancy. After birth, muscle tone is diminished and the abdominal muscles are soft and flabby. Specific exercises are necessary to help the woman regain muscle tone. Fortunately, diastasis responds well to exercise, and abdominal muscle tone can be improved. (See Chapter 16 for more information about exercises to improve muscle tone.)

TAKE NOTE!

If rectus muscle tone is not regained through exercise, support may not be adequate during future pregnancies.

Integumentary System Adaptations

Another system that experiences lasting effects of pregnancy is the integumentary system. As estrogen and progesterone levels decrease, the darkened pigmentation on the abdomen (linea nigra), face (melasma), and nipples gradually fades. Some women experience hair loss during pregnancy and the postpartum periods. Approximately 90% of hairs are growing at any one time, with the other 10% entering a resting phase. Because of the high estrogen levels present during pregnancy, an increased number of hairs go into the resting phase, which is part of the normal hair loss cycle. The most common period for hair loss is within 3 months after birth, when estrogen returns to normal levels and more hairs are allowed to fall out. This hair loss is temporary, and regrowth generally returns to normal levels in 4 to 6 months in two thirds of women and by 15 months in the remainder, though hair may be less abundant than before pregnancy (King et al., 2019).

Striae gravidarum (stretch marks) that developed during pregnancy on the breasts, abdomen, and hips gradually fade to silvery lines. However, these lines do not disappear completely. Although many products on the market claim to make stretch marks disappear, their effectiveness is highly questionable.

The profuse diaphoresis (sweating) that is common during the early postpartum period is one of the most noticeable adaptations in the integumentary system. Many women will wake up drenched with perspiration during the puerperium. This postpartum diaphoresis is a mechanism to reduce the amount of fluids retained during pregnancy and restore prepregnant body fluid levels. It can be profuse at times. It is common, especially at night during the first week after birth. Reassure the client that this is normal and encourage her to change her night clothes to prevent chilling.

Respiratory System Adaptations

Respirations usually remain within the normal adult range of 16 to 24 breaths per minute. As the abdominal organs resume their nonpregnant positions, the diaphragm returns to its usual position. Anatomic changes in the thoracic cavity and rib cage caused by increasing uterine growth resolve quickly. As a result, discomforts such as shortness of breath and rib aches are relieved. Tidal volume, minute volume, vital capacity, and functional residual capacity return to prepregnant values, typically within 1 to 3 weeks of birth (Kellerman & Rakel, 2019).

Endocrine System Adaptations

With the delivery of the placenta, there is rapid clearance of placenta hormones. The endocrine system rapidly undergoes several changes after birth. Levels of circulating estrogen and progesterone drop quickly with delivery of the placenta. Decreased estrogen levels are associated with breast engorgement and with the diuresis of excess extracellular fluid accumulated during pregnancy (Blackburn, 2018). Estrogen is at its lowest level a week after birth. For the

woman who is not breastfeeding, estrogen levels begin to increase by 2 weeks after birth. For the breastfeeding woman, estrogen levels remain low until breastfeeding frequency decreases.

Other placental hormones (human chorionic gonadotropin [hCG], human placental lactogen [hPL], progesterone) decline rapidly after birth. The hCG levels are nonexistent at the end of the first postpartum week, and hPL is undetectable within 1 day after birth (Cunningham et al., 2018). Progesterone levels are undetectable by 3 days after childbirth, and production is reestablished with the first menses. Prolactin is a hormone secreted by the anterior pituitary gland involved with lactation and reproduction. Prolactin levels decline within 2 weeks for the woman who is not breastfeeding, but remain elevated for the lactating woman (Webster et al., 2018).

Weight Loss after Childbirth

For all women of reproductive age, excessive weight gain and postpartum weight retention can increase the risk of obesity. Breastfeeding has been shown to have many health benefits for both mother and infant; however, evidence of its effectiveness in postpartum weight loss is mixed. Lactation is usually not sufficient for mothers to return to the prepregnant weight. More research studies are needed to reliably assess the impact of breastfeeding on postpartum weight management (Pattison et al., 2019).

The rate and amount of weight loss in the postpartum period seem to be determined by the same factors that determine weight loss at any point in a woman's life, including existing weight, body mass index (BMI), diet, age, and activity level (Ramos et al., 2019). Thus, there is benefit from overall lifestyle interventions on weight loss in postpartum women which include exercise plus dietary changes to achieve any weight reduction goals. See Evidence-Based Practice 15.2.

EVIDENCE-BASED PRACTICE 15.2

Excessive Gestational Weight Retention and Weight Gain in Postpartum: Perception of Women

STUDY

Women experience significant weight gain during pregnancy and need to lose it after childbirth. Postpartum weight retention contributes to the development of obesity in midlife and postmenopausal periods. Overweight and obesity comprise a global public health problem and a major risk factor for diabetes, dyslipidemia, hypertension, and cardiovascular disease. Breastfeeding is a known intervention to assist in weight loss during the postpartum period. Regular physical exercise is another intervention to help with weight loss. This study included 200 women with a BMI greater than 25 kg/m^2. The semistructured interview was validated by maternal and child experts with a content validation index of 0.88.

Findings

The major findings were related to barriers to physical activity, including pain, tiredness, lack of sleep, and high demands of the infant. Most women felt overwhelmed and exhausted, and many ate to reduce stress. Several women were ignorant about weight maintenance and lacked nutritional knowledge. One of the significant results was the misconception that breastfeeding automatically leads to weight loss, so it didn't matter how much food the women consumed during the postpartum period as long as they kept breastfeeding.

Nursing Implications

The findings of this study highlighted that women in the postpartum period perceived low physical activity, sedentary lifestyle behavior, lack of knowledge, breastfeeding misconceptions, high caloric intake, and lack of support as reasons contributing to excessive gestational weight retention. The postpartum period is a challenging and stressful time for women, and many feel overwhelmed and exhausted due to sleep deprivation, hormonal changes, high demands of the infant, lack of time, and adaptation to the new mothering role. Postpartum weight retention has important public health implications as it has a significant impact on long-term obesity and future health risks. Nurses should identify women who retain weight and provide instruction of healthy lifestyle activities that would assist in weight loss. Women look to nurses for direction about their health, eating, and appropriate weight ranges.

Adapted from Ganapathy, T. (2019). Excessive weight retention and weight gain in postpartum: Perception of women. Indian Journal of Health Sciences and Biomedical Research, 12(1), 28–34. https://doi.org/10.4103/kleuhsj.kleuhsj_150_18

Sexual Health

Childbirth is an important period in a woman's life. Postpartum adaptations affect her physical well-being, mood, relationship, and sexual health. Hormones, physical and psychological changes, parenting roles, infant care, breastfeeding, insomnia, fatigue, customs, beliefs, and traditions are all factors that influence sexual functioning in the postpartum period. The sexual problems women face during this period typically relate to sexual drive, arousal, orgasmic disorders, and uncomfortable intercourse (Sahin & Erenel, 2019). Based on research findings, women consider their health care staff as the most influential concerning when they can and should resume sexual activity after childbirth (DeMaria et al., 2019). Thus, nurses need to provide women with opportunities to express, identify and resolve their sexual problems, contributing to enhancing health

and quality of life. Nurses can provide anticipatory guidance and counseling to women and their partners about sexual problems during the postpartum period as well as their causes and possible solutions.

Global Health of Childbearing Women

Globalization has changed our society in numerous ways, but the health of women is remaining stagnant or growing worse in many parts of the world. The increase in global health awareness for improving health and affecting social change is key in the global health landscape today. Many women in developing counties are denied the fundamental right to enjoy a complete state of health as defined by the World Health Organization (O'Connor et al., 2019). The issues of disrespect and abuse during and after childbirth and the need for respectful maternity care are key elements that need to be addressed to improve outcomes. More than half a million women die each year from complications during and after childbirth (bleeding and infections), the vast majority of them in Africa and Asia. Nurses can play a role in raising awareness of this issue, which is often the first step in change (Polan & Taylor, 2019).

Women throughout the world continue to face enormous obstacles in attempting to access obstetric care. Skilled attendance at childbirth is critical for decreasing maternal and neonatal mortality, yet many women in developing countries give birth outside health facilities, without skilled help. Nurses throughout the world can help advocate for cost-effective, evidence-based interventions to prevent and battle complications from childbirth to save women's lives. The challenge is to guarantee that every pregnant woman who needs care gets it. Nurses can make a difference outside their own countries' borders by advocating for all women globally through their governmental political systems and encouraging those governments to offer help and save lives.

Lactation

Lactation is the secretion of milk by the breasts. It is thought to be brought about by the interaction of progesterone, estrogen, prolactin, and oxytocin. Breast milk typically appears within 4 to 5 days after childbirth.

Think back to Betsy, the woman experiencing painful changes in her breasts. What might Betsy be describing? Why has the condition of her breasts changed compared with when she was in the hospital?

Breastfeeding

Breastfeeding is a dynamic process, which requires coupling between periodic motions of the infant's jaws, undulation of the tongue, and breast milk ejection reflex. All mechanisms must be coordinated to be successful. All major health organizations recommend breastfeeding. The American Academy of Pediatrics (AAP) recommends exclusive breastfeeding for 6 months followed by the introduction of appropriate complementary foods and continued breastfeeding to 1 year and beyond (AAP, 2019). This recommendation is considered to be the standard of care today. Nurses have an important role in promoting, supporting, and protecting breastfeeding. They must have the necessary knowledge and skills to provide breastfeeding education to all mothers. Proper positioning, latching-on, sucking, and swallowing are the foundation for successful breastfeeding. Although breastfeeding is recommended by international and national organizations, the nurse must respect and support all mothers in either of the infant feeding methods chosen.

During pregnancy, the breasts increase in size and functional ability in preparation for breastfeeding. Estrogen stimulates growth of the milk collection (ductal) system, while progesterone stimulates growth of the milk production system. Within the first month of gestation, the ducts of the mammary glands grow branches, forming more lobules and alveoli. These structural changes make the breasts larger, more tender, and heavy. Each breast gains nearly 1 lb in weight by term, the glandular cells fill with secretions, blood vessels

increase in number, and the amounts of connective tissue and fat cells increase (Jordan et al., 2019).

Prolactin from the anterior pituitary gland, secreted in increasing levels throughout pregnancy, triggers the synthesis and secretion of milk after the woman gives birth. During pregnancy, prolactin, estrogen, and progesterone cause synthesis and secretion of *colostrum*, which contains protein and carbohydrate but no milk fat. It is only after birth takes place, when the high levels of estrogen and progesterone are abruptly withdrawn, that prolactin is able to stimulate the glandular cells to secrete milk instead of colostrum. This takes place within 4 to 5 days after giving birth.

Oxytocin acts so that milk can be ejected from the alveoli to the nipple. Therefore, sucking by the newborn will release milk. A decrease in the quality of stimulation causes a decrease in prolactin surges and thus a decrease in milk production. Prolactin levels increase in response to nipple stimulation during feedings. Prolactin and oxytocin result in milk production if stimulated by sucking (Blackburn, 2018) (Fig. 15.3). If the stimulus (sucking) is not present, as with a woman who is not breastfeeding, breast engorgement and milk production will subside within days postpartum.

Skin-to-skin contact during the first hour following birth is the gold standard to initiate breastfeeding if the mother decides this is the method of feeding for her newborn. A newborn's instinct is to seek nourishment after birth. A newborn moves on their mother's abdomen up to her breast instinctively. Researchers term this movement the *breast crawl* that helps initiate breastfeeding immediately after childbirth. This instinct occurs when a newborn, left undisturbed and skin-to-skin on the mother's trunk following birth, moves toward the mother's breast for the purpose of locating and self-attaching for the first feeding. From there, the newborn uses leg and arm movements to propel toward the breast. Upon reaching the sternum, the newborn will bounce the head up and down and side to side. As the newborn approaches the nipple, the mouth opens and after several attempts, latch-on and suckling take place. Newborns have senses and skills that enable early initiation of feeding at the breast. Nurses can help facilitate the breast crawl as a continuation

of the birthing process. Nurses have a responsibility to promote the health of their childbearing families and provide evidence-based care. Encouraging use of the breast crawl can be the first step in health promotion for every newborn. Additionally, it achieves the same benefits if carried out by fathers (Huang et al., 2019).

Breast milk production can be summarized as follows:

- Prolactin levels increase at term with a decrease in estrogen and progesterone levels.
- Estrogen and progesterone levels decrease after the placenta is delivered.

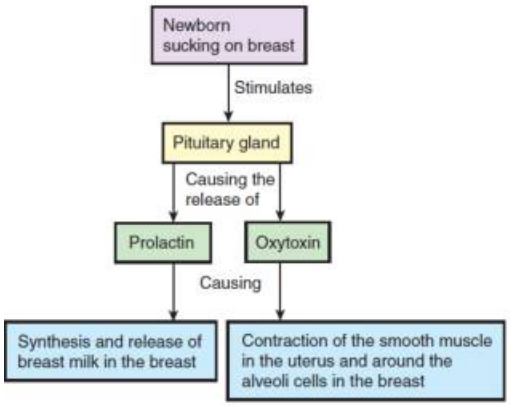

FIGURE 15.3. Physiology of lactation.

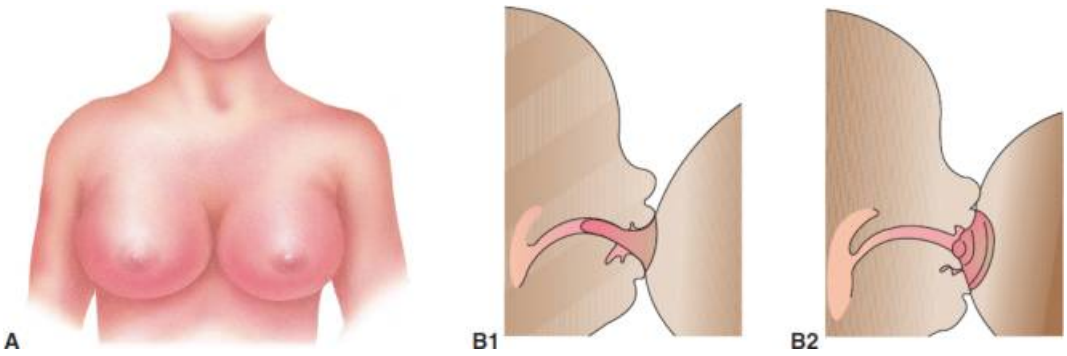

FIGURE 15.4. **A.** Image of engorged breasts. Note swelling and inflammation of both breasts. **B.** Breast engorgement can disrupt breastfeeding: (1) When sucking at a normal breast, the infant's lips compress the areola and fit neatly against the sides of the nipple. The infant also has adequate room to breathe. (2) When a breast is engorged, however, the infant has difficulty grasping the nipple and breathing ability is compromised. (From Pillitteri, A. [2014]. *Maternal and child nursing* (7th ed.). Lippincott Williams & Wilkins.)

- Prolactin is released from the anterior pituitary gland and initiates milk production.
- Oxytocin is released from the posterior pituitary gland to promote milk let-down.
- Infant sucking at each feeding provides continuous stimulus for prolactin and oxytocin release (Resnik et al., 2019).

Typically, during the first 2 days after birth, the breasts are soft and nontender. The woman may also report a tingling sensation in both breasts, which is the "let-down reflex" that occurs immediately before or during breastfeeding. After this time, breast changes depend on whether the mother is breastfeeding or taking measures to prevent lactation.

Engorgement is a postnatal physiologic painful condition in which distention and swelling of the breast tissue occurs as a result of an increase in blood and lymph supply as a precursor to lactation (Fig. 15.4). Breast engorgement usually peaks in 3 to 5 days postpartum and usually subsides within the following 24 to 36 hours. If milk is not removed as it is formed, the alveolar space can become overdistended, causing tender, swollen, and painful breasts (Berens, 2020). Engorgement can occur from infrequent feeding or ineffective

emptying of the breasts and typically lasts about 24 hours. Breasts increase in vascularity and swell in response to prolactin 2 to 4 days after birth. If engorged, the breasts will be hard and tender to touch. They are temporarily full, tender, and uncomfortable until the milk supply is ready. Frequent emptying of the breasts helps minimize discomfort and resolve engorgement. Standing in a warm shower or applying warm compresses immediately before feedings will help to soften the breasts and nipples in order to allow the newborn to latch on more easily.

Treatments to reduce the pain of breast engorgement include heat or cold applications, cabbage leaf compresses, breast massage and milk expression, ultrasound, breast pumping, and antiinflammatory agents (King et al., 2019). A nonprescription antiinflammatory medication can also be taken for the breast discomfort and swelling resulting from engorgement. These measures will also enhance the let-down reflex. Between feedings, applying cold compresses to the breasts helps reduce swelling. To maintain milk supply, the breasts need to be stimulated by a nursing infant, a breast pump, or manual expression of the milk (Fig. 15.5).

Remember Betsy, who experienced breast discomfort? The lactation consultant explains that Betsy was experiencing normal breast engorgement and offered several suggestions to help her. What relief measures might be suggested? What reassurance can be given to Betsy at this time?

SUPPRESSING LACTATION

Various pharmacologic and nonpharmacologic interventions have been used to suppress lactation after childbirth and relieve associated symptoms. Despite the large volume of literature on the subject, there is currently no universal guideline on the most appropriate approach for suppressing lactation in postpartum women (Cunningham et al., 2018). It is estimated that more than 30% of women in the United States do not breastfeed their infants, and a larger proportion discontinues breast-feeding within 2 weeks of childbirth (CDC, 2019a). Although physiologic cessation of lactation

eventually occurs in the absence of physical stimulus such as infant suckling, a large number of women experience moderate to severe milk leakage and discomfort before lactation ceases.

FIGURE 15.5. Nurse instructs the new breastfeeding mother about use of a breast pump. (Photo by B. Proud.)

Up to two thirds of women who do not breastfeed experience moderate to severe engorgement and breast pain when no treatment is applied (La Leche League International, 2019). If a woman does not desire to breastfeed, some relief measures include wearing a tight, supportive bra 24 hours daily, applying ice to her breasts for approximately 15 to 20 minutes every other hour, avoiding sexual stimulation, and not stimulating the breasts by squeezing or manually expressing milk from the nipples. In addition, avoiding exposing the breasts to warmth (e.g., a hot shower) will help relieve breast engorgement. In women who are not breast-feeding, engorgement typically subsides within 2 to 3 days with application of these measures.

Ovulation and Return of Menstruation

Changing hormone levels constantly interact with one another to produce bodily changes. Four major hormones are influential during the postpartum period: estrogen, progesterone, prolactin, and oxytocin. Estrogen plays a major role during pregnancy, but levels drop profoundly at birth and reach their lowest level a week into the postpartum period. Progesterone quiets the uterus to prevent a preterm birth during pregnancy, and its increasing levels during pregnancy prevent lactation from starting before birth takes place. As with estrogen, progesterone levels decrease dramatically after birth and are undetectable 72 hours after birth. Progesterone levels are reestablished with the first menstrual cycle (Resnik et al., 2019).

During the postpartum period, oxytocin stimulates the uterus to contract during the breastfeeding session and for as long as 20 minutes after each feeding. Oxytocin also acts on the breast by eliciting the milk let-down reflex during breastfeeding. Prolactin is also associated with the breastfeeding process by stimulating milk production. In women who breastfeed, prolactin levels remain elevated into the 6th week after birth (Kellerman & Rakel, 2019). The levels of prolactin fluctuate in proportion to nipple stimulation. Prolactin levels decrease in nonlactating women, reaching prepregnant levels by the third postpartum week. High levels of prolactin have been found to delay ovulation by inhibiting ovarian response to follicle-stimulating hormone (Blackburn, 2018).

The timing of first menses and ovulation after birth differs between women who are breastfeeding and women who are not breastfeeding. For nonlactating women, menstruation may resume as early as 7 to 9 weeks after giving birth, but the majority take up to 3 months, with the first cycle being anovulatory (Jordan et al., 2019). The return of menses in the lactating woman depends on breastfeeding frequency and duration. It can return any time after childbirth, depending on whether the woman is exclusively breastfeeding or supplementing with formula.

TAKE NOTE!

Ovulation may occur before menstruation. Therefore, breastfeeding is not a totally reliable method of contraception unless the mother exclusively breastfeeds, has had no menstrual period since giving birth, and has an infant younger than 6 months (Stevens, 2019).

Betsy tries several of the measures the lactation consultant suggested to relieve her breast discomfort but is still having heaviness and pain. She feels discouraged and tells the nurse she is thinking of reducing her breastfeeding and using formula to feed her newborn. What should Betsy consider when deciding if this is a good choice for her and her baby? Why or why not? What interventions will help Betsy get through this difficult time?

CULTURAL CONSIDERATIONS FOR THE POSTPARTUM PERIOD

Cultures vary in their postpartum beliefs, practices, and customs. Nurses practice in an increasingly multicultural society. Therefore, they must be open, respectful, nonjudgmental, and willing to learn about ethnically diverse populations. Although childbirth and the postpartum period are unique experiences for each individual woman, how the woman perceives and makes meaning of them is culturally defined. Somali women are highly regarded in Somali society for their roles as mothers. Postpartum women stay at home and refrain from sexual activity for 40 days. At the end of 40 days, there is a celebration and this typically marks the first time the mother and infant have left the home since childbirth. The majority of Somali and Arab women breastfeed and do so for extended periods of time (Giger, 2019). Nurses need to offer early breastfeeding instruction to support their efforts while still in the hospital setting before discharge.

Balance of Hot and Cold

Two areas that are significantly different from Western culture involve beliefs about the balance of hot and cold and confinement after childbirth. Vietnamese women view the postpartum period as a cold state (duong) and protect themselves with warmth. Cultural practices include warm water for hygiene and stimulation of lactation, consuming warm foods, and staying indoors. In the United States, childbearing and recovery are viewed as healthy states, and mothers receive little formal support for both their recovery and infant care. In China, childbearing and postpartum are viewed as states that disturb the normal health balance between yin and yang. In order to restore balance in health, postpartum women engage in practices for a month related to the maternal role, physical activity, maintenance of body warmth, and certain food consumption that will restore balance. Recent research findings in a small sample of Chinese women found that postpartum confinement negatively correlates with aerobic endurance and positively correlated with depression. These findings may challenge the assumption that practices of confinement are healthy for Chinese women's recovery after childbirth (Withers et al., 2018).

Many cultures believe good health requires the balancing of hot and cold substances. Because childbirth involves the loss of blood, which is considered hot, the postpartum period is considered cold, so the mother must balance that with the intake of hot food. Foods consumed should be hot in nature, and cold foods, such as fruits and vegetables, avoided. Western practices frequently use cold packs or sitz baths to reduce perineal swelling and discomfort. These practices are not acceptable to women of many cultures and can be viewed as harmful. Hot–cold beliefs are present in Latin American, African, and Asian cultures (Giger, 2019).

Postpartum Cultural Beliefs

With increasing multiculturalism in the United States, understanding various cultures' views of the postnatal period as it relates to their recovery and well-being after childbirth is important for all nurses. Postpartum nurses need to understand these diverse cultural beliefs

and provide creative strategies for encouraging hygiene (sponge baths, perineal care), exercise, and balanced nutrition while remaining respectful of the cultural significance of different practices. The best approach is to ask each woman to describe what cultural practices are important to her and plan accordingly.

PSYCHOLOGICAL ADAPTATIONS

The process of becoming a mother requires extensive psychological, social, and physical work. Women experience heightened vulnerability and face tremendous challenges as they make this transition. Nurses have a remarkable opportunity to help women learn, gain confidence, and experience growth as they assume the mother identity.

The transition to parenthood, while an exciting time to celebrate the life of a new child, causes parents to face new challenges such as physical exhaustion, role overload, and less time for themselves and each other (Kanter & Prouix, 2019). Mothers' and their partners' experiences of pregnancy are necessarily different, and this difference continues after childbirth as they both adjust to their new parenting roles. Many couples struggle to adapt to parenthood. Parenting involves caring for infants physically and emotionally to foster the growth and development of responsible, caring people. A substantial body of research finds no biologically based differences between mothers and partners in sensitivity to infants, capacity to provide care, or acquisition of parenting skills. Mothers may experience postpartum depression, but their partners also are affected. Studies show that about one in 10 partners develop postpartum depression and about one in nine mothers will also develop depression. Partner postpartum depression is less discussed. Nurses need to learn more about partner depression and reach out to partners to provide care to them as well (Altenau, 2020). Early parent–infant contact after birth improves attachment behaviors.

Parental Attachment Behaviors

The postpartum period is a unique time distinguished by the inseparable relationship parents have with the newborn. To enable an attachment to be built, closeness of this family unit is essential. **Attachment** is the formation of a relationship between a parent and a newborn through a process of physical and emotional interactions. Attachment between a woman and her newborn has lifelong implications (King et al., 2019). Maternal attachment has the potential to affect both child development and parenting. The bond between a parent and the newborn is one of strength, power, and potential. Attachment begins before birth, during the prenatal period when acceptance and nurturing of the growing fetus takes place. It continues after giving birth as parents learn to recognize the newborn's cues, adapt to the newborn's behaviors and responses, and meet the newborn's needs.

Several factors take place during the early postpartum period that can have a large influence on the attachment and bonding that occurs during this time. Oxytocin plays an essential role in the chemistry aspect of bonding, and its effects can be enhanced by skin-to-skin contact; breastfeeding; eye contact; social vocalizations; maternal and milk odors, which are soothing for the newborn; and newborn massage during the first postpartum hour (Jordan et al., 2019; Sultan, 2019). Early and sustained contact between newborns and their parents is vital for initiating this relationship.

Nurses play a crucial role in assisting the attachment process by promoting early parent–newborn interactions. In addition, nurses can facilitate skin-to-skin contact (kangaroo care) by placing the infant onto the bare chests of mothers and their partners to enhance parent–newborn attachment. This activity will enable them to get close to their newborn and experience an intense feeling of connectedness and evoke feelings of being nurturing parents. Encouraging breastfeeding is another way to foster attachment between mothers and their newborns. Finally, nurses can encourage nurturing activities and contact such as touching, talking, singing,

comforting, changing diapers, feeding—in short, participating in routine newborn care.

The process of attachment is complex and influenced by many factors including environmental circumstances, the newborn's health status, and the quality of nursing care (Kim, 2019). Nurses need to minimize parent–newborn separation by promoting parent–newborn interactions through kangaroo care, breastfeeding, and participation in their newborn care. Nurses who provide positive psychosocial support and clear communication to parents will help support the attachment process within family units.

Maternal Psychological Adaptations

Childbirth can be a joyous period in a woman's life and involves the sometimes spiritual experience of giving life to another being. For many, this is life-changing and through history has been anticipated with excitement and joy, often considered a blessing. However, childbirth and child-rearing can also be stressful, financially challenging, and emotionally demanding.

Mood Disorders

Many people consider childbirth a time of happiness and well-being, but it is common for women to experience changes in their mood during this time. This may include being fatigued, irritable, and worried, and frequently these feelings become severe enough to require medical intervention. Perinatal mood disorders are one of the most common complications to occur during the postpartum period, impairing maternal caregiving skills. In the postpartum period, mood disorders can be divided into three distinct entities in ascending order of severity: "maternal (baby) blues," postpartum depression, and psychosis. These disorders, however, have not been clearly demarcated, and it is a matter of much debate whether they are discrete disorders or a single disorder that ranges along a continuum of severity (Stewart & Vigod, 2019).

Up to 85% of new mothers suffer from the short-lived postpartum mood disorder colloquially called the “baby blues” or “maternal blues,” which are characterized by mild depressive symptoms, anxiety, irritability, mood swings, loss of appetite, trouble sleeping, tearfulness (often for no discernible reason), increased sensitivity, and fatigue (CDC, 2019b). These symptoms typically peak on postpartum days 4 and 5, may last hours to days, and usually resolve by day 10. Although these symptoms may be distressing, they do not reflect psychopathology, and they typically do not affect the mother’s ability to function and care for her child. For additional information, see Chapter 22.

Phases of Maternal Adaptation to Parenthood

Parenthood is a highly anticipated and frequently a positive event for many women. Becoming a mother is an important transition that adds new roles and responsibilities to daily life. It is a time of great change and heightened vulnerability, and a mother faces tremendous challenges as she undergoes this transition. Motherhood is often portrayed as idealized, romanticized, and joyful. However, a large proportion of women do not feel this way and instead experience postnatal psychological distress. Society has constructed many ideal images of motherhood, creating sometimes unrealistic standards for women to live up to, frequently setting them up for disappointment. Most women are able to experience this mismatch between their ideal and actual selves and adapt with minimal disruption (O’Neill et al, 2019). The woman experiences a variety of responses as she adjusts to a new family member and to postpartum discomforts, changes in her body image, and the reality of change in her life. In the early 1960s, Reva Rubin identified three phases that a mother goes through to adjust to her new maternal role. Rubin’s maternal role framework can be used to monitor the client’s progress as she “tries on” her new role as a mother. The absence of these processes or inability to progress through the phases satisfactorily may impede the appropriate development of the maternal role. Maternal role attainment is an interactional and

developmental process occurring over time in which the mother becomes attached to her infant, acquires competence in her caregiving tasks, and feels a sense of harmony (Khandan et al., 2018; Rubin, 1984). Although Rubin's maternal role development theories are of value, some of her observations regarding the length of each phase may not be completely relevant for the contemporary woman of the 21st century. Today, many women know their infant's sex, have "seen" their fetus in utero through four-dimensional ultrasound, and have a working knowledge of childbirth and child care. They are less passive than in years past and progress through the phases of attaining the maternal role at a much faster pace than Rubin expected in her research. Still, Rubin's framework is timeless for assessing and monitoring expected role behaviors when planning care and appropriate interventions.

FIGURE 15.6. Mother bonding with newborn during the taking-in phase.

TAKING-IN PHASE

The **taking-in phase** is the time immediately after birth when the client needs sleep, depends on others to meet her needs, and relives the events surrounding the birth process. This phase is characterized by dependent behavior. During the first 24 to 48 hours after giving birth, mothers often assume a passive role in meeting their own basic needs for food, fluids, and rest, allowing the nurse to make decisions for them concerning activities and care. They spend time recounting their labor experience to others. Such actions help the mother integrate the birth experience into reality; the pregnancy is over and the newborn is now a unique individual, separate from herself. When interacting with the newborn, new mothers spend time claiming the newborn and touching them, commonly identifying specific features in the newborn, such as “he has my nose” or “his fingers are long like his father’s” (Fig. 15.6).

TAKE NOTE!

The taking-in phase typically lasts 1 to 2 days and may be the only phase observed by nurses in the hospital setting because of the shortened postpartum stays that are the norm today.

TAKING-HOLD PHASE

The **taking-hold phase**, the second phase of maternal adaptation, is characterized by dependent and independent maternal behavior. This phase typically starts on the second to third day postpartum and may last several weeks.

As the client regains control over her bodily functions during the next few days, she will be taking hold and becoming preoccupied with the present. She will be particularly concerned about her health, the infant’s condition, and her ability to care for them. She demonstrates increased autonomy and mastery of her own body’s functioning, and a desire to take charge with support and help from others. She will show independence by caring for herself and learning to care for her newborn, but she still requires assurance that

she is doing well as a mother. She expresses a strong interest in caring for the infant by herself.

LETTING-GO PHASE

In the **letting-go phase**, the third phase of maternal adaptation, the woman reestablishes relationships with other people. She adapts to parenthood in her new role as a mother. She assumes the responsibility and care of the newborn with a bit more confidence (Jordan et al., 2019). The focus of this phase is to move forward by assuming the parental role and to separate herself from the symbiotic relationship that she and her newborn had during pregnancy. She establishes a lifestyle that includes the infant. The mother relinquishes the fantasy infant and accepts the real one.

Nurses have recognized the importance of the process of becoming a mother (BAM) to maternal–infant nursing since Rubin's report on maternal role attainment (MRA). Mothers' perceptions of their competence and/or confidence in mothering and their expressions of love for their infants are affected by age, relationship with the father or partner, socioeconomic status, birth experience, stress, available support, personality traits, self-concept, child-rearing attitudes, role strain, health status, preparation during pregnancy, relationships with their own mothers, depression, and anxiety. Infant variables identified as influencing MRA/BAM include appearance, responsiveness, temperament, and health status (Cabrera, 2018). More current research has led to renaming the four stages a woman progresses through in establishing a maternal identity in BAM:

1. Commitment, attachment to the unborn baby, and preparation for delivery and motherhood during pregnancy
2. Acquaintance/attachment to the infant, learning to care for the infant, and physical restoration during the first 2 to 6 weeks following birth
3. Moving toward a new normal
4. Achievement of a maternal identity through redefining self to incorporate motherhood (around 4 months); the mother feels self-

confident and competent in her mothering and expresses love for and pleasure interacting with her infant (Alligood, 2018)

The woman's work in the first stage is to make a commitment to the pregnancy and to the safe birth and care of her unborn child. This commitment is associated with a positive adaptation to motherhood. During the second stage while the mother is placing the infant in her family context and learning how to care for her infant, her attachment and attitude toward her infant, and her self-confidence and/or sense of competence in mothering consistently indicate an interdependence of these two variables. The nursing care provided during the first two stages is especially important in assisting mothers as they begin to mother. Follow-up is needed as mothers move toward a new normal and recognizing a transformation of themselves can continue to reinforce their capabilities (Alligood, 2018).

To foster maternal role attainment, three specific interventions for nurses were identified in a review of the literature (Cabrera, 2018). First, instructions about infant care and the infant's capabilities are more effective if they are specifically focused on that particular mother's infant. Second, mothers prefer live classes rather than videos so they can ask questions. In short, interactive nurse–client relationships are associated with positive maternal growth. Third, identifying barriers that reduce skin-to-skin periods of mother-to-infant contact during the postpartum hospital stay and intervening to reduce them have implications for both maternal role development and breastfeeding success, if the mother has chosen this method. Providing times for skin-to-skin contact has a positive impact on the long-term health of both the mother and baby. Nurses who interact with clients long-term during pregnancy, childbirth, and well-child care help build maternal competence. Pregnancy, birth, and becoming a mother collectively represent a critical period of physical and emotional upheaval in a woman's life. The need for a holistic care approach that supports the emotional and physical health of the dyad is imperative (King et al., 2019).

Transition to motherhood theories describe women in a prescribed role—that of being a mother and in a way, a predetermined type of mother. In that sense transition to motherhood theory is baby-centered. New theories need to be developed that are woman-centered and conceptualize the woman as an embodied self who is powerful in her own life.

Partner Psychological Adaptations

For partners, whether they are husbands, significant others, same-sex life partners, or friends, becoming a parent or simply sharing in the childbirth experience can be a perplexing time as well as a time of great change. This transition is influenced by many factors, including participation in childbirth, relationships with significant others, competence in child care, the family role organization, the individual's cultural background, and the method of infant feeding.

Nurses can play a key role in supporting a partner's transition to parenthood by keeping partners informed about birth and postpartum routines, reporting on their newborn's health status, and reviewing infant development. They can also contribute by creating participative space for new partners during the postpartum period. This can be achieved, for example, by helping partners take on the new role by supporting and promoting their degree of involvement in the process. They can also be encouraged to actively participate in caring for and maintaining contact with the newborns.

TAKE NOTE!

Most research findings stress the importance of early contact between the partner and the newborn as well as participation in infant care activities to foster the relationship (Robinson et al., 2020).

Infants have a powerful effect on their parents and others, who become intensely involved with them (Fig. 15.7). The partner's

developing bond with the newborn—a time of intense absorption, preoccupation, and interest—is called **engrossment**.

Engrossment

Engrossment is characterized by seven behaviors:

1. Visual awareness of the newborn—the partner perceives the newborn as beautiful.
2. Tactile awareness of the newborn—the partner has a desire to touch or hold the newborn and considers this activity pleasurable.
3. Perception of the newborn as perfect—the partner does not "see" any imperfections.
4. Strong attraction to the newborn—the partner focuses all their attention on the newborn when in the room.
5. Awareness of distinct features of the newborn—the partner can distinguish the newborn from others in the nursery.
6. Extreme elation—the partner feels a "high" after the birth of the child.
7. Increased sense of self-esteem—the partner feels proud, "bigger," more mature, and older after the birth of the child (Sears & Sears, 2020).

FIGURE 15.7. Engrossment of the father and his newborn.

Frequently, partners are portrayed as well-meaning but bumbling when caring for newborns. However, they have their own unique way of relating to their newborns and can become as nurturing as mothers. A partner's nurturing responses may be less automatic and slower to unfold than a mother's, but they are capable of a strong bonding attachment to their newborns (Sears & Sears, 2020). Encouraging partners to express their feelings by seeing, touching, and holding the newborn and by cuddling, talking to, and feeding them will help cement this new relationship. Reinforcement of this engrossing behavior helps partners make a positive attachment during this critical period.

Three-Stage Role Development Process

Similar to mothers, partners also go through a predictable three-stage process during the first 3 weeks as they too “try on” their roles as parents. The three stages are expectations, reality, and transition to mastery (Sears & Sears, 2020).

STAGE 1: EXPECTATIONS

New partners pass through stage 1 (expectations) with preconceptions about what home life will be like with a newborn. Many partners may be unaware of the dramatic changes that can occur when this newborn comes home to live with them. For some, it is an eye-opening experience.

STAGE 2: REALITY

Stage 2 (reality) occurs when partners realize that their expectations in stage 1 are not in line with reality. Their feelings change from elation to sadness, ambivalence, jealousy, and frustration. Many wish to be more involved in the newborn’s care and yet do not feel prepared to do so. Some find parenting fun but at the same time do not feel fully prepared to take on that role.

A partner’s stress, irritability and frustration in the days, weeks, and months after the birth of the child can turn into depression, just like that experienced by the mother. Unfortunately, partners rarely discuss their feelings or ask for help, especially during a time when they are supposed to be the “strong one” for the new mother. Depression in partners can lead to marital conflicts, reckless or violent behavior, withdrawn parental interactions with the newborn, poor job performance, and substance abuse. In addition, it can have a detrimental effect on the child’s future development, such as depression and defiant behavior (Cheung & Theule, 2019).

Risk factors for partner postpartum depression include previous history of depression, financial problems, a poor relationship with the mother, and an unplanned pregnancy. Symptoms of depression appear 1 to 3 weeks after birth and can include feelings of high stress, anxiety, discouragement, fatigue, headaches, and resentment

toward the infant and the attention they are getting. Partners experiencing these symptoms should understand that it is not a sign of weakness, and professional help can be helpful.

STAGE 3: TRANSITION TO MASTERY

In stage 3 (transition to mastery), the partner makes a conscious decision to take control and be at the center of the newborn's life regardless of preparedness. This adjustment period is similar to that of the mother's letting-go phase when she incorporates the newest member into the family.

KEY CONCEPTS

- The puerperium period refers to the first 6 weeks after delivery. During this period, the mother experiences many physiologic and psychological adaptations to return her to the prepregnant state.
- Involution involves three processes: contraction of muscle fibers to reduce stretched ones, catabolism (which reduces enlarged, individual cells), and regeneration of uterine epithelium from the lower layer of the decidua after the upper layers have been sloughed off and shed in lochia.
- Lochia passes through three stages: lochia rubra, lochia serosa, and lochia alba during the postpartum period.
- Maternal blood plasma volume decreases rapidly after birth and returns to normal within 4 weeks postpartum.
- Reva Rubin (1984) identified three phases the mother goes through to adjust to her new maternal role: the taking-in, taking-hold, and letting-go phases.
- The transition to parenthood for a partner is influenced by many factors, including participation in childbirth, relationships with significant others, competence in child care, the family role organization, the cultural background, and the method of infant feeding.
- Like mothers, partners go through a predictable three-stage process during the first 3 weeks as they too “try on” their roles as partners. The three stages include expectations, reality, and transition to mastery.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. Postpartum breast engorgement occurs 48 to 72 hours after giving birth. What physiologic change influences breast engorgement?

   a. An increase in blood and lymph supply to the breasts
   b. An increase in estrogen and progesterone levels
   c. A dramatic increase in colostrum production
   d. Fluid retention in the breasts due to the intravenous fluids given during labor

2. In the taking-in maternal role phase described by Rubin (1984), the nurse would expect the woman's behavior to be characterized in what way?

   a. Gaining self-confidence
   b. Adjusting to her new relationships
   c. Being passive and dependent
   d. Resuming control over her life

3. The nurse is explaining to a postpartum woman 48 hours after childbirth that the afterpains she is experiencing can be the result of which factor?

   a. Abdominal cramping as a sign of endometriosis
   b. A small infant weighing less than 8 lb
   c. Pregnancies that were too closely spaced
   d. Contractions of the uterus after birth

4. The nurse would expect a postpartum woman to experience lochia in which sequence?

   a. Rubra, alba, serosa
   b. Rubra, serosa, alba

c. Serosa, alba, rubra
d. Alba, rubra, serosa

5. The nurse is assessing Ms. Smith, who gave birth to her first child 5 days ago. What findings would the nurse expect?

a. Cream-colored lochia; uterus above the umbilicus
b. Bright red lochia with clots; uterus two fingerbreadths below umbilicus
c. Light pink or brown lochia; uterus four to five fingerbreadths below umbilicus
d. Yellow, mucousy lochia; uterus at the level of the umbilicus

6. Prioritize the postpartum mother's needs 4 hours after giving birth by placing a number 1, 2, 3, or 4 in the blank before each need.

a. _____ Learn how to hold and cuddle the infant.
b. _____Watch a baby bath demonstration given by the nurse.
c. _____ Sleep and rest without being disturbed for a few hours.
d. _____ Interaction time (first 30 minutes) with the infant to facilitate bonding.

7. Immediately after childbirth in the recovery area, the nurse observes the mother's partner's fascination and interest in the new child. This behavior is often termed

a. attachment.
b. engrossment.
c. bonding.
d. temperament.

8. After the nurse provides instructions to a postpartum woman about postpartum blues, which statement indicates understanding?

a. “I will need to take medication daily to treat the anxiety and sadness.”
b. “I will call the OB support line only if I start to hear voices.”
c. “I will contact my doctor if I become dizzy and fell nauseated.”
d. “I will feel like laughing one minute and crying the next minute.”

CRITICAL THINKING EXERCISES

1. A new nurse assigned to the postpartum mother–baby unit makes a comment to the oncoming shift that a 25-year-old primipara seems lazy and shows no initiative in taking care of herself or her baby. The nurse reported that this new mother talks excessively about her labor and birth experience and seems preoccupied with herself and her needs, not her newborn’s care. She wonders if something is wrong with this mother because she seems so self-centered and has to be directed to do everything.
   a. Is there something to be concerned about in this new mother’s behavior? Why or why not?
   b. What maternal role phase is being described by the nurse?
   c. What role can the nurse play to support the mother through this phase?

2. A primipara gave birth to a healthy baby boy yesterday. Her partner seemed elated at the birth, calling their friends and family on his cell phone minutes after the birth. He passed out cigars and praised his wife for her efforts. Today, when the nurse walked into their room, her partner seemed anxious around his new son and called for the nurse whenever the baby cried or needed a diaper change. He seemed standoffish when asked to hold his son, and he spent time talking to other fathers in the waiting room, leaving his wife alone in the room.

a. Would you consider this behavior to be normal at this time?
b. What might the partner be feeling at this time?
c. How can the nurse help this new father adjust to his new role?

STUDY ACTIVITIES

1. Find an internet resource that discusses general postpartum care for new mothers who might have questions after discharge. Evaluate the website's information as to how credible, accurate, and current the information is.
2. Prepare a teaching plan for new mothers, outlining the various physiologic changes that will take place after discharge.
3. The term that describes the return of the uterus to its prepregnant state is _____.
4. A deviated fundus to the right side of the abdomen would indicate a _____.

BRINGING IT ALL TOGETHER: A CASE STUDY

A 29-year-old married Latina mother of four children lived with her migrant husband and his parents in a small rural border town. She gave birth to her fourth child 7 weeks ago. She has now had four children in the past 4 years. Her pregnancy, labor, and birth had been uneventful, and an untrained female neighbor helped conduct the home birth. Because pregnancy was viewed as a normal occurrence that did not require any medical attention, the mother did not receive any prenatal care for any of her four pregnancies. For the first month after birth, she felt normal but then began to exhibit restless and anxious behavior. She became isolated from her family, stopped speaking to them, and ceased to care for her newborn or other children. Her family wondered about her isolation but seemed

indifferent to her condition, as they were all busy with their own lives. One day when all of her family members and her children had gone to daycare, school, and work, she ended her life.

Go to thePoint to find questions to consider about this case.

Nursing Management During the Postpartum Period

WOW

WORDS OF WISDOM

Parenting is an intimate, interactive, and continuous lifelong process.

KEY TERMS

attachment

bonding

en face position

pelvic floor exercises

peribottle

postpartum blues

sitz bath

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Characterize the normal physiologic and psychological adaptations to the postpartum period.
2. Determine the parameters that need to be assessed during the postpartum period.
3. Compare and contrast bonding to the attachment process.
4. Select behaviors that enhance or inhibit the attachment process.
5. Outline nursing management for the woman and her family during the postpartum period.
6. Examine the role of the nurse in promoting successful breastfeeding.
7. Plan areas of health education needed for discharge planning, home care, and follow-up.

A 24-year-old Muslim primipara has just been admitted to the postpartum unit. Her husband sits at the bedside but doesn't seem to outwardly provide her any physical or emotional support after her lengthy labor and difficult birth.

INTRODUCTION

Motherhood can be special, but the postpartum period is a time of major adjustments and adaptations not just for the mother, but for all members of the family. It is during this time that parenting starts and a relationship with the newborn begins. A positive, loving relationship between parents and the newborn promotes the emotional well-being of all. This relationship endures and has profound effects on the child's growth and development.

TAKE NOTE!

Parenting is a skill that is often learned by trial and error with varying degrees of success. Successful parenting, a continuous and complex interactive process, requires parents to learn new skills and integrate the new member into the family.

Once the infant is born, each system in the mother's body takes several weeks to return to its nonpregnant state. The physiologic changes in women during the postpartum period are dramatic. Nurses should be aware of these changes and should be able to make observations and assessments to validate normal occurrences and detect any deviations.

This chapter describes the nursing management of the woman and her family during the postpartum period. (See Chapter 21 for a detailed discussion of the postpartum care of the woman undergoing a surgical birth.) Nursing management during the postpartum period focuses on assessing the woman's ability to adapt to the physiologic and psychological changes occurring at this time (see Chapter 15 for a detailed discussion of these adaptations). This chapter outlines physical assessment parameters for new mothers and newborns. It also focuses on bonding and attachment behaviors; nurses need to be aware of these behaviors so they can perform appropriate interventions as needed. Family members are also assessed to determine how well they are making the transition to this new stage.

FIGURE 16.1. Parents and grandmother interacting with the newborn.

Based on assessment findings, the nurse plans and implements care to address the family's needs. Steps to address physiologic needs such as comfort, self-care, nutrition, and contraception are described. Ways to help the woman and her family adapt to the birth of the newborn are also discussed (Fig. 16.1). Because of today's shortened hospital stays, the nurse may be able to focus only on priority needs and may need to arrange for follow-up in the home to ensure that all the family's needs are met.

SOCIAL SUPPORT AND CULTURAL CONSIDERATIONS

The postpartum period is a critical stage in which a series of changes in the woman occur, which impact her at the physical, psychological, and social levels. In addition to physical assessment and care of the woman in the postpartum period, strong social support is vital to help her integrate the baby into the family. A key to providing effective postpartum care is to understand the woman in

her social and cultural context so that all care provided demonstrates cultural humility and is sensitive. In today's mobile society, extended families may live far away and may be unable to help care for the new family. As a result, many new parents turn to health care providers for information as well as physical and emotional support during this adjustment period. Nurses can be an invaluable resource by serving as mentors, teaching about self-care measures and baby care basics, and providing emotional support. Nurses can "mother" the new mother by offering physical care, emotional support, information, and practical help. The nurse's support and care through this critical time can increase the new parents' confidence, giving them a sense of accomplishment in their parenting skills. One important intervention during the postpartum period is promotion of breastfeeding. *Healthy People 2030* includes breastfeeding as a goal for maternal, infant, and child health (U.S. Department of Health and Human Resources [USDHHS], 2019). See *Healthy People 2030* 16.1.

HEALTHY PEOPLE 2030 • 16.1

Objective	Nursing Significance
MICH-2030-15 Increase the proportion of infants who are breastfed exclusively through 6 months.	Will provide infants with the most complete form of nutrition, improving their health, growth and development, and immunity. Will improve maternal and child health via breastfeeding's beneficial effects.

Adapted from USDHHS. (2020). *Proposed objectives for inclusion in Healthy People 2030*. https://www.healthypeople.gov/sites/default/files/ObjectivesPublicComment508.pdf

As in all nursing care, nurses should provide culturally competent care during the postpartum period. The nurse should engage in ongoing cultural self-assessment and overcome any stereotypes that perpetuate prejudice or discrimination against any cultural group. The postpartum period is noted for traditional practices related to rest, healing, and consumption of food and drink. In many cultures,

mothers and mothers-in-law have a great deal of influence over the new mother, so nurses need to be aware of the client's culture and help them integrate their beliefs and practices into contemporary health care practice (Giger, 2019). Providing culturally humble and competent nursing care during the postpartum period requires time, open-mindedness, and patience. It is vital that nurses know the cultural preferences of the women they serve since we live in a multicultural society. The global migration of diverse populations presents nurses with the challenge of providing care to unprecedented numbers of clients and their families with health care beliefs and practices that differ from their own. Sensitivity cannot be assumed; it needs to be nurtured and developed. The skill set needed by nurses to provide culturally humble care to postpartum clients and their families includes understanding their beliefs, experiences, and family environment; facilitating their language through appropriate use of interpreters so that the information provided can be understood; and compassionately respecting clients and their human rights. For instance, many Chinese cultures value traditions and the involvement of elders in the extended family. Some Chinese women living in the United States practice transnational parenting, a process of sending their American-born child to China to be raised by extended family there. This has implications for breastfeeding success among these mothers (Andrews & Boyle, 2019). To promote positive outcomes, the nurse should be sensitive to the woman's and family's culture, religion, and ethnic influences (see "Providing Optimal Cultural Care" in the "Nursing Interventions" section).

Remember the couple introduced at the beginning of the chapter? When the postpartum nurse comes to examine Raina, the mother, her husband quickly leaves the room and returns a short time later after the examination is complete. How do you interpret his behavior toward his wife? What might you communicate to this couple?

NURSING ASSESSMENT IN THE POSTPARTUM PERIOD

Many adaptations and adjustments must be made to accommodate the new family member. Nurses need to carry out a thorough assessment of maternal discomfort and attempt to implement both preventive and therapeutic measures to reduce any discomfort to improve the mother's quality of life in one of the most complex phases of her life (Martinez-Galiano et al., 2019). The nurse's focus is on assistance for families to maximize their adjustment, surveillance for maladaptation, education, consultation, and collaboration as needed. Comprehensive nursing assessment begins within an hour after the woman gives birth and continues through discharge.

TAKE NOTE!

Nurses need a firm grasp of normal findings to be able to recognize abnormal findings and intervene appropriately.

This postpartum assessment includes vital signs and physical and psychosocial assessments. It also includes assessing the parents and other family members, such as siblings and grandparents, for attachment and bonding with the newborn. Although the exact protocol may vary among facilities, postpartum assessment is typically performed as follows:

- During the first hour: every 15 minutes
- During the second hour: every 30 minutes
- During the first 24 hours: every 4 hours
- After 24 hours: every 8 hours (Jordan et al., 2019; King et al., 2019)

During each assessment, keep in mind risk factors that may lead to complications such as infection or hemorrhage during the recovery period (Box 16.1). Early identification is critical to ensure prompt intervention.

BOX 16.1 Factors Increasing a Woman's Risk for Postpartum Complications

Risk Factors for Postpartum Infection

- Operative procedure (forceps, cesarean birth, vacuum extraction)
- History of diabetes, including gestational-onset diabetes
- Prolonged labor (more than 24 hours)
- Use of indwelling urinary catheter
- Anemia (hemoglobin <10.5 mg/dL)
- Multiple vaginal examinations during labor
- Prolonged rupture of membranes (>24 hours)
- Manual extraction of placenta
- Compromised immune system (HIV-positive)

Risk Factors for Postpartum Hemorrhage

- Precipitous labor (less than 3 hours)
- Uterine atony
- Placenta previa or abruptio placenta
- Labor induction or augmentation
- Operative procedures (vacuum extraction, forceps, cesarean birth)
- Retained placental fragments
- Prolonged third stage of labor (more than 30 minutes)
- Multiparity, more than three births closely spaced
- Uterine overdistention (large infant, twins, hydramnios)

BOX 16.2 Postpartum Danger Signs

- Fever >100.4°F (38°C)
- Foul-smelling lochia or an unexpected change in color or amount
- Large blood clots or bleeding that saturates a peripad in an hour
- Severe headaches or blurred vision
- Visual changes, such as blurred vision or spots, or headaches
- Calf pain with dorsiflexion of the foot
- Swelling, redness, or discharge at the episiotomy, epidural, or abdominal sites
- Dysuria, burning, or incomplete emptying of the bladder
- Shortness of breath or difficulty breathing without exertion
- Depression or extreme mood swings

The postpartum period is a time of transition for women. The end of the pregnancy and childbirth initiates physiologic changes as

many body systems return to their nonpregnant states. Nurses need to be aware of the normal physiologic and psychological changes that take place in clients' bodies and minds in order to provide comprehensive care during the postpartum period. In addition to client and family teaching, one of the most significant responsibilities of the postpartum nurse is to recognize potential complications after childbirth.

As with any assessment, always review the woman's medical record for information about her pregnancy, labor, and birth. Note any preexisting conditions, any complications that occurred during pregnancy, labor, birth, and immediately afterward, and any treatments provided.

Postpartum assessment of the mother typically includes vital signs, pain level, epidural site inspection for infection, and a systematic head-to-toe review of body systems. The acronym BUBBLE-EE—*b*reasts, *u*terus, *b*ladder, *b*owels, *l*ochia, *e*pisiotomy/perineum/epidural site, *e*xtremities, and *e*motional status—can be used as a guide for this head-to-toe review (Cunningham et al., 2018).

While assessing the woman and her family during the postpartum period, be alert for danger signs (Box 16.2). Notify the primary health care provider immediately if any are noted.

Vital Signs Assessment

Obtain vital signs and compare them with the previous values, noting and reporting any deviations. Vital sign changes can be an early indicator of complications.

Temperature

Use a consistent measurement technique (oral, axillary, or tympanic) to get the most accurate readings. Typically, the new mother's temperature during the first 24 hours postpartum is within the normal range or a low-grade elevation. Some women experience a slight fever, up to 100.4°F (38°C), during the first 24 hours. This elevation

may be the result of dehydration because of fluid loss during labor. Temperature should be normal after 24 hours with replacement of fluids lost during labor and birth (Stevens, 2019).

A temperature above 100.4°F (38°C) at any time or an abnormal temperature after the first 24 hours may indicate infection and must be reported. Abnormal temperature readings warrant continued monitoring until an infection can be ruled out through cultures or blood studies. An elevated temperature can identify maternal sepsis, which results in significant maternal morbidity and mortality worldwide. To improve the outcome, it is essential that nurses be vigilant in obtaining accurate values and monitoring their clients' temperatures.

Pulse

Pulse rates of 60 to 80 beats per minute (bpm) at rest are normal during the first week after birth. This pulse rate is called puerperal bradycardia. During pregnancy, the heavy gravid uterus causes a decreased flow of venous blood to the heart. After giving birth, there is an increase in intravascular volume. The cardiac output is most likely caused by an increased stroke volume from the venous return now. The elevated stroke volume leads to a decreased heart rate (Resnik et al., 2019). Tachycardia in the postpartum woman can suggest anxiety, excitement, fatigue, pain, excessive blood loss or delayed hemorrhage, infection, or underlying cardiac problems. Any pulse rate higher than 100 bpm warrants further investigation to rule out complications.

Respirations

Respiratory rates in the postpartum woman should be within the normal range of 12 to 20 breaths per minute at rest. Pulmonary function typically returns to the prepregnant state after childbirth when the diaphragm descends and the organs revert to their normal positions. Any change in respiratory rate out of the normal range might indicate pulmonary edema, atelectasis (a side effect of

epidural anesthesia), or pulmonary embolism and must be reported. Lungs should be clear on auscultation.

Blood Pressure

Assess the woman's blood pressure and compare it with her usual range. Report any deviation from this range. Immediately after childbirth, the blood pressure should remain the same as during labor. An increase in blood pressure could indicate gestational hypertension, while a decrease could indicate shock or orthostatic hypotension or dehydration, a side effect of epidural anesthesia. Blood pressure readings should not be higher than 140/90 mm Hg or lower than 85/60 mm Hg (King et al., 2019). Blood pressure may also vary based on the woman's position, so assess blood pressure with the woman in the same position every time. Be alert for orthostatic hypotension, which can occur when the woman moves rapidly from a lying or sitting position to a standing one.

Pain

Pain, the fifth vital sign, is assessed along with the other four parameters. Question the woman about the type of pain and its location and severity. Have the woman rate the pain using a numeric scale from 0 to 10 points. Nursing care should focus on providing comfort measures to ease pain which might include perineal care, a clean gown, mouth care, providing warm blankets, ensuring adequate fluid intake to facilitate healing, repositioning frequently, and encouraging rest between assessments (Mills et al., 2019).

Many postpartum orders will have the nurse premedicate the woman routinely for afterbirth pains rather than waiting for her to experience them first. The goal of pain management is to have the woman's pain scale rating maintained between 0 and 2 points at all times, especially after breastfeeding. This can be accomplished by assessing the woman's pain level frequently and preventing pain by administering analgesics. If the woman has severe pain in the perineal region despite use of physical comfort measures, check for

a hematoma by inspecting and palpating the area. If one is found, notify the health care provider immediately.

Physical Examination

Physical examination of the postpartum woman focuses on assessing the breasts, uterus, bladder, bowels, lochia, episiotomy/perineum and epidural site, and extremities.

Breasts

Inspect the breasts for size, contour, asymmetry, engorgement, or erythema. Check the nipples for cracks, redness, fissures, or bleeding, and note whether they are erect, flat, or inverted. Flat or inverted nipples can make breastfeeding challenging for both mother and infant. Cracked, blistered, fissured, bruised, or bleeding nipples in the breastfeeding woman are generally indications that the baby is improperly positioned on the breast. Palpate the breasts lightly to ascertain if they are soft, filling, or engorged, and document your findings. For women who are not breastfeeding, use a gentle, light touch to avoid breast stimulation, which would exacerbate engorgement.

Lactogenesis (the onset of milk secretion) is initially triggered by the delivery of the placenta, which results in falling levels of estrogen and progesterone with the continued presence of prolactin. If the mother is not breastfeeding, the prolactin levels fall and return to normal levels within 2 to 3 weeks. As milk is starting to come in, the breasts become firmer; this is charted as “filling.” Engorged breasts are hard, tender, and taut. Ask the woman if she is having any nipple discomfort. Palpate the breasts for any nodules, masses, or areas of warmth, which may indicate a plugged duct that may progress to mastitis if not treated promptly. Any discharge from the nipple should be described and documented if it is not colostrum (creamy yellow) or foremilk (bluish white). Over the first week, the breast milk matures and contains all necessary nutrients in the neonatal period.

The breast milk continues to change throughout the period of breastfeeding to meet the changing demands of the growing infant.

Uterus

Assess the fundus (top portion of the uterus) to determine the degree of uterine involution. If possible, have the woman empty her bladder before assessing the fundus and auscultate her bowel sounds prior to uterine palpation. If the client has had a cesarean birth and has a patient-controlled anesthesia (PCA) pump, instruct her to self-medicate prior to fundal assessment to decrease her discomfort.

Using a two-handed approach with the woman in the supine position with her knees flexed slightly and the bed in a flat position or as low as possible, palpate the abdomen gently, feeling for the top of the uterus while the other hand is placed on the lower segment of the uterus to stabilize it (Fig. 16.2).

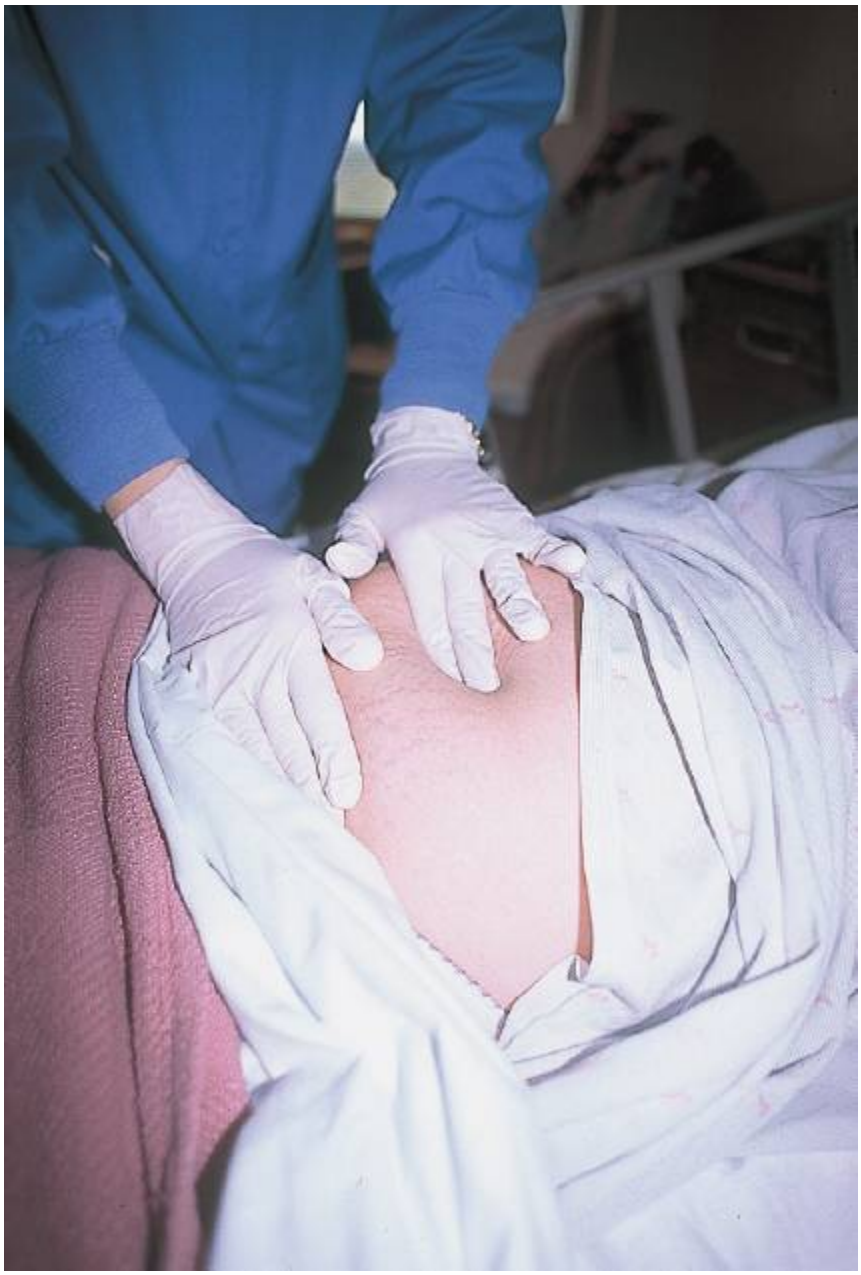

FIGURE 16.2. Palpating the fundus.

The fundus should be midline and should feel firm. A boggy or relaxed uterus is a sign of uterine atony (loss of muscle tone in the uterus). This can be the result of bladder distention, which displaces the uterus upward and to the right, or retained placental fragments. Either situation predisposes the woman to hemorrhage.

Once the fundus is located, place your index finger on the fundus and count the number of fingerbreadths between the fundus and the

umbilicus (one fingerbreadth is approximately equal to 1 cm). One to 2 hours after birth, the fundus is typically between the umbilicus and the symphysis pubis. Approximately 6 to 12 hours after birth, the fundus is usually at the level of the umbilicus. If the fundal height is above the umbilicus, which would be an abnormal finding, investigate this immediately to prevent excessive bleeding. Frequently, the woman's bladder is full, thus displacing the uterus up and to either side of the midline. Ask the woman to empty her bladder, and reassess the uterus again.

Normally, the fundus progresses downward at a rate of 1 cm per day after childbirth and should be nonpalpable by 10 to 14 days postpartum. By day 14, the uterus has descended below the rim of the symphysis pubis and is no longer palpable (Cunningham et al., 2018). On the first postpartum day, the top of the fundus is located 1 cm below the umbilicus and is recorded as u/1. Similarly, on the second postpartum day, the fundus would be 2 cm below the umbilicus and should be recorded as u/2, and so on. Health care agencies differ according to how fundal heights are charted, so follow their protocols for this. If the fundus is not firm, gently massage the uterus using a circular motion until it becomes firm.

Bladder

Considerable diuresis—as much as 3,000 mL/day—begins within 12 hours after childbirth and continues for several days. A single voiding may be 500 mL or more. By 21 days postpartum, the diuresis is usually complete (Jordan et al., 2019). However, many postpartum women do not sense the need to void even if their bladder is full. In this situation, the bladder can become distended and displace the uterus upward and to the side, which prevents the uterine muscles from contracting properly and can lead to excessive bleeding. Postpartum urinary retention is defined as the inability to empty the bladder within 6 hours after a vaginal birth. Urinary retention as a result of decreased bladder tone and emptying can lead to urinary tract infections and postpartum hemorrhage. It is imperative that nurses monitor clients for signs of urinary tract infections, including

fever, urinary frequency and/or urgency, difficult or painful urination, and tenderness over the costovertebral angle (Downey et al., 2019). Women who received regional anesthesia during labor are at risk for urinary tract infections due to continuous urinary catheterization to prevent urinary retention during labor, which is thought to delay fetal descent. They also experience difficulty voiding and loss of sensation and must wait until it returns to feel a full bladder which might be several hours after childbirth.

Assess for voiding problems by asking the woman the following questions:

- Have you (voided, urinated, gone to the bathroom) yet?
- Have you noticed any burning or discomfort with urination?
- Do you have any difficulty passing your urine?
- Do you feel that your bladder is empty when you finish urinating?
- Do you have any signs of infection such as urgency, frequency, or pain?
- Are you able to control the flow of urine by squeezing your muscles?
- Have you noticed any leakage of urine when you cough, laugh, or sneeze?

Assess the bladder for distention and adequate emptying after efforts to void. Palpate the area over the symphysis pubis. If empty, the bladder is not palpable. Palpation of a rounded mass suggests bladder distention. Also percuss the area; a full bladder is dull to percussion. If the bladder is full, lochia drainage will be more than normal because the uterus cannot contract to suppress the bleeding.

TAKE NOTE!

Note the location and condition of the fundus; a full bladder tends to displace the uterus up and to the right.

After the woman voids, palpate and percuss the area again to determine adequate emptying of the bladder. If the bladder remains distended, the woman may be retaining urine in her bladder, and

measures to initiate voiding should be instituted. Be alert for signs of infection, including infrequent or insufficient voiding (less than 200 mL), discomfort, burning, urgency, or foul-smelling urine (Berens, 2019). Document all urine output.

Bowels

Constipation is one of the most common gastrointestinal symptoms in postpartum mothers. The etiology of postpartum constipation is multifactorial. Local pelvic floor trauma, taking pain medications, lack of dietary fiber, fluids, and infant care all contribute to constipation. Spontaneous bowel movements may not occur for 1 to 3 days after giving birth because of a decrease in muscle tone in the intestines as a result of elevated progesterone levels. Normal patterns of bowel elimination usually return within a week after birth (Norwitz et al., 2019). Often women are hesitant to have a bowel movement due to pain in the perineal area resulting from an episiotomy, lacerations, or hemorrhoids. Some are fearful that they may "rip their stitches" should they strain. Nurses should reassure their clients that stool softeners and/or laxatives to treat constipation have been prescribed for them to reduce discomfort.

Inspect the woman's abdomen for distention, auscultate for bowel sounds in all four quadrants prior to palpating the uterine fundus, and palpate for tenderness. The abdomen typically is soft, nontender, and nondistended. Bowel sounds are present in all four quadrants. Ask the woman if she has had a bowel movement or has passed gas since giving birth, because constipation is common during the postpartum period, and many women do not offer this information unless asked about it. Normal assessment findings are active bowel sounds, passing gas, and a nondistended abdomen.

Lochia

Assess lochia in terms of amount, color, odor, and change with activity and time. To assess how much a woman is bleeding, ask her how many perineal pads she has used in the past 1 to 2 hours and how much drainage was on each pad. For example, did she saturate

the pad completely, or was only half of the pad covered with drainage? Ask about the color of the drainage, odor, and the presence of any clots. Lochia has a definite musky scent, with an odor similar to that of menstrual flow without any large clots (fist size). Foul-smelling lochia suggests an infection, and large clots suggest poor uterine involution, necessitating additional intervention.

To determine the amount of lochia, observe the amount of lochia saturation on the perineal pad and relate it to time (Fig. 16.3). Also, take into consideration the specific type of peripad used, because some are more absorbent than others. Lochia flow will increase when the woman gets out of bed (lochia pools in the vagina and the uterus while she is lying down) and when she breastfeeds (oxytocin release causes uterine contractions). A woman who saturates a perineal pad within 30 to 60 minutes is bleeding much more than one who saturates a pad in 2 hours.

FIGURE 16.3. Assessing lochia.

Typically, the amount of lochia is described as:

- *Scant:* a 1- to 2-in lochia stain on the perineal pad or approximately a 10-mL loss
- *Light or small:* an approximately 4-in stain or a 10- to 25-mL loss
- *Moderate:* a 4- to 6-in stain with an estimated loss of 25 to 50 mL
- *Large or heavy:* a pad is saturated within 1 hour after changing it (Kellerman & Rakel, 2019)

The total volume of lochial discharge varies in women based on their parity, but the amount decreases daily. Check under the woman by turning her to either side to make sure additional blood is not hidden and not absorbed on her perineal pad. This also a good time to assess for the presence and condition of hemorrhoids since the nurse is visually inspecting the perineum.

Report any abnormal findings, such as heavy, bright red lochia with large tissue fragments or a foul odor. If excessive bleeding occurs, the first step would be to massage the boggy fundus until it is firm to reduce the flow of blood. Document all findings.

Women who had cesarean births will have less lochia discharge than those who had vaginal births, but stages and color changes remain the same. Although the woman's abdomen will be tender after surgery, the nurse must palpate the fundus and assess the lochia to make sure they are within the normal range and that there is no excessive bleeding.

Anticipatory guidance to give the woman at discharge should include information about lochia and the expected changes. Urge the woman to notify her health care provider if lochia rubra returns after the serosa and alba transitions have taken place. This is abnormal and may indicate subinvolution or that the woman is too active and needs to rest more. Lochia is an excellent medium for bacterial growth. Explain to the woman that frequent changing of perineal pads, continued use of her peribottle for rinsing her perineal area, and hand hygiene before and after pad changes are important infection control measures.

Episiotomy/Perineum and Epidural Site

If the woman has an episiotomy, which is no longer routinely done, to assess the episiotomy and perineal area, position the woman on her side with her top leg flexed upward at the knee and drawn up toward her waist. If necessary, use a penlight to provide adequate lighting during the assessment. Wearing gloves and standing at the woman's side with her back to you, gently lift the upper buttock to expose the perineum and anus (Fig. 16.4). Inspect the episiotomy for irritation, ecchymosis, tenderness, or hematomas. Assess for hemorrhoids and their condition.

FIGURE 16.4. Inspecting the perineum.

During the early postpartum period, the perineal tissue surrounding the episiotomy is typically edematous and slightly bruised. The normal episiotomy site should not have redness, discharge, or edema. The majority of healing takes place within the first 2 weeks, but it may take 4 to 6 months for the episiotomy to heal completely (King et al., 2019).

Lacerations to the perineal area sustained during the birthing process that were identified and repaired also need to be assessed

to determine their healing status. Lacerations are classified based on severity and tissue involvement:

- *First-degree laceration:* involves only skin and superficial structures above muscle
- *Second-degree laceration:* extends through perineal muscles
- *Third-degree laceration:* extends through the anal sphincter muscle
- *Fourth-degree laceration:* continues through anterior rectal wall

Assess the episiotomy and any lacerations at least every 8 hours to detect hematomas or signs of infection. Large areas of swollen, bluish skin with complaints of severe pain in the perineal area indicate pelvic or vulvar hematomas. Redness, swelling, increasing discomfort, or purulent drainage may indicate infection. Both findings need to be reported immediately.

A white line running the length of the episiotomy is a sign of infection, as is swelling or discharge. Severe, intractable pain, perineal discoloration, and ecchymosis indicate a perineal hematoma, a potentially dangerous condition. Report any unusual findings. Ice can be applied to relieve discomfort and reduce edema; sitz baths also can promote comfort and perineal healing (see “Promoting Comfort” in the “Nursing Interventions” section).

If the woman has had an epidural during labor, assessment of the epidural wound site is important as well as checking for any side effects of the medication injected such as itching, nausea and vomiting, or urinary retention. Visual inspection of the epidural site and an accurate documentation of intake and output are essential.

Extremities

Pregnancy is associated with an increased risk of venous thromboembolism (VTE), which includes pulmonary embolism (PE) and deep vein thrombosis (DVT). During pregnancy, the state of hypercoagulability protects the mother against excessive blood loss during childbirth and placental separation. However, this hypercoagulable state can increase the risk of thromboembolic disorders during pregnancy and postpartum. Three factors predispose women to thromboembolic disorders during pregnancy:

stasis (compression of the large veins because of the gravid uterus); altered coagulation (state of pregnancy); and localized vascular damage (may occur during the birthing process). All of these factors increase the risk of clot formation and having it travel to the lungs.

While inspecting the woman's extremities, also determine the degree of sensory and motor function return (recovery from anesthesia) by asking the woman if she feels sensation at various areas the nurse touches and also by observing her ambulation stability.

TAKE NOTE!

Pulmonary embolism occurs in up to three per 1,000 births and is a major cause of maternal mortality (CDC, 2019d).

A PE typically results from a dislodged DVT in the lower extremities. Risk factors associated with thromboembolic conditions include:

- Anemia
- Diabetes mellitus
- Cigarette smoking
- Obesity
- Preeclampsia
- Hypertension
- Severe varicose veins
- Pregnancy
- Multiple pregnancies
- Cardiovascular disease
- Sickle cell disease
- Postpartum hemorrhage
- Oral contraceptive use
- Cesarean birth
- Severe infection
- Previous thromboembolic disease
- Multiparity
- Bed rest or immobility for 4 days or more

- Maternal age older than 35 (Troiano et al., 2019)

Because of the subtle presentation of thromboembolic disorders, the physical examination may not be enough to detect them. When DVT progresses to PE, it may do so without any signs or symptoms until the woman presents with hypotension or syncope. Dyspnea and chest pain are the most common symptoms that should prompt further evaluation. An accurate diagnosis of PE is needed because it requires (1) prolonged therapy (at least 9 months of heparin after pregnancy); (2) prophylaxis during future pregnancies; and (3) avoidance of oral contraceptive pills. The woman may report lower extremity tightness or aching when ambulating that is relieved with rest and elevation of the leg. Edema in the affected leg (typically the left), along with warmth and tenderness, and a low-grade fever may also be noted. A duplex ultrasound (two-dimensional ultrasound and Doppler ultrasound that compresses the vein to assess for changes in venous flow) in conjunction with the physical findings frequently is needed for a conclusive diagnosis (Resnik et al., 2019).

Women with an increased risk for this condition during the postpartum period should wear antiembolism or graduated compression stockings or use sequential compression devices to reduce the risk of venous stasis by preventing blood from pooling in the calves of the legs. Encouraging the client to ambulate after childbirth reduces the incidence of thrombophlebitis. See Evidence-Based Practice 16.1.

Psychosocial Assessment

Psychosocial assessment of the postpartum woman focuses on emotional status and bonding and attachment.

Emotional Status

Assess the woman's emotional status by observing how she interacts with her family, her level of independence, energy levels, eye contact with her infant (within a cultural context), posture and

comfort level while holding the newborn, and sleep and rest patterns. Be alert for mood swings, irritability, or crying episodes.

> Remember Raina and her quiet husband, the Muslim couple? The postpartum nurse informs Raina that her doctor, Dr. Nancy Schultz, has been called away for emergency surgery and won't be available the rest of the day. The nurse explains that Dr. Robert Nappo will be making rounds for her. Raina and her husband become upset. Why? Is culturally humble care being provided to this couple?

Bonding and Attachment

Nurses can be instrumental in promoting attachment by assessing attachment behaviors (positive and negative) and intervening appropriately if needed. Nurses must be able to identify any family discord that might interfere with the attachment process. Remember, however, that mothers from different cultures may behave differently from what is expected in one's own culture. For example, some Native American mothers may handle their newborns less often and use cradle boards to carry them. Some Native American mothers and many Asian American mothers delay breastfeeding until their milk comes in, because colostrum is believed to be harmful for the newborn (Giger, 2019). Do not assume that a behavior different from those of the predominant culture is wrong.

EVIDENCE-BASED PRACTICE 16.1

Graduated Compression Stockings for Prevention of Deep Vein Thrombosis

STUDY

Deep vein thrombosis (DVT) is a blood clot that forms in a vein deep in the body, usually in the leg. Several factors such as reduced mobility, obesity, surgery (cesarean section), history of pervious DVT, and the hypercoagulability state of pregnancy all create increased risk. Women who have one or more of these risk factors are at particular high risk of developing DVT and pulmonary embolism (PE). Symptoms of DVT vary from none to pain and swelling in the leg. A blood clot can move from the legs to the lungs, with the danger of PE and death. The purpose of the study was to evaluate the effectiveness and safety of graduated compression stockings in preventing DVT in high-risk clients.

Findings

Included in this study were 20 randomized controlled studies involving a total of 1,681 individuals. The individuals were divided into two groups, ones with the stockings and ones without them. Graduated compression stockings were applied on the day before surgery or on the day of surgery and worn until discharge. Thigh-length stockings were used in most cases. The researchers found that wearing graduated compression stockings reduced the overall risk of developing DVT.

Nursing Implications

This study confirmed that graduated compression stockings were effective in reducing the risk of DVT in hospitalized clients and potentially a PE when clinically appropriate. Nurses can apply this information to high-risk clients to make sure they wear them and

the reasons behind them. This intervention works and should be carried out to reduce the incidence of this medical condition in women that fall into high-risk categories.

Adapted from Sachdeva, A., Dalton, M., & Lees, T. (2018). Graduated compression stockings for prevention of deep vein thrombosis. Cochrane Database of Systematic Reviews, 11(11):CD001484. https://doi.org/10.1002/14651858.CD001484.pub4.

Meeting the newborn for the first time after birth can be an exhilarating experience for parents. Although the mother has spent many hours dreaming of her unborn and how they will look, it is not until after birth that they meet face to face. They both need to get to know one another and to develop feelings for one another.

Bonding is the close emotional attraction to a newborn by the parents that develops during the first 30 to 60 minutes after birth. It is unidirectional, from parent to infant. It is thought that optimal bonding of the parents to a newborn requires a period of close contact within the first few minutes to a few hours after birth. Bonding is a continuation of the relationship that began during pregnancy (Sears & Sears, 2020a). It is affected by a multitude of factors, including the parents' socioeconomic status, family history, role models, support systems, cultural factors, and birth experiences. The mother initiates bonding when she caresses her infant and exhibits certain behaviors typical of a mother tending her child. The infant's responses to this, such as body and eye movements, are a necessary part of the process. During this initial period, the infant is in a quiet, alert state, looking directly at the person holding them.

TAKE NOTE!

The length of time necessary for bonding depends on the health of the infant and mother as well as the circumstances surrounding the labor and birth (Hill & Flanagan, 2019).

Attachment is the development of strong affection between an infant and a significant other (mother, father, sibling, and caregiver). This attachment is reciprocal; both the significant other and the newborn exhibit attachment behaviors. The attachment relationship formed between the infant and primary caregiver influences the child's view of the world and future relationships (Schwartz, 2019). This tie between two people is psychological rather than biologic, and it does not occur overnight. The process of attachment follows a progressive or developmental course that changes over time. Attachment is an individualized and multifactorial process that differs based on the health of the infant, the mother, environmental circumstances, and the quality of care the infant receives. The newborn responds to the significant other by cooing, grasping, smiling, and crying. Nurses can assess for attachment behaviors by observing the interaction between the newborn and the person holding them (Jordan et al., 2019). It occurs through mutually satisfying experiences. Maternal attachment begins during pregnancy as the result of fetal movement and maternal fantasies about the infant and continues through the birth and postpartum periods. Attachment behaviors include seeking; physical caregiving behaviors; emotional attentiveness to the infant's needs; staying close to, touching, kissing, cuddling, and choosing the ***en face*** position (face-to-face) while holding or feeding the newborn; expressing pride in the newborn; and exchanging gratifying experiences with the infant (Hill & Flanagan, 2019). In a high-risk pregnancy, the attachment process may be complicated by premature birth (lack of time to develop a relationship with the unborn baby) and by parental stress due to fetal and/or maternal vulnerability.

Bonding is a vital component of the attachment process and is necessary in establishing parent–infant attachment and a healthy, loving relationship. During this early period of acquaintance, mothers touch their infants in a characteristic manner. Mothers visually and physically "explore" their infants, initially using their fingertips on the infant's face and extremities and progressing to massaging and stroking the infant with their fingers. This is followed by palm contact

on the trunk. Eventually, mothers draw their infant toward them and hold the infant (Fig. 16.5).

Generally, research on attachment has found that the process is similar for partners as for mothers, but the pace may be different. Like mothers, partners manifest attachment behaviors during pregnancy. Partners develop emotional ties with their infants in a variety of ways. They seek and maintain closeness with the infant and can recognize characteristics of the infant. Another study further described partner attachment as a permanent, cyclical concept characterized by changes in response to the child's developmental stage. When children have a secure, supportive, and sensitive relationship with the mother's partner, they are generally better adjusted than those who have a nonsupportive relationship (Bentenuto & Venuti, 2019).

FIGURE 16.5. *En face* position.

Attachment is a process; it does not occur instantaneously, even though many parents believe in a romanticized version of attachment, which happens right after birth. A delay in the attachment process can occur if a mother's physical and emotional states are adversely affected by exhaustion, pain, and the absence of a support system; if she has an infant in neonatal intensive care unit (NICU) and is separated from them; or had a traumatic birth experience, substance abuse, anesthesia, or an unwanted outcome, such as an ill infant (Skene et al., 2019).

TAKE NOTE!

Touch is a basic instinctual interaction between a parent and their infant and has a vital role in the infant's early development. Attachment is established, in part, through sensory processes. Parents provide a variety of tactile stimulation while addressing their infant's daily care routines (Walbam, 2019).

The developmental task for the infant is learning to differentiate between trust and mistrust. If the mother or caregiver is consistently responsive to the infant's care, meeting the baby's physical and psychological needs, the infant will likely learn to trust the caregiver, view the world as a safe place, and grow up to be secure, self-reliant, trusting, cooperative, and helpful. However, if the infant's needs are not met, the child is more likely to face developmental delays, neglect, and child abuse (Sears & Sears, 2020a).

Factors associated with the health care facility or birthing unit can also hinder attachment. These include:

- Separation of infant and parents immediately after birth and for long periods during the day.
- Policies that discourage unwrapping and exploring the infant.
- Intensive care environment, restrictive visiting policies.
- Staff indifference or lack of support for parent's caretaking attempts and abilities.

Concept Mastery Alert

Grief after Delivery of a Child with Special Needs

It is important for the mother to visit the child in the special care nursery, but the priority is to assist the mother in dealing with the grief that accompanies giving birth to a child with special needs. The mother must first mourn the loss of the "perfect child."

CRITICAL ATTRIBUTES OF ATTACHMENT

The terms "bonding" and "attachment" are often used interchangeably, even though they involve different time frames and interactions. Attachment stages include proximity, reciprocity, and commitment.

Proximity refers to the physical and psychological experience of the parents being close to their infant. This attribute has three dimensions:

1. *Contact:* The sensory experiences of touching, holding, and gazing at the infant are part of proximity-seeking behavior.
2. *Emotional state:* The emotional state emerges from the affective experience of the new parents toward their infant and the parental role.
3. *Individualization:* Parents are aware of the need to differentiate the infant's needs from themselves and to recognize and respond to them appropriately, making the attachment process also, in a way, one of detachment.

Reciprocity is the process by which the infant's abilities and behaviors elicit parental response. Reciprocity is described by two dimensions: complementary behavior and sensitivity. Complementary behavior involves taking turns and stopping when the other is not interested or becomes tired. An infant can coo and stare at the parent to elicit a similar parental response to complement their behavior. Parents who are sensitive and responsive to their infant's cues will promote their development and growth. Parents who become skilled at recognizing the ways their infant communicates will respond appropriately by smiling, vocalizing, touching, and kissing.

Commitment refers to the enduring nature of the relationship. The components of this are twofold: centrality and parent role exploration. In centrality, parents place the infant at the center of their lives. They acknowledge and accept their responsibility to promote the infant's safety, growth, and development. Parent role exploration is the parents' ability to find their own way and integrate the parental identity into themselves (Sears & Sears, 2020a).

POSITIVE AND NEGATIVE ATTACHMENT BEHAVIORS

Positive bonding behaviors include maintaining close physical contact; making eye-to-eye contact; speaking in soft, high-pitched tones; and touching and exploring the infant. Table 16.1 highlights typical positive and negative attachment behaviors.

NURSING INTERVENTIONS

In terms of postpartum hospital stays today, "less is more." If the woman had a vaginal delivery, she may be discharged within 24 to 48 hours or sooner. If she had a cesarean birth, she may remain hospitalized for up to 72 hours. These shortened lengths of stay leave little time for nurses to prepare the woman and her family for the many changes that will occur when she returns home (see Nursing Care Plan 16.1). Research shows that mothers feel unprepared, uninformed, and unsupported during the postpartum period as they struggle with physical and emotional issues, infant caregiving, breastfeeding concerns, and lifestyle adjustments (Benzies et al., 2019). Nurses need to focus on pain and discomfort, immunizations, nutrition, activity and exercise, infant care, lactation instruction, discharge teaching, sexuality and contraception, and follow-up with the limited time they have with their clients.

TABLE 16.1 Positive and Negative Attachment Behaviors

	Positive Behaviors	Negative Behaviors
Infant	Smiles; is alert; demonstrates strong grasp reflex to hold parent's finger; sucks well, feeds easily; enjoys being held close; makes eye-to-eye contact; follows parent's face; appears facially appealing; is consolable when crying	Feeds poorly, regurgitates often; cries for long periods, colicky and inconsolable; shows flat affect, rarely smiles even when prompted; resists holding and closeness; sleeps with eyes closed most of time; stiffens body when held; is unresponsive to parents; doesn't pay attention to parents' faces
Parent	Makes direct eye contact; assumes *en face* position when holding infant; claims infant as family member, pointing out common features; expresses pride in infant; assigns meaning to infant's actions; smiles and gazes at infant; touches infant, progressing from fingertips to holding; names infant; requests to be close to infant as much as allowed; speaks positively about infant	Expresses disappointment or displeasure in infant; fails to "explore" infant visually or physically; fails to claim infant as part of family; avoids caring for infant; finds excuses not to hold infant close; has negative self-concept; appears uninterested in having infant in room; frequently asks to have infant taken back to nursery to be cared for; assigns negative attributes to infant and calls infant inappropriate, negative names

Hill, R., & Flanagan, J. (2019). The maternal-infant bond: Clarifying the concept. *International Journal of Nursing Knowledge*, *31*(1), 14–18. https://doi.org/10.1111/2047-3095.12235; Kellerman, R. D., & Rakel, D. P. (2019). *Conn's current therapy 2019* Elsevier; and King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning.

TAKE NOTE!

Always adhere to standard precautions when providing direct care to reduce the risk of disease transmission.

Providing Optimal Cultural Care

As America is becoming more diverse, nurses must be prepared to care for childbearing families from various cultures. In many cultures, women and their families are cared for and nurtured by their communities for weeks and even months after the birth of a new family member. Cultural humility helps nurses explore cultural competency as a process rather than an outcome. Overall, culturally humble care for all childbearing families includes understanding traditional folk beliefs; involvement and support by family members; respect; presence of a significant other; breastfeeding and healthy eating; observing the principles of hot and cold; avoidance of postnatal sexual intercourse; encouragement; empowerment; the importance of spiritual dimensions; avoidance of evil spirits; and the hope that nurses will anticipate the needs of the mother and infant (Andrews & Boyle, 2019). Box 16.3 highlights some of the major cultural variants during the postpartum period.

Nurses need to remember that childbearing practices and beliefs vary from culture to culture. To provide appropriate nursing care, the nurse should determine the client's preferences before intervening. Cultural practices may include dietary restrictions, certain clothes, taboos, activities for maintaining mental health, and the use of silence, prayer, or meditation. Restoring health may involve taking folk medicines or conferring with a tribal healer. A language barrier might interfere with communication between the woman and health providers followed by the health care provider's lack of cultural sensitivity, leading to a woman's reluctance to use health services (Goldman & Trimmer, 2019). Providing culturally diverse care within our global community is challenging for all nurses, because they must remember that one's culture cannot be easily summarized in a

reference book but rather must be viewed through one's own life experiences.

> Raina and her husband are upset at the thought of having a male doctor care for her because as a Muslim woman, she prefers having a same-sex care provider. What should the nurse do in this situation?

Promoting Comfort

The postpartum woman may have discomfort and pain from a variety of sources, such as an episiotomy, perineal lacerations, backache as a result of the epidural, pain from a full bladder, an edematous perineum, inflamed hemorrhoids, engorged breasts, afterbirth pains secondary to uterine contractions in breastfeeding and multiparous mothers, and sore nipples if breastfeeding. Relieving the underlying problem is the first step in pain management. Most practices traditionally employed for postpartum discomforts are not evidence-based, so both nonpharmacologic and pharmacologic measures are often used in tandem (King et al., 2019).

NURSING CARE PLAN 16.1 Overview of the Postpartum Woman

A 26-year-old G2P2 is a client on the mother–baby unit after giving birth to a term 8-lb, 12-oz baby boy yesterday. The night nurse reports that she has an episiotomy, complains of a pain rating of 7 points on a scale of 1 to 10, is having difficulty breastfeeding, and had heavy lochia most of the night. The nurse also reports that the client seems focused on her own needs and not on those of her infant. Assessment this morning reveals the following:

B: **Breasts** are soft with colostrum leaking; nipples cracked
U: **Uterus** is 1 cm below the umbilicus; deviated to right
B: **Bladder** is palpable; client states she hasn't been up to void yet
B: **Bowels** have not moved; bowel sounds present; passing flatus
L: **Lochia** is moderate; peripad soaked from night accumulation
E: **Episiotomy** site intact; swollen, bruised; hemorrhoids present
E: **Extremities** have no edema over tibia, no warmth or tenderness in calf
E: **Emotional status** is distressed as a result of discomfort and fatigue

NURSING ANALYSIS: Altered tissue integrity related to episiotomy

OUTCOME IDENTIFICATION AND EVALUATION

The client will remain free of infection without any signs and symptoms of infection and exhibit evidence of progressive healing as demonstrated by clean, dry, decreased/absent edema, and an intact episiotomy site.

INTERVENTIONS: *Promoting Tissue Integrity*

- Monitor episiotomy site for redness, edema, warmth or discharge *to identify infection.*
- Assess vital signs at least every 4 hours *to identify changes suggesting infection.*
- Apply ice pack to episiotomy site *to reduce swelling.*
- Instruct client on use of sitz bath *to promote healing, hygiene, and comfort.*
- Encourage frequent perineal care and peripad changes *to prevent infection.*
- Recommend ambulation *to improve circulation and promote healing.*
- Instruct client on positioning *to relieve pressure on perineal area.*
- Demonstrate use of anesthetic sprays *to numb perineal area.*

NURSING ANALYSIS: Acute pain related to episiotomy, sore nipples, and hemorrhoids

OUTCOME IDENTIFICATION AND EVALUATION

The client will experience a decrease in pain as evidenced by reporting that her pain has diminished to a tolerable level and rating it as 2 points or less.

INTERVENTIONS: *Providing Pain Relief*

- Thoroughly inspect perineum *to rule out hematoma as cause of pain*.
- Administer analgesic medication as ordered as needed *to promote comfort*.
- Carry out comfort measures to episiotomy as outlined earlier *to reduce pain*.
- Explain discomforts and reassure the client that they are time-limited *to assist in coping with pain*.
- Apply witch hazel pads to swollen hemorrhoids *to induce shrinkage and reduce pain*.
- Suggest frequent use of sitz bath *to reduce hemorrhoid pain*.
- Administer stool softener and laxative *to prevent straining with first bowel movement*.
- Observe positioning and latching-on technique while breastfeeding. Offer suggestions based on observations *to correct positioning/latching on to minimize trauma to the breast*.
- Suggest air-drying of nipples after breastfeeding and use of plain water *to prevent nipple cracking*.
- Teach relaxation techniques when breastfeeding *to reduce anxiety and discomfort*.

NURSING ANALYSIS: Risk for coping impairment related to mood alteration and pain

OUTCOME IDENTIFICATION AND EVALUATION

The client will cope with mood alterations, as evidenced by positive statements about newborn and participation in newborn care.

INTERVENTIONS: *Promoting Effective Coping*

- Provide a supportive, nurturing environment and encourage the mother to vent her feelings and frustrations *to relieve anxiety*.
- Provide opportunities for the mother to rest and sleep *to combat fatigue.*
- Encourage the mother to eat a well-balanced diet *to increase her energy level.*
- Provide reassurance and explanations that mood alterations are common after birth secondary to waning hormones after pregnancy *to increase the mother's knowledge.*
- Allow the mother relief from newborn care *to afford opportunity for self-care.*

- Discuss with partner expected behavior from mother and how additional support and help are needed during this stressful time *to promote partner's participation in care.*
- Make appropriate community referrals for mother–infant support *to ensure continuity of care.*
- Encourage frequent skin-to-skin contact and closeness between mother and infant *to facilitate bonding and attachment behaviors.*
- Encourage client to participate in infant care and provide instructions as needed *to foster a sense of independence and self-esteem.*
- Offer praise and reinforcement of positive mother–infant interactions *to enhance self-confidence in care.*

BOX 16.3 Cultural Influences during the Postpartum Period

African American

- Mother may share care of the infant with extended family members.
- Experiences of older women within the family influence infant care.
- Mothers may protect their newborns from strangers for several weeks.
- Mothers may not bathe their newborns for the first week. Oils are applied to skin and hair to prevent dryness and cradle cap.
- Silver dollars may be taped over the infant's umbilicus in an attempt to flatten the slightly protruding umbilical stump.
- Sleeping with parents is a common practice.

Amish

- Women consider childbearing their primary role in society.
- Generally oppose birth control.
- Pregnancy and childbirth are considered a private matter; may conceal it from public knowledge.
- Women typically do not respond favorably when hurried to complete a self-care task. Nurses need to take cues from women indicating their readiness to complete morning self-care activities.

Appalachian

- Infant colic is treated by passing the newborn through a leather horse's collar or administering weak catnip tea.
- An *asafetida* bag (a gum resin with a strong odor) is tied around the infant's neck to ward off disease.
- Women may avoid eye contact with nurses and health care providers.
- Women typically avoid asking questions even if they do not understand directions.
- The grandmother may rear the infant for the mother.

Filipino American

- Grandparents often assist in the care of their grandchildren.
- Breastfeeding is encouraged, and some mothers breastfeed their children for up to 2 years.
- Women may feel uncomfortable discussing birth control and sexual matters.
- Strong religious beliefs predominate, and bedside prayer is common.
- Families are close-knit and numerous visitors can be expected at the hospital after childbirth.

Japanese American

- Cleanliness and protection from cold are essential components of newborn care. Nurses should bathe the infant daily.
- Newborns are routinely not taken outside the home because it is believed that they should not be exposed to outside or cold air. Infants are kept in a quiet,

clean, warm place for the first month of life.
- Breastfeeding is the primary method of feeding.
- Many women stay in their parents' home for 1 to 2 months after birth.
- Bathing the infant can be the center of family activity at home.

Mexican American

- The newborn's grandmother lives with the mother for several weeks after birth to help with housekeeping and child care.
- Many women will breastfeed for more than 1 year. The infant is carried in a *rebozo* (shawl) that allows easy access for breastfeeding.
- Women may avoid eye contact and may not feel comfortable being touched by a stranger. Nurses need to respect this preference.
- Some women may bring religious icons to the hospital and may want to display them in their rooms.

Muslim

- Modesty is a primary concern; nurses need to protect the client's modesty.
- Muslims often will not eat pork; check all food items before serving.
- Muslims may prefer a same-sex health care provider; male–female touching is prohibited except in an emergency situation.
- A Muslim woman often stays in the house for 40 days after birth, being cared for by female members.
- Most women will breastfeed, but some holidays and religious events call for periods of fasting, which may increase the risk of dehydration or malnutrition.
- Women are exempt from obligatory five-times-daily prayers as long as lochia is present.
- Extended family is likely to be present throughout much of the woman's hospital stay. They may need an empty room to perform prayers without having to leave the hospital.

Native American

- Women may be secretive about pregnancies and choose to not reveal them early.
- Touching is not a typical female behavior, and eye contact is brief.
- Resent being hurried and need time for sitting and talking.
- Most mothers breastfeed and practice birth control.

Giger, J. N. (2019). *Transcultural nursing: Assessment and intervention* (8th ed.). Elsevier; Goldman, N., & Trimmer, K. (2019). Towards a culturally inclusive model of care: Quality practice and care through the lens of a practicing nurse. In K. Trimmer, T. Newman, & F. Padro (Eds.), *Ensuring quality in professional education* (*Vol. 1*). Springer Nature; and Stevens, S. (2019). *Evidence-based obstetric nursing*. Kendall Hunt Publishing Company.

Applications of Cold and Heat

COLD

An ice pack is commonly the first measure used after a vaginal birth to relieve perineal discomfort from edema, an episiotomy, or a laceration. An ice pack can minimize edema, reduce inflammation, decrease capillary permeability, and reduce nerve conduction to the site. It is applied during the fourth stage of labor and can be used for the first 24 hours to reduce perineal edema and to prevent hematoma formation, thus reducing pain and promoting healing. Ice packs are wrapped in a disposable covering or clean washcloth and are applied to the perineal area. Usually the ice pack is applied intermittently for 20 minutes and removed for 10 minutes. Many commercially prepared ice packs are available, but a surgical glove filled with crushed ice and covered can also be used if the mother is not allergic to latex. Ensure that the ice pack is changed frequently to promote good hygiene and to allow for periodic assessments.

HEAT

The **peribottle** is a plastic squeeze bottle filled with warm tap water that is sprayed over the perineal area after each voiding and before applying a new perineal pad. Usually the peribottle is introduced to the woman when she is assisted to the bathroom to freshen up and void for the first time—in most instances, once vital signs are stable after the first hour. Provide the woman with instructions on how and when to use the peribottle. Reinforce this practice each time she changes her pad, voids, or defecates, making sure that she understands to direct the flow of water from front to back. The woman can take the peribottle home and use it over the next several weeks until her lochia discharge stops. The peribottle can be used by women who had either vaginal or cesarean births to provide comfort and hygiene to the perineal area.

After the first 24 hours, a sitz bath with room temperature water may be prescribed and substituted for the ice pack to reduce local swelling and promote comfort for an episiotomy, perineal trauma, or inflamed hemorrhoids. The change from cold to room temperature

therapy enhances vascular circulation and healing. Before using a sitz bath, the woman should cleanse the perineum with a peribottle or take a shower using mild soap.

The use of hydrotherapy is the external use of any form of water for health promotion or treatment with varying temperatures, duration, and application sites (Yadav et al., 2019). Most health care agencies use plastic disposable sitz baths that women can take home. The plastic sitz bath consists of a basin that fits on the commode; a bag filled with warm water is hung on a hook and connected via a tube onto the front of the basin (Fig. 16.6). Teaching Guidelines 16.1 highlights the steps in using a sitz bath.

TEACHING GUIDELINES 16.1
Using a Sitz Bath

1. Close clamp on tubing before filling bag with water to prevent leakage.
2. Fill sitz bath basin and plastic bag with room-temperature water (comfortable to touch).
3. Place the filled basin on the toilet with the seat raised and the overflow opening facing toward the back of the toilet.
4. Hang the filled plastic bag on a hook close to the toilet or an IV pole.
5. Attach the tubing to the opening on the basin.
6. Sit on the basin positioned on the toilet seat and release the clamp to allow warm water to irrigate the perineum.
7. Remain sitting on the basin for approximately 15 to 20 minutes.
8. Stand up and pat the perineum area dry. Apply a clean peripad.
9. Tip the basin to remove any remaining water and flush the toilet.
10. Wash the basin with warm water and soap, and dry it in the sink.
11. Store basin and tubing in a clean, dry area until the next use.
12. Wash hands with soap and water.

FIGURE 16.6. Sitz bath setup.

Advise the woman to use the sitz bath several times daily to provide hygiene and comfort to the perineal area. Encourage her to continue this measure after discharge. Some facilities have hygienic sitz baths called Suri-Gators in the bathroom that spray an

antiseptic, water, or both onto the perineum. The woman sits on the toilet with legs apart so that the nozzle spray reaches her perineal area.

Keep in mind that tremendous hemodynamic changes are taking place within the mother during this early postpartum period, and her safety must be a priority. Fatigue, blood loss, the effects of medications, and lack of food may cause her to feel weak when she stands up. Assisting the woman to the bathroom to instruct her on how to use the peribottle and sitz bath is necessary to ensure her safety. Many women become light-headed or dizzy when they get out of bed and need direct physical assistance. Staying in the woman's room, ensuring that the emergency call light is readily available, and being available if needed during this early period will ensure safety and prevent accidents and falls.

Topical Preparations

Several treatments may be applied topically for temporary relief of perineal pain and discomfort. One such treatment is a local anesthetic spray such as benzocaine topical. These agents numb the perineal area and are used after cleansing the area with water via the peribottle and/or a sitz bath.

Postpartum women are predisposed to hemorrhoid development due to pressure during vaginal birth, constipation, relaxation of the smooth muscles in vein walls, and impaired blood return, all related to increased pressure from the heavy gravid uterus. Nonpharmacologic measures to reduce hemorrhoid discomfort include ice packs, ice sitz baths, and application of cool witch hazel pads. The pads are placed at the rectal area, between the hemorrhoids and the perineal pad. These pads cool the area, help relieve swelling, and minimize itching. Pharmacologic methods used to reduce hemorrhoid pain include local anesthetics (dibucaine) or steroids (hydrocortisone acetate). Prevention or correction of constipation, encouraging the use of the side-lying position, proper toileting habits, assuming positions that minimize putting pressure on

the hemorrhoids, and not straining during defecation will be helpful in reducing discomfort (King et al., 2019).

The first few days of life are a critical period to facilitate breastfeeding. Nurses must have a thorough knowledge of breastfeeding techniques in order to minimize interferences and discomfort. Nipple pain is the second most common reason for early weaning, exceeded only by insufficient milk supply (de Barros et al., 2019). Nipple pain is difficult to treat, though a wide variety of topical creams, ointments, and gels are available to do so. This group includes beeswax, glycerin-based products, petrolatum, lanolin, and hydrogel products. Many women find these products comforting. Beeswax, glycerin-based products, and petrolatum all need to be removed before breastfeeding. These products should be avoided in order to limit infant exposure because the process of removal may increase nipple irritation. Applying expressed breast milk to nipples and allowing it to dry has been suggested to reduce nipple pain. Usually the pain is due to an incorrect latch and/or removal of the nursing infant from the breast. Early assistance with breastfeeding to ensure correct positioning can help prevent nipple trauma.

Analgesics

Analgesics such as acetaminophen and oral nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen or naproxen are prescribed to relieve mild postpartum discomfort. For moderate to severe pain, a narcotic analgesic such as codeine or oxycodone in conjunction with aspirin or acetaminophen may be prescribed. Instruct the woman about adverse effects of any medication prescribed. Common adverse effects of oral analgesics include dizziness, light-headedness, nausea and vomiting, constipation, and sedation (Skidmore-Roth, 2021).

Also inform the woman that the drugs are secreted in breast milk. Nearly all medications that the mother takes are passed into her breast milk; however, mild analgesics (e.g., acetaminophen or ibuprofen) are considered relatively safe for breastfeeding mothers (King et al., 2019). Administering a mild analgesic approximately an

hour before breastfeeding will usually relieve afterpains and/or perineal discomfort.

Assisting with Elimination

The bladder is edematous, hypotonic, and congested immediately postpartum. Consequently, bladder distention, incomplete emptying, and inability to void are common. A full bladder interferes with uterine contraction and may lead to hemorrhage, because it will displace the uterus out of the midline. Encourage the woman to void. Often, assisting her in assuming the normal voiding position on the commode facilitates this. If the woman has difficulty voiding, pouring warm water over the perineal area, hearing the sound of running tap water, blowing bubbles through a straw, taking a warm shower, drinking fluids, providing her with privacy, or placing her hand in a basin of warm water may stimulate voiding. If these actions do not stimulate urination within 4 to 6 hours after giving birth, catheterization may be needed. Palpate the bladder for distention and ask the woman if she is voiding in small amounts (less than 100 mL) frequently (retention with overflow). If catheterization is necessary, use sterile technique to reduce the risk of infection.

Constipation is one of the most common postpartum problems. Decreased bowel motility during labor, high iron content in prenatal vitamins, postpartum fluid loss, and the adverse effects of pain medications and/or anesthesia may predispose the postpartum woman to constipation. In addition, the woman may fear that bowel movements will cause pain or injury, especially if she had an episiotomy or a laceration that was repaired with sutures.

The choice of treatments for postpartum constipation remains a challenge. Usually a stool softener, such as docusate, with or without a laxative might be helpful if the client has difficulty with bowel elimination. Other measures, such as ambulating and increasing fluid and fiber intake, may also help. Nutritional instruction might include increasing fruits and vegetables in the diet; drinking plenty of fluids (8 to 12 c daily) to keep the stool soft; drinking small amounts of prune juice and/or hot liquids to stimulate peristalsis; eating high-

fiber foods such as bran cereals, whole grains, dried fruits, fresh fruits, and raw vegetables; and walking daily.

Promoting Activity, Rest, and Exercise

The postpartum period is an ideal time for nurses to promote the importance of physical fitness, help women incorporate exercise into their lifestyles, and encourage them to overcome barriers to exercise. The lifestyle changes that occur postpartum may affect a woman's health for decades. Early ambulation is encouraged to reduce the risk of thromboembolism and to improve strengthening.

Many changes occur postpartum, and caring for a newborn alters the woman's eating and sleeping habits, work schedules, and time allocation. Postpartum fatigue is common during the early days after childbirth, and it may continue for weeks or months. Having adequate sleep is critical for new mothers because shorter sleep time, a high percentage of sleep disturbances, and greater fatigue are associated with depressive symptoms in postpartum women (Stewart & Vigod, 2019). Working partners with newborns experience fatigue during early parenthood and are unable to recover due to interrupted and poor sleep patterns. This sleep deficit can compromise their work safety and can also have long-term adverse effects for years (Richter et al., 2019). For women, it affects the mother's relationships with significant others and her ability to fulfill household and child care responsibilities. Be sure that the mother recognizes her need for rest and sleep and is realistic about her expectations. Some suggestions include:

- Nap when the infant is sleeping because getting uninterrupted sleep at night is difficult.
- Reduce participation in outside activities, and limit the number of visitors.
- Determine the infant's sleep–wake cycles and attempt to increase wakeful periods during the day so the baby sleeps for longer periods at night.
- Eat a balanced diet to promote healing and to increase energy levels.

- Share household tasks to conserve energy.
- Ask the partner or other family members to provide infant care during the night periodically so that mothers can get an uninterrupted night of sleep if they are not breastfeeding.
- Review the family's daily routine, and try to "cluster" activities to conserve energy and promote rest.

The demands of parenthood may reduce or prevent exercise in even the most committed person. A targeted exercise program and proper body mechanics can help new mothers deal with the physical challenges of motherhood. Emphasize the benefits of a regular exercise program, which include:

- Helps the woman lose pregnancy weight
- Reduces the risk of obesity later in life
- Increases overall postpartum well-being
- Increases energy level so the woman can cope with her new responsibilities
- Speeds the return to prepregnant size and shape
- Reduces risk of postpartum depression
- Reduces risk of constipation
- Reduces mental fatigue
- Provides an outlet for stress (Isaacs, 2019)

Overweight and obesity constitute an epidemic in the United States. Obesity is a risk factor for numerous conditions, including diabetes, hypertension, high cholesterol, stroke, heart disease, cancer, and arthritis. More than one third of American women are overweight (ACOG, 2019a). Although the average gestational weight gain is small (approximately 25 to 35 lb), excess weight gain and failure to lose weight after pregnancy are important predictors of long-term obesity. The postpartum period is a vulnerable time for excessive weight retention, particularly for the increasing number of women who are overweight at the start of pregnancy and subsequently find it difficult to lose the additional weight gained during pregnancy. Breastfeeding and exercise may help to control weight in the long term (Walker et al., 2019).

TAKE NOTE!

Women who are unable to return to a healthy weight by 6 months postpartum increase their risk factors for the development of chronic diseases including metabolic syndrome, obesity, and cardiovascular disease (Siegel et al., 2019). Encourage women to lose pregnancy weight by 6 months postpartum, and refer those who don't to community weight loss programs.

The postpartum woman may face some obstacles to exercising, including physical changes (ligament laxity), competing demands (newborn care), lack of information about weight retention (inactivity equates to weight gain), and stress incontinence (leaking of urine during activity).

A healthy woman with an uncomplicated vaginal birth can resume light exercise in the immediate postpartum period. Advise the woman to start slowly and increase the level of exercise over a period of several weeks as tolerated. Infant strollers and carriers may be an option for some women, allowing them to walk with their newborns for exercise. Jogging strollers can be used later when the infant is 6 to 12 months old and can hold their head up. Also, exercise videos and home exercise equipment allow mothers to work out while the newborn naps.

Exercising after giving birth promotes feelings of well-being and restores muscle tone lost during pregnancy. Routine exercise should be resumed gradually, beginning with pelvic floor exercises on the first postpartum day and by the second week, progressing to abdominal, buttock, and thigh-toning exercises. Most postpartum women fail to meet national guidelines for physical activity which may elevate their risk for morbidity and contribute to the intergenerational impact of obesity on their offspring (Jordan et al., 2019). Walking is an excellent form of early exercise as long as the woman avoids jarring and bouncing movements, because joints do not stabilize until 6 to 8 weeks postpartum. Exercising too much too soon can cause the woman to bleed more, and her lochia may return to bright red. If this occurs, instruct the woman to stop exercising and rest lying down until the bleeding slows. This increase in bleeding

should be a warning to the woman that she is overextending herself and needs to slow down her exercise routine.

Recommended exercises for the first few weeks postpartum include abdominal breathing, head lifts, modified sit-ups, double knee roll, and pelvic tilt (Teaching Guidelines 16.2). The number of exercises and their duration is gradually increased as the woman gains strength.

TEACHING GUIDELINES 16.2

Postpartum Exercises

Abdominal Breathing

1. While lying on a flat surface (floor or bed), take a deep breath through your nose, and expand your abdominal muscles (they will rise up from your midsection).
2. Slowly exhale and tighten your abdominal muscles for 3 to 5 seconds.
3. Repeat this several times.

Head Lift

1. Lie on a flat surface with knees flexed and feet flat on the surface.
2. Lift your head off the flat surface, tuck it onto your chest, and hold for 3 to 5 seconds.
3. Relax your head and return to the starting position.
4. Repeat this several times.

Modified Sit-Ups

1. Lie on a flat surface and raise your head and shoulders 6 to 8 in so that your outstretched hands reach your knees.
2. Keep your waist on the flat surface.
3. Slowly return to the starting position.
4. Repeat, increasing in frequency as your comfort level allows.

Double Knee Roll

1. Lie on a flat surface with your knees bent.
2. While keeping your shoulders flat, slowly roll your knees to your right side to touch the flat surface (floor or bed).
3. Roll your knees back over your body to the left side until they touch the opposite side of the flat surface.
4. Return to the starting position on your back and rest.
5. Repeat this exercise several times.

Pelvic Tilt

1. Lie on your back on a flat surface with your knees bent and your arms at your side.

2. Slowly contract your abdominal muscles while lifting your pelvis up toward the ceiling.
3. Hold for 3 to 5 seconds and slowly return to your starting position.
4. Repeat several times.

Remember that cultures have different attitudes toward exercise. Some cultures (e.g., Haitian, Arab American, Chinese, and Mexican) expect new mothers to observe a specific period of bed rest or activity restriction; thus, it would be inappropriate to recommend active exercise during the early postpartum period (Giger, 2019).

Preventing Stress Incontinence

Urinary incontinence is a condition in which the woman experiences involuntary leakage of urine. Of all parous women, 25% to 50% develop some degree of pelvic prolapse in their lifetime that is associated with stress incontinence (ACOG, 2019b). Stress incontinence causes reduced quality of life and withdrawal from fitness and exercise activities typically. Research suggests that having a vaginal delivery results in direct pelvic muscle trauma and disruption of fascial supports and also causes damage to the levator ani muscle and pudendal nerve injury. Offering pelvic floor muscle exercise instruction to all women during their first pregnancy and again after having a vaginal birth is recommended by the National Institute for Health and Care Excellence (NICE) guidelines. Nurses can offer them as a first-line intervention in the prevention of urinary incontinence postpartum (Swearingen & Wright, 2019). The more vaginal deliveries a woman has had, the more likely she is to have stress incontinence. Stress incontinence can occur with any activity that causes an increase in intra-abdominal pressure. Postpartum women might consider low-impact activities such as walking, biking, swimming, or low-impact aerobics so they can resume physical activity while strengthening the pelvic floor.

Suggestions to prevent stress incontinence are:

- Start a regular program of pelvic floor muscle training exercises after childbirth.
- Lose weight if necessary; obesity is associated with stress incontinence.
- Avoid smoking, and limit the intake of alcohol and caffeinated beverages, which irritate the bladder.
- Adjust fluid intake to produce a 24-hourly urine output of 1,000 to 2,000 mL.

Pelvic floor exercises (Kegel exercises) help strengthen the pelvic floor muscles if done properly and regularly (Soave et al., 2019). These pelvic floor strengthening exercises were originally developed by Dr. Arnold Kegel in the 1940s as a method of controlling incontinence in women after childbirth. The principle behind these exercises is that strengthening the muscles of the pelvic floor improves urethral sphincter function.

While providing postpartum care, instruct women about primary prevention of stress incontinence by discussing the value and purpose of pelvic floor muscle exercises. Approach the subject sensitively, avoiding the term *incontinent*. The terms *leakage*, *loss of urine*, or *bladder control issues* are more acceptable to most women.

TAKE NOTE!

When properly performed, pelvic floor exercises have been effective in preventing or improving urinary continence (Soave et al., 2019).

Women can perform pelvic floor exercises, doing 10 5-second contractions whenever they change diapers, talk on the phone, or watch TV. Teach the woman to perform pelvic floor exercises properly; help her identify the correct muscles by trying to stop and start the flow of urine when sitting on the toilet (Teaching Guidelines 16.3). Pelvic floor exercises can be done without anyone knowing.

TEACHING GUIDELINES 16.3

Performing Pelvic Floor Muscle Training Exercises

1. Identify the correct pelvic floor muscles by contracting them to stop the flow of urine while sitting on the toilet.
2. Repeat this contraction several times to become familiar with it.
3. Start the exercises by emptying the bladder.
4. Tighten the pelvic floor muscles and hold for 10 seconds.
5. Relax the muscles completely for 10 seconds.
6. Perform 10 exercises at least three times daily. Progressively increase the number you perform.
7. Perform the exercises in different positions, such as standing, lying, and sitting.
8. Keep breathing during the exercises.
9. Don't contract your abdominal, thigh, leg, or buttocks muscles during these exercises.
10. Relax while doing pelvic floor muscle training exercises, and concentrate on isolating the right muscles.
11. Attempt to tighten your pelvic muscles before sneezing, jumping, or laughing.
12. Remember that you can perform these exercises anywhere without anyone noticing.

Assisting with Self-Care Measures

Demonstrate and discuss with the woman ways to prevent infection during the postpartum period. Because she may experience lochia drainage for as long as a month after childbirth, describe practices to promote well-being and healing. These measures include:

- Frequently change perineal pads, applying and removing them from front to back to prevent spreading contamination from the rectal area to the genital area.
- Avoid using tampons after giving birth to decrease the risk of infection.
- Shower once or twice daily using a mild soap. Avoid using soap on nipples.

- Use a sitz bath after every bowel movement to cleanse the rectal area and relieve enlarged hemorrhoids.
- Use the peribottle filled with warm water after urinating and before applying a new perineal pad.
- Avoid tub baths for 4 to 6 weeks until joints and balance are restored to prevent falls.
- Wash your hands before changing perineal pads, after disposing of soiled pads, and after voiding (King et al., 2019).

To reduce the risk of infection at the episiotomy site, reinforce proper perineal care with the client, showing her how to rinse her perineum with the peribottle after she voids or defecates. Stress the importance of always patting gently from front to back and washing her hands thoroughly before and after perineal care. For hemorrhoids, have the client apply witch hazel-soaked pads, ice packs to relieve swelling, or hemorrhoidal cream or ointment if ordered.

Ensuring Safety

One safety concern during the postpartum period is orthostatic hypotension. When the woman rapidly moves from a lying or sitting position to a standing one, her blood pressure can suddenly drop, causing her pulse rate to increase. She may become dizzy and faint. Be aware of this problem and initiate the following safeguards:

- Check blood pressure first before ambulating the client.
- Check for low hemoglobin and hematocrit on lab work before ambulating client.
- Elevate the head of the bed for a few minutes before ambulating the client.
- Have the client sit on the side of the bed for a few moments before getting up.
- Help the client to stand up, and stay with her.
- Ambulate alongside the client and provide support if needed.
- Frequently ask the client how her head feels.
- Stay close by to assist if she feels light-headed.

Additional topics to address orthostatic hypotension that may concern infant safety include instructing the woman to place the newborn back in the crib on their back if she is feeling sleepy to prevent a fall. If the woman falls asleep while holding the infant, she might drop them. Also, instruct mothers to keep the door to the room closed when their infant is in the room with them. They should check the identification of anyone who enters their room or who wants to take the infant out of the room. This will prevent infant abduction.

Counseling about Sexuality and Contraception

Pregnancy and childbirth are special periods in a woman's life that involve significant physical, hormonal, psychological, social, and cultural changes that may influence her own sexuality as well as the health of a couple's sexual relationship. This is often a time period filled with excitement, changes, and challenges. Mothers often face changes in their own sexuality in their adjustment to motherhood. Sexuality is an important part of every woman's life. Women want to get back to "normal" as soon as possible after giving birth, but a couple's sexual relationship cannot be isolated from the psychological and psychosocial adjustments that both partners are going through.

Childbirth is a significant life transition that has a measurable impact on postpartum women's sexual function. There are physical, psychological, and contextual factors that contribute to the change in many women's sex lives after experiencing childbirth. Postpartum women may hesitate to resume sexual relations for a number of reasons. Many postpartum women have fatigue, weakness, loss of sexual desire, perception of decreased attractiveness, change in body appearance, vaginal bleeding, perineal discomfort, hemorrhoids, sore breasts, decreased vaginal lubrication resulting from low estrogen levels, and dyspareunia. Fatigue, the physical demands made by the infant, and the stress of new roles and responsibilities may stress the emotional reserves of couples. New parents may not get much privacy or rest, both of which are necessary for sexual pleasure (Jordan et al., 2019).

Partners may feel they now have a secondary role within the family, and they may not understand the mother's daily routine. The delicate nature of postpartum sexuality makes it difficult for couples to discuss. These issues, combined with the mother's increased investment in the mothering role, can strain the couple's sexual relationship.

Although couples are reluctant to ask, they often want to know when they can safely resume sexual intercourse after childbirth. Typically, sexual intercourse can be resumed once bright red bleeding has stopped and the perineum is healed from an episiotomy or lacerations. This is usually by the third to the sixth week postpartum. However, there is no set, prescribed time at which to resume sexual intercourse after childbirth. There is no scientific basis for the traditional recommendation to delay sexual activity until the 6-week postpartum check-up. Each couple must set their own time frame when they feel it is appropriate to resume sexual intercourse. Despite fears and myths about sexual activity during pregnancy, maintaining a couple's sexual interactions throughout pregnancy and the postpartum period can promote sexual health and well-being and a greater depth of intimacy.

Postpartum sexual health and sexual problems are common; they may receive little attention from health care providers during the postpartum period, but they need to be addressed (Saydam et al., 2019). When counseling the couple about sexuality, determine what knowledge and concerns the couple have about their sexual relationship. Inform the couple that fluctuations in sexual interest are normal. Reassure the breastfeeding mother that she may notice a let-down reflex during orgasm and find her breasts are sensitive when touched by her partner. Also inform the couple about how to prevent discomfort. Precoital vaginal lubrication may be impaired during the postpartum period, especially in women who are breastfeeding. Use of water-based gel lubricants can help. Pelvic floor muscle training exercises, in addition to preventing stress incontinence, can also enhance sensation.

Initiation of contraception during the postpartum period is important to prevent unintended pregnancy and short birth intervals,

which can lead to negative health outcomes for the mother and infant. Contraceptive options should be included in the discussions with the couple so that they can make an informed decision before resuming sexual activity. Many couples are overwhelmed with the amount of new information given to them during their brief hospitalization, so many are not ready for a lengthy discussion about contraceptives. Presenting a brief overview of the options, along with literature, may be appropriate. It may be suitable to ask them to think about contraceptive needs and preferences and advise them to use a barrier method (condom with spermicidal gel or foam) until they choose another form of contraception. This advice is especially important if the follow-up appointment will not occur for 4 to 6 weeks after childbirth, because many couples will resume sexual activity before this time. Some postpartum women ovulate before their menstrual period returns and thus need contraceptive protection to prevent another pregnancy.

Use of hormonal contraceptives in breastfeeding women raises questions about the effect on milk production and the risk to the mother. Progestin-only contraceptives are the hormonal contraceptives of choice because they appear to have no effect on the quality or quantity of milk. Combined estrogen-progestin contraceptive pills are not ideal during lactation because they reduce the quantity and quality of milk and may increase the risk of DVT in the already hypercoagulable postpartum period. If used at all, they should not be started until 6 weeks postpartum and after lactation is well established (Resnik et al., 2019).

Open and effective communication is necessary for effective contraceptive counseling so that information is clearly understood. Provide clear, consistent information appropriate to the woman and her partner’s language, culture, and educational level. This will help the couple select the best contraceptive method. Research supports that postpartum education about contraception leads to more contraception use and fewer unplanned pregnancies and that both short-term and multiple-contact interventions had effects. The use of contraceptives was highest when contraceptive counseling was

provided prenatally and again in the postpartum period (Toscano et al., 2019).

Promoting Maternal Nutrition

During postpartum, it is critical for women to develop healthy eating patterns to adequately support breastfeeding, optimize weight, and become good role models to their children. The postpartum period can be a stressful one for myriad reasons, such as fatigue, the physical stress of pregnancy and birth, and the nonstop work required to take care of the newborn and to meet the needs of other family members. As a result, the new mother may ignore her own nutrition needs. Whether she is breastfeeding or bottle-feeding, encourage the new mother to take good care of herself and eat a healthy diet so that the nutrients lost during pregnancy can be replaced and she can return to a healthy weight. In general, nutrition recommendations for the postpartum woman include:

- Eat a wide variety of foods with high nutrient density.
- Eat meals that require little or no preparation.
- Make sure all foods are well-cooked to prevent bacteria ingestion.
- Avoid high-fat fast foods.
- Drink plenty of fluids daily—at least 2,500 mL (approximately 84 oz).
- Avoid fad weight-reduction diets and harmful substances such as alcohol, tobacco, and drugs.
- Avoid excessive intake of fat, salt, sugar, and caffeine.
- Eat the recommended daily servings from each food group (Box 16.4).

Nutrition for the Breastfeeding Mother

The breastfeeding mother's nutritional needs are higher than they were during pregnancy. The mother's diet and nutritional status influence the quantity and quality of breast milk. To meet the needs for breast milk production, the woman's nutritional needs increase as follows:

BOX 16.4 Recommendations for Nutrition During the Postpartum Period

Recommendations for the Lactating Woman from the *MyPlate* Food Guide

- Fruits: 4 servings
- Vegetables: 4 servings
- Milk: 4 to 5 servings
- Drink a glass of water every time you breastfeed.
- Bread, cereal, pasta: 12 or more servings
- Meat, poultry, fish, eggs: 7 servings
- Fats, oils, and sweets: 5 servings (USDA, 2019c)

General Dietary Guidelines for Americans from the *MyPlate* Food Guide for the Nonlactating Woman

- Fruits: Make half of your plate fruits and vegetables.
- Vegetables: Eat red, orange, and dark green vegetables.
- Milk: Switch to skim milk or 1%.
- Breads, grains, and cereals should be whole grains.
- Meat, poultry, fish, and eggs: Eat seafood twice a week and beans, which are high in fiber.
- Eat the right amount of calories for you; enjoy your food, but eat less.
- Be physically active with activities you enjoy.
- Fats, oils, and sweets: Cut back.
- Use food labels to help you make better choices.

(U.S. Department of Agriculture [USDA], 2019b).

- *Calories:* +500 cal/day for the first and second 6 months of lactation
- *Protein:* +20 g/day, adding an extra 2 c of skim milk
- *Calcium:* +400 mg daily—consumption of four or more servings of milk
- *Iodine:* 290 µg daily—dairy products, seafood and iodized salt
- *Fluid:* +2 to 3 qt of fluids daily (milk, juice, or water); no sodas

Some foods eaten by the breastfeeding mother may affect the flavor of the breast milk or cause gastrointestinal problems for the infant. Not all infants are affected by the same foods. It is suggested that the mother identify the food item that may be causing a problem for the infant and reduce or eliminate her intake of it.

Nutritional needs for breastfeeding mothers are based on the nutritional content of breast milk and the energy expended to produce it. If intake of calories exceeds the energy expended, weight gain occurs. The highest incidence of obesity in women occurs during the childbearing years. Women need to be made aware that weight gained during the reproductive years will have a negative impact on health with age. Nurses can assist women in their postpartum weight management program by assessing their readiness to change to lose their pregnancy weight gain; assessing their breastfeeding status, dietary intake, and activity levels; and assessing them for stress and depressive symptoms, which might hinder weight loss (Swearingen & Wright, 2019).

TAKE NOTE!

During a woman's brief stay in a health care facility, she may demonstrate a healthy appetite and eat well. Nutritional problems usually start at home when the mother needs to make her own food selections and prepare her own meals. This is a crucial area to address during follow-up.

Supporting the Woman's Choice of Infant Feeding Method

Both national and international health care organizations have released position statements in support of breastfeeding, and nurses should be encouraging it as part of evidence-based practice (Alexander et al., 2021). Although there is considerable evidence that breastfeeding has numerous health benefits for both mother and infant, many mothers choose to feed their infants formula for the first year of life. Nurses must be able to deliver sound, evidence-based information to help the new mother choose the best way to feed her infant and must support her in her decision. Many factors affect a woman's choice of feeding method, such as culture, employment demands, support from significant others and family, and knowledge base. Although breastfeeding is encouraged, be sure that couples have the information they need to make informed decisions.

Encouraging breastfeeding to improve the child's health is an important message for nurses to impart to new mothers (Evidence-Based Practice 16.2). However, the woman's autonomy is paramount, and nurses must support and respect her choice.

Women Who Should Not Breastfeed

Breastfeeding is the optimal way to feed infants, benefitting both women and infants. However, certain women should not breastfeed. Drugs such as antithyroid drugs, antineoplastic drugs, alcohol, active herpes infection on the breasts, or street drugs (methamphetamines, cocaine, PCP, marijuana) enter the breast milk and can harm the infant, so women taking these substances should not breastfeed. To prevent human immunodeficiency virus (HIV) transmission to the newborn, women who are HIV-positive should not breastfeed. Other contraindications to breastfeeding include a newborn with an inborn error of metabolism such as galactosemia or phenylketonuria (PKU); active, untreated tuberculosis; or a mother with a serious mental health disorder that would prevent her from remembering to feed the infant consistently (Meek, 2019).

Providing Assistance with Breastfeeding and Bottle-Feeding

First-time mothers often have many questions about feeding, and even women who have had experience with feeding may have questions. Regardless of whether the postpartum woman is breastfeeding or bottle-feeding her newborn, she can benefit from instruction.

PROVIDING ASSISTANCE WITH BREASTFEEDING

The American Academy of Pediatrics (AAP, 2019) recommends breastfeeding for all full-term newborns. Exclusive breastfeeding is sufficient to support optimal growth and development for approximately the first 6 months of life. Breastfeeding should be

continued for at least the first year of life and beyond for as long as mutually desired by mother and child. Educating a mother about breastfeeding will increase the likelihood of a successful breastfeeding experience.

EVIDENCE-BASED PRACTICE 16.2

Breastfeeding Initiation and Duration and Child Health Outcomes in the First Baby Study

STUDY

According to the AAP, there is sufficient evidence that breastfeeding provides the best nutrition for newborns and should be continued for the first 6 months followed by continued breastfeeding during the first year or more as solid foods are introduced. The short- and long-term benefits of breastfeeding are well supported, showing evidence of reduced incidences of childhood illnesses. Although extensive research touts the medical benefits of breastfeeding, research examining the relationship between breastfeeding and infant weight gain has been mixed. Childhood obesity rates have tripled in America and doubled worldwide. The objective of this study was to investigate potential associations between breastfeeding duration on childhood illnesses and child weight through the age of 3 years.

Findings

The sample size included 1,626 women who were placed in either a breastfeeding group or nonbreastfeeding group. Measurements were obtained every 6 months regarding their breastfeeding continuation, reported childhood illnesses and their children's height and weight. Body mass index (BMI) was calculated at each interval. A logistic regression model was used to analyze the data. It was found that the longer the duration of breastfeeding, the lower the incidence of reported childhood illnesses and lower rate of overweight and obese children when compared to the nonbreastfeeding group.

Nursing Implications

This study provides valuable insight into the relationship between breastfeeding and child health outcomes. In general, there were fewer reported illnesses and overweight and obese children at the age of 3 within the breastfeeding group. In addition, the longer the duration that the mother breastfed her child, the fewer childhood illnesses were reported. Efforts to promote continued breastfeeding throughout a child's first year of life by nurses is a worthwhile endeavor to improve the overall health of children. Additionally, the lower rate of childhood obesity would be impacted. Nurses can impart this study's findings to new mothers on the postpartum unit or prenatally to provide women information as they decide on infant nutrition.

Adapted from Pattison, K. L., Kraschnewski, J. L., Lehman, E., Savage, J. S., Downs, D. S., Leonard, K. S., … Kjerulff, K. H. (2019). Breastfeeding initiative and duration and child health outcomes in the first baby study. Preventive Medicine, 118, 1–6. https://doi.org/10.1016/j.ypmed.2018.09.020

At birth, all newborns should be quickly dried, assessed, and if stable, placed immediately in uninterrupted skin-to-skin contact (kangaroo care) with the mother. This is good practice whether the mother is going to breastfeed or bottle-feed her infant. Numerous benefits of kangaroo care have been reported related to both the physiologic (thermoregulation, cardiorespiratory stability), and behavioral (sleep, breastfeeding duration, and degree of exclusivity) domains as an effective therapy to relieve procedural pain and improve neurodevelopment. In addition, kangaroo care provides the newborn with optimal physiologic stability, warmth, and opportunities for the first feed (Vittner et al., 2019).

The benefits of breastfeeding for infants are clear (see Chapter 18). To promote breastfeeding, the Baby-Friendly Hospital Initiative, an international program of the World Health Organization (WHO) and the United Nations International Children's Emergency Fund (UNICEF), was started in 1991. This global health promotion initiative was put forth to improve maternal–infant health by

improving rates of exclusive breastfeeding. The initial guidelines have been revised to reflect more evidence-based practice. As part of this program, the hospital or birth center should take the following 10 steps to provide “an optimal environment for the promotion, protection, and support of breastfeeding”:

1. Have a written breastfeeding policy that is communicated to all staff.
2. Ensure that staff have sufficient knowledge, competence, and skills to support breastfeeding.
3. Discuss the importance and management of breastfeeding with pregnant women and their families.
4. Facilitate immediate and uninterrupted skin-to-skin contact, and support mothers in initiating breastfeeding as soon as possible after birth.
5. Support mothers in initiating and maintaining breastfeeding, and manage common difficulties.
6. Demonstrate to all mothers how to initiate and maintain breastfeeding.
7. Encourage breastfeeding on demand.
8. Counsel mothers on the use and risks of feeding bottles, teats, and pacifiers.
9. Establish breastfeeding support groups and refer mothers to them.
10. Enable mothers and their infants to remain together and to practice rooming-in 24 hours a day (Bass et al., 2019; CDC, 2019b; WHO, 2019b).

The nurse is responsible for protecting, promoting, and supporting breastfeeding when appropriate. For the woman who chooses to breastfeed her infant, the nurse or lactation consultant will need to spend time instructing her about how to do so successfully. Many women have the impression that breastfeeding is simple. Although it is a natural process, women may experience some difficulty in breastfeeding their newborns. Nurses can assist mothers in smoothing out this transition. Assist and provide one-to-one instruction to breastfeeding mothers, especially first-time

breastfeeding mothers, to ensure correct technique. Suggestions are highlighted in Teaching Guidelines 16.4.

TAKE NOTE!

Some newborns “latch on and catch on” right away, and others take more time and patience. Inform new mothers about this to reduce their frustration and uncertainty about their ability to breastfeed.

Tell mothers that they need to believe in themselves and their ability to accomplish this task. They should not panic if breastfeeding does not go smoothly at first; it takes time and practice. Additional suggestions to help mothers relax and feel more comfortable breastfeeding, especially when they return home, include:

TEACHING GUIDELINES 16.4

Breastfeeding Suggestions

1. Explain that breastfeeding is a learned skill for both parties.

2. Offer a thorough explanation of the actions involved.
3. Instruct the mother to wash her hands before starting.
4. Inform her that her afterpains will increase during breastfeeding.
5. Make sure the mother is comfortable (pain-free) and not hungry.
6. Tell the mother to start the feeding with an awake and alert infant showing hunger signs.
7. Assist the mother in positioning herself correctly for comfort.
8. Urge the mother to relax to encourage the let-down reflex.

9. Guide the mother's hand to form a "C" to access the breast with thumb on top and other four fingers under the breast.
10. Have the mother lightly tickle the infant's upper lip with her nipple to stimulate the infant to open the mouth wide.
11. Aid her in helping the infant latch on by bringing the infant rapidly to the breast with a wide-open mouth.
12. Show her how to check that the newborn's mouth position is correct, and tell her to listen for a sucking noise.
13. Demonstrate correct removal from the breast, using her finger to break the suction.
14. Instruct the mother on how to burp the infant before changing from one breast to another.
15. Show her different positions, such as cradle and football holds and side-lying positions (see Chapter 18).
16. Reinforce and praise the mother for her efforts.
17. Allow ample time to answer questions and address concerns.
18. Refer the mother to support groups and community resources.

- Select a quiet corner or room where you won't be disturbed.
- Use a rocking chair to soothe both you and your infant.
- Take long, slow deep breaths to relax before nursing.
- Drink water while breastfeeding to replenish body fluids.
- Listen to soothing music while breastfeeding.
- Cuddle and caress the infant while feeding.
- Set out extra cloth diapers within reach to use as burping cloths.
- Allow sufficient time to enjoy each other in an unhurried atmosphere.
- Involve other family members in all aspects of the infant's care from the start.
- Contact a local La Leche League or a nursing mothers' group for continued guidance and support.

Because obesity in America is increasing, it is important for nurses to be knowledgeable about how it impacts breastfeeding and ways to support the obese mother. Research shows that mothers who are obese (have a BMI over 30) are less likely to initiate lactation, have difficulties with latching, have delayed lactogenesis, experience mechanical challenges, and are prone to early cessation of

breastfeeding. Having skin-to-skin contact with their newborns can help these women decrease breastfeeding disparities (Kair et al., 2019). Obesity rates are highest among African American women, who also have the lowest rate of breastfeeding initiation and shortest duration when compared with women of other demographic groups (Chang et al., 2019; CDC, 2019a). Women who are overweight and obese have lowered prolactin responses to infant sucking, thus milk production may be inhibited. Lactation plays a significant role in preventing future obesity in both the mother and the infant (Gatta et al., 2019).

Nurses can assist in managing obesity-related lactation challenges by keeping the mother and newborn together to facilitate early and frequent sucking to trigger prolactin and oxytocin production, which will help negate the obesity-related blunting of the prolactin response. Suggesting a sandwich technique to insert the mother's breast into the newborn's mouth to elicit sucking might be helpful for the mother with large breasts. In the sandwich technique, the mother is taught to grasp her breast by making a "C" with her thumb and index finger. The thumb stabilizes the top of the breast while the remaining four fingers support her breast from below. Massage or pumping the breast may soften and extend the nipple for easier infant latch-on. In short, nurses can make a difference by observing lactation, assessing infant hydration and satisfaction, and reassuring the mother about her breastfeeding capacity.

PROVIDING ASSISTANCE WITH BOTTLE-FEEDING

If the mother or couple has chosen to bottle-feed the newborn, the nurse should respect and support this decision. Discuss with the parents what type of formula they will use. Commercial formulas are classified as cow's milk-based, soy protein-based, or specialized or therapeutic formulas for infants with protein allergies. Commercial formulas can also be purchased in various forms: powdered (must be mixed with water), condensed liquid (must be diluted with equal

amounts of water), ready to use (poured directly into bottles), and prepackaged (ready to use in disposable bottles).

Breast milk is a dynamic fluid with compositional changes occurring throughout the period of lactation that reflects the growth rate and developmental needs of the infant. Infant formula, in contrast, has a static composition intended to meet the nutritional requirements of infants from birth to 12 months of age (Grodner & Dorner, 2020). Nurses need to bring this information to the attention of mothers who choose to formula-feed their infants that changes may be needed in different stages of growth to meet the nutritional needs of the infant.

Newborns need about 100 to 110 cal/kg or approximately 650 cal/day (Sizer & Whitney, 2020). Therefore, explain to parents that a newborn will need 2 to 4 oz to feel satisfied at each feeding. Until about age 4 months, most bottle-fed infants need six feedings a day. After this time, the number of feedings declines to accommodate other foods in the diet, such as fruits, cereals, and vegetables (Sizer & Whitney, 2020). For more information on newborn nutrition and bottle-feeding, see Chapter 18.

When teaching the mother about bottle-feeding, provide the following guidelines:

- Wash hands with hot, soapy water, and dry using a clean or disposable cloth.
- Make sure all bottles, nipples, and other utensils are clean.
- Make feeding a relaxing time, a time to provide both food and comfort to the newborn.
- Use the feeding period to promote bonding by smiling, singing, making eye contact, and talking to the infant.
- Powdered formula mixes more easily and the lumps dissolve faster if you use room-temperature water.
- Store any formula prepared in advance in the refrigerator to keep bacteria from growing.
- Do not microwave formula; the microwave won’t heat it evenly, causing hot spots.
- Always hold the newborn when feeding; never prop the bottle.

- Use a comfortable position when feeding the newborn. Place the newborn in the dominant arm, which is supported by a pillow. Alternately, have the newborn in a semi-upright position supported in the crook of your arm. This position reduces choking and the flow of milk into the middle ear.
- Tilt the bottle so that the nipple and the neck of the bottle are always filled with formula. This prevents the infant from taking in too much air.
- Stimulate the sucking reflex by touching the nipple to the infant's lips.
- Refrigerate any powdered formula that has been combined with tap water.
- Discard any formula not taken; do not keep it for future feedings.
- Burp the infant frequently, and place the baby on their back for sleeping.
- Avoid adding anything to the bottle to encourage fullness, such as cereal.
- Do not force feed at any time; monitor the infant's intake at each feeding.
- Do not dilute powder formula to save money. This can lead to water intoxication.
- Prepared formula should be discarded within 1 hour after feeding an infant (USDA, 2019a).

Teaching about Breast Care

Breasts and nipples do not need special care unless there are specific problems. Regardless of whether the mother is breastfeeding her newborn, urge her to wear a supportive, snug bra 24 hours a day to support enlarged breasts and promote comfort. A woman who is breastfeeding should wear a supportive bra throughout the lactation period. A woman who is not nursing should wear it until engorgement ceases and then should wear a less restrictive one. The bra should fit snugly while still allowing the mother to breathe without restriction. All new mothers should use

plain water to clean their breasts, especially the nipple area; soap is drying and should be avoided.

Assessing the Breasts

Instruct the mother how to examine her breasts daily. Daily assessment includes the milk supply (breasts will feel full as they are filling), the condition of the nipples (red, bruised, fissured, or bleeding), and the success of breastfeeding. The fullness of the breasts may progress to engorgement in the breastfeeding mother if feedings are delayed or breastfeeding is ineffective. Palpating both breasts will help identify whether the breasts are soft, filling, or engorged. A similar assessment of the breasts should be completed on the nonlactating mother to identify any problems, such as engorgement or mastitis.

Alleviating Breast Engorgement

Breast engorgement usually occurs during the first week postpartum. It is a common response of the breasts to the sudden change in hormones and the presence of an increased amount of milk. Reassure the woman that this condition is temporary and usually resolves within 72 hours.

ALLEVIATING BREAST ENGORGEMENT IN THE BREASTFEEDING WOMAN

If the mother is breastfeeding, encourage frequent feedings at least every 2 to 3 hours, using manual expression just before feeding to soften the breast so the newborn can latch on more effectively. Advise the mother to allow the newborn to feed on the first breast until it softens before switching to the other side (La Leche League International, 2020). See Chapter 18 for more information on alleviating breast engorgement and other common breastfeeding concerns.

ALLEVIATING BREAST ENGORGEMENT AND SUPPRESSING LACTATION IN THE BOTTLE-FEEDING WOMAN

If the woman is bottle-feeding, explain that breast engorgement is a self-limiting phenomenon that disappears as increasing estrogen levels suppress milk formation (i.e., lactation suppression). Encourage the woman to use ice packs, to wear a snug, supportive bra 24 hours a day, and to take mild analgesics such as acetaminophen. Encourage her to avoid any stimulation to the breasts that might foster milk production, such as warm showers or pumping or massaging the breasts. Medication is no longer given to hasten lactation suppression because these agents had limited effectiveness and adverse side effects. Teaching Guidelines 16.5 provides tips on lactation suppression.

> **TEACHING GUIDELINES 16.5**
>
> **Suppressing Lactation**
>
> 1. Wear a supportive, snugly fitting bra 24 hours daily, but not one that binds the breasts too tightly or interferes with breathing.
> 2. Suppression may take 5 to 7 days to accomplish.
> 3. Take mild analgesics to reduce breast discomfort.
> 4. Let shower water flow over your back rather than your breasts.
> 5. Avoid any breast stimulation in the form of sucking or massage.
> 6. Drink to quench your thirst. Restricting your fluid intake will not dry up your milk.
> 7. Reduce your salt intake to decrease fluid retention.
> 8. Use ice packs or cool compresses inside the bra to decrease local pain and swelling; change them every 30 minutes (King et al., 2019).

Promoting Family Adjustment and Well-Being

The postpartum period involves extraordinary physiologic, psychological, and sociocultural changes in the life of a woman and

her family. Adapting to the role of a parent is not an easy process. The postpartum period is a “getting-to-know-you” time when parents begin to integrate the newborn into their lives as they reconcile the fantasy child with the real one. This can be a challenging period for families. Nurses play a major role in assisting families with adapting to the changes, promoting a smooth transition into parenthood. Appropriate and timely interventions can help parents adjust to the role changes and promote attachment to the newborn (Fig. 16.7).

For couples who already have children, the addition of a new member may cause role conflict and challenges. The nurse should provide anticipatory guidance about siblings’ potential responses to the new baby, increased emotional tension, child development, and meeting the multiple needs of the expanding family. Although the multiparous woman has had experience with newborns, do not assume that her knowledge is current and accurate, especially if some time has elapsed since her previous child was born. Reinforcing information is important for all families.

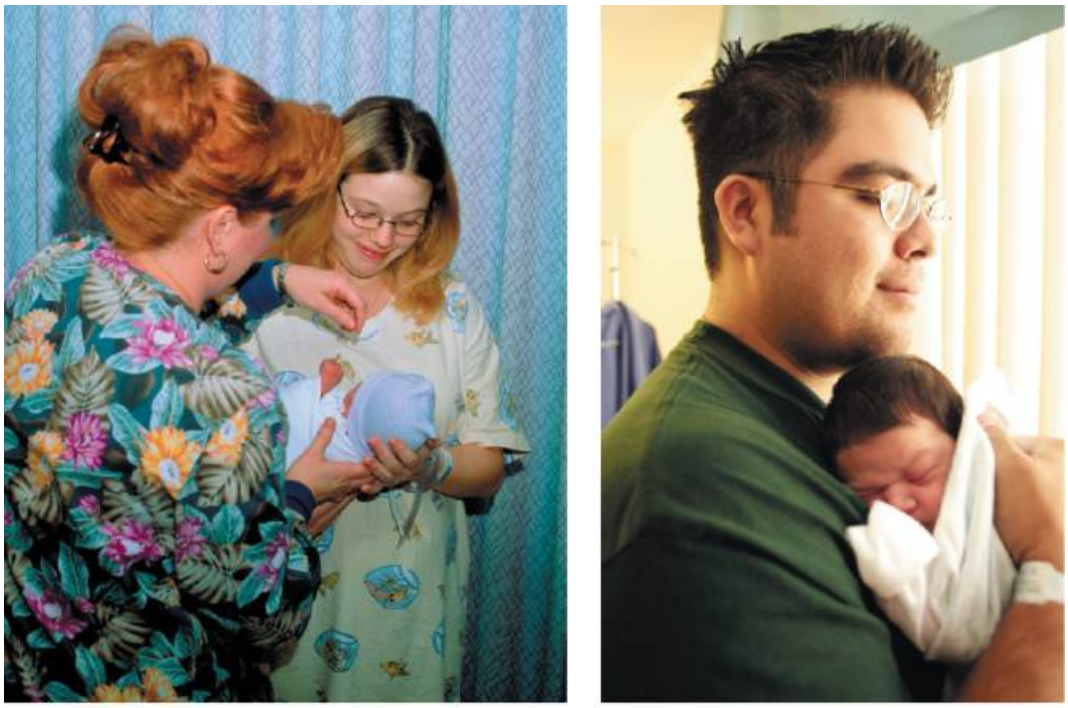
Promoting Parental Roles

Parents’ roles develop and grow when they interact with the newborn (see Chapter 15 for information on parental adaptation). The pleasure they derive from this interaction stimulates and reinforces this behavior. With repeated, continued contact with the newborn, parents learn to recognize cues and understand the newborn’s behavior. This positive interaction contributes to family harmony.

Nurses need to know the stages parents go through as they make their new parenting roles fit into their life experience. Assess the parents for attachment behaviors (normal and deviant), adjustment to the new parental role, family member adjustment, social support system, and educational needs. To promote parental role adaptation and parent–newborn attachment, provide the following nursing interventions:

- Provide as many opportunities as possible for parents to interact with their newborn. Encourage parents to explore, hold, and provide care for their newborn. Praise them for their efforts.

- Model behaviors by holding the newborn close, calling the newborn's name, and speaking positively.
- Speak directly to the newborn in a calm voice while pointing out the newborn's positive features to the parents.
- Evaluate the family's strengths, weaknesses, and readiness for parenting.
- Assess for risk factors such as lack of social support and the presence of stressors.
- Observe the effect of culture on the family interaction to determine healthy family dynamics.
- Monitor parental attachment behaviors to determine whether alterations require referral. Positive behaviors include holding the newborn closely or in an *en face* position, talking to or admiring the newborn, or demonstrating closeness. Negative behaviors include avoiding contact with the newborn, calling them names, or showing a lack of interest in caring for them (see Table 16.1).
- Monitor the parents' coping behaviors to determine alterations that need intervention. Positive coping behaviors include positive conversations between the partners, both parents wanting to be involved with newborn care, and lack of arguments between the parents. Negative behaviors include not visiting, limited conversations or periods of silence, and heated arguments or conflict.



A B C

FIGURE 16.7. Examples of family members carrying out roles to promote adjustment and well-being. **A.** An aunt admiring the newest member of the family. **B.** A father holding his newborn closely on his chest. **C.** Grandparents welcoming the newest member to the family circle.

- Identify the support systems available to the new family and encourage them to ask for help. Ask direct questions about home

or community support. Make referrals to community resources to meet the family's needs.

- Arrange for community home visits in high-risk families to provide positive reinforcement of parenting skills and nurturing behaviors with the newborn.
- Provide anticipatory guidance about the following before discharge to reduce the new parents' frustration:
  - Newborn sleep–wake cycles (they may be reversed)
  - Variations in newborn appearance and developmental milestones (growth spurts)
  - How to interpret crying cues (hunger, wet, discomfort) and what to do about them
  - Sensory enrichment and stimulation (colorful mobile)
  - Signs and symptoms of illness and how to assess for fever
  - Important phone numbers, follow-up care, and needed immunizations
  - Physical and emotional changes associated with the postpartum period
  - Need to integrate siblings into care of the newborn; stress that sibling rivalry is normal and offer ways to reduce it
  - Ways to make time together for the couple

In addition, nurses can help partners feel more competent in assuming their parental role by teaching and providing information (Fig. 16.8). Education can dispel any unrealistic expectations they may have, helping them cope more successfully with the demands of parenthood, thereby fostering a nurturing family relationship.

Explaining Sibling Roles

Sibling adjustment is an important part of family adaptation. It can be overwhelming to a young child to have another family member introduced into their small, stable world. Although most parents try to prepare siblings for the arrival of a new little brother or sister, many young children experience stress. They may view the new infant as competition, or fear that they will receive less of the parents' affection. All siblings need extra attention from their parents and reassurance that they are loved and important. Anticipatory guidance

by nurses can help families navigate these sibling adjustments. Many parents need reassurance that sibling rivalry is normal. Suggest the following to help parents minimize sibling rivalry:

FIGURE 16.8. Father participating in newborn care.

- Expect and tolerate some regression (thumb sucking, bedwetting).
- Explain childbirth in an appropriate way for the child's age.
- Encourage discussion about the new infant during relaxed family times.
- Encourage the sibling(s) to participate in decisions, such as the baby's name and toys to buy.
- Take the sibling on a tour of the maternity suite.
- Buy a T-shirt that says "I'm the big (brother or sister)."
- Spend "special time" with the child.
- Read with the child. Some suggested titles include *Who? A Celebration of Babies* (Harris, 2018); *Poppy's Best Babies* (Eaddy, 2018); *The New Baby* (Mayer, 2019); and *The New Small Person* (Child, 2015).
- Plan time for each child throughout the day.

- Role-play safe handling of a newborn using a doll. Give the preschooler or school-age child a doll to care for.
- Encourage older children to verbalize emotions about the newborn.
- Purchase a gift that the child can give to the newborn.
- Purchase a gift that can be given to the child by the newborn.
- Arrange for the child to come to the hospital to see the newborn (Fig. 16.9).

FIGURE 16.9. Sibling visitation.

- Move the sibling from their crib to a youth bed months in advance of the birth of the newborn.

- Show the older sibling photos of the baby growing. Let them pat the baby beneath the bulge, talk to the baby, and feel the baby kick.
- Make the older sibling feel important by giving them the title, “mommy’s helper.”
- Encourage grandparents to pay attention to the older child when visiting.
- Tell the older sibling that their friends come and go, but siblings are forever.
- Encourage “Do unto others as you would have them do unto you” (Sears & Sears, 2020b).

CONSIDER THIS

Katie and Molly have been excited about having a new baby sister ever since they were told about their mother's pregnancy. The 6-year-old twins are eagerly looking out the front window, waiting for their parents to bring their new sister, Jessica, home. The girls are big enough to help their mother care for their new sibling, and for the past few months they have been fixing up the new nursery and selecting baby clothes. They practiced diapering their dolls—their mother was specific about not using any powder or lotion on Jessica's bottom—and holding them correctly to feed them bottles. Finally, their mother arrives home from the hospital with Jessica in her arms.

The girls notice that their mother is protective of Jessica and watches them carefully when they care for her. They fight over the opportunity to hold her or feed her. What is special to both of them is the time they spend alone with their parents. Although a new family member has been added, the twins still feel special and loved by their parents.

Thoughts: Bringing a new baby into an established family can cause conflict and jealousy. What preparation did the older siblings have before Jessica arrived? Why is it important for parents to spend time with each sibling separately?

Discussing Grandparents' Role

Grandparents can be a source of support and comfort to the postpartum family if effective communication skills are used and roles are defined. The grandparents' role and involvement will depend on how close they live to the family, their willingness to become involved, and cultural expectations of their role. Just as parents and siblings go through developmental changes, so too do grandparents. These changes can have a positive or negative effect on the relationship.

Newborn care, feeding, and child-rearing practices have changed since the grandparents raised the parents. New parents may lack parenting skills but nonetheless want their parents' support without

criticism. A grandparent's "take-charge approach" may not be welcome by new parents who are testing their own parenting roles, and family conflict may ensue. However, many grandparents respect their adult children's wishes for autonomy and remain "resource people" for them when requested.

TAKE NOTE!

Grandparents' involvement can enrich the lives of the entire family if accepted in the right context and dose by the family.

Nurses can assist in the grandparents' role transition by assessing their communication skills, role expectations, and support skills during the prenatal period. Find out whether the grandparents are included in the couple's social support network and whether their support is wanted or helpful. If they are and it is, encourage the grandparents to learn about the parenting, feeding, and child-rearing skills their children have learned in childbirth classes. This information is commonly found in "grandparenting" classes, which introduce new parenting concepts and bring the grandparents up to date on today's childbirth practices.

Teaching about the Postpartum Blues

The postpartum period is typically a happy yet stressful time, because the birth of an infant is accompanied by enormous physical, social, and emotional changes. A sharp fall in hormones can be a predictor of mood changes in the postpartum period. **Postpartum blues** is a phase of emotional lability characterized by crying episodes, irritability, anxiety, confusion, and sleep disorders. Symptoms usually arise within the first few days after childbirth, reaching a peak at 3 to 5 days and spontaneously disappearing within 10 days (Jordan et al., 2019). See Chapter 15 for postpartum blues discussion. Although postpartum blues is usually benign and self-limited, these mood changes can be frightening to the woman. It is prudent to ask the new mother about having pleasure and interest

in things, or feeling predominately down, depressed, or hopeless. Once postpartum blues are determined to be the likely cause of the mood symptoms, the nurse can offer anticipatory guidance that these mood swings are commonly experienced and usually resolve spontaneously within a week, offering reassurance. Women should also be counseled to seek further evaluation if these moods do not resolve within 2 weeks as postpartum depression may be developing (King et al., 2019).

TAKE NOTE!

Postpartum blues have been regarded as brief, benign, and without clinical significance, but several studies have proposed a link between blues and subsequent depression in the 6 months following childbirth (Danko et al., 2019).

Postpartum blues require no formal treatment other than support and reassurance because they do not usually interfere with the woman's ability to function and care for her infant. Nurses can ease a mother's distress by encouraging her to vent her feelings and by demonstrating patience and understanding with her and her family. Suggest that getting outside help with housework and infant care might help her feel less overwhelmed until the blues ease. Provide telephone numbers she can call when she feels down during the day. Making women aware of this disorder while they are pregnant will increase their knowledge about this mood disturbance, which may lessen their embarrassment and increase their willingness to ask for and accept help if it does occur.

The postpartum woman is also at risk for postpartum depression and postpartum psychosis; these conditions are discussed in Chapter 22.

Preparing for Discharge

The WHO recommends that the length of stay in the health care facility should be individualized for each mother and baby but should

be at least 24 hours after birth (2019a). A shortened hospital stay may be indicated if the following criteria are met:

- Mother is afebrile and vital signs are within normal range.
- Lochia is appropriate amount and color for stage of recovery.
- Hemoglobin and hematocrit values are within normal range.
- Uterine fundus is firm; urinary output is adequate.
- ABO blood groups and RhD status are known and if indicated, anti-D immunoglobulin has been administered.
- Surgical wounds are healing, and no signs of infection are present.
- Mother is able to ambulate without difficulty.
- Food and fluids are taken without difficulty.
- Self-care and infant care are understood and demonstrated.
- Family or other support system is available to care for both.
- Mother is aware of possible complications (WHO, 2019a).

Providing Immunizations

Prior to discharge, check the immunity status for rubella for all mothers and give a subcutaneous injection of rubella vaccine if they are not serologically immune (titer less than 1:8). Be sure that the client signs a consent form to receive the vaccine. The rubella vaccine should not be given to any woman who is immunocompromised, and the immune status of her close contacts needs to be determined before any vaccine is administered to her to prevent a more virulent case of the vaccine-preventable illness or potential death. With the recent increase in the number of cases of pertussis in infants younger than 3 months of age, the Centers for Disease Control and Prevention (CDC) is also recommending vaccination with (Tdap) (combination of diphtheria, pertussis, and tetanus vaccines) for the mother during her postpartum stay (CDC, 2019c). If it is flu season, the inactivated influenza vaccines are recommended to be administered. Nursing mothers can be vaccinated because the live, attenuated rubella virus is not communicable. Inform all mothers receiving immunization about adverse effects (rash, joint symptoms, and a low-grade fever 5 to 21 days later) and the need to avoid pregnancy for at least 28 days after

being vaccinated because of the risk of teratogenic effects (CDC, 2019c).

Rh Status

Each individual's blood is one of four major types: A, B, AB, or O. Blood types are determined by the types of antigens on the red blood cells. Antigens are proteins on the surface of blood cells that can cause a response from the immune system. Approximately 15% of the U.S. population has Rh-negative blood (Blackburn, 2018). If the woman is Rh-negative, check the Rh status of the newborn. Verify that the woman is Rh-negative and has not been sensitized, that her indirect Coombs test (antibody screen) is negative, and that the newborn is Rh-positive. Mothers who are Rh-negative and have given birth to an infant who is Rh-positive should receive an injection of Rh immunoglobulin within 72 hours after birth to prevent a sensitization reaction in the Rh-negative woman who received Rh-positive blood cells during the birthing process. Administering RhoGAM prevents initial isoimmunization in Rh-negative mothers by destroying fetal erythrocytes in the maternal system before maternal antibodies can develop and maternal memory cells become sensitized. This is a classic passive immunization technique. The usual protocol for the Rh-negative woman is to receive two doses of RhoGAM, one at 28 weeks' gestation and the second dose within 72 hours after childbirth. The standard dose of RhoGAM is 300 mcg given intramuscularly, which prevents the development of antibodies for an exposure of up to 15 mL of fetal red blood cells (King et al., 2019). A signed consent form is needed after a thorough explanation is provided about the procedure, including its purpose, possible adverse effects, and effect on future pregnancies.

RhoGAM contains actual Rh antibodies produced by people who have become sensitized. It is therefore, a blood product. Each dose contains enough anti-D to suppress the immune response of 15 mL of Rh-positive red blood cells (Jordan et al., 2019). Jehovah's Witnesses and others who belong to religions prohibiting the use of blood products should decide based on their conscience and

possibly ecclesiastical leaders about the use of RhoGAM. Nurses need to respect whatever the mother's decision is.

Ensuring Follow-Up Care

New mothers and their families need to be attended to over an extended period of time by nurses knowledgeable about mother care, infant feeding (both breastfeeding and bottle-feeding), infant care, and nutrition. Although continuous nursing care stops on discharge from the hospital or birthing center, extended episodic nursing care needs to be provided at home. Some of the challenges faced by families after discharge are described in Box 16.5.

Many new mothers are reluctant to "cut the cord" after their brief stay in the health care facility and need expanded community services. Women who are discharged too early from the hospital run the risk of uterine subinvolution, discomfort at an episiotomy or cesarean site, infection, fatigue, and maladjustment to their new role. Postpartum nursing care should include a range of family-focused care, including telephone calls, outpatient clinics, and home visits. Typically, public health nurses, community and home health nurses, and the health care provider's office staff will provide postpartum care after hospital discharge.

PROVIDING TELEPHONE FOLLOW-UP

Telephone follow-up typically occurs during the first week after discharge to check on how things are going at home. Calls can be made by perinatal nurses within the agency as part of follow-up care or by the local health department nurses. One disadvantage of a phone call assessment is that the nurse cannot see the client and thus must rely on the mother or the family's observations. The experienced nurse needs to be able to recognize distress and give appropriate advice and referral information if needed.

BOX 16.5 Challenges Facing Families after Discharge

- Lack of role models for breastfeeding and infant care.
- Lack of support from the new mother's own mother if she did not breastfeed.
- Increased mobility of society, which means that extended family may live far away and cannot help care for the newborn and support the new family.
- Nonsupportive, overwhelmed, and fatigued partner.
- Feelings of isolation and limited community ties for women who work full-time.
- Shortened hospital stays; parents may be overwhelmed by all the information they are given in the brief hospital stay.
- Prenatal classes usually focus on the birth itself rather than on skills needed to care for themselves and the newborn during the postpartum period.
- Limited access to education and support systems for families from diverse cultures.

PROVIDING OUTPATIENT FOLLOW-UP

For mothers with established health care providers such as private pediatricians and obstetricians, visits to the office are arranged soon after discharge. For the woman with an uncomplicated vaginal birth, an office visit is usually scheduled for 4 to 6 weeks after childbirth. A woman who had a cesarean birth is typically seen within 2 weeks after hospital discharge. Hospital discharge orders will specify when these visits should be made. Newborn examinations and further diagnostic laboratory studies are scheduled within the first week.

TAKE NOTE!

The hospital stay of the mother and her healthy term newborn should be long enough to allow identification of early problems and to ensure that the family is able and prepared to care for the infant at home (WHO, 2019a).

Outpatient clinics are available in many communities. If family members run into a problem, the local clinic is available to provide

assessment and treatment. Clinic visits can replace or supplement home visits. Although these clinics are open during daytime hours only and the staff members are unfamiliar with the family, they can be a valuable resource for the new family with a problem or concern.

PROVIDING HOME VISIT FOLLOW-UP

Reduction in the postpartum lengths of stay has been advocated within the context of reducing health care system costs. Early discharge in combination with home visit follow-up programs has shown safe outcomes for both the mother and infant. Home visits are usually made within the first week after discharge to assess the mother and newborn. During the home visit, the nurse assesses for and manages common physical and psychosocial problems. In addition, the home nurse can help the new parents adjust to the change in their lives. Postpartum home visits usually include:

- *Maternal assessment:* general well-being, vital signs, breast health and care, abdominal and musculoskeletal status, voiding status, fundus and lochia status, psychological and coping status, family relationships, proper feeding technique, environmental safety check, newborn care knowledge, and health teaching needed (Fig. 16.10).
- *Infant assessment:* physical examination, general appearance, vital signs, home safety check, child development status, any education needed to improve parents' skills

B

FIGURE 16.10. Sample postpartum home visit assessment form. **A.** Maternal assessment. **B.** Newborn assessment. (Used with permission: Copyright Briggs Corporation. Professional Nurse Associates.)

The home care nurse must be prepared to support and educate the woman and her family in the following areas:

- Breastfeeding or bottlefeeding technique and procedures

- Appropriate parenting behavior and problem solving
- Maternal/newborn physical, psychosocial, and cultural–environmental needs
- Emotional needs of the new family
- Warning signs of problems and how to prevent or eliminate them
- Sexuality issues, including contraceptive use
- Immunization needs for both mother and infant
- Family dynamics for smooth transition
- Links to health care providers and community resources

KEY CONCEPTS

- The transitional adjustment period between birth and parenthood includes education about baby care basics, the role of the new family, emotional support, breastfeeding or bottle-feeding support, and maternal mentoring.
- Sensitivity to how childbearing practices and beliefs vary for multicultural families and how best to provide appropriate nursing care to meet their needs are important during the postpartum period.
- A thorough postpartum assessment is key to preventing complications as is frequent hand hygiene by the nurse, especially between handling mothers and infants.
- The postpartum assessment that uses the acronym BUBBLE-EE (breasts, uterus, bowel, bladder, lochia, episiotomy/perineum/epidural site, extremities, and emotions) is a helpful guide in performing a systematic head-to-toe postpartum assessment.
- Lochia is assessed according to its amount, color, and change with activity and time. It proceeds from lochia rubra to serosa to alba.
- Because of shortened agency stays, nurses must use this brief time with the client to address areas of comfort, elimination, activity, rest and exercise, self-care, sexuality and contraception, nutrition, family adaptation, discharge, and follow-up.
- The AAP advocates breastfeeding for all full-term newborns, maintaining that breast milk should ideally be the sole nutrient for the first 6 months and continued with foods until 12 months of life or longer.
- Successful parenting is a continuous and complex interactive process that requires the acquisition of new skills and the integration of the new member into the existing family unit.
- Bonding is a vital component of the attachment process and is necessary in establishing parent–infant attachment and a healthy, loving relationship; attachment behaviors include seeking and maintaining proximity to and exchanging gratifying experiences with the infant.
- Nurses can be instrumental in facilitating attachment by first understanding attachment behaviors (positive and negative) of

newborns and parents, and intervening appropriately to promote and enhance attachment.
- New mothers and their families need to be attended to over an extended period of time by nurses knowledgeable about mother care, newborn feeding (breastfeeding and bottle-feeding), newborn care, and nutrition.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. When assessing a postpartum woman, which finding would lead the nurse to suspect postpartum blues?

   a. Panic attacks and suicidal thoughts
   b. Anger toward self and infant
   c. Periodic crying and insomnia
   d. Obsessive thoughts and hallucinations

2. Which of these activities would best help the postpartum nurse provide culturally sensitive care for the childbearing family?

   a. Taking a transcultural course
   b. Caring for only families of the nurse's cultural origin
   c. Teaching Western beliefs to culturally diverse families
   d. Educating themselves about diverse cultural practices

3. Which suggestion would be most appropriate to include in the teaching plan for a postpartum woman who needs to lose weight?

   a. Increase fluid intake and acid-producing foods in her diet.
   b. Avoid empty-calorie foods, breastfeed, and increase exercise.
   c. Start a high-protein, low-carbohydrate diet, and restrict fluids.
   d. Eat no snacks or carbohydrates after dinner.

4. After teaching a group of breastfeeding women about nutritional needs, the nurse determines that the teaching

was successful when the women state that they need to increase their intake of which nutrients?

a. Carbohydrates and fiber
b. Fats and vitamins
c. Calories and protein
d. Iron-rich foods and minerals

5. Which finding would lead the nurse to suspect that a postpartum woman was developing a complication?

a. Fatigue and irritability
b. Perineal discomfort and pink discharge
c. Pulse rate of 60 bpm
d. Swollen, tender, hot area on the breast

6. Which assessment finding indicates positive bonding between the parents and their newborn?

a. Holding the infant close to the body
b. Having visitors hold the infant
c. Buying expensive infant clothes
d. Requesting that the nurses care for the infant

7. Which activity would the nurse include in the teaching plan for parents with a newborn and an older child to reduce sibling rivalry when the newborn is brought home?

a. Punishing the older child for bedwetting behavior
b. Sending the sibling to the grandparents' house
c. Planning a daily "special time" for the older sibling
d. Allowing the sibling to share a room with the infant

8. The major purpose of the first postpartum home care visit is to

a. identify complications that require interventions.
b. obtain a blood specimen for PKU testing.
c. complete the official birth certificate.

d. support the new parents in their parenting roles.

9. The nurse is instructing the postpartum client who plans to bottle-feed her newborn about measures to prevent breast engorgement when she is discharged. Which measure should the nurse include in the teaching plan?

a. Decreasing her fluid intake for the first week at home
b. Wearing a tight-fitting supportive bra 24 hours daily
c. Take a diuretic to release the extra fluid in the breasts
d. Manually express the milk that is accumulating

10. A new mother gave birth 12 hours ago. Because this is her first child, which goal planned by the nurse is most appropriate?

a. Early discharge for the mother and newborn
b. Rapid transition into the role of being a parent/caregiver
c. Minimal need for expression of feelings now
d. Effective education of both parents before discharge

CRITICAL THINKING EXERCISES

1. As a nurse working on a postpartum unit, you enter the room of a 22-year-old primipara and find her chatting on the phone while her newborn is crying loudly in the bassinette, which has been pushed into the bathroom. You pick up and comfort the newborn. While holding the baby, you ask the client if she was aware her newborn was crying. She replies, “That’s about all that monkey does since she was born!” You hand the newborn to her and she places the newborn on the bed away from her and continues her phone conversation.

a. What is your nursing assessment of this encounter?
b. What nursing interventions would be appropriate?
c. What specific discharge interventions may be needed?

2. A 34-year-old single primipara left the hospital after a 36-hour stay with her newborn son. She lives alone in a one-bedroom walk-up apartment. As the postpartum home health nurse visiting her 2 days later, you find:
   - Tearful client pacing the floor holding her crying son
   - Home cluttered and in disarray
   - Fundus firm and displaced to right of midline
   - Moderate lochia rubra; episiotomy site clean, dry, and intact
   - Vital signs within normal range; pain rating less than 3 points on scale of 1 to 10
   - Breasts engorged slightly; supportive bra on
   - Newborn assessment within normal limits
   - Distended bladder upon palpation; reporting urinary frequency

   a. Which of these assessment findings warrants further investigation?
   b. What interventions are appropriate at this time and why?
   c. What health teaching is needed before you leave this home?

3. The nurse walks into the room of a 24-year-old primigravida. She asks the nurse to hand her the bottle sitting on the bedside table, stating, “I’m going to finish it off because my baby only ate half of it 3 hours ago when I fed him.”

   a. What response by the nurse would be appropriate at this time?
   b. What action should the nurse take?
   c. What health teaching is needed for this new mother prior to discharge?

STUDY ACTIVITIES

1. Identify two questions that a nurse would ask a postpartum woman to assess for postpartum blues.
2. Find a website that offers advice to new parents about breastfeeding. Critique the site, the author's credentials, and the accuracy of the content.
3. Outline instructions you would give to a new mother on how to use her peribottle.
4. Breast tissue swelling secondary to vascular congestion after childbirth and preceding lactation describes _____.
5. Listen to the postpartum story of one of your assigned clients and share it with your peers in class or as part of online discussion.

BRINGING IT ALL TOGETHER: A CASE STUDY

A 26-year-old woman gave birth to a healthy term neonate yesterday and is preparing for discharge. The mother is illiterate and lives in a poor agricultural area of town not far from the hospital. This is her fourth infant in 5 years. The postpartum nurse comes into the room and observes that this mother has wrapped a piece of unclean cloth tightly around the infant's abdomen with a quarter which covers the cord stump. The take-home infant outfit is not clean and not appropriate for the weather conditions outside. The mother is waiting for a ride home from a friend. The postpartum nurse is here to provide her with discharge instructions.

ASSESSMENT

Client's general appearance is healthy, but appears fatigued. Vital signs are as follows: BP 120/74; pulse 78; temp 98.2°F; respirations 20 breaths per minute. Her breasts are soft upon palpation, no engorgement present. She plans to bottle-feed her infant. Her abdominal exam is without significant findings and involution is proceeding

normally. Fundus is at the level of the umbilicus and firm. Lochia rubra is moderate, with no clots. Voiding well and has had a bowel movement this morning. No episiotomy site to assess. Newborn physical exam was normal per pediatrician's notes.

Go to thePoint to find questions to consider about this case.

Newborn Transitioning

WOW

WORDS OF WISDOM

Newborns can’t always be judged by their outer wrapping; rather, we should focus on the awesome gift inside.

KEY TERMS

cold stress

jaundice (jawn´dis)

meconium (mē-kō´nē-ŭm)

neonatal period

neurobehavioral response

neutral thermal environment

periodic breathing

reflex

surfactant (sŭr-fak´tănt)

thermoregulation (thĕr´mō-reg´yū-lā´shŭn)

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Examine the major physiologic changes that occur as the newborn transitions to extrauterine life.
2. Describe the cardiovascular changes that take place from fetal circulation to extrauterine circulation after birth.
3. Interpret the factors that influence the initiation of newborn respirations.
4. Relate characteristics that predispose newborns to heat loss after birth.
5. Distinguish primary immunoglobulins that help strengthen the newborn's immunologic system.
6. Determine the primary challenges faced by the newborn during the transition to extrauterine life.
7. Differentiate the behavioral patterns that newborns progress through after birth.
8. Assess the typical behavioral responses triggered by external stimuli of the newborn.

The Healthy Start home care nurse reviewed the client's file in her car before she got out: 18-year-old primipara, 1 week postpartum with a term newborn girl weighing 7 lb. The new mother, Maria, greets the nurse at the door and lets her inside the house. After performing a postpartum assessment on Maria and an assessment of her newborn daughter, the nurse asked Maria if she has any questions or concerns. Maria's eyes well up with tears; she is worried that her daughter can't see.

INTRODUCTION

When a child is born, the exhaustion and stress of labor are over for the parents, but now the newborn must begin the work of physiologically and behaviorally adapting to the new environment. Birth is a relatively hypoxic event as newborns undergo a transition from the placenta as the organ of gas exchange to the lungs. The first 24 hours of life can be the most precarious (King et al., 2019).

The **neonatal period** is defined as the first 28 days of life. It is a period of the most dramatic and rapid physiologic changes in humans. After birth, the newborn is exposed to a whole new world of sounds, colors, smells, and sensations. The newborn, previously confined to the warm, dark, wet intrauterine environment, is now thrust into an environment that is much brighter and cooler. As the newborn adapts to life after birth, numerous physiologic changes occur (Table 17.1).

Awareness of the adaptations that are occurring forms the foundation for providing support to the newborn during this crucial time. Physiologic and behavioral changes occur quickly during this transition period. Being aware of any deviations from the norm is crucial to ensure early identification and prompt intervention.

This chapter describes the physiologic changes of the newborn's major body systems. It also discusses the behavioral adaptations, including behavioral patterns and the newborn's behavioral responses, which occur during this transition period.

PHYSIOLOGIC TRANSITIONING

At birth, the newborn has limited functional and structural adaptability. The first hour is often called the “golden hour of life,” in recognition of the fact that the newborn’s intrauterine to extrauterine transition is both dramatic and critical. This adaptation is complex and difficult but required for all humans. Maternal medical and fetal conditions can have a profound effect on the successful transition. The mechanics of birth require a change in the newborn for survival outside the uterus. Immediately at birth, respiratory gas exchange, along with circulatory modifications, must occur to sustain extrauterine life. During this time, as newborns strive to attain homeostasis, they also experience complex changes in major organ systems. The newborn’s most dramatic and most rapid extrauterine transitions occur in four interdependent areas: circulatory, respiratory, thermoregulation, and their ability to stabilize their blood glucose levels. All four areas must make successful transitions for the newborn to adapt to extrauterine life. Although the transition usually takes place within the first 6 to 10 hours of life, many adaptations take weeks to attain full maturity.

Cardiovascular System Adaptations

It is important for the newborn, while taking their first breath, to shut down and rewire the intrauterine cardiovascular shunts present in its body. Failure to do so can cause physiologic imbalances, such as not getting enough oxygen to the brain. During fetal life, the heart relies on certain unique structures that assist it in providing adequate perfusion of vital body parts. The umbilical vein carries oxygenated blood from the placenta to the fetus. The ductus venosus allows the majority of the umbilical vein blood to bypass the liver and merge with blood moving through the vena cava, bringing it to the heart sooner. The foramen ovale allows more than half the blood entering the right atrium to cross immediately to the left atrium, bypassing the pulmonary circulation. The ductus arteriosus connects the pulmonary artery to the aorta, which allows bypassing of the pulmonary circuit.

Only a small portion of blood passes through the pulmonary circuit for the main purpose of perfusion of the structure, rather than for oxygenation. The fetus depends on the placenta to provide oxygen and nutrients and to remove waste products.

TABLE 17.1 Anatomic and Physiologic Comparison of the Fetus and Newborn

Topic of Comparison	Fetus	Newborn
Respiratory system	Fluid-filled, high-pressure system causes blood to be shunted from the lungs through the ductus arteriosus to the rest of the body.	Air-filled, low-pressure system encourages blood flow through the lungs for gas exchange; increased oxygen content of blood in the lungs contributes to the closing of the ductus arteriosus (becomes a ligament).
Site of gas exchange	Placenta	Lungs
Circulation through the heart	Pressures in the right atrium are greater than in the left, encouraging blood flow through the foreman ovale.	Pressures in the left atrium are greater than in the right, causing the foreman ovale to close.
Hepatic portal circulation	Ductus venosus bypasses; maternal liver performs filtering functions.	Ductus venosus closes (becomes a ligament); hepatic portal circulation begins.
Thermoregulation	Body temperature is maintained by maternal body temperature and the warmth of the intrauterine environment.	Body temperature is maintained through a flexed posture and brown fat.

(2019). *Creasy & Resnik's maternal-fetal medicine: Principles & practice*. Elsevier.

With the birth of the newborn and removal of the low-resistance placenta, there are major cardiovascular responses related to

pressures, blood flow, and pulmonary circulation. At birth, the circulatory system must switch from fetal to newborn circulation and from placental to pulmonary gas exchange. Successful transition from fetal to postnatal circulation requires increased pulmonary blood flow, removal of the placenta, and closure of the intracardiac (foramen ovale) and extracardiac shunts (ductus venosus and ductus arteriosus). These changes are needed to equalize the right ventricular output with that of the left (Elshazzly & Caban, 2019). The physical forces of the contractions of labor and birth, mild asphyxia, increased intracranial pressure as a result of cord compression and uterine contractions, and the cold stress experienced immediately after birth lead to an increased release of catecholamines that is critical for the changes involved in the transition to extrauterine life. The increased levels of epinephrine and norepinephrine stimulate increased cardiac output and contractility, surfactant release, and promotion of pulmonary fluid clearance (Blackburn, 2018).

Fetal to Neonatal Circulation Changes

Changes in circulation occur immediately at birth as the fetus separates from the placenta (Fig. 17.1). At birth, circulation alters in response to changes taking place in the lungs which now become the primary organs of respiration. When the umbilical cord is clamped, the first breath is taken and the lungs begin to function. As a result, systemic vascular resistance increases and blood return to the heart via the inferior vena cava decreases. Concurrently with these changes, there is a rapid decrease in pulmonary vascular resistance and an increase in pulmonary blood flow (Deshpande et al., 2018). The foramen ovale functionally closes with a decrease in pulmonary vascular resistance, which leads to a decrease in right-sided heart pressures. An increase in systemic pressure, after clamping of the cord, leads to an increase in left-sided heart pressures. The ductus arteriosus, ductus venosus, and umbilical vessels that were vital during fetal life are no longer needed. Over a period of months these fetal vessels form nonfunctional ligaments.

Before birth, the foramen ovale allowed most of the oxygenated blood entering the right atrium from the inferior vena cava to pass into the left atrium of the heart. With the newborn's first breath, air pushes into the lungs, triggering an increase in pulmonary blood flow and pulmonary venous return to the left side of the heart. As a result, the pressure in the left atrium becomes higher than in the right atrium. The increased left atrial pressure causes the foramen ovale to close, thus allowing the output from the right ventricle to flow entirely to the lungs. With closure of this fetal shunt, oxygenated blood is now separated from nonoxygenated blood. The subsequent increase in tissue oxygenation further promotes the increase in systemic blood pressure and continuing blood flow to the lungs. The foramen ovale normally closes functionally at birth when left atrial pressure increases and right atrial pressure decreases. Permanent anatomic closure, though, really occurs throughout the next several weeks.

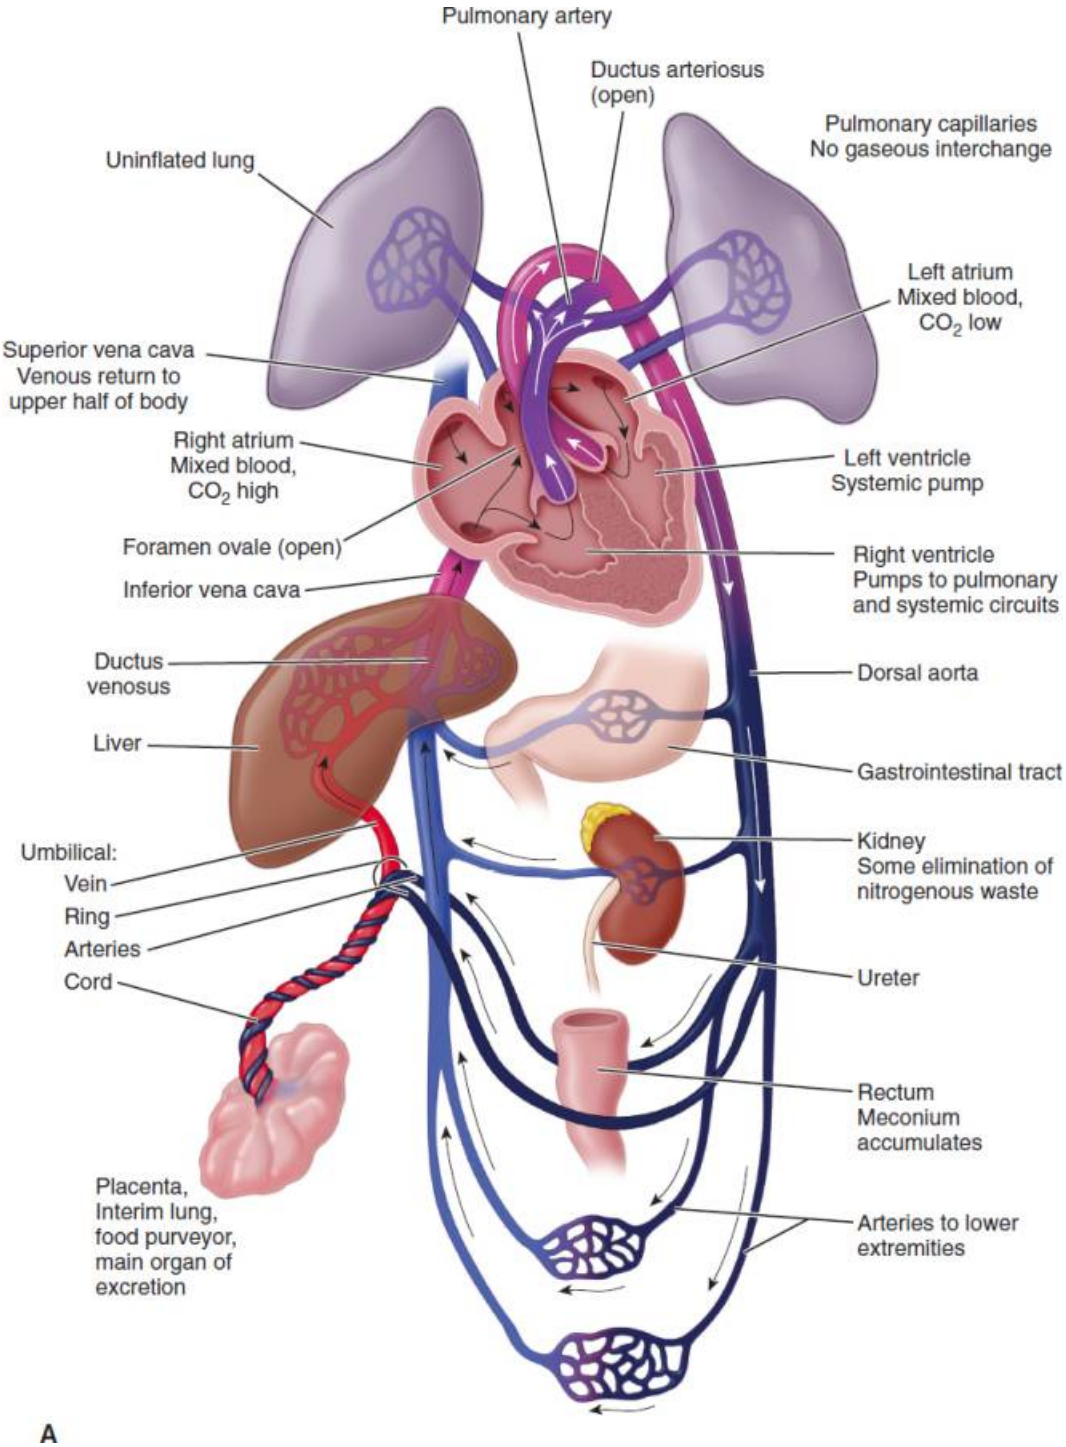
During fetal life, the ductus arteriosus, located between the aorta and the pulmonary artery, protected the lungs against circulatory overload by shunting blood (right to left) into the descending aorta, bypassing pulmonary circulation. Its patency during fetal life is promoted by continual production of prostaglandin E2 (PGE2) by the ductus arteriosus (Gleason & Juul, 2018). The ductus arteriosus becomes functionally closed within the first few hours after birth. Oxygen is the most important factor in controlling its closure. Closure depends on the high oxygen content of the aortic blood that results from aeration of the lungs at birth. At birth, pulmonary vascular resistance decreases, allowing pulmonary blood flow to increase and oxygen exchange to occur in the lungs. It occurs secondary to an increase in PO_2 coincident with the first breath and umbilical cord occlusion when it is clamped.

The ductus venosus shunted blood from the left umbilical vein to the inferior vena cava during intrauterine life. It closes within a few days after birth because this shunting is no longer needed as a result of activation of the liver. The activated liver now takes over the functions of the placenta (which was expelled at birth). The ductus venosus becomes a ligament in extrauterine life.

The two umbilical arteries and one umbilical vein begin to constrict at birth because with placental expulsion, blood flow ceases. In addition, peripheral circulation increases. Thus, the vessels are no longer needed and they too become ligaments. Successful transition and closure of the three fetal shunts creates a neonatal circulation by which deoxygenated blood returns to the heart through the inferior and superior vena cava. Deoxygenated blood enters the right atrium then into the right ventricle and travels through the pulmonary artery to the pulmonary vascular bed. Oxygenated blood returns through pulmonary veins to the left atrium, the left ventricle, and through the aorta to the systemic circulation (Resnik et al., 2019). Box 17.1 provides a summary of fetal to neonatal circulation.

Heart Rate

During the first few minutes after birth, the newborn's heart rate is approximately 110 to 160 bpm. Thereafter, it begins to decrease to an average of 120 to 130 bpm (Blackburn, 2018). The newborn is highly dependent on heart rate for maintenance of cardiac output and blood pressure. Although blood pressure is not taken routinely in the healthy term newborn, it is usually highest after birth and reaches a plateau within a week after birth. Cardiac defects may be identified in the newborn nursery by conducting a thorough and systematic physical assessment, including inspection, palpation, auscultation, and measurement of blood pressure and oxygen saturations. The ability of the nurse to identify irregular findings during physical assessment aids rapid identification and treatment.



Pulmonary artery
Ductus arteriosus (open)
Pulmonary capillaries No gaseous interchange
Uninflated lung
Left atrium Mixed blood, CO_2 low
Superior vena cava Venous return to upper half of body
Right atrium Mixed blood, CO_2 high
Left ventricle Systemic pump
Foramen ovale (open)
Right ventricle Pumps to pulmonary and systemic circuits
Inferior vena cava
Ductus venosus
Dorsal aorta
Liver
Gastrointestinal tract
Kidney Some elimination of nitrogenous waste
Umbilical:
Vein
Ring
Arteries
Cord
Ureter
Rectum Meconium accumulates
Placenta, Interim lung, food purveyor, main organ of excretion
Arteries to lower extremities

A

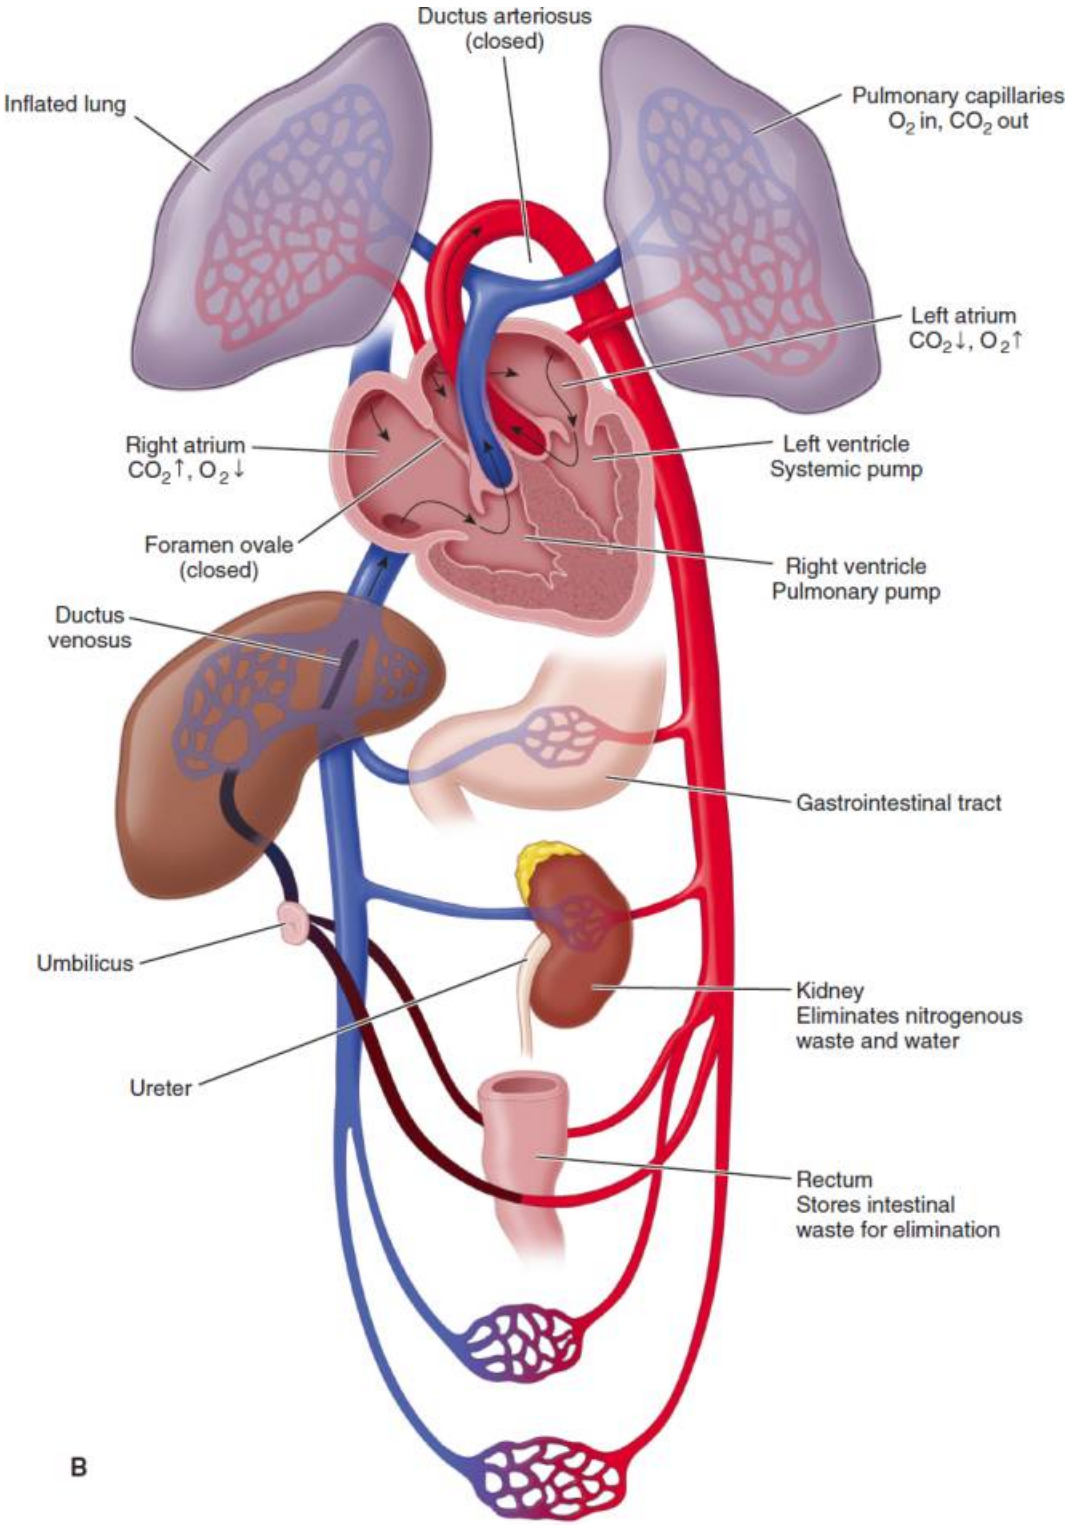


FIGURE 17.1. Cardiovascular adaptations of the newborn. Note the changes in oxygenation between (**A**) prenatal circulation and (**B**) postnatal (pulmonary) circulation.

TAKE NOTE!

Transient functional cardiac murmurs may be heard during the neonatal period as a result of the changing dynamics of the cardiovascular system at birth. Usually, they are benign (Ungerleider et al., 2019).

Cardiac murmurs arise from turbulent blood flow around structures of the heart. The fluctuations in both the heart rate and blood pressure tend to follow the changes in the newborn's behavioral state. An increase in activity, such as wakefulness, movement, or crying, corresponds to an increase in heart rate and blood pressure. In contrast, the compromised newborn demonstrates markedly less physiologic variability overall. Tachycardia may be found with volume depletion, cardiorespiratory disease, drug withdrawal, and hyperthyroidism. Bradycardia is often associated with apnea and is often seen with hypoxia.

BOX 17.1 Summary of Fetal to Neonatal Circulation

- Clamping the umbilical cord after birth eliminates the placenta as a reservoir for blood.
- Onset of respirations causes a rise in PO2 in the lungs and a decrease in pulmonary vascular resistance, *which…*
- Increases pulmonary blood flow and increases pressure in the left atrium, *which…*
- Decreases pressure in the right atrium of the heart, which causes closure of the foramen ovale (closes within minutes after birth secondary to a decreased pulmonary vascular resistance and increased left heart pressure).
- With an increase in oxygen levels after the first breath, an increase in systemic vascular resistance occurs, *which…*
- Decreases vena cava return, which reduces blood flow in the umbilical vein (constricts, becomes a ligament with functional closing).
- Closure of the ductus venosus (becomes a ligament) causes an increase in pressure in the aorta, which forces closure of the ductus arteriosus within 10 to 15 hours after birth.

Blood Volume

The blood volume of the newborn depends on the amount of blood transferred from the placenta at birth. It is usually estimated to be 80 to 100 mL/kg of body weight in the term infant (Blackburn, 2018). However, the volume may vary by as much as 25% to 40%, depending on when clamping of the umbilical cord occurs. Early (before 30 to 40 seconds) or late (after 3 minutes) clamping of the umbilical cord changes circulatory dynamics during transition. Recent studies indicate that the benefits of delayed cord clamping include improving the newborn's cardiopulmonary adaptation, preventing iron-deficiency anemia in full-term newborns without increasing hypervolemia-related risks and increased iron stores, increasing blood pressure, improving oxygen transport, and increasing red blood cell (RBC) flow (Zhao et al., 2019). Although a tailored approach is required in the case of cord clamping, current available data suggest that delayed cord clamping offers the newborn many physiologic benefits, including at least a 30% increase in blood volume for term infants and a 50% increase in preterm infants, improvement of systemic blood pressure, increase in the cerebral oxygen index, higher hemoglobin levels at 24 to 48 hours of age, and increased serum iron levels at 4 to 6 months (Rana et al., 2019; WHO, 2019). Cord blood has also been described as "nature's first stem cell transplant" because it possesses regenerative properties and can grow into different types of cells in the body (Atala et al., 2019).

The American Academy of Pediatrics (AAP, 2017) and American College of Obstetricians and Gynecologists (ACOG, 2018) have released opinions that support delayed cord clamping for at least 30 to 60 seconds after birth given the numerous benefits to most newborns. The World Health Organization (WHO, 2019) released a report recommending delayed cord clamping for "all births" as a best practice. A Cochrane Review study on term infants and timing of umbilical cord clamping reported that those with delayed cord clamping had up to a 60% increase in RBCs, high hemoglobin levels, and higher iron levels at 4 to 6 months. Infants whose cords were clamped early were twice as likely to be iron-deficient at 3 to 6

months (Sloan, 2017). So at this time, there is no uniform agreement about this practice.

Blood Components

Fetal RBC development is independent from the mother. The fetus has more RBCs per cubic millimeter than an adult and they have a greater affinity for oxygen at a lower oxygen pressure than adult RBCs. Fetal RBCs are larger in size when compared to an adult, thus each cell can carry more oxygen (Blackburn, 2018). After birth, the RBC count gradually increases as the cell size decreases, because the cells now live in an environment with much higher PO2. A newborn's RBCs have a lifespan of 80 to 100 days, compared with 120 days in adults.

Hemoglobin levels are higher in newborns within the first few hours after birth. Levels peak at 4 to 6 hours, then slowly decrease over the next 12 to 18 hours and within the first few months of life. Hemoglobin initially declines as a result of a decrease in neonatal red cell mass (physiologic anemia of infancy). Leukocytosis (elevated white blood cells) is present as a result of birth trauma soon after birth. Fetal hemoglobin is gradually replaced by adult forms during infancy (Webster et al., 2018). The newborn's platelet count and aggregation ability are the same as those of adults.

The newborn's hematologic values are affected by the site of the blood sample (capillary blood has higher levels of hemoglobin and hematocrit compared with venous blood), placental transfusion (delayed cord clamping and normal shift of plasma to extravascular spaces, which causes higher levels of hemoglobin and hematocrit), and gestational age (increased age is associated with increased numbers of red cells and hemoglobin) (Blackburn, 2018). Table 17.2 lists normal newborn blood values.

Respiratory System Adaptations

Physiologic responsibility for gas exchange is transferred from the placenta to the newborn's lungs and pulmonary system at birth. The

newborn's transition from fetal to neonatal life includes aeration of the lungs, establishment of pulmonary gas exchange, and changing the fetal circulation into the adult type. Lung aeration leads to the establishment of functional residual capacity, allowing pulmonary gas exchange to start. The first breath of life is a gasp that generates an increase in transpulmonary pressure and results in diaphragmatic descent. Hypercapnia, hypoxia, and acidosis resulting from normal labor become stimuli for initiating respirations. Inspiration of air and expansion of the lungs allow for an increase in tidal volume (amount of air brought into the lungs). **Surfactant** is a surface tension–reducing lipoprotein found in the newborn's lungs that prevents alveolar collapse at the end of expiration and loss of lung volume. It lines the alveoli to enhance aeration of gas-free lungs, thus reducing surface tension and lowering the pressure required to open the alveoli. Normal lung function depends on surfactant, which permits a decrease in surface tension at end expiration (to prevent atelectasis) and an increase in surface tension during lung expansion (to facilitate elastic recoil on inspiration). Surfactant provides the lung stability needed for gas exchange. The newborn's first breath, in conjunction with surfactant, overcomes the surface forces to permit aeration of the lungs. The chest wall of the newborn is floppy because of the high cartilage content and poorly developed musculature. Thus, accessory muscles that help in breathing are ineffective.

TABLE 17.2 Normal Newborn Blood Values

Lab Data	Normal Range
Hemoglobin	16–18 g/dL
Hematocrit	46–68%
Platelets	150,000–350,000/μL
Red blood cells	4.5–7.0 (1,000,000/μL)
White blood cells	10–30,000/mm^3

Elsevier; and Webster, S., Morris, G., & Kevelighan, E. (2018). *Essential human development*. John Wiley & Sons.

One of the most crucial adaptations that the newborn makes at birth is adjusting from a fluid-filled intrauterine environment to a gaseous extrauterine environment. During fetal life, the lungs are expanded with an ultrafiltrate of the amniotic fluid. During and after birth, this fluid must be removed and replaced with air. Passage through the birth canal allows intermittent compression of the thorax, which helps eliminate two thirds of the fluid in the lungs. Pulmonary capillaries and the lymphatics remove the remaining fluid.

If fluid is removed too slowly or incompletely (e.g., with decreased thoracic squeezing during birth or diminished respiratory effort), transient tachypnea (respiratory rate above 60 bpm) of the newborn occurs. Examples of situations involving decreased thoracic compression and diminished respiratory effort include cesarean birth and sedation in newborns. Research findings support the need for thoracic compression because the absence of the neonate's exposure to labor contractions in these situations is associated with an increased risk of transient tachypnea at term with oxygen supplementation being needed for a longer duration (Indraccolo et al., 2019).

TAKE NOTE!

A neonate born by cesarean section does not have the same benefit of the birth canal squeeze as does the newborn born by vaginal birth. Closely observe the respirations of the newborn after cesarean births.

Lungs

Before the newborn's lungs can maintain respiratory function, certain events must occur:

- Initiation of respiratory movement
- Expansion of the lungs
- Establishment of functional residual capacity (ability to retain some air in the lungs on expiration)
- Increased pulmonary blood flow
- Redistribution of cardiac output (Kellerman & Rakel, 2019)

Initial breathing is probably the result of a reflex triggered by pressure changes, noise, light, temperature changes, touching, compression of the fetal chest during the birthing process, and high carbon dioxide and low oxygen concentrations of the newborn's blood. Central chemoreceptors stimulated by hypoxia and hypercapnia further increase the respiratory drive. Many theories address the initiation of respiration in the newborn, but most are based on speculation from observations rather than empirical research (Cunningham et al., 2018). Research continues to search for answers to these questions.

Respirations

After respirations are established in the newborn, they are shallow and irregular, ranging from 30 to 60 breaths per minute, with short periods of apnea (less than 15 seconds). The newborn's respiratory rate varies according to their activity; the more active the newborn, the higher the respiratory rate on average. Signs of respiratory distress to observe for include cyanosis, tachypnea, expiratory grunting, sternal retractions, and nasal flaring. Respirations should not be labored, and chest movements should be symmetric. In some

cases, **periodic breathing** may occur, which is the cessation of breathing that lasts 5 to 10 seconds without changes in color or heart rate (Norwitz et al., 2019). Periodic breathing may be observed in newborns within the first few days of life and requires close monitoring.

TAKE NOTE!

Apneic periods lasting more than 15 seconds with cyanosis and heart rate changes require further evaluation (King et al., 2019).

Body Temperature Regulation

Upon birth, the fetus moves from a warm, moist intrauterine environment to the colder, drier extrauterine environment. Newborns are dependent on their environment for the maintenance of body temperature, much more so immediately after birth than later in life. One of the most important elements in a newborn's survival is obtaining a stable body temperature to promote an optimal transition to extrauterine life. On average, a newborn's temperature ranges from 97.9°F to 99.7°F (36.6°C to 37.6°C). Since newborns lose heat easily after birth, having skin-to-skin contact with their mothers is recommended as the initial method for maintaining newborn body temperature. Skin-to-skin contact should be the first line of treatment for hypothermia and as a measure to establish successful breastfeeding immediately after birth. See Evidence-Based Practice 17.1.

Thermoregulation is the process of maintaining the balance between heat loss and heat production in order to maintain the body's core internal temperature. It is a critical physiologic function that is closely related to the transition and survival of the newborn. An appropriate thermal environment is essential for maintaining a normal body temperature. Compared with adults, newborns tolerate a narrower range of environmental temperatures and are extremely vulnerable to both underheating and overheating. Nurses play a key

role in providing an appropriate environment to help newborns maintain thermal stability (Fig. 17.2).

FIGURE 17.2. Father and mother looking at their newborn after birth. Note the newborn's hat and warm blanket to preserve body heat.

Heat Loss

Newborns have several characteristics that predispose them to heat loss:

- Thin skin with blood vessels close to the surface
- Increased skin permeability to water
- Lack of shivering ability to produce heat until 3 months old
- Limited stores of metabolic substrates (glucose, glycogen, fat)
- Limited use of voluntary muscle activity or movement to produce heat
- Large surface area-to-body mass ratio

EVIDENCE-BASED PRACTICE 17.1 The Effect of Mother-Infant Skin-to-Skin Contact on Success and Duration of First Breastfeeding: A Systematic Review and Meta-Analysis

STUDY

Breastfeeding initiation after birth is one of the WHO's recommendations. However, in many hospitals, mother-infant contact and breastfeeding initiation are delayed due to routine care of both. Initial moments after birth are a sensitive period because this is the optimal time to establish effective breastfeeding. Frequently, the mother and newborn are separated to place the newborn under radiant heat to prevent hypothermia. However, hypothermia can be prevented by initiating skin-to-skin contact without separation. Skin-to-skin contact makes newborns able to move toward the mother's nipples and latch effectively to breastfeed. The purpose of this study was to determine the effect of mother-infant skin-to-skin contact immediately after birth on the success rate and duration of the first breastfeeding.

Findings

In total, 597 participants were assigned to the intervention group, and 553 participants were assigned to the comparison group. The results of this systematic review and meta-analysis study showed that the mother-infant skin-to-skin contact has a statistically significant effect on the success rate and duration of first lactation compared to routine care. In all studies, assessment of the breastfeeding success assessed four parameters: infant state of arousal or readiness to feed; rooting reflex; latch-on; and suckling patterns.

Nursing Implications

The results of this systematic review and meta-analysis found that mother–infant skin-to-skin contact after birth increases the success rate and duration of breastfeeding, so it is a best practice for postnatal care for newborns. Mother–infant skin-to-skin contact after birth has beneficial effects on breastfeeding and can increase the rate and duration of the first lactation. The results of this study can be used by nurses in evidence-based decision-making about ways to increase breastfeeding rates and change hospital policy to enhance this practice.

The effect of mother-infant skin to skin contact on success and duration of first breastfeeding: A systematic review and meta-analysis. Taiwanese Journal of Obstetrics & Gynecology, 58(1), 1–9. https://doi.org/10.1016/j.tjog.2018.11.002

- Lack of subcutaneous fat, which provides insulation
- Little ability to conserve heat by changing posture (fetal position)
- No ability to adjust their own clothing or blankets to achieve warmth
- Inability to communicate that they are too cold or too warm

Every newborn struggles to maintain body temperature from the moment of birth, when the newborn's wet body is exposed to the much cooler environment of the birthing room. The amniotic fluid covering the newborn cools as it evaporates rapidly in the low humidity and air conditioning of the room. The newborn's temperature may decrease 3 to 5 degrees within minutes after leaving the warmth of the mother's uterus (99.6°F [37.5°C]). The skin of a newborn adjusts quickly to the challenging environmental conditions of extrauterine life. However, certain functions, for example, microcirculation, continue to develop beyond the neonatal period (Stevens, 2019).

The transfer of heat depends on the temperature of the environment, air speed, and water vapor pressure or humidity. Heat exchange between the environment and the newborn involves the same mechanisms as those with any physical object and its

environment. Heat can be lost by four mechanisms including conduction (3%), convection (34%), evaporation (24%), and radiation (39%) (Resnik et al., 2019). Prevention of heat loss is a key nursing intervention (Fig. 17.3).

CONSIDER THIS

When I look down at my little miracle of life in my arms, I can't help but beam with pride at this great accomplishment. She seems so vulnerable and defenseless and yet is equipped with everything she needs to survive at birth. When the nurse brought my daughter in for the first time after birth, I wanted to see and feel every part of her. Much to my dismay, she was wrapped up like a mummy in a blanket and she had a pink knit cap on her head. I asked the nurse why all the babies had to look like they were bound for the North Pole with all these layers on. Wasn't the nurse aware it was summertime and probably at least 85 degrees outside?

The nurse explained that newborns lose body heat easily and need to be kept warm until their temperature stabilizes. Even though I wanted to get up close and personal with my baby, I decided to keep the pink polar bear outfit on her.

Thoughts: Newborns may be born with "everything they need to survive" on the outside, but they still experience temperature instability and lose heat through radiation, evaporation, convection, and conduction. Because the newborn's head is the largest body part, a great deal of heat can be lost if a cap is not kept on the head. What guidance can be given to this mother before discharge to stabilize her daughter's temperature while at home? What simple examples can be used to demonstrate your point?

CONDUCTION

Conduction involves the transfer of heat from one object to another when the two objects are in direct contact with each other. Conduction refers to heat fluctuation between the newborn's body surface when in contact with other solid surfaces, such as a cold mattress, scale, or circumcision restraining board. Heat loss by conduction can also occur when touching a newborn with cold hands or when the newborn has direct contact with a colder object such as a metal scale or a cool mattress, blanket, or clothing. Using a warmed cloth diaper or blanket to cover any cold surface touching a newborn directly helps prevent heat loss through conduction. Placing the newborn skin-to-skin with the mother also helps prevent heat loss through conduction.

CONVECTION

Convection involves the flow of heat from the body surface to cooler surrounding air or to air circulating over a body surface. Examples of convection-related heat loss would be a cool breeze that flows over the newborn, a cool room, cool corridors, or outside air currents. To prevent heat loss by this mechanism, keep the newborn out of direct cool drafts (open doors, windows, fans, air conditioners) in the environment; work inside an isolette as much as possible and minimize opening portholes that allow cold air to flow inside; and warm any oxygen or humidified air that comes in contact with the newborn. Using clothing and blankets in isolettes is an effective means of reducing the newborn's exposed surface area and providing external insulation. Also, transporting the newborn to the nursery in a warmed isolette rather than carrying them helps maintain warmth and reduce exposure to the cool air.

EVAPORATION

Evaporation involves the loss of heat when a liquid is converted to vapor. Evaporative loss may be insensible (such as from skin and respiration) or sensible (such as from sweating). Insensible loss occurs, but the individual is not aware of it. Sensible loss is objective

and can be noticed. It depends on air speed and the absolute humidity of the air. For example, when the baby is born, the body is covered with amniotic fluid. The fluid evaporates into the air, leading to heat loss. Heat loss via evaporation also occurs when bathing a newborn. Drying newborns immediately after birth with warmed blankets and placing a cap on their heads will help prevent heat loss through evaporation. In addition, drying the newborn after bathing will help prevent heat loss through evaporation. Promptly changing wet linens, clothes, or diapers will also reduce heat loss and prevent chilling.

RADIATION

Radiation involves the loss of body heat to cooler, solid surfaces that are in proximity but not in direct contact with the newborn. The amount of heat loss depends on the size of the cold surface area, the surface temperature of the newborn's body, and the temperature of the receiving surface area. For example, when a newborn is placed in a single-wall isolette next to a cold window, heat loss from radiation occurs. A newborn will become cold even though they are in a heated isolette. To reduce heat loss by radiation, keep cribs and isolettes away from outside walls, cold windows, and air conditioners. Also, using radiant warmers for transporting newborns and when performing procedures that may expose the newborn to the cooler environment will help reduce heat loss.

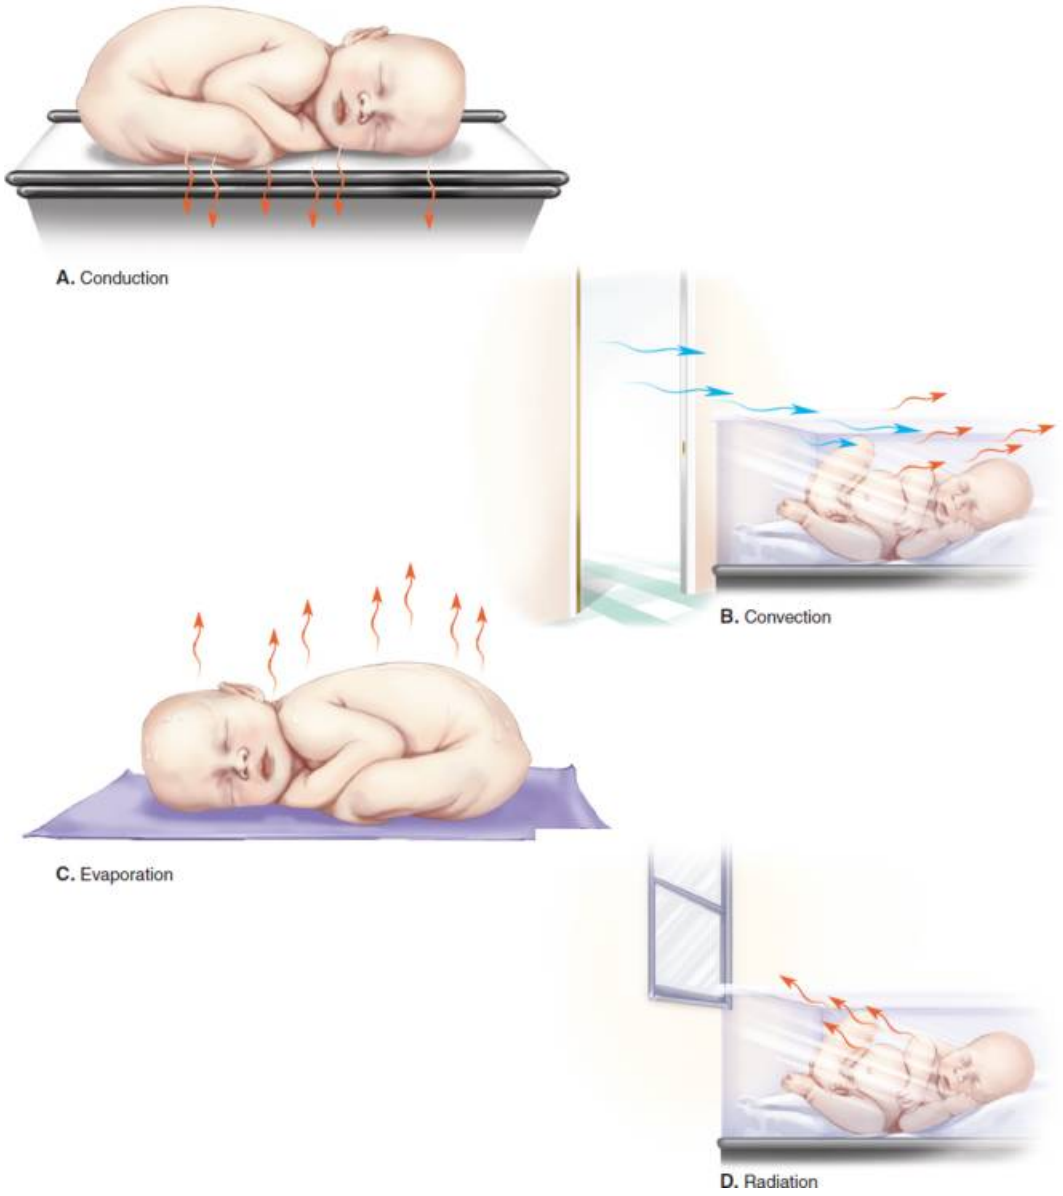

FIGURE 17.3. The four mechanisms of heat loss in the newborn. **A.** Conduction. **B.** Convection. **C.** Evaporation. **D.** Radiation.

A warmed transporter is an enclosed isolette on wheels. A radiant warmer is an open bed with a radiant heat source above. This type of environment allows health care providers to reach the newborn to carry out procedures and treatments.

Overheating

The newborn is also prone to overheating. Limited insulation and limited sweating ability can predispose any newborn to overheating. Control of body temperature is achieved via a complex negative feedback system that creates a balance between heat production, heat gain, and heat loss. The primary heat regulator is located in the hypothalamus and the central nervous system (CNS). The immaturity of the newborn's CNS makes it difficult to create and maintain this balance. Therefore, the newborn can become overheated easily. For example, an isolette that is too warm or one that is left too close to a sunny window may lead to hyperthermia. Although heat production can substantially increase in response to a cool environment, basal metabolic rate and the resultant heat produced cannot be reduced. Overheating increases fluid loss, the respiratory rate, and the metabolic rate considerably.

Thermoregulation

Humans have the ability to regulate body temperature within a narrow range. Newborns have a decreased ability to regulate body temperature, producing heat through nonshivering thermogenesis. Thermoregulation, the balance between heat loss and heat production, is related to the newborn's rate of metabolism and oxygen consumption. The newborn attempts to conserve heat and increase heat production by increasing the metabolic rate, oxidative glucose, fat and protein metabolism, nonshivering thermogenesis of brown fat, muscular activity through movement, and peripheral vasoconstriction, and by assuming a fetal position to hold in heat and minimize exposed body surface area.

Concept Mastery Alert

Effects of Cold Stress in the Newborn's Brown Fat Metabolism

The newborn first experiences an increase in norepinephrine in response to a cold environment. This then influences the triglycerides to stimulate brown fat metabolism.

An environment in which body temperature is maintained without an increase in metabolic rate or oxygen use is called a **neutral thermal environment**. Within a neutral thermal environment, the rates of oxygen consumption and metabolism are minimal, and internal body temperature is maintained because of thermal balance. A neutral thermal environment promotes growth and stability, conserves energy for basic bodily functions, and minimizes heat (energy) and water loss (Chamberlain et al., 2019). Because newborns have difficulty maintaining body heat through shivering or other mechanisms, they need a higher environmental temperature to maintain a neutral thermal environment. If the environmental temperature decreases, the newborn responds by consuming more oxygen. The respiratory rate increases (tachypnea) in response to the increased need for oxygen. As a result, the newborn's metabolic rate increases.

As noted earlier, the newborn's primary method of heat production is through nonshivering thermogenesis. This is a process in which brown fat (adipose tissue) is oxidized in response to cold exposure. Brown fat is a special kind of highly vascular fat that scientists once thought disappears by adulthood, but new research shows adults have brown fat as well (NIH, 2019). Brown adipose tissue is a unique tissue that is able to convert chemical energy directly into heat when activated by the sympathetic nervous system. It is produced during the third trimester; it ordinarily is reduced by 3 to 5 weeks after birth and is vital for thermogenesis. The brown coloring is derived from the fat's rich supply of blood vessels and nerve endings. These fat deposits, which are capable of intense metabolic activity—and thus can generate a great deal of heat—are found between the scapulae, axillae, at the nape of the neck, in the mediastinum, and in areas surrounding the kidneys and adrenal glands. Brown fat makes up about 6% of term body weight in the full-term newborn (Blackburn, 2018). When the newborn experiences a cold environment, norepinephrine is released. This in turn stimulates brown fat metabolism by breaking down triglycerides. Cardiac output increases, increasing blood flow through the brown fat tissue.

Subsequently, this blood becomes warmed as a result of the increased metabolic activity of the brown fat (Fig. 17.4).

FIGURE 17.4. Areas of brown fat in a newborn.

Newborns can experience heat loss through all four mechanisms, ultimately resulting in cold stress. **Cold stress** is excessive heat loss that requires a newborn to use compensatory mechanisms (such as nonshivering thermogenesis and tachypnea) to maintain core body temperature (Gleason & Juul, 2018). The consequences of cold stress can be quite severe. As the body temperature decreases, the newborn becomes less active, lethargic, hypotonic, and weaker. All newborns are at risk for cold stress, particularly within the first 12 hours of life. However, preterm newborns are at the greatest risk for cold stress and experience more profound effects than full-term

newborns because they have fewer fat stores, poorer vasomotor responses, and less insulation to cope with a hypothermic event.

Cold stress in the newborn can lead to the following problems if not reversed: depleted brown fat stores, increased oxygen and glucose consumption, respiratory distress, depletion of glycogen leading to hypoglycemia, pulmonary vasoconstriction, metabolic acidosis, jaundice, hypoxia, and decreased surfactant production (King et al., 2019).

TAKE NOTE!

Nurses must be aware of the thermoregulatory needs of the newborn and must ensure that these needs are met to provide the newborn with the best start possible. Maintenance of temperature stability should be focused on preventative measures.

To minimize the effects of cold stress, the following interventions are helpful:

- Prewarming blankets and hats to reduce heat loss through conduction
- Keeping the infant transporter (warmed isolette) fully charged and heated at all times
- Drying the newborn completely after birth to prevent heat loss from evaporation
- Encouraging skin-to-skin contact with the mother if the newborn is stable
- Promoting early breastfeeding to provide fuels for nonshivering thermogenesis
- Using heated and humidified oxygen
- Always using radiant warmers and double-wall isolettes to prevent heat loss from radiation
- Deferring bathing until the newborn is medically stable, and using a radiant heat source while bathing (Fig. 17.5)
- Avoiding the placement of a skin temperature probe over a bony area or one with brown fat, because it does not give an accurate assessment of the whole-body temperature (most temperature

probes are placed over the liver when the newborn is supine or side-lying)

FIGURE 17.5. Bathing a newborn under a radiant warmer to prevent heat loss.

These interventions allow the newborn to minimize their metabolic rate and oxygen consumption, thereby conserving vital energy stores required for optimum growth.

Hepatic System Function

The liver has an essential role in the synthesis, degradation, and regulation of pathways involved in the metabolism of carbohydrates, proteins, lipids, trace elements, and vitamins. At birth, the newborn's liver slowly assumes the functions that the placenta handled during fetal life. Most enzymatic pathways are present in the newborn but are inactive at birth and generally become fully active at 3 months of age. These functions include blood coagulation, and also iron storage, carbohydrate metabolism, and conjugation of bilirubin, as discussed next. Glycogen reserves provide energy and may become depleted if the metabolic needs of the newborn increase, such as during cold or respiratory stress.

Iron Storage

Maturity, birth weight, and hemoglobin level determine the iron status of the newborn. As RBCs are destroyed after birth, their iron is released and stored by the liver until new RBCs need to be produced. If the mother's iron intake was adequate during pregnancy, sufficient iron has been stored in the newborn's liver for use during the first 6 months of age.

Carbohydrate Metabolism

Birth results in the loss of maternal glucose source. Glucose is an essential fuel for brain metabolism. When the placenta is lost at birth, the maternal glucose supply is cut off. Initially, the newborn's serum glucose levels decline. Newborns must learn to regulate their blood glucose concentration and adjust to an intermittent feeding schedule. Usually, a term newborn's blood glucose level is about 80% of the maternal blood glucose level at birth. Hypoglycemia is one of the most frequent problems encountered, and maintaining glucose

homeostasis is one of the important physiologic events during the fetal-to-newborn transition. During the first 24 to 48 hours of life, as normal neonates' transition from intrauterine to extrauterine life, their plasma glucose levels are usually lower than later in life (Blackburn, 2018).

Glucose is the main source of energy for the first several hours after birth. With the newborn's increased energy needs after birth, the liver releases glucose from glycogen stores for the first 24 hours. Initiating early breastfeeding or bottle-feeding helps stabilize the newborn's blood glucose levels. No evidence supports universal invasive routine measurement of glucose in healthy term newborns. Selective screening of at-risk newborns is more appropriate (Levy-Khademi et al., 2019).

Bilirubin Conjugation

Before birth, bilirubin clearance is handled efficiently by the placenta and mother's liver. After birth, the newborn's liver must assume full responsibility for bilirubin metabolism. Bilirubin is the yellow-to-orange bile pigment produced by the breakdown of RBCs.

Bilirubin normally circulates in plasma, is taken up by liver cells, and is changed to a water-soluble pigment that is excreted in the bile. This conjugated form of bilirubin is excreted from liver cells as a constituent of bile.

The principal source of bilirubin in the newborn is the hemolysis of erythrocytes. This is a normal occurrence after birth, when fewer RBCs are needed to maintain extrauterine life. When RBCs die after approximately 80 days of life, the heme in their hemoglobin is converted to bilirubin. Bilirubin is released in an unconjugated form called indirect bilirubin, which is fat-soluble. Enzymes, proteins, and different cells in the reticuloendothelial system and liver process the unconjugated bilirubin into conjugated bilirubin or direct bilirubin. This form is water-soluble and now enters the gastrointestinal system via the bile and is eventually excreted through feces. The kidneys also excrete a small amount.

Newborns produce bilirubin at a rate of approximately 8 to 10 mg/kg/day. This is more than twice the production rate in adults, primarily because of relative polycythemia and increased RBC turnover. Bilirubin production typically declines to the adult level within 10 to 14 days after birth (Martin & Rosenfeld, 2019). In addition, the metabolic pathways of the liver are relatively immature and thus cannot conjugate bilirubin as quickly as needed.

Failure of the liver cells to break down and excrete bilirubin can cause an increased amount of bilirubin in the bloodstream, leading to jaundice (Blackburn, 2018). Bilirubin is toxic to the body and must be excreted. Blood tests ordered to determine bilirubin levels measure bilirubin in the serum. Total bilirubin is a combination of indirect (unconjugated) and direct (conjugated) bilirubin. When unconjugated bilirubin pigment is deposited in the skin and mucous membranes as a result of increased bilirubin levels, **jaundice**, also known as icterus, develops, with a yellowing of the skin, sclera, and mucous membranes. Visible jaundice as a result of increased blood bilirubin levels occurs in more than half of all healthy newborns. Even in healthy term newborns, extremely elevated blood levels of bilirubin during the first week of life can cause bilirubin encephalopathy, a permanent and devastating form of brain damage (Martin & Rosenfeld, 2019).

Common risk factors for the development of jaundice include fetal–maternal blood group incompatibility, prematurity, asphyxia at birth, an insufficient intake of milk during breastfeeding, drugs (such as diazepam [Valium], oxytocin [Pitocin], sulfisoxazole/erythromycin [Pediazole], and chloramphenicol [Chloromycetin]), maternal gestational diabetes, infrequent feedings, male gender, trauma during birth, resulting in cephalohematoma, cutaneous bruising from birth trauma, polycythemia, previous sibling with hyperbilirubinemia, intrauterine infections such as TORCH (toxoplasmosis, other viruses, rubella, cytomegalovirus, herpes simplex viruses), and Asian or Native American ethnicity (Pace et al., 2019).

The causes of newborn jaundice can be classified into three groups based on the mechanism of accumulation:

1. Bilirubin overproduction, such as from blood incompatibility (Rh or ABO), drugs, trauma at birth, polycythemia, delayed cord clamping, and breast milk jaundice
2. Decreased bilirubin conjugation, as seen in physiologic jaundice, hypothyroidism, and breastfeeding
3. Impaired bilirubin excretion, as seen in biliary obstruction (biliary atresia, gallstones, neoplasm), sepsis, hepatitis, chromosomal abnormality (Turner syndrome, trisomies 18 and 21), and drugs (aspirin, acetaminophen, sulfa, alcohol, steroids, antibiotics) (Martin & Rosenfeld, 2019)

Jaundice in the newborn is discussed in more detail in Chapter 24.

Gastrointestinal System Adaptations

The full-term newborn has the capacity to swallow, digest, metabolize, and absorb food taken in soon after birth. At birth, the pH of the stomach contents is mildly acidic, reflecting the pH of the amniotic fluid. The once-sterile gut changes rapidly, depending on what feeding is received. Bowel sounds are normally heard shortly after birth but may be hypoactive on the first day.

Mucosal Barrier Protection

Humans start their development in a sterile intrauterine environment, but from the moment of birth, all epithelial surfaces in direct contact with the environment (skin, respiratory, gastrointestinal, and urogenital tract) are colonized by microorganisms. The intestinal mucosal barrier remains immature for 4 to 6 months following birth. An important adaptation of the gastrointestinal system is the development of this mucosal barrier to prevent the penetration of harmful substances (bacteria, toxins, and antigens) present within the intestinal lumen. At birth, the newborn must be prepared to deal with bacterial colonization of the gut. Colonization is dependent on oral intake. Nutrition, be it via breast milk or formula, plays a major role in early colonization patterns in the neonatal gut. It usually occurs within 24 hours of age and is required for the production of

vitamin K (Gleason & Juul, 2018). After birth, environmental, oral, and cutaneous microbes from the mother will be mechanically transferred to the newborn by several processes including suckling, kissing, and caressing. Thus, the proximity of the birth canal and the anus, as well as parental expression of neonatal care, are effective methods of ensuring transmission of microbes from one generation to the next. If harmful substances are allowed to penetrate the mucosal epithelial barrier under pathologic conditions, they can cause inflammatory and allergic reactions (Resnik et al., 2019).

TAKE NOTE!

Human breast milk provides a passive mechanism to protect the newborn against the dangers of a deficient intestinal defense system. It contains antibodies, viable leukocytes, and many other substances that can interfere with bacterial colonization and prevent harmful penetration.

Stomach and Digestion

The newborn must rapidly adapt from receiving all nutrient and energy requirements via the placenta to obtaining them orally after birth. The physiologic capacity of the newborn stomach is considerably less than its anatomic capacity. There is a rapid gain in physiologic capacity during the first 4 days of life. After the first 4 days, the anatomic and physiologic capacities more closely approximate each other. Researchers have found that for the first 24 hours after birth, the newborn's small stomach does not stretch to hold more, as it will within a day or two later (Kellerman & Rakel, 2019). This explains the experience of countless hospital nurses who have learned the hard way that when newborns are fed an ounce or two by bottle during the first day of life, most of it tends to come right backup. The walls of the newborn stomach stay firm, expelling extra milk rather than stretching to hold it.

For bottle-fed newborns, small, frequent feedings set up a healthy eating pattern right from the start (breastfed newborns self-regulate how much they consume). Experts now advise adults that it is

healthier to eat smaller amounts more often, and the same is true for babies and children. Coaxing an infant to take more milk leads to overfeeding. If feeling overfull at feedings becomes the norm for a young infant, this may lead to unhealthy eating habits that contribute to childhood and adult obesity later. Early-onset obesity is a precursor to a lifelong weight struggle and numerous comorbidities (Bagchi, 2019; Martin & Rosenfeld, 2019).

The cardiac sphincter and nervous control of the stomach is immature, which may lead to uncoordinated peristaltic activity and frequent regurgitation. Immaturity of the pharyngoesophageal sphincter and absence of lower esophageal peristaltic waves also contribute to the reflux of gastric contents. Avoiding overfeeding and stimulating frequent burping may minimize regurgitation. Most digestive enzymes are available at birth, allowing newborns to digest simple carbohydrates and protein. However, they have limited ability to digest complex carbohydrates and fats, because amylase and lipase levels are low at birth. As a result, newborns excrete a fair amount of lipids, resulting in fatty stools.

Adequate digestion and absorption are essential for newborn growth and development. Normally, term newborns lose 5% to 10% of their birth weight as a result of insufficient caloric intake within the first week after birth, shifting of intracellular water to extracellular space, and insensible water loss. To gain weight, the term newborn requires an intake of 108 kcal/kg/day from birth to 6 months of age. Understanding the role and importance of nutrition in early postnatal life on growth and development is vital, but how it links to later health has the potential of health benefits for all future generations (Koletzko et al., 2019).

Bowel Elimination

The frequency, consistency, color, and type of stool passed by newborns vary widely. The evolution of a stool pattern begins with a newborn’s first stool, which is meconium. Meconium is composed of amniotic fluid, shed mucosal cells, intestinal secretions, and blood. It is greenish black, has a tarry consistency, and is usually passed

within 12 to 24 hours of birth. The first meconium stool passed is semi-sterile, but this changes rapidly with ingestion of bacteria through feedings. After feedings are initiated, a transitional stool develops, which is greenish brown to yellowish brown, thinner in consistency, and seedy in appearance. If breastfed, the stools will resemble light mustard with seed-like particles. If formula-fed, the stools will be tan or yellow in color and firmer. The frequency of bowel movements varies widely from one infant to another.

TAKE NOTE!

Newborns that are fed early pass stools sooner, which helps reduce bilirubin buildup (Pace et al., 2019).

The last development in the stool pattern is the milk stool. Its characteristics differ in breastfed and formula-fed newborns. The stools of the breastfed newborn are yellow-gold, loose, stringy to pasty in consistency, and typically sour-smelling. The stools of the formula-fed newborn vary depending on the type of formula ingested. They may be yellow, yellow-green, or greenish and loose, pasty, or formed in consistency, and they have an unpleasant odor.

Renal System Changes

A full complement of 1 million nephrons is present by 34 weeks' gestation. The glomeruli and nephrons are functionally immature at birth, resulting in a reduced glomerular filtration rate (GFR) and limited concentrating ability. A limited ability to concentrate urine and the reduced GFR make the newborn susceptible to both dehydration and fluid overload (Blackburn, 2018). Frequently the newborn's kidneys are described as immature, but they are able to carry out their usual responsibilities and can handle the challenge of excretion and maintaining acid–base balance. Only when the newborn is faced with unexpected imbalances of water, electrolytes, or a disruption of acid–base status secondary to a preterm birth or illness does it lack

the ability to handle the body's fluid homeostasis. A newborn infant's body mass is 75% water, the highest proportion of body water at any stage of a person's life. The majority of term newborns void immediately after birth, indicating adequate renal function. Although the newborn's kidneys can produce urine, they are limited in their ability to concentrate it until about 3 months of age, when the kidneys mature more. Until that time, a newborn voids frequently and the urine has a low specific gravity (1.001 to 1.020). About six to eight voidings daily is average for most newborns; this indicates adequate fluid intake (Martin & Rosenfeld, 2019).

The renal cortex is relatively underdeveloped at birth and does not reach maturity until 12 to 18 months of age. The GFR is the amount of fluid filtered each minute by all the glomeruli of both kidneys and is one index of kidney function. At birth, the newborn's GFR is approximately 30% of normal adult values, reaching approximately 50% of normal adult values by the 10th day of life and full adult values by the first year of life (Oh et al., 2019). The low GFR and the limited excretion and conservation capability of the kidney affect the newborn's ability to excrete salt, water loads, and drugs.

TAKE NOTE!

The possibility of fluid overload is increased in newborns; keep this in mind when administering intravenous therapy to a newborn.

Immune System Adaptations

Essential to the newborn's survival is the ability to respond effectively to hostile environmental forces. The newborn's immune system begins working early in gestation, but many of the responses do not function adequately during the early neonatal period. The newborn is protected from certain infections, in part because of maternal antibodies circulating in their systems until about 6 months of age. Immunoglobulin G (IgG) crosses the placenta to the fetus while in utero. Newborns who are breastfed receive antibodies from the

breast milk, which includes IgE, IgA, IgM, and IgG (Abbas et al., 2020). The risk of acquiring an infection is great because a newborn's immune system is immature and is not able to respond for long periods of time to fight infections. The intrauterine environment usually protects the fetus from harmful microorganisms and the need for defensive immunologic responses. With exposure to a wide variety of microorganisms at birth, the newborn must develop a balance between host defenses and the hostile environmental organisms to ensure a safe transition to the outside world. Healthy infants begin to produce their own antibodies starting at 2 to 3 months of age.

Responses of the immune system serve three purposes: defense (protection from invading organisms), homeostasis (elimination of worn-out host cells), and surveillance (recognition and removal of enemy cells). The newborn's immune system response involves recognition of the pathogen or other foreign material followed by activation of mechanisms to react against and eliminate it. All immune responses primarily involve leukocytes (white blood cells).

The immune system's responses can be divided into two categories: natural and acquired immunity. These mechanisms are interrelated and interdependent; both are required for immunocompetency.

Natural Immunity

Natural immunity includes responses or mechanisms that do not require previous exposure to the microorganism or antigen to operate efficiently. Physical barriers (such as intact skin and mucous membranes), chemical barriers (such as gastric acids and digestive enzymes), and resident nonpathologic organisms make up the newborn's natural immune system. Natural immunity involves the most basic host defense responses: ingestion and killing of microorganisms by phagocytic cells.

Acquired Immunity

Acquired immunity involves two primary processes: (1) the development of circulating antibodies or immunoglobulins capable of targeting specific invading agents (antigens) for destruction and (2) formation of activated lymphocytes designed to destroy foreign invaders. Acquired immunity is absent until after the first invasion by a foreign organism or toxin.

Immunologic ability depends heavily on immunoglobulins such as IgG, IgM, and IgA. The newborn depends largely on these three immunoglobulins for defense against microorganisms associated with illness. Newborns remain susceptible to infections for months.

IgG is the major immunoglobulin and the most abundant, making up about 80% of all circulating antibodies (Abbas et al., 2020). It is found in serum and interstitial fluid. It is the only class able to cross the placenta, with active placental transfer beginning at approximately 20 to 22 weeks' gestation. IgG produces antibodies against bacteria, bacterial toxins, and viral agents.

IgA is the second most abundant immunoglobulin in the serum. IgA does not cross the placenta, and maximum levels are reached during childhood. This immunoglobulin is believed to protect mucous membranes from viruses and bacteria. IgA is predominantly found in the gastrointestinal and respiratory tracts, tears, saliva, colostrum, and breast milk.

TAKE NOTE!

A major source of IgA is human breast milk, so breastfeeding is believed to have significant immunologic advantages over formula feeding. Breast milk has high levels of IgA that is thought to contribute to the colonization of the infant gut microbiome (Meyer et al., 2019).

IgM is found in blood and lymph fluid and is the first immunoglobulin to respond to infection. It does not cross the placenta, and levels are generally low at birth unless a congenital intrauterine infection is present. IgM offers a major source of protection from blood-borne infections. The predominant antibodies formed during neonatal or intrauterine infection are of this class.

Integumentary System Adaptations

The newborn skin is critical to its transition from intrauterine to extrauterine environments and to the journey to self-sufficiency. The newborn's skin is a large organ, making up approximately 13% of body weight in contrast to 3% of body weight in an adult. It is sensitive, fragile, with a neutral pH on the surface, lower lipid content, and higher water content when compared with adults. Because of these characteristics, newborn skin is vulnerable to injury and infections (Blackburn, 2018). The most important function of the skin is to provide a protective barrier between the body and the environment. It limits the loss of water, prevents absorption of harmful agents, protects thermoregulation and fat storage, and protects against physical trauma. The epidermal barrier begins to develop during midgestation and is fully formed by about 32 weeks' gestation. Although the neonatal epidermis is similar to the adult epidermis in thickness and lipid composition, skin development is not complete at birth (King et al., 2019). The basic structure is the same as that of an adult, but the less mature the newborn, the less mature the skin functions. Fewer fibrils connect the dermis and epidermis in the newborn compared with that of the adult. Also, in a newborn, the risk of injury producing a break in the skin from the use of tapes and monitors and from handling is greater than for an adult. Improper handling of the newborn during daily skin care practices, such as bathing, can cause damage, prevent healing, and interfere with the normal maturation process.

Newborns vary greatly in appearance. Many of the variations are temporary and reflect the physiologic adaptations that the newborn is experiencing. Skin coloring varies, depending on the newborn's age, race, or ethnic group; temperature; and whether they are crying. Skin color changes with both the environment and health status.

Neurologic System Adaptations

The nervous system is immature and continues to develop to achieve a full complement of cortical and brain stem cells by 1 year

of age. The brain increases its size threefold during the first year of life. The nervous system consists of the brain, spinal cord, 12 cranial nerves, and a variety of spinal nerves that come from the spinal cord. Neurologic development follows cephalocaudal (head-to-toe) and proximal–distal (center-to-outside) patterns. Myelin develops early on in sensory impulse transmitters. Thus, the newborn has an acute sense of hearing, smell, and taste. The newborn's sensory capabilities include:

- *Hearing*—well developed at birth, responds to noise by turning to sound
- *Taste*—ability to distinguish between sweet and sour by 72 hours old
- *Smell*—ability to distinguish between mother's breast milk and breast milk from others
- *Touch*—sensitivity to pain, responds to tactile stimuli
- *Vision*—incomplete at birth; maturation is dependent on nutrition and visual stimulation. Newborns have the ability to focus only on close objects (8 to 10 in away) with a visual acuity of 20/140; they can track objects in midline or beyond (90 in). This is the least mature sense at birth. The ability to fix, follow, and be alert is indicative of an intact CNS (King et al., 2019).

Remember Maria, the new mother who is worried that her daughter can't see? What might the new mother notice about her daughter's behavior? What might be the new mother's expectations?

Congenital Reflexes

Successful adaptations demonstrated by the respiratory, circulatory, thermoregulatory, and musculoskeletal systems indirectly indicate the CNS's successful transition from fetal to extrauterine life, because the CNS plays a major role in all these adaptations. In the newborn, congenital reflexes are the hallmarks of maturity of the CNS, viability, and adaptation to extrauterine life.

The presence and strength of a reflex is an important indication of neurologic development and function. A **reflex** is an involuntary muscular response to a sensory stimulus. It is built into the nervous

system and does not need the intervention of conscious thought to take effect. The physical assessment of the neurologic system of the newborn includes evaluating the major reflexes (gag, Babinski, Moro, and Galant) and minor ones (finger grasp, toe grasp, rooting, sucking, head righting, stepping, and tonic neck).

To assess each reflex, the nurse progresses methodically, taking care to document each finding (Jarvis & Eckhardt, 2020). Many neonatal reflexes disappear with maturation, though some remain throughout adulthood. The arcs of these reflexes end at different levels of the spine and brain stem, reflecting the function of the cranial nerves and motor systems. The ways newborns blink, move their limbs, focus on a caregiver's face, turn toward sound, suck, swallow, and respond to the environment are all indications of their neurologic abilities. Congenital defects within the CNS are frequently not overt but may be revealed in abnormalities in tone, posture, or behavior (Webster et al., 2018). Damage to the nervous system (e.g., from birth trauma, perinatal hypoxia) during the birthing process can cause delays in the normal growth, development, and functioning of the newborn. Early identification may help to identify the cause and facilitate start early intervention to decrease long-term complications or permanent sequelae.

Newborn reflexes are assessed to evaluate neurologic function and development. Absent or abnormal reflexes in a newborn, persistence of a reflex past the age when it is normally lost, or redevelopment of an infantile reflex in an older child or adult may indicate neurologic pathology. (See Chapter 18 for a description of newborn reflex assessment.)

The nurse explains to Maria that all newborns are born with some degree of myopia (inability to see distances) and that 20/20 vision is not generally achieved until 2 years of age. What developmental information should the nurse discuss with Maria?

BEHAVIORAL ADAPTATIONS

In addition to adapting physiologically, the newborn also adapts behaviorally. All newborns progress through a specific pattern of events after birth, regardless of their gestational age or the type of birth they experienced.

Behavioral Patterns

The newborn usually demonstrates a predictable pattern of behavior during the first several hours after birth, characterized by two periods of reactivity separated by a sleep phase. Behavioral adaptation is a defined progression of events triggered by stimuli from the extrauterine environment after birth.

First Period of Reactivity

The first period of reactivity begins at birth and may last from 30 minutes up to 2 hours. The newborn is alert and moving and may appear hungry. This period is characterized by myoclonic movements of the eyes, spontaneous Moro reflexes, sucking motions, chewing, rooting, and fine tremors of the extremities. Muscle tone and motor activity are increased (Resnik et al., 2019). Respiration and heart rate are elevated but gradually begin to slow as the next period begins.

This period of alertness allows parents to interact with their newborn and to enjoy close contact with their new baby (Fig. 17.6). The appearance of sucking and rooting behaviors provides a good opportunity for initiating breastfeeding. Many newborns latch on the nipple and suck well at this first experience.

FIGURE 17.6. The first period of reactivity is an optimal time for interaction.

Period of Decreased Responsiveness

At 30 to 120 minutes of age, the newborn enters the second stage of transition—that of the *sleep period* or a decrease in activity. This phase is referred to as a period of decreased responsiveness. Movements are less jerky and less frequent. Heart and respiratory rates decline as the newborn enters the sleep phase. The muscles become relaxed, and responsiveness to outside stimuli diminishes. During this phase, it is difficult to arouse or interact with the newborn. No interest in sucking is shown. This quiet time can be used for both mother and newborn to remain close and rest together after labor and the birthing experience.

Second Period of Reactivity

The second period of reactivity begins as the newborn awakens and shows an interest in environmental stimuli. This period lasts 2 to 8

hours in the normal newborn (King et al., 2019). Heart and respiratory rates increase. Peristalsis also increases. Thus, it is not uncommon for the newborn to pass meconium or void during this period. In addition, motor activity and muscle tone increase in conjunction with an increase in muscular coordination (Fig. 17.7).

Interaction between the mother and the newborn during this second period of reactivity is encouraged if the mother has rested and desires it. This period also provides a good opportunity for the parents to examine their newborn and ask questions.

TAKE NOTE!

Teaching about feeding, positioning for feeding, and diaper-changing techniques can be reinforced during the second period of reactivity.

FIGURE 17.7. Newborn during the second period of reactivity. Note the newborn's wide-eyed interest.

Behavioral Responses

Newborn development is a reflection of the dynamic relationship between endowment and environment. Newborns demonstrate several predictable responses when interacting with their environments. How they react to the world around them is termed a **neurobehavioral response**. It comprises predictable periods that are probably triggered by external stimuli. Expected newborn behaviors include orientation, habituation, motor maturity, self-quieting ability, and social behaviors. Any deviation in behavioral responses requires further assessment, because it may indicate a complex neurobehavioral problem.

Orientation

The response of newborns to stimuli is called orientation. They become more alert when they sense a new stimulus in their environment. Orientation reflects newborns' response to auditory and visual stimuli, demonstrated by their movement of head and eyes to focus on that stimulus. Newborns prefer the human face and bright shiny objects. As the face or object comes into their line of vision, newborns respond by staring at the object intently. Newborns use this sensory capacity to become familiar with people and objects in their surroundings.

> Remember Maria, who was concerned about her newborn daughter's vision? She told the nurse that her daughter did not show any interest in her pastel-colored homemade mobile she had hung across the room from her crib. What suggestions can the nurse make to Maria regarding the placement of the mobile and the types and colors of objects used to promote orientation in her daughter?

Habituation

Habituation is the newborn's ability to process and respond to visual and auditory stimuli. It is a measure of how well and appropriately an infant responds to the environment. Habituation is the ability to block out external stimuli after the newborn has become accustomed to

the activity. During the first 24 hours after birth, newborns should increase their ability to habituate to environmental stimuli and sleep. Habituation provides a useful indicator of neurobehavioral intactness.

Motor Maturity

Motor maturity depends on gestational age and involves evaluation of posture, tone, coordination, and movements. These activities enable newborns to control and coordinate movement. When stimulated, newborns with good motor organization demonstrate movements that are rhythmic and spontaneous. Bringing the hand up to the mouth is an example of good motor organization. As newborns adapt to their new environments, smoother movements should be observed. Such motor behavior is a good indicator of the newborn's ability to respond and adapt accordingly; it indicates that the CNS is processing stimuli appropriately.

Self-Quieting Ability

Self-quieting ability (also called self-soothing) refers to newborns' ability to quiet and comfort themselves. Newborns vary in their ability to console themselves or to be consoled. "Consolability" is how newborns are able to change from the crying state to an active alert, quiet alert, drowsy, or sleep state. They console themselves by hand-to-mouth movements and sucking, alerting to external stimuli, and motor activity (Mohr et al., 2019). Recent research outlines five things (the five "Ss") that parents can do to calm a fussy infant:

1. Swaddling tightly
2. Side/stomach position on the lap of the caregiver
3. Shushing loudly or continuous white noise
4. Swinging using any rhythmic movement
5. Sucking (Mohr et al., 2019)

Assisting parents in identifying consoling behaviors to quiet the newborn if the newborn is not able to self-quiet is important.

Social Behaviors

Newborns begin extrauterine life able to engage in it with their sensory capabilities and communicate with their environments through a complex repertoire of behaviors. Social behaviors include cuddling and snuggling into the arms of the parent when the newborn is held. Newborns are usually sensitive to being touched, cuddled, and held. Cuddliness is important to parents because they frequently gauge their ability to care for their newborn by the newborn's acceptance or positive response to their actions. This can be assessed by the degree to which the newborn nestles into the contours of the holder's arms. Most newborns cuddle, but some will resist. Assisting parents in assuming comforting behaviors (e.g., cooing while holding their newborn) and praising them for their efforts can help foster cuddling behaviors.

KEY CONCEPTS

- The neonatal period is defined as the first 28 days of life. As the newborn adapts to life after birth, numerous physiologic changes occur.
- At birth, the cardiopulmonary system must switch from fetal to neonatal circulation and from placental to pulmonary gas exchange.
- One of the most crucial adaptations that the newborn makes at birth is the adjustment of a fluid medium exchange from the placenta to the lungs and that of a gaseous environment.
- Neonatal RBCs have a lifespan of 80 to 100 days in comparison with the adult RBC lifespan of 120 days. This difference in RBC lifespan causes several adjustment problems.
- Thermoregulation is the maintenance of balance between heat loss and heat production. It is a critical physiologic function that is closely related to the transition and survival of the newborn.
- The newborn's primary method of heat production is through nonshivering thermogenesis, a process in which brown fat (adipose tissue) is oxidized in response to cold exposure. Brown fat is a special kind of highly vascular fat found in all humans.
- Heat loss in the newborn is the result of four mechanisms: conduction, convection, evaporation, and radiation.
- Responses of the immune system serve three purposes: defense (protection from invading organisms), homeostasis (elimination of worn-out host cells), and surveillance (recognition and removal of enemy cells).
- In the newborn, congenital reflexes are the hallmarks of maturity of the CNS, viability, and adaptation to extrauterine life.
- The newborn usually demonstrates a predictable pattern of behavior during the first several hours after birth, characterized by two periods of reactivity separated by a sleep phase.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. When assessing the term newborn, the following are observed: newborn is alert, heart and respiratory rates have stabilized, and meconium has been passed. The nurse determines that the newborn is exhibiting behaviors indicating the

   a. initial period of reactivity.
   b. second period of reactivity.
   c. decreased responsiveness period.
   d. sleep period.

2. A nurse observes a 3-day-old term newborn who is starting to appear mildly jaundiced. What might explain this condition?

   a. Physiologic jaundice secondary to breastfeeding
   b. Hemolytic disease of the newborn due to blood incompatibility
   c. Exposing the newborn to high levels of oxygen
   d. Overfeeding the newborn with too much glucose water

3. After teaching a group of nursing students about thermoregulation and appropriate measures to prevent heat loss by evaporation, which student behavior indicates successful teaching?

   a. Transporting the newborn in an isolette
   b. Maintaining a warm room temperature
   c. Placing the newborn on a warmed surface
   d. Drying the newborn immediately after birth

4. After birth, the nurse would expect which fetal structure to close as a result of increases in the pressure gradients on the left side of the heart?

   a. Foramen ovale
   b. Ductus arteriosus
   c. Ductus venosus
   d. Umbilical vein

5. Which newborn could be described as breathing normally?

   a. Newborn A is breathing deeply with a regular rhythm at a rate of 20 bpm.
   b. Newborn B is breathing diaphragmatically with sternal retractions at a rate of 70 bpm.
   c. Newborn C is breathing shallowly with 40-second periods of apnea and cyanosis.
   d. Newborn D is breathing shallowly at a rate of 36 bpm with short periods of apnea.

6. When assessing a term newborn (6 hours old), the nurse auscultates bowel sounds and documents recent passing of meconium. These findings would indicate

   a. abnormal gastrointestinal newborn transition that requires reporting.
   b. an intestinal anomaly that needs immediate surgery.
   c. a patent anus with no bowel obstruction and normal peristalsis.
   d. malabsorption syndrome resulting in fatty stools.

7. A nursing student asks the nursery nurse why they do not bathe the newborn immediately upon admission to the nursery observation area after birth. The nurse states that this would increase the risk of

   a. jaundice.
   b. infection.

c. hypothermia.
d. anemia.

8. Because the newborn's RBCs break down much sooner than those of an adult, what might result?

a. Anemia
b. Bruising
c. Apnea
d. Jaundice

9. The nurse performs a physical examination on a newborn 2 hours after birth. Which findings indicate a need for a pediatric consultation? Select all that apply.

a. Respiratory rate of 50 breaths per minute
b. Intermittent episodes of apnea lasting less than 10 seconds each
c. Absent Moro reflex when startled
d. Preauricular skin tag noted on left ear
e. White raised bumps noted on nose and face
f. Yellow blanching of the skin when pressure applied to the nose

CRITICAL THINKING EXERCISES

1. As the nurse manager, you have been orienting a new nurse in the nursery for the past few weeks. Although he has been demonstrating adequacy with most procedures, today you observe him bathing several newborns without covering them, weighing them on the scale without a cover, leaving the storage door open with the transporter nearby, and leaving the newborns' head covers and blankets off after showing them to family members through the nursery observation window.

a. What is your impression of this behavior?
b. What principles concerning thermoregulation need to be reinforced?

c. How will you evaluate whether your instructions have been effective?

2. The most important adaptations for the newborn to make after birth are to establish respirations, make cardiovascular adjustments, and establish thermoregulation. Nursing care focuses on monitoring and supporting adjustments to extrauterine adaptation. Write appropriate nursing interventions to help achieve the following newborn adaptations:

   a. Respiratory adaptation
   b. Safety, including prevention of infection
   c. Thermoregulation

STUDY ACTIVITIES

1. While in the nursery clinical setting, identify the period of behavioral reactivity (first, inactivity, or second period) for two newborns born at different times. Share your findings during the post conference for that clinical day.
2. Dramatic changes occur in the cardiovascular system at birth. When the umbilical cord is clamped and the placenta is separated, there is a resultant increase in systemic blood pressure and changes to the three major fetal shunts (ductus venosus, foramen ovale, and ductus arteriosus) occur. Outline what happens to cause their functional closures during this period of transition.
3. Find two websites about the transition to extrauterine life that can be shared with other nursing students as well as nursery nurses. Critique the information presented in terms of how accurate and current it is.
4. The most common mechanism of heat loss in the newborn is _____.
5. The newborn creates heat in three ways—by shivering, through muscle activity, and through thermogenesis by the metabolism of brown adipose tissue. Which is the most effective?

BRINGING IT ALL TOGETHER: A CASE STUDY

An 18-year-old woman gave birth to her first infant 3 days ago, but she does not smile when the Healthy Start nurse greets her at a home visit. The nurse questions her about what has happened since she was discharged from the hospital 2 days ago. She tells the nurse that her breasts are swollen, hot, and painful when touched. She states she knows that breastfeeding is best for her child, but she is not sure she wants to continue to breasfeed because of the pain. Her infant is lying on the bare kitchen table in a diaper crying.

ASSESSMENT

Upon examining the woman's breasts, the nurse finds that they are both swollen and hot to the touch, but there is no redness or palpated lump. (The client bites her lip and a tear falls from her eye when the nurse palpates her breasts). Milk drips freely from both nipples. Temperature is 37.7°C. The nurse examines the infant girl, who weighs 2,580 g. Her extremities are cyanotic and cold to touch. The infant has lost 100 g since birth and appears hungry. The nurse requests the client to breastfeed her infant so that she can observe the infant, and finds that the infant is having trouble grasping the swollen areola. When the infant finally latches on, she does not seem to suck vigorously.

Go to thePoint to find questions to consider about this case.

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Perform the assessments needed during the immediate newborn period.
2. Employ interventions that meet the immediate needs of the term newborn.
3. Demonstrate the components of a typical physical examination of a newborn.

4. Distinguish common variations that may be noted during a newborn's physical examination.
5. Characterize common concerns in the newborn and appropriate interventions.
6. Compare the importance of the newborn screening tests.
7. Plan for common interventions that are appropriate during the early newborn period.
8. Analyze the nurse's role in meeting the newborn's nutritional needs.
9. Outline discharge planning content and education needed for the family with a newborn.

Kelly, a 16-year-old first-time mother, calls the hospital maternity unit 3 days after being discharged home. She tells the nurse that her newborn son "looks yellow, like a canary" and "isn't nursing well." She wonders what is wrong.

INTRODUCTION

The birth of a newborn is an exciting time for the parents and the family. Immediately after the birth of a newborn, all mother and father/support persons/significant others are faced with the task of learning and understanding as much as possible about caring for this new family member, even if the parents already have other children. In their new or expanded role as parents, they will face many demands and challenges. For most, this is a wonderful, exciting time filled with many discoveries and much information.

Mother and father/support persons or significant others learn as they watch the nurse interacting with their newborn. Nurses play a major role in teaching the newborn's caretakers about normal newborn characteristics and about ways to foster optimal growth and development. This role is even more important today because of limited hospital stays.

The newborn has come from a dark, small, enclosed space in the mother's uterus into the bright, cold, extrauterine environment. The newborn transitions from a warm, calm and fluid environment to one in which physiologic adaptations must be made quickly in order to sustain extrauterine life successfully. Nurses can easily forget that they are caring for a small human being who is experiencing his or her first taste of human interaction outside the uterus. The newborn period is an extremely important one, and two national health goals have been developed to address this critical period (see the *Healthy People 2030* feature; U.S. Department of Health and Human Services [USDHHS], 2020).

It is also easy to overlook the intensity with which mother and father/support persons/significant others and visitors observe the actions of nurses as they care for the new family member. Nurses need to serve as a model for giving nurturing care to newborns. This chapter provides information about assessment and interventions in the period immediately following the birth of a newborn and during the early newborn period.

NURSING MANAGEMENT DURING THE IMMEDIATE NEWBORN PERIOD

The period of transition from intrauterine to extrauterine life occurs during the first several hours after birth. During this time, the newborn is undergoing numerous adaptations, many of which are occurring simultaneously (see Chapter 17 for more information on the newborn's adaptation). The neonate's temperature, respirations, and cardiovascular dynamics stabilize during this period. Close observation of the newborn's status is essential. Careful examination of the newborn at birth allows for detection of anomalies, birth injuries, and disorders that can compromise adaptation to extrauterine life. Problems that occur during this critical time can have a lifelong impact.

HEALTHY PEOPLE 2030

Objective	Nursing Significance
• MICH-2030-14 Increase the proportion of infants who are put to sleep on their backs. • MICH-2030-15 Increase the proportion of infants who are breastfed exclusively through 6 months.	• This back position will help prevent SIDS in young infants. Instruction of this safe position needs to begin after childbirth before discharge. • Will emphasize the importance of breast milk as the most complete form of nutrition for infants • Will help promote infant health, growth, immunity, and development throughout the newborn and infant periods
• Increase the proportion of newborns who are screened for hearing loss by no later than age 1 month, have audiologic evaluation by age 3 months, and are enrolled in appropriate intervention service no later than age 6 months.	• To insure best hearing in infants to facilitate language development

Assessment

The initial newborn assessment is completed in the birthing area to determine whether the newborn is stable enough to stay with the parents or whether resuscitation or other immediate interventions are necessary. Recently, an easy, rapid newborn assessment tool, the RAPP, has been developed to enhance the nurse's ability to quickly and accurately assess the newborn's physiologic condition. The RAPP assessment (**r**espiratory **a**ctivity, **p**erfusion/color, and **p**osition/tone) provides a method to swiftly evaluate the newborn's condition so that decisions can be made regarding newborn stability (Tappero & Honeyfield, 2019). A second assessment may be performed within the first 2 to 4 hours, when the newborn is admitted to the nursery or the labor and birth room. A third assessment is usually completed before discharge, according to the hospital policy. The purpose of these assessments is to determine the newborn's

overall health status, to provide information to the mother and father/support persons/significant others about their newborn, and to identify apparent physical abnormalities (Jnah & Trembath, 2019).

During the initial newborn assessment, look for signs that might indicate a problem, including:

1. Nasal flaring
2. Chest retractions
3. Grunting on exhalation
4. Labored breathing
5. Generalized cyanosis
6. Abnormal breath sounds: rhonchi, crackles (rales), wheezing, and stridor
7. Abnormal respiratory rates (tachypnea, more than 60 breaths/min; bradypnea, less than 25 breaths/min)
8. Flaccid body posture
9. Pallor
10. Apneic episodes
11. Abnormal heart rates (tachycardia, more than 160 bpm; bradycardia, less than 100 bpm)
12. Abnormal newborn size: small or large for gestational age

If any of these findings is noted, medical intervention may be necessary.

Apgar Scoring

The **Apgar score**, introduced in 1952 by Dr. Virginia Apgar, an anesthesiologist at Columbia University is used worldwide to evaluate a newborn's physical condition at 1 minute and 5 minutes after birth. An additional Apgar assessment is done at 10 minutes if the 5-minute score is less than 7 points. The heart rate was found to be the most important diagnostic and prognostic of the five signs (Simon & Hashmi, 2020). It can be used as a rapid method for assessing a newborn immediately after birth and its ability to survive. Assessment of the newborn at 1 minute provides data about the newborn's initial adaptation to extrauterine life. Assessment at 5

minutes provides a clearer indication of the newborn's overall central nervous system (CNS) status.

Five parameters are assessed with Apgar scoring. A quick way to remember the parameters of Apgar scoring is as follows:

- **A:** appearance (color)
- **P:** pulse (heart rate)
- **G:** grimace (reflex irritability)
- **A:** activity (muscle tone)
- **R:** respiratory (respiratory effort)

Each parameter is assigned a score ranging from 0 to 2 points. A score of 0 points indicates an absent or poor response; a score of 2 points indicates a normal response (Table 18.1). A normal newborn's score should be 8 to 10 points. The higher the score indicates the better condition of the newborn. If the Apgar score is 8 points or higher, no intervention is needed other than supporting normal respiratory efforts and maintaining thermoregulation. Scores of 4 to 7 points signify moderate difficulty and scores of 0 to 3 points represent severe distress in adjusting to extrauterine life. The Apgar score is influenced by the presence of infection, newborn maturity, mother's age, congenital anomalies, birth weight, maternal medications, physiologic immaturity, maternal sedation via medications, labor management, and neuromuscular disorders (Tiemeier & McCormick, 2019).

When the newborn experiences physiologic depression, the Apgar score characteristics disappear in a predictable manner: first the pink coloration is lost, next the respiratory effort, and then the tone, followed by the reflex irritability and finally heart rate (Lindsay et al., 2018).

TABLE 18.1 Apgar Scoring for Newborns

Parameter (Assessment Technique)	0 Point	1 Point	2 Points
Heart rate (auscultation of apical heart rate for 1 full minute)	Absent	Slow (<100 bpm)	>100 bpm
Respiratory effort (observation of the volume and vigor of the newborn's cry; auscultation of depth and rate of respirations)	Apneic	Slow, irregular, shallow	Regular respirations (usually 30–60 breaths/min), strong, good cry
Muscle tone (observation of the extent of flexion in the newborn's extremities and newborn's resistance when the extremities are pulled away from the body)	Limp, flaccid	Some flexion, limited resistance to extension	Tight flexion, good resistance to extension with quick return to flexed position after extension
Reflex irritability (flicking of the soles of the feet or suctioning of the nose with a bulb syringe)	No response	Grimace or frown when irritated	Sneeze, cough, or vigorous cry
Skin color (inspection of trunk and extremities with the appropriate color for ethnicity appearing	Cyanotic or pale	Appropriate body color; blue extremities (acrocyanosis)	Completely appropriate color (pink on both trunk and extremities)

within minutes
after birth)

(2019). Assessment of the mother, fetus, and newborn. In K. Marcdante & R. M. Kliegman (Eds.), *Nelson essentials of pediatrics* (8th ed.). Elsevier.

TAKE NOTE!

Although Apgar scoring is done at 1 and 5 minutes, it can also be used as a guide during the immediate newborn period to evaluate the newborn's status for any changes because it focuses on critical parameters that must be assessed throughout the early transition period.

Length and Weight

Parents are eager to know their newborn's length and weight. These measurements are taken soon after birth. A disposable tape measure or a built-in measurement board located on the side of some scales can be used. Length is measured from the head of the newborn to the heel with the newborn unclothed (Fig. 18.1). Because of the flexed position of the newborn after birth, place the newborn in a supine position and extend the leg completely when measuring the length. The expected length range of a full-term newborn is usually 44 to 55 cm (17 to 22 in). Molding can affect measurement (Chiocca, 2020).

Most often, newborns are weighed using a digital scale that reads the weight in grams. Typically, the term newborn weighs 2,500 to 4,000 g (5 lb, 8 oz to 8 lb, 14 oz; Fig. 18.2). Birth weights less than 10% or more than 90% on a growth chart are outside the normal range and need further investigation. Weights taken at later times are compared with previous weights and are documented with regard to gain or loss on a nursing flow sheet. Newborns can lose up to 10% of their initial birth weight by 3 to 4 days of age secondary to loss of meconium, extracellular fluid, and limited food intake. This

weight loss is usually regained by the 10th day of life (King et al., 2019).

FIGURE 18.1. Measuring a newborn's length.

FIGURE 18.2. Weighing the newborn. Note how the nurse guards the newborn with her hand to prevent falling.

Newborns can be classified by their birth weight regardless of their gestational age (American College of Obstetricians and Gynecologists [ACOG], 2019) as follows:

- Low birth weight: >2,500 g (>5.5 lb)
- Very low birth weight: >1,500 g (>3.5 lb)
- Extremely low birth weight: >1,000 g (>2.5 lb)

Vital Signs

Heart rate and respiratory rate are assessed immediately after birth with Apgar scoring. Heart rate, obtained by taking an apical pulse for 1 full minute, typically is 110 to 160 bpm. Newborns' respirations are assessed when they are quiet or sleeping. Place a stethoscope on the right side of the chest and count the breaths for 1 full minute to identify any irregularities. The newborn respiratory rate is 30 to 60 breaths/min with symmetric chest movement. Heart and respiratory rates are usually assessed every 30 minutes until stable for 2 hours after birth. Once stable, the heart rate and respiratory rates are checked every 8 hours. These assessment time frames may vary per hospital protocols, so nurses should follow the facility's procedures (Jefferson & Bibb, 2019).

Vital signs are assessed at birth, within 1 to 4 hours after birth according to hospital policy. Vital signs are used for identifying a variety of complications and for ensuring well-being of the newborn. In some health care agencies, temperatures are taken immediately after the Apgar score has been taken to allow for identification of hypothermia, which then requires a glucose check, but nurses need to follow their hospital protocols on this assessment timing. In term newborns, the normal axillary temperature range should be maintained at 97.7° to 99.5° F (36.5° to 37.5° C). Rectal temperatures are no longer taken because of the risk of perforation (Martin & Rosenfeld, 2019). The thermometer or temperature probe is held in the midaxillary space according to manufacturer's directions and hospital protocol. Blood pressure is not usually assessed as part of a normal newborn examination unless there is a clinical indication or low Apgar scores. If assessed, an oscillometer

(Dinamap) is used. The typical range is 50 to 75 mm Hg (systolic) and 30 to 45 mm Hg (diastolic) (Soghier, 2017). Typical values for newborn vital signs are provided in Table 18.2.

TABLE 18.2 Newborn Vital Signs

Newborn Vital Signs	Ranges of Values
Temperature	97.7–99.5°F (36.5–37.5°C)
Heart rate (pulse) to 180 during crying	110–160 bpm; can increase
Respirations	30–60 breaths/min at rest; will increase with crying
Blood pressure	50–75 mm Hg systolic, 30–45 mm Hg diastolic

Data from Gowen, C. W. (2019). Assessment of the mother, fetus, and newborn. In K. Marcdante & R. M. Kliegman (Eds.), *Nelson essentials of pediatrics* (8th ed.). Elsevier; Martin, G. I., & Rosenfeld, W. (2019). *Common problems in the newborn nursery: An evidence and case-based guide*. Springer.

Gestational Age Assessment

To determine a newborn's **gestational age** (the stage of maturity), physical signs and neurologic characteristics are assessed. Typically, gestational age is determined by using a tool such as the Ballard gestational age assessment or Ballard Scale. It determines a newborn's gestational age between 20 and 44 weeks. A score is assigned to the various parameters, and the total score corresponds to a maturity rating in weeks of gestation (Fig. 18.3). This scoring system provides an objective estimate of gestational age by scoring the specific parameters of physical as well as neuromuscular maturity. Points are given for each assessment parameter, with a low score of –1 point or –2 points for extreme immaturity to 4 or 5 points for postmaturity. The scores from each section are added to correspond to a specific gestational age in weeks.

The physical maturity section of the examination is done during the first 2 hours after birth. The physical maturity assessment section

of the Ballard examination evaluates physical characteristics that appear different at different stages depending on a newborn's gestational maturity. Newborns who are physically mature have higher scores than those who are not. The areas assessed on the physical maturity examination include:

- *Skin texture*—typically ranges from sticky and transparent to smooth, with varying degrees of peeling and cracking, to parchment-like or leathery with significant cracking and wrinkling.
- *Lanugo*—soft downy hair on the newborn's body, which is absent in preterm newborns, appears with maturity, and then disappears again with postmaturity.
- *Plantar creases*—creases on the soles of the feet, which range from absent to covering the entire foot, depending on maturity (the greater the number of creases, the greater the newborn's maturity).
- *Breast tissue*—the thickness and size of breast tissue and areola (the darkened ring around each nipple), which range from being imperceptible to full and budding.
- *Eyes and ears*—eyelids can be fused or open and ear cartilage and stiffness determine the degree of maturity (the greater the amount of ear cartilage with stiffness, the greater the newborn's maturity).
- *Genitals*—in males, evidence of testicular descent and appearance of scrotum (which can range from smooth to covered with rugae) determine maturity; in females, appearance and size of clitoris and labia determine maturity (a prominent clitoris with flat labia suggests prematurity, whereas a clitoris covered by labia suggests greater maturity).

The neuromuscular maturity section typically is completed within 24 hours after birth. Six activities or maneuvers that the newborn performs with various body parts are evaluated to determine the newborn's degree of maturity:

1. *Posture*—How does the newborn hold his or her extremities in relation to the trunk? The greater the degree of flexion, the greater the maturity. For example, extension of arms and legs is scored as 0 points and full flexion of arms and legs is scored as 4 points.

2. *Square window*—How far can the newborn's hands be flexed toward the wrist? The angle is measured and scored from more than 90 degrees to 0 degrees to determine the maturity rating. As the angle decreases, the newborn's maturity increases. For example, an angle of more than 90 degrees is scored as –1 point and an angle of 0 degrees is scored as 4 points.
3. *Arm recoil*—How far do the newborn's arms "spring back" to a flexed position? This measure evaluates the degree of arm flexion and the strength of recoil. The reaction of the arm is then scored from 0 to 4 points based on the degree of flexion as the arms are returned to their normal flexed position. The higher the points assigned, the greater the neuromuscular maturity (e.g., recoil less than a 90-degree angle is scored as 4 points).
4. *Popliteal angle*—How far will the newborn's knees extend? The angle created when the knee is extended is measured. An angle of less than 90 degrees indicates greater maturity. For example, an angle of 180 degrees is scored as –1 point and an angle of less than 90 degrees is scored as 5 points.
5. *Scarf sign*—How far can the elbows be moved across the newborn's chest? An elbow that does not reach midline indicates greater maturity. For example, if the elbow reaches or nears the level of the opposite shoulder, this is scored as –1 point; if the elbow does not cross the proximate axillary line, it is scored as 4 points.
6. *Heel to ear*—How close can the newborn's feet be moved to the ears? This maneuver assesses hip flexibility: the lesser the flexibility, the greater the newborn's maturity. The heel-to-ear assessment is scored in the same manner as the scarf sign.

							TOTAL PHYSICAL MATURITY SCORE	

FIGURE 18.3. Gestational age assessment tool. The New Ballard Score (2014). (Adapted from http://www.ballardscore.com)

After the scoring is completed, the 12 scores are totaled and then compared with standardized values to determine the appropriate gestational age in weeks. Scores range from very low in preterm newborns to very high for mature and postmature newborns.

Typically, newborns are also classified according to their gestational age as:

- *Preterm or premature*—born prior to 37 completed weeks' gestation, regardless of birth weight
- *Term*—born between 38 and 42 weeks' gestation

- *Post-term or postdates*—born after completion of week 42 of gestation
- *Postmature*—born after 42 weeks and demonstrating signs of placental aging

Using the information about gestational age and then considering birth weight, newborns can also be classified as follows:

- *Small for gestational age (SGA)*—weight less than the 10th percentile on standard growth charts (usually >5.5 lb)
- *Appropriate for gestational age (AGA)*—weight between 10th and 90th percentiles
- *Large for gestational age (LGA)*—weight more than the 90th percentile on standard growth charts (usually >9 lb)

Chapter 23 describes these variations in birth weight and gestational age in greater detail.

> *TAKE NOTE!*
>
> Gestational age assessment is important because it allows the nurse to plot growth parameters and to anticipate problems related to prematurity, postmaturity, and growth abnormalities.

Nursing Interventions

During the immediate newborn period, care focuses on helping the newborn to make the transition to extrauterine life. The nursing interventions include maintaining airway patency, ensuring proper identification, administering prescribed medications, and maintaining thermoregulation.

Maintaining Airway Patency

Immediately after birth, a newborn is suctioned to remove fluids and mucus from the mouth and nose (Fig. 18.4). Typically, the newborn's mouth is suctioned first with a bulb syringe to remove debris and then the nose is suctioned. Suctioning in this manner helps prevent aspiration of fluid into the lungs by an unexpected gasp. Recent

studies, along with recommendations from leading maternal health experts and the World Health Organization (WHO), support using a towel to wipe secretions from the mouth and nose of newborns for stable newborns. Routine suctioning of the mouth and airways is not required. Despite evidence showing that the use of routine suctioning shows no benefit and may produce harm, the practice remains commonplace (Coté, et al., 2019; Edwards, 2018).

When suctioning a newborn with a bulb syringe, compress the bulb before placing it into the oral or nasal cavity. Release bulb compression slowly, making sure the tip is placed away from the mucous membranes to draw up the excess secretions. Remove the bulb syringe from the mouth or nose, and then, while holding the bulb syringe tip over an emesis basin lined with paper towel or tissue, compress the bulb to expel the secretions. Repeat the procedure several times until all secretions are removed or use a towel to wipe away secretions per hospital policy.

FIGURE 18.4. A newborn is suctioned by means of a bulb syringe to remove mucus from the mouth and nose. The head-down-and-to-the-side position facilitates drainage. Care is given with the infant under a radiant heat source. (Copyright Caroline Brown, RNC, MS, DEd.)

TAKE NOTE!

Always keep a bulb syringe near the newborn in case he or she develops sudden choking or a blockage in the nose. It may be lifesaving.

Ensuring Proper Identification

The 21st century has brought many challenges to health care security, from the possibility of a terrorist attack, active shooters, and infant abductions. **Infant abduction** continues to be a threat in hospitals and health care organizations across the country. The abduction by nonfamily members of newborns from health care facilities has clearly become a subject of concern for parents, maternal–child care nurses, health care security and risk management administrators, law enforcement officials, and the National Center for Missing & Exploited Children (NCMEC). Staff identification (ID) badges, training, video surveillance, access control, and tagging systems can help prevent a newborn from being abducted from the hospital. Proactive security measures must become everyone's responsibility to ensure the safety of all newborns and their families in all hospital settings. Infant abductions have commonly been given security code names such as "Code Pink" in many hospitals.

Before the newborn and family leave the birthing area, be sure that agency policy about identification has been followed. Typically, the mother, the newborn, and the father or any significant other or support person of the mother's choosing receive ID bracelets. The newborn commonly receives two ID bracelets, one on a wrist and one on an ankle. The mother receives a matching one, usually on her wrist. The ID bands usually state name, gender, date and time of birth, and identification number. The same identification number is on the bracelets of all family members.

FIGURE 18.5. The nurse checks the newborn's identification band against the mother's.

These ID bracelets are provided for the safety of the newborn and must be secured before the mother and newborn leave the birthing area. The ID bracelets are checked by all nurses to validate that the correct newborn is brought to the right mother if they are separated for any period of time (Fig. 18.5). They also serve as the official newborn identification and should be checked before initiating any procedure on that newborn and on discharge from the unit (NCMEC, 2020). Taking the newborn's picture within 2 hours after birth with a color camera or color video/digital image also helps prevent mix-ups and abduction. Many facilities use electronic devices that sound an alarm if a newborn is taken beyond a certain point on the unit or removed from the area.

Newborns' footprints may also be taken, using a form that includes the mother's fingerprint, name, date, and time of the birth. Some states require footprints of the newborn, although many studies point out that birthing room staff does not take consistently legible footprints suitable for identification purposes. Many hospitals are

using a digital scan of the newborn's feet rather than using ink and paper to take newborn footprints. More footprint ridge pattern detail is picked up with scans (Widhalm, n. d.). Many states have stopped requiring newborn footprints, and thus other means of identification are needed, such as collecting cord blood at the time of birth for DNA testing; facial biometric recognition, and live scans to capture digital forensic-quality prints that are suitable for identification purposes. The Joint Commission (TJC, 2018) has created new requirements (barcoding) for hospitals with the goal of providing more distinguishing identification methods for newborns.

Prevention of infant abductions has been successful through a combination of increased security measures in hospitals, including video cameras and alarm devices, and education of staff and parents about precautions to take while in the hospital. It is critical not to allow anyone without identification to take an infant for any reason and to keep the infant within the sight of the parent or nursery staff at all times. These measures should be largely invisible and create a sense of security rather than increasing parental fears about abduction.

Although infant abduction rates are rare, the safety and security of mothers and infants should remain a high priority for nurses. By being aware of physical security of maternity units, educating expectant parents on the methods used by potential abductors, and working with community resources, these tragic incidents can be prevented.

Administering Prescribed Medications

During the immediate newborn period, two medications are commonly ordered: vitamin K and eye prophylaxis with either erythromycin or tetracycline ophthalmic ointment (Drug Guide 18.1).

VITAMIN K

Prophylactic treatment of newborns with intramuscular vitamin K has been the standard of care for decades in the United States. Vitamin K, a fat-soluble vitamin, promotes blood clotting by increasing the

synthesis of prothrombin by the liver. A deficiency of this vitamin delays clotting and might lead to hemorrhage. Newborns are at risk for vitamin K deficiency and subsequent bleeding unless supplemented at birth. Vitamin K deficiency is an acquired coagulopathy in newborn infants because of an accumulation of inactive vitamin K coagulation factors, which leads to an increased bleeding tendency. Supplementation of vitamin K at birth has been recommended in the United States since 1961 and successfully reduces the risk of bleeding in newborns. Vitamin K is not only an important public health intervention, but also an indicator of future parental health care decision-making behaviors such as that concerning immunizations. Some parents are refusing it to be administered to their newborns, placing them at risk of bleeding. Nurses need to make parents aware of the benefits of vitamin K prophylaxis, the risk for not receiving it, and the lack of evidence for any serious harms (Majid et al., 2019).

Generally, the bacteria of the intestine produce vitamin K in adequate quantities. However, the newborn's bowel is sterile, so vitamin K is not produced in the intestine until after microorganisms have been introduced, such as with the first feeding. Usually, it takes about a week for the newborn to produce enough vitamin K to prevent vitamin K deficiency bleeding. An oral vitamin K preparation is also being given to newborns outside the United States, but at least three doses are needed over a 1-month period (Eden & Coviello, 2020).

DRUG GUIDE 18.1 Drugs for the Newborn

Drug	Action/Indication	Nursing Implications
Phytonadione (vitamin K [Aqua-MEPHYTON, Konakion, Mephyton])	Provides the newborn with vitamin K (necessary for production of adequate clotting factors II, VII, IX, and X by the liver) during the first week of birth until newborn can manufacture it Prevents vitamin K deficiency bleeding (VKDB) of the newborn	• Administer within 1 to 2 hours after birth. • Give as an IM injection at a 90-degree angle into the outer middle third of the vastus lateralis muscle. • Use a 25-gauge, 5/8-in needle for injection. • Hold the leg firmly and inject medication slowly. • Adhere to standard precautions. • Assess for bleeding at injection site after administration.
Erythromycin ophthalmic ointment 0.5%	Provides bactericidal and bacteriostatic actions to prevent *Neisseria gonorrhoeae* and *Chlamydia trachomatis* conjunctivitis Prevents ophthalmia neonatorum	• Be alert for chemical conjunctivitis for 1 to 2 days. • Wear gloves, and open eyes by placing the thumb and finger above and below the eye. • Gently squeeze the tube or ampoule to apply medication into the conjunctival sac from the inner canthus to the outer canthus of each eye. • Do not touch the tip to the eye. • Close the eye to make sure the medication permeates.

	• Wipe off excess ointment after 1 minute.

Data from King, T. L., Brucker, M. C., Osborne, K., & Jevitt, C. M. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning; Skidmore-Roth, L. (2019). *Mosby's 2019 nursing drug reference* (32nd ed.). Mosby Elsevier.

The efficacy of vitamin K in preventing early vitamin K deficiency bleeding is firmly established and has been the standard of care since the AAP recommended it in the early 1960s. The American Academy of Pediatrics (AAP, 2019) recommends that vitamin K be administered to all newborns soon after birth in a single intramuscular dose of 0.5 to 1 mg (Fig. 18.6). The AAP also suggests that additional research is needed to validate the efficacy and safety of oral forms of vitamin K, which have been used in many parts of the world, but currently are not recommended in the United States.

EYE PROPHYLAXIS

All newborns in the United States, whether delivered vaginally or by cesarean birth, must receive an installation of a prophylactic agent in their eyes within an hour or two of birth. This is mandated in all 50 states to prevent ophthalmia neonatorum, which can cause neonatal blindness (U.S. Preventive Services Task Force [USPSTF], 2019). **Ophthalmia neonatorum** is a hyperacute purulent conjunctivitis occurring during the first 10 days of life. It is usually contracted during birth when the baby comes in contact with vaginal discharge of the mother infected with gonorrhea and chlamydia (USPSTF, 2019). Most often both eyelids become swollen and red with purulent discharge.

Prophylactic agents that are currently recommended (and in most states legally required) include erythromycin 0.5% ophthalmic ointment in a single application. Erythromycin ophthalmic ointment is the only drug approved by the USFDA for the prophylaxis of gonococcal neonatorium in the United States.

Regardless of which agent is used, instillation should be done as soon as possible after birth (Fig. 18.7). If instillation is delayed to allow visualization and bonding, the nursery staff should make sure the agent is administered when the newborn reaches the nursery for observation and assessment.

Inform all parents about the eye treatment, including why it is recommended, what problems may arise if the treatment is not given, and possible adverse effects of the treatment.

FIGURE 18.6. The nurse administers vitamin K IM to the newborn.

FIGURE 18.7. The nurse administers eye prophylaxis.

TAKE NOTE!

Ophthalmia neonatorum is a severe form of conjunctivitis caused by chlamydia and/or gonococcal infections that is potentially a blinding condition in newborns.

Maintaining Thermoregulation

Newborns have trouble regulating their temperature; especially during the first few hours after birth (see Chapter 17 for a complete discussion). Therefore, maintaining body temperature is crucial.

Concept Mastery Alert

Use of a Radiant Heater in Preventing Newborn Heat Loss

A 1-day-old infant should have adequate thermoregulation to remain out of the radiant heater. The best way to prevent heat loss is to ensure that the infant does not come in contact with cold surfaces.

Assess body temperature frequently during the immediate newborn period. The baby's temperature should be taken every 30 minutes for the first 2 hours or until the temperature has stabilized, and then every 8 hours until discharge or follow hospital protocols (King et al., 2019). Commonly a thermistor probe (automatic sensor) is attached to the newborn to record body temperature on a monitoring device. The probe is taped to the newborn's abdomen, usually in the right upper quadrant, which allows for position changes without having to readjust the probe. The other end of the thermistor probe is inserted into the radiant heat control panel. Temperature parameters are set on an alarm system connected to the heat panel that will sound if the newborn's temperature falls out of the set range. Check the probe connection periodically to make sure that it remains secure. Remember the potential for heat loss in newborns, and perform all nursing interventions in a way that minimizes heat loss and prevents hypothermia.

Axillary temperatures can also be used to assess the newborn's body temperature. Place a thermometer under the newborn's axilla and place the arm over the chest to keep the thermometer in place and provide comfort to the newborn.

Nursing interventions to help maintain body temperature include:

- Dry the newborn immediately after birth to prevent heat loss through evaporation.
- Wrap the baby in warmed blankets to reduce heat loss via convection.
- Skin-to-skin contact with mother as soon as stabilized.
- Use a warmed cover on the scale to weigh the unclothed newborn.
- Warm stethoscopes and hands before examining the baby or providing care.
- Avoid placing newborns in drafts or near air vents to prevent heat loss through convection.
- Delay the initial bath until the baby's temperature has stabilized to prevent heat loss through evaporation.
- Avoid placing cribs near cold outer walls to prevent heat loss through radiation.

- Put a cap on the newborn's head after it is thoroughly dried after birth.
- Place the newborn under a temperature-controlled radiant warmer (Fig. 18.8).

NURSING MANAGEMENT DURING THE EARLY NEWBORN PERIOD

The early newborn period is a time of great adjustment for both the mother and the newborn; both of them are adapting to many physiologic and psychological changes. In the past, mothers and newborns remained in the health care facility while these dramatic changes were taking place, with nurses and doctors readily available. However, today shorter hospital stays are the norm, and new mothers can easily be overwhelmed by having to go through all of these changes in such a short time: the woman gives birth, experiences marked physiologic and psychological changes, and must adapt to her newborn and learn the skills needed to care for herself and the baby, all within 24 to 48 hours.

The nurse's role is to assist the mother and her newborn through this dramatic transition period. The newborn needs continued health assessment, and the mother needs to be taught to care for the new baby. At discharge, the new mother may panic and feel insecure about her role as a primary caretaker. Nurses play a major role in promoting the newborn's transition by providing ongoing assessment and care and in promoting the woman's confidence by serving as a role model and teaching about proper newborn care.

FIGURE 18.8. Maintaining thermoregulation. **A.** Radiant warmer. **B.** Isolette.

Assessment

The newborn requires ongoing assessment after leaving the birthing area to ensure that his or her transition to extrauterine life is progressing without problems. The nurse uses the data gathered during the initial assessment as a baseline for comparison.

Perinatal History

Pertinent maternal and fetal data are vital to formulate a plan of care for the mother and her newborn. Historical information is obtained from the medical record and from interviewing the mother. Review the maternal history because it provides pertinent information, such as the presence of certain risk factors that could affect the newborn. Keep in mind that a comprehensive maternal history may not be available, especially if the mother has had limited or no prenatal care. Historical information usually includes the following:

- Mother's name, medical record number, blood type, serology result, rubella and hepatitis status, and history of substance abuse

- Other maternal tests that are relevant to the newborn and care, such as human immunodeficiency virus (HIV) and group B streptococcus status
- Intrapartum maternal antibiotic therapy (type, dose, and duration)
- Maternal illness that can affect the pregnancy, evidence of chorioamnionitis, maternal use of medications such as steroids
- Prenatal care, including timing of first visit and subsequent visits
- Risk for blood group incompatibility, including Rh status and blood type
- Fetal distress or any nonreassuring fetal heart rate patterns during labor
- Known inherited conditions such as sickle cell anemia and phenylketonuria (PKU)
- Birth weights of previous live-born children, along with identification of any newborn problems
- Social history, including tobacco, alcohol, and recreational drug use
- History of depression or domestic violence
- Cultural factors, including primary language and educational level
- Pregnancy complications associated with abnormal fetal growth, fetal anomalies, or abnormal results from tests of fetal well-being
- Information on the progress of labor, birth, labor complications, duration of ruptured membranes, and presence of meconium in the amniotic fluid
- Medications given during labor, at birth, and immediately after birth
- Time and method of delivery, including presentation and the use of forceps or a vacuum extractor
- Status of the newborn at birth, including Apgar scores at 1 and 5 minutes, the need for suctioning, weight, gestational age, vital signs, and umbilical cord status
- Medications administered to the newborn
- Postbirth maternal information, including placental findings, positive cultures, and presence of fever

Newborn Physical Examination

The initial newborn physical examination, which may demonstrate subtle differences related to the newborn’s age, is carried out within

the first 24 hours after birth. For example, a newborn who is 30 minutes old has not yet completed the normal transition from intrauterine to extrauterine life, and thus variability may exist in vital signs and in respiratory, neurologic, gastrointestinal, skin, and cardiovascular systems. Therefore, a comprehensive examination should be delayed until after the newborn has completed the transition.

The physical examination should not be initiated if the newborn is crying or appears to be upset. Instead, it is best to postpone the assessment until the newborn is calm. In a quiet newborn, begin the examination with the least invasive and noxious elements of the examination (auscultation of heart and lungs). Then examine the areas most likely to irritate the newborn (e.g., examining the hips and eliciting the Moro reflex). A general visual assessment provides an enormous amount of information about the well-being of a newborn. Initial observation gives an impression of a healthy (stable) versus an ill newborn and a term versus a preterm newborn.

A typical physical examination of a newborn includes a general survey of skin color, posture, state of alertness, head size, overall behavioral state, respiratory status, gender, and any obvious congenital anomalies. Check the overall appearance for anything unusual. Then complete the examination in a systematic fashion.

Remember Kelly, who called the home health nurse and said her newborn son “looks like a canary”? What additional information is needed about the baby? What might be causing his yellow color?

ANTHROPOMETRIC MEASUREMENTS

Shortly after birth, after the gender of the child is revealed, most women and their partners/significant others want to know the vital statistics of their newborn—length and weight—to report to their family and friends. Additional measurements, including head and chest circumference, are also taken and recorded. Abdominal measurements are not routinely obtained unless there is a suspicion of pathology that causes abdominal distention. The newborn’s progress from that point onward will be validated based on these

early measurements. These measurements will be compared with future serial measurements to determine growth patterns, which are plotted on growth charts to evaluate normalcy. Therefore, accuracy is paramount.

Length

The average length of most newborns is 50 cm (20 in), but it can range from 44 to 55 cm (17 to 22 in). Measure length with the unclothed newborn lying on a warmed blanket placed on a flat surface with the knees held in an extended position. Then run a tape measure down the length of the newborn—from the head to the soles of the feet—and record this measurement in the newborn's record (see Fig. 18.1).

Weight

At birth the average newborn weighs 3,400 g (7.5 lb), but normal birth weights can range from 2,500 to 4,000 g (5 lb, 8 oz to 8 lb, 13 oz). Newborns are weighed immediately after birth and then daily. Newborns usually lose up to 10% of their birth weight within the first few days of life but regain it in approximately 10 days.

Newborns are weighed on admission to the nursery or are taken to a digital scale to be weighed and returned to the mother's room. First, balance the scale if it is not balanced. Place a warmed protective cloth or paper as a barrier on the scale to prevent heat loss by conduction; recalibrate the scale to zero after applying the barrier. Next, place the unclothed newborn in the center of the scale. Keep a hand above the newborn for safety (see Fig. 18.2).

Weight is affected by racial origin, genetics, maternal age, size of the parents, maternal nutrition, maternal weight prenatally, and placental perfusion (Tappero & Honeyfield, 2019). Weight should be correlated with gestational age. A newborn who weighs more than normal might be LGA or an infant of a diabetic mother; a newborn who weighs less than normal might be SGA, preterm, or have a genetic syndrome. It is important to identify the cause for the deviation in size and to monitor the newborn for complications common to that etiology.

Head Circumference

The average newborn head circumference is 32 to 38 cm (13 to 15 in). Measure the circumference at the head's widest diameter (the occipitofrontal circumference). Wrap a flexible or paper measuring tape snugly around the newborn's head and record the measurement (Fig. 18.9A).

TAKE NOTE!

Head circumference may need to be remeasured at a later time if the shape of the head is altered from birth.

The head circumference should be approximately one fourth of the newborn's length or about half the infant's body length plus 10 cm. Expected head circumference for a term infant is between 32 and 37 cm (12.5 and 14.5 in) (Martin & Rosenfeld, 2019). A small head might indicate microcephaly caused by rubella, toxoplasmosis, or SGA status; an enlarged head might indicate hydrocephalus or increased intracranial pressure. Both need to be documented and reported for further investigation.

Chest Circumference

The chest circumference is generally 1 to 2 cm less than the head circumference (Chiocca, 2020). Place a flexible or paper tape measure around the unclothed newborn's chest just below the nipple line without pulling it taut (see Fig. 18.9B).

FIGURE 18.9. **A.** Measuring head circumference. **B.** Measuring chest circumference.

TAKE NOTE!

The head and chest circumferences are usually equal by about 1 year of age.

VITAL SIGNS

In the newborn, temperature, pulse, and respirations are monitored frequently and compared with baseline data obtained immediately after birth. Generally, vital signs (excluding blood pressure) are taken:

- On admission to the nursery or in the labor and birth room after the woman/parents are allowed to hold and bond with the newborn
- Once every 30 minutes until the newborn has been stable for 2 hours
- Then once every 4 to 8 hours until discharge (Jain & Suresh, 2019)

Blood pressure is not routinely assessed in a normal newborn unless the baby's clinical condition warrants it. This schedule can change depending on the baby's health status.

Obtain a newborn's temperature by placing an electronic temperature probe in the midaxillary area or by monitoring the electronic thermistor probe that has been taped to the abdominal skin (applied when the newborn was placed under a radiant heat source). Monitor the newborn's temperature frequently per hospital protocol for changes until it stabilizes. If the temperature is higher, adjust the environment, such as removing some clothing or blankets. If the temperature is lower, check the radiant warmer setting or add a warmed blanket. Report any abnormalities to the primary health care provider if simple adjustments to the environment do not change the baby's temperature.

Obtain an apical pulse by placing the stethoscope over the fourth intercostal space on the chest. Listen for a full minute, noting rate, rhythm, and abnormal sounds such as murmurs. In the typical newborn, the heart rate is 120 to 160 bpm, with wide fluctuations with activity and sleep. Sinus arrhythmia is a normal finding. Murmurs detected during the newborn period do not necessarily

indicate congenital heart disease, but they need to be evaluated further if they persist. Also palpate the apical, femoral, and brachial pulses for presence and equality (Fig. 18.10). Report any abnormalities to the primary health care provider for evaluation.

Assess respirations by observing the rise and fall of the chest for 1 full minute. Respirations should be symmetric, slightly irregular, shallow, and unlabored at a rate of 30 to 60 breaths/min. The newborn's respirations are predominantly diaphragmatic, but they are synchronous with abdominal movements. Also auscultate breath sounds. Note any abnormalities, such as tachypnea, bradypnea, grunting, gasping, periods of apnea lasting longer than 20 seconds, asymmetry or decreased chest expansion, abnormal breath sounds (rhonchi and crackles), or sternal retractions. Some variations might exist early after birth, but if the abnormal pattern persists, notify the primary health care provider.

SKIN

The newborn's skin is similar in structure to the adult's, but many of the functions are not fully developed. Observe the overall appearance of the skin, including color, texture, turgor, and integrity. The newborn's skin should be smooth and flexible, and the color should be consistent with genetic background.

Skin Condition and Color

Check skin turgor by pinching a small area of skin over the chest or abdomen and note how quickly it returns to its original position. In a well-hydrated newborn, the skin should return to its normal position immediately. Skin that remains "tented" after being pinched may indicate dehydration. A small amount of lanugo (fine downy hair) may be observed over the shoulders and on the sides of the face and upper back. There may be some cracking and peeling of the skin. The skin should be warm to the touch and intact.

FIGURE 18.10. Assessing the newborn's vital signs. **A.** Assessing the apical pulse. **B.** Palpating the femoral pulse. **C.** Palpating the brachial pulse.

The newborn's skin often appears blotchy or mottled, especially in the extremities. Persistent cyanosis of fingers, hands, toes, and feet with mottled blue or red discoloration and coldness is called **acrocyanosis** (Fig. 18.11). It may be seen in newborns during the first few weeks of life in response to exposure to cold. Acrocyanosis is normal and intermittent. Any change in color of the newborn skin needs further investigation.

FIGURE 18.11. Acrocyanosis. This commonly appears on the feet and hands of babies shortly after birth. This infant is a 32-week newborn. (From Fletcher M. [1998]. *Physical diagnosis in neonatology*. Lippincott-Raven Publishers.)

Newborn Skin Variations

While assessing the skin, make note of any rashes, ecchymoses or petechiae, nevi, or dark pigmentation. Skin lesions can be congenital or transient; they may be a result of infection or may result from the mode of birth. If any of them are present, observe the anatomic location, arrangement, type, and color. Bruising may result from the use of devices such as a vacuum extractor during delivery. Petechiae may be the result of pressure on the skin during the birth process. Forceps marks may be observed over the cheeks and ears. A small puncture mark may be seen if internal fetal scalp electrode monitoring was used during labor.

Common skin variations include vernix caseosa, stork bites or salmon patches, milia, Mongolian spots, erythema toxicum, harlequin sign, nevus flammeus, and nevus vasculosus (Fig. 18.12).

Vernix caseosa is a thick white substance that protects the skin of the fetus. It is formed by secretions from the fetus's oil glands and is found during the first 2 or 3 days after birth in body creases and the hair. It does not need to be removed because it will be absorbed into the skin.

Stork bites or salmon patches are superficial vascular areas found on the nape of the neck, on the eyelids, and between the eyes and upper lip (see Fig. 18.12A). The name comes from the marks on the back of the neck where, as myth goes, a stork may have picked up the baby. They are caused by a concentration of immature blood vessels and are most visible when the newborn is crying. They are considered a normal variant, and most fade and disappear completely within the first year.

FIGURE 18.12. Common skin variations. **A.** Stork bite. **B.** Milia. **C.** Mongolian spots. **D.** Erythema toxicum. **E.** Nevus flammeus (port-wine stain). **F.** Strawberry hemangioma.

Milia are multiple pearly-white or pale yellow unopened sebaceous glands frequently found on a newborn's nose. They may also appear on the chin and forehead (see Fig. 18.12B). They form from oil glands and disappear on their own within 2 to 4 weeks. When they occur in a newborn's mouth and gums, they are termed **Epstein pearls**. Milia occur in approximately 40% of newborns. As

most lesions break spontaneously within the first few weeks of life, no therapy is indicated (Schmitt, 2020).

Mongolian spots are benign blue or purple splotches that appear solitary on the lower back and buttocks of newborns but may occur as multiple over the legs and shoulders (see Fig. 18.12C). They tend to occur in African American, Asian, Hispanic, and Indian newborns but can occur in dark-skinned newborns of all races. The spots are caused by a concentration of pigmented cells and usually disappear spontaneously within the first 4 years of life. They should not be confused with bruises caused by trauma (Nguyen & Maguiness, 2019).

Erythema toxicum (newborn rash) is a benign, idiopathic, generalized, transient rash that occurs in up to 70% of all newborns during the first week of life. It consists of small papules or pustules on the skin resembling flea bites. It is often mistaken for staphylococcal pustules. The rash is common on the face, chest, and back (see Fig. 18.12D). One of the chief characteristics of this rash is its lack of pattern. It is caused by the newborn's eosinophils reacting to the environment as the immune system matures. Histologically, erythema toxicum shows an abundance of eosinophils. Although it has been recognized and described for centuries, its etiology and pathogenesis remain unclear (Gibbs & Seago, 2018). It does not require any treatment and disappears in a few days.

Harlequin sign refers to the dilation of blood vessels on only one side of the body, giving the newborn the appearance of wearing a clown suit. It gives a distinct midline demarcation, which is described as pale on the nondependent side and red on the opposite, dependent side. It results from immature autoregulation of blood flow and is commonly seen in low–birth-weight newborns when there is a positional change (Mathes & Lalor, 2019). It is transient, lasting as long as 20 minutes, and no intervention is needed.

Nevus flammeus, also called a port-wine stain, commonly appears on the newborn's face or other body areas (see Fig. 18.12E). It is a capillary angioma located directly below the dermis. It is flat with sharp demarcations and is purple red. This skin lesion is

made up of mature capillaries that are congested and dilated. It ranges in size from a few millimeters to large, occasionally involving as much as half the body surface. Although it does not grow in area or size, it is permanent and will not fade. Although they may occur anywhere on the body, the majority are located in the head and neck areas. Port-wine stains may be associated with structural malformations, bony or muscular overgrowth, and certain cancers. The optimal time for treatment is before 1 year of age. Recent studies have noted an association between port-wine birthmarks and childhood cancer, so newborns with these lesions should be monitored with periodic eye examinations, neurologic imaging, and extremity measurements. Lasers and intense pulsed light have been used to remove larger lesions with some success, but the efficacy of therapy has not improved in several decades, despite numerous technical innovations and pharmacologic interventions (van Raath et al., 2019).

Nevus vasculosus, also called a strawberry mark or strawberry hemangioma, is a benign capillary hemangioma in the dermal and subdermal layers. It is raised, rough, dark red, and sharply demarcated (see Fig. 18.12F). It is commonly found in the head region within a few weeks after birth and can increase in size or number. They are commonly found in about 10% of children. This type of hemangioma may be very subtle or even absent in the first few weeks of life, but they proliferate in the first few months of life. Commonly seen in premature infants weighing less than 1,500 g (Tappero & Honeyfield, 2019), these hemangiomas tend to resolve by age 3 without any treatment.

The most important aspects of nursing management related to newborn skin variations include adequate recognition of the lesions and knowledge of their natural history so that accurate information can be offered to the parents/significant other or partner. The majority of the skin lesions do not require any therapeutic intervention, but referral is necessary if there is: visual, airway or ear-canal obstruction, extensive growth, severe facial disfigurement, recurrent bleeding, infection, or ulceration, or excessive concern by the parents.

HEAD

Head size varies with age, gender, and ethnicity and has a general correlation with body size. Inspect a newborn's head from all angles. The head should appear symmetric and round. As many as 90% of the congenital malformations present at birth are visible on the head and neck, so careful assessment is very important (Jain & Suresh, 2019).

The newborn has two fontanels at the juncture of the cranial bones. The anterior fontanel is diamond shaped and closes by 18 to 24 months. Typically, it measures 4 to 6 cm at the largest diameter (bone to bone). The posterior one is triangular, smaller than the anterior fontanel (usually fingertip size or 0.5 to 1 cm) and closes by 6 to 12 weeks. Palpate both fontanels, which should be soft, flat, and open. Then palpate the skull. It should feel somewhat smooth and fused, except at the area of the fontanels, over molding areas, and sutures. Also assess the size of the head and the anterior and posterior fontanels, and compare them with appropriate standards.

Variations in Head Size and Appearance

During inspection and palpation, be alert for common variations that may cause asymmetry. These include molding, caput succedaneum, and cephalhematoma.

Molding is the elongated shaping of the fetal head to accommodate passage through the birth canal (Fig. 18.13). It occurs with a vaginal birth from a vertex position in which elongation of the fetal head occurs with prominence of the occiput and overriding sagittal suture line. It typically resolves within a week after birth without intervention.

Caput succedaneum describes localized edema on the scalp that occurs from the pressure of the birth process. It is commonly observed after prolonged labor. Clinically, it appears as a poorly demarcated soft tissue swelling that crosses suture lines. Pitting edema and overlying petechiae and ecchymosis are noted (Fig. 18.14A). The swelling will gradually dissipate in about 3 days without

any treatment. Newborns who were delivered via vacuum extraction usually have a caput in the area where the cup was used.

FIGURE 18.13. Molding in a newborn's head.

Cephalhematoma is a localized subperiosteal collection of blood of the skull which is always confined by one cranial bone. This condition is due to pressure on the head and disruption of the vessels during birth. It occurs after prolonged labor and use of obstetric interventions such as low forceps or vacuum extraction. The clinical features include a well-demarcated, often fluctuant

swelling with no overlying skin discoloration. The swelling does not cross suture lines and is firmer to the touch than an edematous area (see Fig. 18.14B). Aspiration is not required for resolution and is likely to increase the risk of infection. Hyperbilirubinemia occurs following the breakdown of the red blood cells within the hematoma. This type of hyperbilirubinemia occurs later than classic physiologic hyperbilirubinemia. Cephalhematoma usually appears on the second or third day after birth and disappears within weeks or months. Large cephalhematomas can lead to increased bilirubin levels and subsequent jaundice (Martin & Rosenfeld, 2019).

Common Abnormalities in Head or Fontanel Size

Common abnormalities in head or fontanel size that may indicate a problem include:

- *Microcephaly*—a head circumference more than two standard deviations below average or less than 10% of normal parameters for gestational age, caused by failure of brain development. There is a reduced production of neurons leading to a reduction of brain volume and as a consequence of that a reduced skull size. Microcephaly is not common, affecting one in 800 to 5,000 infants in the United States each year (CDC, 2020). Children with severe microcephaly, defined as more than three standard deviations below the mean for age and sex, are more likely to have imaging abnormalities and more severe developmental impairments than those with milder microcephaly. Conditions associated with microcephaly include seizures, developmental delay, intellectual disability, hearing loss, and problem with vision, movement, balance, or feeding.
- It can be genetically derived or may be associated with infections (cytomegalovirus, rubella, toxoplasmosis), Zika virus exposure, syndromes such as trisomy 13, 18, or 21 and in utero exposure to alcohol or certain other drugs (Kerr et al., 2019; Woods & Parker, 2019).
- *Macrocephaly*—usually a benign condition that does not require intervention. It is a head with a circumference more than 90% of normal, typically related to hydrocephalus (Nguyen & Thomson, 2019). It is often familial (with autosomal dominant inheritance) and

can be either an isolated anomaly or a manifestation of other anomalies, including hydrocephalus and skeletal disorders (achondroplasia).

- *Large fontanels*—more than 6 cm in the anterior diameter bone to bone or more than a 1-cm diameter in the posterior fontanel; possibly associated with malnutrition, hydrocephaly, congenital hypothyroidism, trisomies 13, 18, and 21, and various bone disorders such as osteogenesis imperfecta.
- *Small or closed fontanels*—smaller-than-normal anterior and posterior diameters or fontanels that are closed at birth. Craniosynostosis and abnormal brain development refer to the premature fusion of cranial sutures, with inhibition of perpendicular cranial bone growth and are associated with a small fontanel or early fontanel closure associated with microcephaly. Management strategies for syndromic craniosynostosis infants require multidisciplinary subspecialty teams to provide optimal care for complex reconstructive approaches (Sawh-Martinez & Steinbacher, 2019).

FACE

Observe the newborn's face for fullness and symmetry. The face should have full cheeks and should be symmetric when the baby is resting and crying. If forceps were used during birth, the newborn may have bruising and reddened areas over both cheeks and parietal bones secondary to the pressure of the forceps blades. Reassure the parents that this resolves without treatment, and point out improvement each day.

Problems with the face can also involve facial nerve paralysis caused by trauma from the use of forceps. Paralysis is usually apparent on the first or second day of life. Typically, the newborn will demonstrate asymmetry of the face with an inability to close the eye and move the lips on the affected side. Newborns with facial nerve paralysis have difficulty making a seal around the nipple, and consequently milk or formula drools from the paralyzed side of the mouth. Most facial nerve palsies resolve spontaneously within days,

although full recovery may require weeks to months. Attempt to determine the cause from the newborn's history.

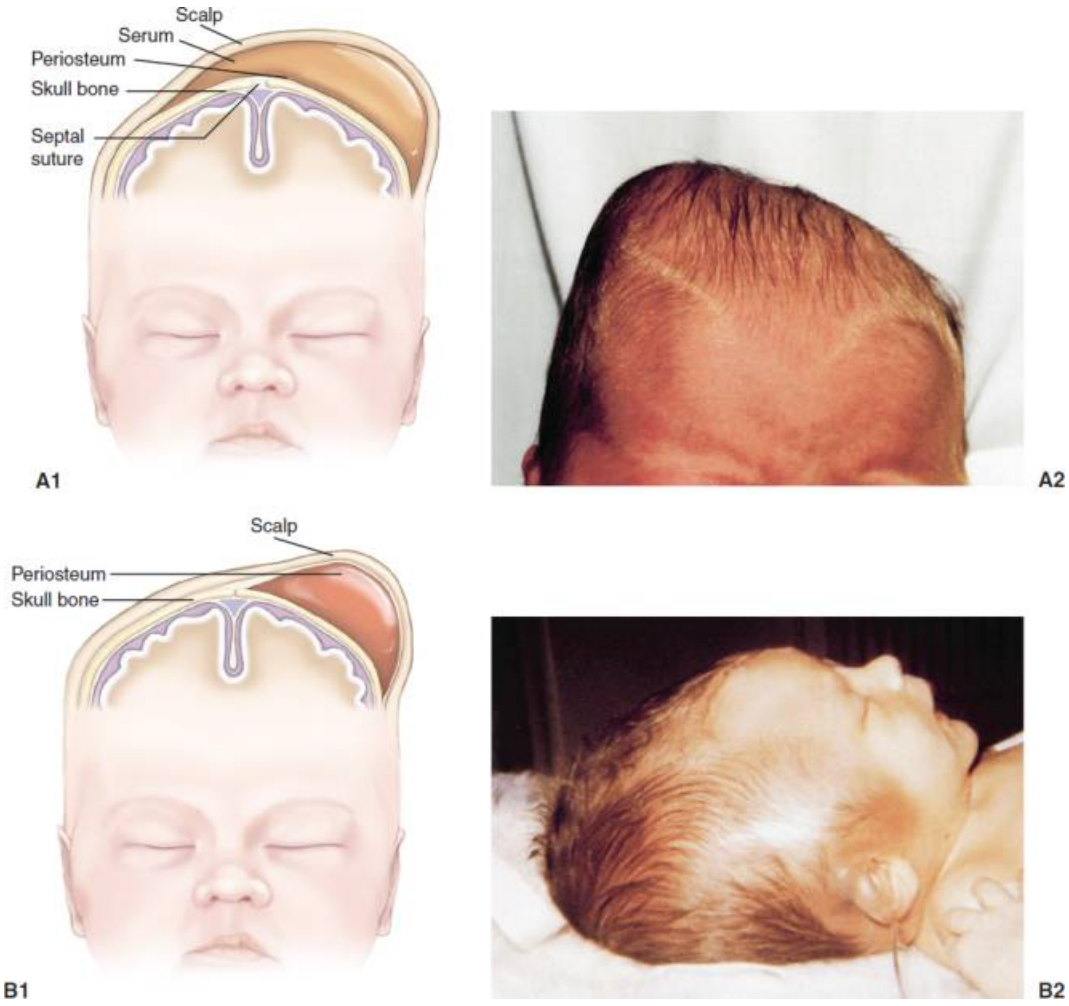

FIGURE 18.14. A1 and **A2.** Caput succedaneum involves the collection of serous fluid and often crosses the suture line. **B1** and **B2.** Cephalhematoma involves the collection of blood and does not cross the suture line. (**A2** and **B2**: Stroup, K. T., & Kersten, H. B. (2015). Chapter 2: Scalp swellings in the newborn. In E. Chung, L. R. Atkinson-McVoy, N. L. Lai, & M. Terry. *Visual Diagnosis and Treatment in Pediatrics* (3rd ed.). Wolters Kluwer Health.)

Nose

Inspect the nose for size, symmetry, position, and lesions. The newborn's nose is small and narrow. The nose should have a midline placement, patent nares, and an intact septum. The nostrils should

be of equal size and should be patent. A slight mucous discharge may be present, but there should be no actual drainage. The newborn is a preferential nose breather and will use sneezing to clear the nose if needed. The newborn can smell after the nasal passages are cleared of amniotic fluid and mucus (Salandy et al., 2019).

Mouth

Inspect the newborn's mouth, lips, and interior structures. The lips should be intact with symmetric movement and positioned in the midline; there should not be any lesions. Inspect the lips for pink color, moisture, and cracking. The lips should encircle the examiner's finger to form a vacuum. Variations involving the lip might include cleft upper lip (separation extending up to the nose) or thin upper lip associated with fetal alcohol syndrome.

FIGURE 18.15. A natal tooth in a 16-day-old neonate. Natal teeth can be present at birth and are usually considered benign. No treatment is needed if they don't interfere with feeding.

Assess the inside of the mouth for alignment of the mandible, intact soft and hard palate, sucking pads inside the cheeks, a midline

uvula, a free-moving tongue, and working gag, swallow, and sucking reflexes. The mucous membranes lining the oral cavity should be pink and moist, with minimal saliva present.

Normal variations might include Epstein pearls (small, white epidermal cysts on the gums and hard palate that disappear in weeks), erupted natal teeth that may need to be removed to prevent aspiration (Fig. 18.15), and thrush (white plaque inside the mouth caused by exposure to *Candida albicans* during birth), which cannot be wiped away with a cotton-tipped applicator.

Eyes

Inspect the external eye structures, including the eyelids, lashes, conjunctiva, sclera, iris, and pupils, for position, color, size, and movement. There may be marked edema of the eyelids and subconjunctival hemorrhages due to pressure during birth. The eyes should be clear and symmetrically placed. Test the blink reflex by bringing an object close to the eye; the newborn should respond quickly by blinking. Also test the newborn's pupillary reflex: pupils should be equal, round, and reactive to light bilaterally. Assess the newborn's gaze: he or she should be able to track objects to the midline. Movement may be uncoordinated during the first few weeks of life. Many newborns have transient strabismus (deviation or wandering of eyes independently) and searching nystagmus (involuntary repetitive eye movement), which is caused by immature muscular control. These are normal for the first 3 to 6 months of age.

Examine the internal eye structures. A red reflex (luminous red appearance seen on the retina) should be seen bilaterally on retinoscopy. The red reflex normally shows no dullness or irregularities.

Chemical conjunctivitis commonly occurs within 24 hours of instillation of eye prophylaxis after birth. There is lid edema with sterile discharge from both eyes. Usually it resolves within 48 hours without treatment.

Ears

Inspect the ears for size, shape, skin condition, placement, amount of cartilage, and patency of the auditory canal. The ears should be soft and pliable and should recoil quickly and easily when folded and released. Ears should be aligned with the outer canthi of the eyes. Low-set ears and abnormally shaped ears are characteristic of many syndromes and genetic abnormalities, such as trisomy 13 or 18, and internal organ abnormalities involving the renal system. Findings of sinuses or preauricular skin tags should prompt further evaluation for possible renal abnormalities since both systems develop at the same time.

An otoscopic examination is not typically done because the newborn's ear canals are filled with amniotic fluid and vernix caseosa, which would make visualization of the tympanic membrane difficult.

Newborn hearing screening is required by law in most states (discussed later in the chapter). Hearing loss is the most common birth defect in the United States: About 1.7 in 1,000 newborns have some degree of hearing impairment (CDC, 2019d). The WHO notes that globally, at least 34 million children have disabling hearing loss and it is estimated that by 2050, more than 900 million people will have disabling hearing loss (2020a). Delays in identification and intervention may affect the child's cognitive, verbal, behavioral, and emotional development. Screening at birth has reduced the age at which newborns with hearing loss are identified and has improved early intervention rates dramatically.

Available treatments include cochlear implantation, hearing augmentation, and follow-up by an audiologist, otolaryngologist, pediatrician, geneticist, and deaf education specialist (Marx et al., 2019). Prior to universal newborn screening, children were usually older than 2 years before significant congenital hearing loss was detected; by this time, it had already affected their speech and language skills (CDC, 2019d).

Causes of hearing loss can be conductive, sensorineural, or central. Risk factors for congenital hearing loss include genetics, maternal infections such as cytomegalovirus infection and preterm birth necessitating a stay in the neonatal intensive care unit.

To assess for hearing ability generally, observe the newborn's response to noises and conversations. The newborn typically turns toward these noises and startles with loud ones.

NECK

Inspect the newborn's neck for movement and ability to support the head. The newborn's neck will appear almost nonexistent because it is so short. Creases are usually noted. The neck should move freely in all directions and should be capable of holding the head in a midline position. The newborn should have enough head control to be able to hold it up briefly without support. Report any deviations such as restricted neck movement or absence of head control.

Also inspect the clavicles (collarbone), which should be straight and intact. The clavicles are the bones mostly commonly broken in infants, especially large ones experiencing difficult births, in operative vaginal births, abnormal fetal positions, and in maternal obesity. In most cases, the fractured clavicle is asymptomatic, but edema, crepitus, and decreased or absent movement and pain or tenderness on movement of the arm on the affected side may be noted. Major risk factors for clavicle fractures are typically vacuum births and large newborn birth weights (Martin & Rosenfeld, 2019). If the newborn with clavicular fracture is in pain, the affected arm should be immobilized, with the arm abducted more than 60 degrees and the elbow flexed more than 90 degrees. In addition to immobilization, treatment involves minimizing pain overall.

CHEST

Inspect the newborn's chest for size, shape, and symmetry. The newborn's chest should be round, symmetric, and 2 to 3 cm smaller than the head circumference. The xiphoid process may be prominent at birth, but it usually becomes less apparent when adipose tissue accumulates. Nipples may be engorged and may secrete a white discharge. This discharge, which occurs in both boys and girls, is a result of exposure to high levels of maternal estrogen while in utero.

This enlargement and milky discharge usually dissipate within a few weeks. Some newborns may have extra nipples, called supernumerary nipples. They are typically small, raised, pigmented areas vertical to the main nipple line, 5 to 6 cm below the normal nipple. Supernumerary nipples may be unilateral or bilateral, and they may include an areola, nipple, or both. They tend to be familial and do not contain glandular tissue. Supernumerary nipples are generally thought to be benign. Some studies have suggested an association with renal or urogenital anomalies, whereas other studies have failed to show this association. There is insufficient evidence to recommend imaging studies or removal in the absence of other clinical concerns or physical findings (Grewal & Lindholm, 2019). Reassure parents that these extra small nipples are harmless.

The newborn chest is usually barrel shaped, with equal anteroposterior and lateral diameters, and symmetric. Auscultate the lungs bilaterally for equal breath sounds. Normal breath sounds should be heard, with little difference between inspiration and expiration. Fine crackles can be heard on inspiration soon after birth as a result of amniotic fluid being cleared from the lungs (Chiocca, 2020). Diminished breath sounds might indicate atelectasis or pneumonia.

Listen to the heart when the newborn is quiet or sleeping. S1 and S2 heart sounds are accentuated at birth. The point of maximal impulse is a lateral to midclavicular line located at the fourth intercostal space. A displaced point of maximal impulse may indicate tension pneumothorax or cardiomegaly. Murmurs are common during the first few hours as the foramen ovale is closing. Although cardiac murmurs in the neonatal period do not necessarily indicate heart disease, they should be evaluated if they persist (King et al., 2019).

ABDOMEN

Inspect the abdomen for shape and movement. Typically, the newborn’s abdomen is protuberant but not distended. This contour is

a result of the immaturity of the abdominal muscles. Abdominal movements are synchronous with respirations because newborns are, at times, abdominal breathers.

Auscultate bowel sounds in all four quadrants and then palpate the abdomen for consistency, masses, and tenderness. Perform auscultation and palpation systematically in a clockwise fashion until all four quadrants have been assessed. Palpate gently to feel the liver, the kidneys, and any masses. The liver is normally palpable 1 to 3 cm below the costal margin in the midclavicular line. The kidneys are 1 to 2 cm above and to both sides of the umbilicus. Normal findings would include bowel sounds in all four quadrants and no masses or tenderness on palpation. Absent or hyperactive bowel sounds might indicate an intestinal obstruction. Abdominal distention might indicate ascites, obstruction, infection, masses, hydronephrosis, or an enlarged abdominal organ. The newborn may also show signs of abdominal tenderness. Imaging is a mainstay to diagnosis abdominal pathology and should be readily performed in a newborn with abdominal distention to determine the underlying etiology.

Inspect the umbilical cord area for the correct amount of blood vessels (two arteries and one vein). The umbilical vein is larger than the two umbilical arteries. Evidence of only a single umbilical artery is associated with renal and gastrointestinal anomalies. Also inspect the umbilical area for signs of bleeding, infection, inflammation, redness, swelling, purulent drainage or bleeding, erythema around the umbilicus, granuloma, or abnormal communication with the intra-abdominal organs. Umbilical infections can occur because of an embryologic remnant or poor hygiene. Traditionally, gram-positive organisms, such as *Staphylococcus aureus* and *Streptococcus pyogenes,* were most commonly identified, but gram-negative and polymicrobial infections are seen today. An umbilical cord infection (omphalitis) can spread to adjacent tissue, causing peritonitis, hepatic vein thrombosis, and hepatic abscess. It is a true medical emergency that can rapidly progress to a systemic infection and death. Immediate evaluation and referral is needed (Painter & Feldman, 2019). (See Evidence-Based Practice Box 18.1.)

EVIDENCE-BASED PRACTICE 18.1

Systematic Review of the Effect of Topical Application of Human Breast Milk on Early Umbilical Cord Separation

STUDY

Umbilical cord care practices vary worldwide due to cultural traditions and global health practices. The World Health Organization recommends dry cord care without the application of a topical substance in countries with low rates of neonatal mortality. Application of topical chlorhexidine is recommended in areas with higher infant mortality. Some studies found that antiseptics prolonged the time of umbilical cord separation. Early cord detachment is preferred. The use of topical breast milk has been suggested as an effective cord care substance because it has antimicrobial, healing properties and antiinflammatory effects. The purpose of this review was to evaluate the efficacy of topical application of human breast milk to reduce cord separation time.

Findings

From more than 1,300 articles screened, 8 articles containing randomized controlled trials were included in this systematic review and meta-analysis. The results showed that infants who received topical application of human breast milk to their umbilical cords had significantly shorter times to cord separation than infants who received dry cord care.

Nursing Implications

Umbilical cord care is an essential component of neonatal care. This review found a significant reduction in the time of the cord separation with the topical application of human breast milk

compared to dry cord care. Optimal umbilical cord care has the potential to reduce neonatal morbidity and mortality. Nurses should instruct mothers to wash their hands before expressing their milk, apply several drops of breast milk to the umbilical stump, and allow it to dry. The human breast milk cord care regimen is safe, convenient, feasible, cost effective, and noninvasive. This regimen should be considered as an alternative method in hospital settings.

Adapted from Kirk, A. H. P., Yang, J, Chia, L. Y. X., & Lau, Y. (2019). Systematic review of the effect of topical application of human breast milk on early umbilical cord separation. Journal of Obstetric, Gynecologic, & Neonatal Nursing, 48(2), 121–130. https:/doi.org/10.1016/j.jogn.2018.12.004

GENITALIA

Male

Inspect the penis and scrotum in the male. In the circumcised male newborn, the glans should be smooth, with the meatus centered at the tip of the penis. It will appear reddened until it heals. For the uncircumcised male, the foreskin should cover the glans. Check the position of the urinary meatus: it should be in the midline at the glans' tip. If it is on the ventral surface of the penis, the condition is termed hypospadias; if it is on the dorsal surface of the penis, it is termed epispadias. In either case, circumcision should be avoided until further evaluation.

Inspect the scrotum for size, symmetry, color, presence of rugae, and location of testes. The scrotum usually appears relatively large with well-formed rugae and that should cover the scrotal sac. There should not be bulging, edema, or discoloration (Fig. 18.16A).

Palpate the scrotum for evidence of the testes, which should be in the scrotal sac. The testes should feel firm and smooth and should be of equal size on both sides of the scrotal sac in the term newborn. Undescended testes (cryptorchidism) might be palpated in the inguinal canal in preterm infants; they can be unilateral or bilateral. If

the testes are not palpable within the scrotal sac, further investigation is needed.

Female

In the female newborn, inspect the external genitalia. The urethral meatus is located below the clitoris in the midline (King et al., 2019). In contrast to the male genitalia, the female genitalia will be engorged: the labia majora and minora may both be edematous. The labia majora is large and covers the labia minora. The clitoris is large and the hymen is thick. These findings are due to the maternal hormones' estrogen and progesterone (see Fig. 18.16B). A vaginal discharge composed of mucus mixed with blood may also be present during the first few weeks of life. This discharge, called pseudomenstruation, requires no treatment. Explain this phenomenon to the parents.

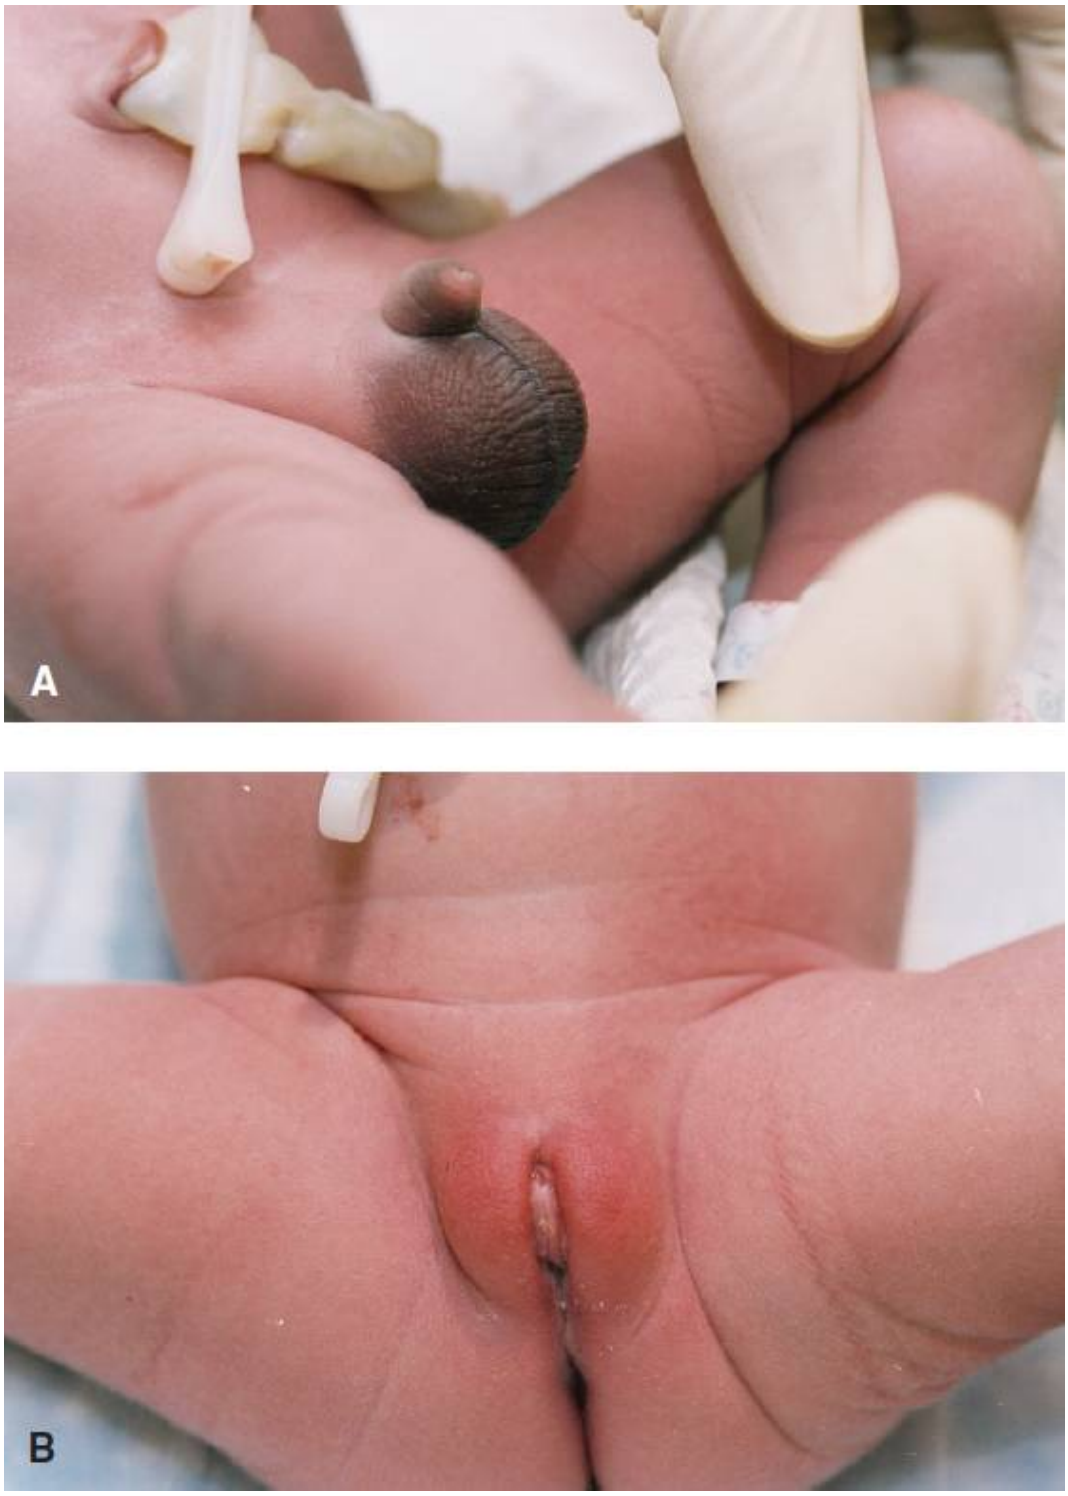

FIGURE 18.16. Newborn genitalia. **A.** Male genitalia. Note the darkened color of the scrotum. **B.** Female genitalia.

Variations in female newborns may include a labial bulge, which might indicate an inguinal hernia, ambiguous genitalia, a rectovaginal fistula with feces present in the vagina, and an imperforate hymen.

Male and Female

Inspect the anus in both male and female newborns for position and patency. Passage of meconium indicates patency. If meconium is not passed, a lubricated rectal thermometer can be inserted or a digital examination can be performed to determine patency. Abnormal findings would include anal fissures or fistulas and no meconium passed within 24 hours after birth.

EXTREMITIES AND BACK

Upper Extremities

Inspect the newborn's upper extremities for appearance and movement. Inspect the hands for shape, number, and position of fingers and presence of palmar creases. The newborn's arms and hands should be symmetric and should move through the range of motion without hesitation. Observe for spontaneous movement of the extremities. Each hand should have five digits. Note any extra digits (polydactyly) or fusing of two or more digits (syndactyly). Most newborns have three palmar creases on the hand. A single palmar crease, called a simian line, is frequently associated with Down syndrome.

A brachial plexus injury can occur during a difficult birth involving shoulder dystocia. Shoulder dystocia is an unpredictable and unpreventable obstetric emergency which can result in newborn physical injury or death. Erb palsy is an injury resulting from damage to the upper plexus, and palsies associated with the lower brachial plexus are termed Klumpke palsies. Factors associated with obstetric brachial plexus paralysis include large birth weight, breech delivery, labor anomalies, operative vaginal birth, and shoulder dystocia. Obstetric brachial plexus paralysis results from excessive

lateral traction on the head away from the shoulder. This force on the brachial plexus can cause varying degrees of injury to the nerves. The affected arm hangs limp alongside the body, and the affected shoulder and arm are adducted, extended, and internally rotated with a pronated wrist. The Moro reflex is absent on the affected side in brachial palsy. Complete recovery may take 6 months or longer. Current research studies support endogenous labor forces as the etiology of this injury. Despite training in the management of shoulder dystocia and a rising institutional cesarean section rate, the incidence of brachial plexus injuries has remained unchanged compared with 10 years earlier (DeFrancesco et al., 2019).

Lower Extremities

Assess the lower extremities in the same manner. They should be of equal length, with symmetric skinfolds. Inspect the feet for clubfoot (a turning-inward position), which is secondary to intrauterine positioning. This may be positional or structural. Perform the Ortolani and Barlow maneuvers to identify congenital hip dislocation, commonly termed developmental dysplasia of the hip. Nursing Procedure 18.1 highlights the steps for performing these maneuvers. Table 18.3 summarizes the newborn assessment.

NEUROLOGIC STATUS

Assess the newborn's state of alertness, posture, muscle tone, and reflexes.

Newborn Alertness, Posture, and Muscle Tone

The newborn should be alert and not persistently lethargic. The normal posture is hips abducted and partially flexed, with knees flexed. Arms are adducted and flexed at the elbow. Fists are often clenched, with fingers covering the thumb.

To assess for muscle tone, support the newborn with one hand under the chest. Observe how the neck muscles hold the head. The neck extensors should be able to hold the head in line briefly. There

should be only slight head lag when pulling the newborn from a supine position to a sitting one.

Newborn Reflexes

Reflexes are present in all newborns and if absent or persistent past a certain time period, it may indicate a CNS problem. Assess the newborn's reflexes to evaluate neurologic function and development. Absent or abnormal reflexes in a newborn, persistence of a reflex past the age when the reflex is normally lost, or return of an infantile reflex in an older child or adult may indicate neurologic pathology (Table 18.4). Reflexes commonly assessed in the newborn include sucking, Moro, stepping, tonic neck, rooting, Babinski, palmar grasp and plantar grasp reflexes. Spinal reflexes tested include truncal incurvation (Galant reflex) and anocutaneous reflex (anal wink).

The *sucking reflex* is elicited by gently stimulating the newborn's lips by touching them. The newborn will typically open the mouth and begin a sucking motion. Placing a gloved finger in the newborn's mouth will also elicit a sucking motion (Fig. 18.17A).

NURSING PROCEDURE 18.1 Performing Ortolani and Barlow Maneuvers

Purpose: To Detect Congenital Developmental Dysplasia of the Hip

Ortolani Maneuver

1. Place the newborn in the supine position and flex the hips and knees to 90 degrees at the hip.
2. Grasp the inner aspect of the thighs and abduct the hips (usually to approximately 180 degrees) while applying upward pressure.

3. Listen for any sounds during the maneuver. There should be no “cluck” or “click” heard when the legs are abducted. Such a sound indicates the femoral head hitting the acetabulum as the head reenters the area. This suggests developmental hip dysplasia.

Barlow Maneuver

1. With the newborn still lying supine and grasping the inner aspect of the thighs (as just mentioned), adduct the thighs while applying outward and downward pressure to the thighs.
2. Feel for the femoral head slipping out of the acetabulum; also listen for a click.

3. Inspect the back. The spine should appear straight and flat and should be easily flexed when the baby is held in a prone position. Observe for the presence of a tuft of hair, a pilonidal dimple in the midline, a cyst, or a mass along the spine. These abnormal findings should be documented and reported to the primary health care provider.

Adapted from Chiocca, E. M. (2020). *Advanced pediatric assessment* (3rd ed.). Springer Publishing Company; Tamai, J., & McCarthy, J. J. (2020). Developmental dysplasia of the hip. *eMedicine*. Retrieved February 6, 2020, from https://emedicine.medscape.com/article/1248135-overview

The *Moro reflex*, also called the embrace reflex, occurs when the neonate is startled. To elicit this reflex, place the newborn on his or her back. Support the upper body weight of the supine newborn by the arms, using a lifting motion, without lifting the newborn off the surface. Then release the arms suddenly. The newborn will throw the arms outward and flex the knees; the arms then return to the chest. The fingers also spread to form a C shape. The newborn initially appears startled and then relaxes to a normal resting position (see Fig. 18.17B).

Assess the *stepping reflex* by holding the newborn upright and inclined forward with the soles of the feet touching a flat surface. The

baby should make a stepping motion or walking, alternating flexion and extension with the soles of the feet (see Fig. 18.17C).

The *tonic neck reflex* resembles the stance of a fencer and is often called the fencing reflex. Test this reflex by having the newborn lie on the back. Turn the baby's head to one side. The arm toward which the baby is facing should extend straight away from the body with the hand partially open, whereas the arm on the side away from the face is flexed and the fist is clenched tightly. Reversing the direction to which the face is turned reverses the position (see Fig. 18.17D).

Elicit the *rooting reflex* by stroking the newborn's cheek. The newborn should turn toward the side that was stroked and should begin to make sucking movements (see Fig. 18.17E).

The *Babinski reflex* should be present at birth and disappears at approximately 1 year of age. It is elicited by stroking the lateral sole of the newborn's foot from the heel toward and across the ball of the foot. The toes should fan out. A diminished response indicates a neurologic problem and needs follow-up (see Fig. 18.17F).

The newborn exhibits two grasp reflexes: *palmar grasp* and *plantar grasp*. Elicit the palmar grasp reflex by placing a finger on the newborn's open palm. The baby's hand will close around the finger. Attempting to remove the finger causes the grip to tighten. Newborns have strong grasps and can almost be lifted from a flat surface if both hands are used. The grasp should be equal bilaterally (see Fig. 18.17G). The plantar grasp is similar to the palmar grasp. Place a finger just below the newborn's toes. The toes typically curl over the finger (see Fig. 18.17H).

TABLE 18.3 Newborn Assessment Summary

Assessment	Usual Findings	Variations and Common Problems
Anthropometric measurements	Head circumference: 33–37 cm (13–14 in) Chest circumference: 30–33 cm (12–13 in) Weight: 2,500–4,000 g (5.5–8.5 lb) Length: 45–55 cm (19–21 in)	SGA, LGA, preterm, post-term
Vital signs	Temperature: 97–99°F (36.5–37.5°C) Apical pulse: 110–160 bpm Respirations: 30–60 breaths/min	
Skin	Normal: smooth, flexible, good skin turgor, well hydrated, warm	Jaundice, acrocyanosis, milia, Mongolian spots, stork bites
Head	Normal: varies with age, gender, and ethnicity	Microcephaly, macrocephaly, enlarged fontanels
Face	Normal: full cheeks, facial features symmetric	Facial nerve paralysis, nevus flammeus, nevus vasculosus
Nose	Normal: small, placement in the midline and narrow, ability to smell	Malformation or blockage
Mouth	Normal: aligned in midline, symmetric, intact soft and hard palate	Epstein pearls, erupted precocious teeth, thrush
Neck	Normal: short, creased, moves freely, baby holds head in midline	Restricted movement, clavicular fractures
Eyes	Normal: clear and symmetrically placed on face; online with ears	Chemical conjunctivitis, subconjunctival hemorrhages

Ears	Normal: soft and pliable with quick recoil when folded and released	Low-set ears, hearing loss
Chest	Normal: round, symmetric, smaller than head	Nipple engorgement, whitish discharge
Abdomen	Normal: protuberant contour, soft, three vessels in umbilical cord	Distended, only two vessels in umbilical cord
Genitals	Normal male: smooth glans, meatus centered at tip of penis Normal female: swollen female genitals as a result of maternal estrogen	Edematous scrotum in males, vaginal discharge in females
Extremities and spine	Normal: extremities symmetric with free movement	Congenital hip dislocation; tuft or dimple on spine

Data from Martin, G. I., & Rosenfeld, W. (2019). *Common problems in the newborn nursery: An evidence and case-based guide*. Springer; Chiocca, E. M. (2020). *Advanced pediatric assessment* (3rd ed.). Springer Publishing Company.

TABLE 18.4 Newborn Reflexes: Appearance and Disappearance

Reflex	Appearance	Disappearance
Blinking	Newborn	Persists into adulthood
Moro	Newborn	3–6 months
Grasp	Newborn	3–4 months
Stepping	Birth	1–2 months
Tonic neck	Newborn	3–4 months
Sneeze	Newborn	Persists into adulthood
Rooting	Birth	4–6 months
Gag reflex	Newborn	Persists into adulthood
Cough reflex	Newborn	Persists into adulthood
Babinski sign	Newborn	12 months

Blinking, *sneezing*, *gagging,* and *coughing* are all protective reflexes and are elicited when an object or light is brought close to the eye (blinking); something irritating is swallowed or a bulb syringe is used for suctioning (gagging and coughing); or an irritant is brought close to the nose (sneezing).

The *truncal incurvation reflex (Galant reflex)* is present at birth and disappears in a few days to 4 weeks (Fig. 18.18). With the newborn in a prone position or held in ventral suspension, apply firm pressure and run a finger down either side of the spine. This stroking will cause the pelvis to flex toward the stimulated side. This indicates T2–S1 innervation. Lack of response indicates a neurologic or spinal cord problem.

FIGURE 18.18. Trunk incurvation reflex. When the paravertebral area is stroked, the newborn flexes his or her trunk toward the direction of the stimulation. (Copyright Caroline Brown, RNC, MS, DEd.)

The *anocutaneous reflex* (*anal wink*) is elicited by stimulating the perianal skin close to the anus. The external sphincter will constrict (wink) immediately with stimulation. This indicates S4–S5 innervations (Beck et al., 2019).

Nursing Interventions

Developing confidence in caring for their newborn is challenging for most parents/significant others/partners. It takes time and patience, and a great deal of instruction provided by the nurse. “Showing and telling” parents about their newborn and all the procedures (e.g., feeding, bathing, changing, and handling) involved in daily care are key nursing interventions.

Providing General Newborn Care

Generally, newborn care involves bathing and hygiene, elimination and diaper area care, cord care, circumcision care, environmental safety measures, and prevention of infection. Nurses should teach these skills to parents and should serve as role models for appropriate and consistent interaction with newborns. Demonstrating respect for the newborn and family helps foster a positive atmosphere to promote the newborn's growth and development.

BATHING AND HYGIENE

Immediately after birth, drying the newborn and removing blood may minimize the risk of infection caused by hepatitis B, herpes virus, and HIV, but the specific benefits of this practice remain unclear. Until the newborn has been thoroughly bathed, standard precautions should be used when handling the newborn. Nurses need to follow their hospital policies regarding the timing and procedures for newborn bathing and hygiene.

Newborns are bathed primarily for aesthetic reasons, and bathing is postponed until thermal and cardiorespiratory stability is ensured. However, recent research suggests that nurses do not need to give the newborn an initial bath rather, the parents could be given this opportunity, supported by nurses. A recent study found that waiting to bathe the newborn 48 hours after birth versus waiting only 24 hours after birth was more effective in preserving the body temperature of the newborn (Gozen et al., 2019). Although this study indicated waiting the longer length of time to bathe the newborn, most mothers are discharged from the hospital before the later time.

Nursing Procedure 18.2 explains the steps for bathing the newborn. It is important for the nurse to wear gloves, because of potential exposure to maternal blood on the newborn, and perform the bath quickly, drying the baby thoroughly to prevent heat loss by evaporation.

After bathing, place the newborn under the radiant warmer and wrap him or her securely in blankets to prevent chilling. Check the baby's temperature within an hour to make sure it is within normal

limits. If it is low, place the newborn under a radiant heat source again.

After the initial bath, the newborn may not receive another full one during the stay in the birthing unit. The diaper area will be cleansed at each diaper change, and any milk spilled into the newborn's neck folds from breastfeeding or formula will be cleaned. Clear water and a mild soap are appropriate to cleanse the diaper area. The use of lotions, baby oil, and powders is not recommended because oils and lotions can lead to skin irritation and can cause rashes. Powders should not be used because they can be inhaled, causing respiratory distress. If the parents want to use oils and lotions, have them apply a small amount onto their hand first, away from the newborn; this warms the lotion. Then the parents should apply the lotion or oil sparingly.

Encourage the parents to gather all items needed before starting the bath: a soft, clean washcloth; two cotton balls to clean the eyes; mild, unscented soap and shampoo; towels or blankets; a tub or basin with warm water; a clean diaper; and a change of clothes. Instruct parents that a bath two or three times weekly is sufficient for the first year; more frequent bathing may dry the skin. Parents should not fully immerse the newborn into water until the umbilical cord area has healed—up to 2 weeks after birth. Encourage parents to give the infant a sponge bath until the umbilical cord falls off and the navel area has healed completely. If the newborn has been circumcised, advise parents to wait until that area has also healed (usually 1 to 2 weeks). Until then, clean the penis with mild soap and water and apply a small amount of petroleum jelly to the tip to prevent the diaper from adhering to the penis. Instruct parents to apply the diaper loosely and place the newly circumcised male infant on his side or back to prevent pressure and irritation on the penis.

Other guidelines for bathing newborns are given in Teaching Guidelines 18.1.

TEACHING GUIDELINES 18.1

Bathing a Newborn

- Select a warm room with a flat surface at a comfortable working height.
- Before the bath, gather all supplies needed so they will be within reach.
- Never leave the newborn alone or unattended at any time during the bath.
- Undress the newborn down to shirt and diaper.
- Always support the newborn's head and neck when moving or positioning him or her.
- Place a blanket or towel underneath the newborn for warmth and comfort.
- In this order, progressing from the cleanest to the dirtiest areas:
  - Wipe eyes with plain water, using either cotton balls or a washcloth. Wipe from the inner corner of the eyes to the outer with separate wipes.
  - Wash the rest of the face, including ears, with plain water.
  - Using baby shampoo, gently wash the hair and rinse with water.
  - Pay special attention to body creases, and dry thoroughly.
  - Wash extremities, trunk, and back. Wash, rinse, dry, cover.
  - Wash diaper area last, using soap and water, and dry; observe for rash.
- Put on a clean diaper and clean clothes after the bath.

ELIMINATION AND DIAPER AREA CARE

Newborn elimination patterns are highly individualized. Usually the urine is light amber in color. Soaking six to 12 diapers a day indicates adequate hydration. Stools can change in color, texture, and frequency without signaling a problem. Meconium is passed for the first 48 hours after birth; the stools appear thick, tarry, sticky, and dark green. Transitional stools (thin, brown to green, less sticky than meconium) typically appear by day 3 after initiation of feeding. The stool characteristics after transitional stool depend on whether the

newborn is breastfed or bottle-fed. Breastfed newborns typically pass mustard-colored, soft stool with a seedy consistency; formula-fed newborns pass yellow to brown, soft stools with a pasty consistency. As long as the newborn seems content, is eating normally, and shows no signs of illness, minor changes in bowel movements should not be a concern.

The newborn needs to be checked frequently to see whether a diaper change is needed, especially after feeding. Adhere to standard precautions when providing diaper area care. Instruct parents to keep the top edge of the diaper folded down below the umbilical cord area to prevent irritation and to allow air to help dry the cord. For a male infant, point the penis down to prevent urine from wetting the top of the diaper where the umbilicus is located.

Meconium can be difficult to remove from the skin. Use plain water or special cleansing wipes if necessary, to clean the area. Teach parents how to clean the diaper area properly and how to prevent skin irritation. Encourage them to avoid products such as powder and fragranced items, which could irritate the newborn's skin.

Discuss the pros and cons of using cloth diapers versus disposable diapers so that the parents can make informed decisions. Regardless of the type of diapers used, up to 10 diapers a day, or about 70 a week, will be needed.

Additional information about diapering might include:

- Before diapering, make sure all supplies are within reach, including clean diaper, cleaning agent or wipes, and ointment.
- Lay the newborn on a changing table and remove the dirty diaper.
- Use water and mild soap or wipes to gently wipe the genital area clean; wipe from front to back for girls to avoid urinary tract infections.
- Wash your hands thoroughly before and after changing diapers.

While performing diaper area care, parents should observe the area closely for irritation or rash. Tips for preventing or healing a diaper rash include:

- Change diapers frequently, especially after bowel movements.
- Apply a "barrier" cream, such as A&D ointment or Desitin, after cleaning with mild soap and water.

- Use dye- and fragrance-free detergents to wash cloth diapers.
- Avoid the use of plastic pants, because they tend to hold in moisture.
- Expose the newborn's bottom to air several times a day.
- Place the newborn's buttocks in warm water after he or she has had a diaper on all night.

TAKE NOTE!

Advise parents that a rash that persists for more than 3 days may be fungal in origin and may require additional treatment. Encourage the parents to notify the health care provider.

CORD CARE

The umbilical cord begins drying within hours after birth and is shriveled and blackened by the second or third day. Within 7 to 10 days, it sloughs off and the umbilicus heals. During this transition, frequent assessments of the area are necessary to detect any bleeding or signs of infection. Cord bleeding is abnormal and may occur if the cord clamp is loosened. Any cord drainage is also abnormal and is generally caused by infection, which requires immediate treatment.

To protect the cord area during each diaper change, apply the appropriate agent (e.g., triple dye, alcohol, or an antimicrobial agent), according to facility policy, to the cord stump to prevent any ascending infections. Single-use agents for cleaning are recommended to prevent cross-contamination with other newborns. Expect to remove the cord clamp approximately 24 hours after birth by using a cord-cutting clamp. However, if the cord is still moist, keep the clamp in place and ensure a referral to home health care so that the home care nurse can remove it after discharge. Always adhere to agency policies regarding cord care; changes in policy may be necessary based on new research findings.

Many parents avoid contact with the cord site to make sure they don't "bother" it. Teach them how to care for the cord site when they

go home to prevent complications (Teaching Guidelines 18.2).

TEACHING GUIDELINES 18.2
Umbilical Cord Care

- Observe for bleeding, redness, drainage, or foul odor from the cord stump and report it to your newborn's primary care provider immediately.
- Avoid tub baths until the cord has fallen off and the area has healed.
- Expose the cord stump to the air as much as possible throughout the day.
- Fold diapers below the level of the cord to prevent contamination of the site and to promote air-drying of the cord.
- Observe the cord stump, which will change color from yellow to brown to black. This is normal.
- Never pull the cord or attempt to loosen it; it will fall off naturally.

NURSING PROCEDURE 18.2 Bathing the Newborn

It is important that the nurse wear gloves, because of potential exposure to maternal blood on the newborn, and performs the bath quickly, drying the baby thoroughly to prevent heat loss by evaporation. Keep the newborn covered to prevent heat loss during the bathing procedure.

1. Begin the newborn bath starting from the cleanest area (the eyes) and proceeding to the most soiled area (the diaper area) to prevent cross-contamination. Use plain warm water on the face and eyes, adding a mild soap (e.g., Dove) to cleanse the remainder of the body. Wash, rinse, and dry each area before proceeding to the next one.

2. Wash the hair using running water so that the scalp can be thoroughly rinsed. A mild shampoo or soap can be used. Wash both fontanel areas. Frequently, parents avoid these “soft spots” because they fear that they will “hurt the

baby's brain" if they rub too hard. Reassure parents that there is a strong membrane providing protection. Urge the parents to clean and rinse these areas well. If the anterior fontanel is not rinsed well after shampooing, cradle cap (dry flakes on the scalp) can develop. Avoid getting water in ears to prevent infection.

3. Make sure to cleanse all body creases, especially the neck folds to remove any milk that may have dripped into these areas.

4. Continue downward washing the trunk and extremities ending up with the diaper area last.

CIRCUMCISION AND CARE OF THE PENIS

Circumcision is one of the oldest and most common surgical procedures performed worldwide but remains controversial. It is performed for medical, religious, cultural, and social reasons. **Circumcision** is the surgical removal of all or part of the foreskin (prepuce) of the penis. Despite the fact that one in three males are currently circumcised worldwide, questions remain about the

procedure and social value (Piontek & Albani, 2019). This has been traditionally done for hygiene and medical reasons and is the oldest known religious rite. In the Jewish faith, circumcision is a ritual that is performed by a *mohel* (ordained circumciser) on the eighth day after birth if possible. The circumcision is followed by a *bris* (the Jewish religious ceremony), typically in the home, during which the newborn is named and symbolically enters the Jewish religious community.

Most other circumcisions are performed in the hospital before the newborn is discharged as this is convenient for parents or taken to the doctor's outpatient office after discharge, is practical, and has a demonstrated record of safety. There are three commonly used methods of circumcision: the Gomco clamp, the Hollister Plastibell device, and the Mogen clamp. During the circumcision procedure, part of the foreskin is removed by clamping and cutting with a scalpel (Gomco or Mogen clamp) or by using a Plastibell. The Plastibell is fitted over the glans, and the excess foreskin is pulled over the plastic ring. A suture is tied around the rim to apply pressure to the blood vessels, creating hemostasis. The excess foreskin is cut away. The plastic rim remains in place until healing occurs. The plastic ring typically loosens and falls off in approximately 1 week. Petroleum jelly should be applied to the circumcised area after the procedure is done with the Gomco or Mogen clamp (Angel & Maddox, 2018) (Fig. 18.19).

The debate over routine newborn circumcision continues in the United States. For many years, the purported benefits and harms of circumcision have been debated in the medical literature and society at large, with no clear consensus to date. Evidence-based policies concur that medical male circumcision, best performed early in life under local anesthesia by a trained provider, is a simple, safe procedure conferring lifetime protection against several adverse medical conditions. Data from numerous clinical trials and hundreds of research studies show benefits greatly exceed risks (Morris et al., 2017).

Policy Statement by American Academy of Pediatrics

A policy statement by the AAP indicates that newborn circumcision has potential disadvantages and risks as well as medical benefits and advantages. Risks to the newborn include infection, hemorrhage, skin dehiscence, adhesions, urethral fistula, and pain. Benefits to the newborn include the following:

- Urinary tract infections are slightly less common in circumcised boys. However, rates are low in both circumcised and uncircumcised boys and are easily treated without long-term sequelae.
- Sexually transmitted infections are less common in circumcised males, but the risk is believed to be related more to behavioral factors than to circumcision status. However, circumcised males have a 50% lower risk of acquiring HIV infection, herpes simplex virus, human papillomavirus (HPV), genital ulcer disease, bacterial vaginosis, and trichomoniasis (Morris et al., 2019).
- There appears to be a lower rate 1% of penile cancer in circumcised males. However, penile cancer is rare and risk factors such as genital warts, infection with HPV, multiple sex partners, and cigarette smoking seem to play a role in causing penile cancer also (Douglawi & Masterson, 2019).

The new AAP recommendations state that if parents decide to circumcise their newborn, pain relief must be provided. Research has found that newborns circumcised without analgesia experience pain and stress, indicated by changes in heart rate, blood pressure, oxygen saturation, and cortisol levels (King et al., 2019). Analgesic methods may include EMLA® cream (a topical mixture of local anesthetics, lidocaine and prilocaine), ring block, a dorsal penile nerve block with buffered lidocaine, acetaminophen, skin-to-skin contact, a sucrose pacifier, and swaddling (Cunningham et al., 2018).

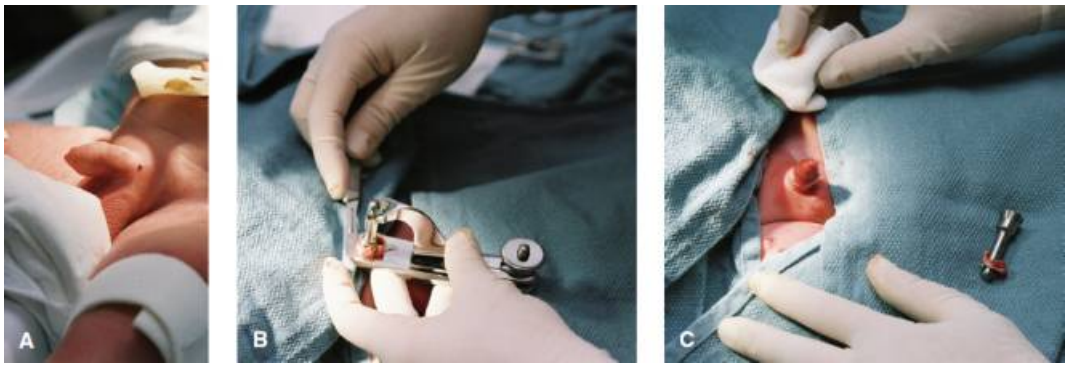

FIGURE 18.19. Circumcision. **A.** Before the procedure. **B.** Clamp applied and foreskin removed. **C.** Appearance after circumcision.

*

The AAP recommends that parents be given accurate and unbiased information about the risks and benefits of circumcision (Freedman, 2017). As with other newborn procedures, research continues. Nurses must keep informed about current medical research to allow parents to make informed decisions. The absence of compelling medical evidence in favor of or against newborn circumcision makes informed consent of parents of paramount importance. The circumcision discussion involves cultural, religious, medical, and emotional considerations. Nurses may have difficulty remaining unbiased and unemotional as they present the facts to parents. Circumcision is a very personal decision for parents, and the nurse's major responsibility is to inform the parents of the risks and benefits of the procedure and to address concerns so that the parents can reach a fully informed decision.

TAKE NOTE!

The decision to circumcise the male newborn is often a social one, with the strongest factor being whether the newborn's father is himself circumcised (Van Howe et al., 2019).

Preoperative circumcision preparation should include confirmation of the following:

- Infant is at least 12 hours old or older

- Infant has received standard vitamin K prophylaxis
- Infant has voided normally at least once since birth
- Infant has not eaten for at least an hour prior to the procedure
- Written parental consent has been obtained
- Correct identification of the infant brought to the procedure room

Immediately after circumcision, the tip of the penis is usually covered with petroleum-jelly–coated gauze to keep the wound from sticking to the diaper. Continued care of this site includes:

- Assess for bleeding every 30 minutes for at least 2 hours.
- Document the first voiding to evaluate for urinary obstruction or edema.
- Squeeze soapy water over the area daily and then rinse with warm water. Pat dry.
- Apply a small amount of petroleum jelly with every diaper change if the Plastibell was used; clean with mild soap and water if other techniques were used.
- Fasten the diaper loosely over the penis and avoiding placing the newborn on his abdomen to prevent friction.

If a Plastibell has been used, it will fall off by itself in about a week. Inform parents of this and advise them not to pull it off sooner. Also instruct the parents to check daily for any foul-smelling drainage, bleeding, or unusual swelling.

If the newborn is uncircumcised, wash the penis with mild soap and water after each diaper change and do not force the foreskin back; it will retract normally over time.

SAFETY

Newborns are completely dependent on those around them to ensure their safety. Their safety must be ensured while in the health care facility and after they are discharged. Parental education is key, especially as the newborn grows and develops and begins to respond to and explore his or her surroundings (Teaching Guidelines 18.3).

TEACHING GUIDELINES 18.3
General Newborn Safety

- Have emergency telephone numbers readily available, such as those for emergency medical assistance and the poison control center.
- Keep small or sharp objects out of reach to prevent them from being aspirated.
- Put safety plugs in wall sockets within the child's reach to prevent electrocution.
- Do not leave the infant alone in any room without a portable intercom on.
- Always supervise the newborn in the tub: a newborn can drown in 2 in of water.
- Make sure the crib or changing table is sturdy, without any loose hardware, and is painted with lead-free paint.
- Avoid placing the crib or changing table near blinds or curtain cords.
- Provide a smoke-free environment for all infants.
- Place all infants on their backs to sleep to prevent sudden infant death syndrome.
- To prevent falls, do not leave the newborn alone on any elevated surface.
- Use sun shields on strollers and hats to avoid overexposing the newborn to the sun.
- To prevent infection, thoroughly wash your hands before preparing formula.
- Thoroughly investigate any infant care facility before using it.

Environmental Safety

People who enter a health care facility for treatment expect to be safe there until they return home, but ensuring a safe environment

can be a daunting challenge to a health care facility.

Consider this scenario: A woman dressed in nurse's clothing entered the hospital room of a new mother soon after she had given birth. This "nurse" told the mother that she needed to take her newborn to the nursery to have him weighed. Sometime later, a staff nurse making her routine rounds realized something was wrong when she saw that the newborn's bassinet in the mother's room was empty and the mother was sound asleep in her bed. The staff nurse called security immediately because she suspected that a newborn abduction had taken place.

This is a typical abduction scenario that is repeated many times throughout the United States each year. In **infant abduction**, someone who is not a family member takes a child less than 1-year-old (NCMEC, 2020). Infant abductions are traumatic for the parents, the community, and the health care facility. The facility may also face huge financial liability if a lawsuit is filed by the parents.

Abductions typically occur during the day and are usually carried out by women who are not criminally sophisticated. Many of these women experienced a pregnancy loss in the past; they are often emotionally immature and compulsive, with low self-esteem. Most female abductors can play the role of a hospital employee convincingly. Infants usually are abducted when taken for testing, during return to the nursery, when left unattended in the nursery, or while a mother was napping or showering (TJC, 2018).

Health care agencies are challenged to prevent infant abduction by instituting sound security practices and systems (TJC, 2018). Such measures include the following:

- All newborns must be transported in cribs and not carried.
- Nurses must respond immediately to any security alarm that sounds on the unit.
- Newborns must never be unattended at any time, especially in hallways.
- All staff must wear appropriate identification at all times.
- Encourage mothers to keep their baby/bassinet on their far side, away from the door.

- Personnel should be wary of visitors who do not seem to be visiting a specific mother.
- The electronic security system should be checked to make sure it works.
- Footprint the newborn, take a color photograph, and record the newborn's physical examination within 2 hours of birth.
- Discontinue publication of birth notices in local newspapers.
- Develop and implement a proactive infant abduction prevention plan.
- Ensure the proper functioning and placement of any electronic sensors used on newborns.
- Parents should be taught what infant abduction is; why infant security is important; the schedule of nursery, feeding, and visiting hours; rules about visitor access; the facility's security policies and procedures; what parents can do to protect their infant in the hospital; which staff members are allowed to handle the newborn; and what a proper ID looks like.

Educating staff, educating mothers, and access control are the three key steps to preventing abductions from any health care facility. Providing a safe and secure environment is a shared responsibility of the facility, staff, and parents. Preventing abductions requires everyone to learn and follow the rules and policies.

Car Safety

Every state requires the use of car seats for infants and children, because motor vehicle accidents are still the leading cause of unintentional injury and death in children under age 5. National Highway Traffic Safety Administration statistics show that nearly one half of deaths and injuries in infants occurred because they were not properly restrained. Child safety seats, when installed and used properly, can prevent injuries and save lives (Roehler et al., 2019).

Despite evidence that the use of car seats can reduce the morbidity and mortality of motor vehicle crashes, parents who lack knowledge about them may underuse or misuse them (O'Toole & Christie, 2018). Make sure that both parents understand the importance of safely transporting their newborn in a federally

approved safety car seat every time the infant rides in a car. Do not release any newborn unless the parents have a car seat in place for their newborn's ride home (Fig. 18.20). If they cannot afford one, many community organizations will provide one for them. According to the AAP's policy statement on child passenger safety (Roehler et al., 2019), no one car seat is considered to be the "safest" or the "best," but rather consistent and proper use is the key to preventing injuries and deaths. Instruct parents in the following:

- Select a car seat that is appropriate for the child's size and weight.
- Caution caregivers against the placement of car seats on elevated or soft surfaces outside the car to prevent falling.
- Use the car seat correctly, every time the child is in the car.
- Use rear-facing car safety seats for most infants up to 2 years of age or until they reach the highest weight or height allowed by the manufacturer of their CSS.
- Make sure the harness (most seats have a three- to five-point harness) is in the slots at or below the shoulders.

FIGURE 18.20. Newborn in a properly secured car seat.

INFECTION PREVENTION

The nurse plays a major role in preventing infection in the newborn environment. Ways to control infection are as follows:

- Minimize exposure of newborns to organisms.
- Wash your hands before and after providing care, and insist that all personnel wash their hands before handling any newborn.
- Do not allow ill staff or visitors to visit or handle newborns.
- Avoid sharing any infant supplies with another infant.
- Monitor the umbilical cord stump and circumcision site for signs of infection.
- Provide eye prophylaxis by instilling prescribed medication soon after birth.
- Educate parents about appropriate home measures that will prevent infections, such as practicing good hand hygiene before and after diaper changes, keeping the newborn well hydrated, avoiding taking the infant into crowds (which may expose him or her to colds and flu viruses), observing for early signs of infection (fever, vomiting, loss of appetite, lethargy, labored breathing, green watery stools, and drainage from umbilical cord site or eyes), and keeping pediatrician appointments for routine immunizations.

Promoting Sleep

Although many parents feel their newborns need them every minute of the day, babies actually need to sleep much of the day initially. Usually newborns sleep up to 15 hours daily. They sleep for 2 to 4 hours at a time, but do not sleep through the night because their stomach capacity is too small to go long periods without nourishment.

TAKE NOTE!

All newborns develop their own sleep patterns and cycles, but it may take several months before the newborn sleeps through the night. Frequently, newborns have their day and night hours reversed and tend to sleep more during the daytime and less during the night.

Parents should place the newborn on his or her back to sleep. To prevent suffocation, all fluffy bedding, quilts, sheepskins, stuffed animals, and pillows should be removed from the crib. Parents should be informed that the practice of “co-sleeping” (sharing a bed) is not safe (Moon, 2020). Suffocation can occur when the infant gets entangled in bedding or caught under pillows, or slips between the bed and the wall or the headboard and mattress. The parent may accidentally roll against or on top of the baby. The safest place for a newborn to sleep is in a crib in the same room with their parents for at least 6 months, and without any movable objects in the crib. Benefits versus risks of co-bedding, bed sharing, or co-sleeping include the following:

- *Benefits*—Promotes breastfeeding practices; increases bonding time between the infant and mother; promotes skin-to-skin contact; and increases maternal vigilance over infant.
- *Risks*—Increases risk for SIDS for infants younger than 4 months; risk of death if parent rolls over the infant; interrupts infant sleeping patterns; risk of asphyxia due to entrapment or airway obstruction; and unsafe design of adult beds for infants (Emond, 2019).

Teach parents to avoid other unsafe conditions, such as placing the newborn in the prone position, using a crib that does not meet federal safety guidelines, allowing window cords to hang loose and in proximity to the crib, placing blankets and pillows in the crib (can potentially smother infant), exposure to tobacco smoke, alcohol, and illicit drugs or setting the room temperature too high (can cause overheating) (CDC, 2019d). Recommendations for safe infant sleeping practices are an important aspect of education for new parents. It is important for nurses to assess families’ cultural beliefs and their prior practices to fully understand how to make recommendations in a culturally sensitive manner.

The *Safe to Sleep Campaign* (National Institute of Child Health and Human Development [NICHD], n. d.) recommends the following to reduce the risk of SIDS:

- Always place the baby on his or her back to sleep for all sleep times, including naps.

- Room share—keep baby's sleep area in the same room next to where you sleep.
- Avoid infant exposure to tobacco smoke during pregnancy and after birth.
- Avoid wrapping infant too tightly with a blanket and stop when infant can roll over.
- Breastfeed infant.
- Use a firm sleep surface, free from soft objects, toys, blankets, and crib bumpers.
- Use a pacifier during infant sleep but not a forced use (Doering et al., 2019).

Enhancing Bonding

Encourage and enhance parent–newborn interaction by involving both parents with the baby and demonstrating appropriate nurturing behaviors:

- Say "hello" and introduce yourself to the newborn.
- Ask the parents' permission to care for and hold their newborn. This helps parents to realize that they are responsible for their child and reminds nurses of their role.
- Show parents the power of a soothing voice to calm the newborn (Fig. 18.21).
- Provide care to the newborn in the least stressful way.
- Demonstrate ways to gently wake up the newborn for better feeding.
- Tell parents what you are doing, why you are doing it, and how they can duplicate what you are doing at home.
- Offer the opportunity for parents to perform care while you observe them. Support their efforts to soothe the newborn throughout the care process.
- Help parents to interpret the communication cues the newborn uses.
- Point out the efforts the newborn is making to connect with the parents (e.g., alerting to the familiar voice, following the parents while they are speaking, quieting when held securely).

FIGURE 18.21. The father uses a soothing voice to calm the newborn.

One of the most pleasurable aspects of newborn care is being close to them. Bonding begins soon after birth when parents cradle their newborn and gently stroke him or her with their fingers. Provide parents with opportunities for “skin-to-skin” contact with the newborn, holding the baby against their own skin when feeding or cradling. Many newborns respond very positively to gentle massage. If necessary, recommend books and videos that cover the subject.

For newborns, crying is their only way to communicate that something is wrong. Try to find out the reason why: Is the diaper

wet? Is the room too hot or too cold? Is the baby uncomfortable (e.g., diaper rash or tight clothing)? Suggest the following ways in which parents can soothe an upset newborn:

- Try feeding or burping to relieve air or stomach gas.
- Lightly rub the newborn's back and speak softly to him or her.
- Let the infant suck on something, such as a pacifier to calm him or her.
- Gently sway side to side, or rock back and forth in a rocking chair.
- Talk with the newborn while making eye contact.
- Take the newborn for a walk in a stroller or carriage to get fresh air.
- Change the baby's position from back to side or vice versa.
- Try singing, reciting poetry and nursery rhymes, or reading to the baby.
- Turn on a musical mobile above the newborn's head.
- Create "white noise" such as shushing, which drowns out other noises.
- Give more physical contact by walking, rocking, or patting the newborn.
- Swaddle the newborn to provide a sense of security and comfort. To do this:
  - Spread out a receiving blanket, with one corner folded slightly.
  - Lay the newborn face up with head at the folded corner.
  - Wrap the left corner over the baby's body and tuck it beneath the baby.
  - Bring the bottom corner over the baby's feet.
  - Wrap the right corner around the baby, leaving only the head exposed.
  - Arms can be released from the blanket to allow for self-comforting.

Assisting with Screening Tests

Newborn screening has been among the most successful public health programs of the 21st century. The aim of screening is to identify newborns who appear healthy but could be a risk of developing conditions with severe complications if left untreated. Newborn screening tests that are required in most states before

discharge are used to check for certain genetic and inborn errors of metabolism and hearing. Early identification and initiation of treatment can prevent significant complications and can minimize the negative effects of untreated disease.

GENETIC AND INBORN ERRORS OF METABOLISM SCREENING

Although each state mandates which conditions must be tested, the most common screening tests are for PKU, hypothyroidism, galactosemia, and sickle cell disease (Table 18.5).

The trend toward early discharge of newborns can affect the timing of screening and the accuracy of some test results. For example, the newborn needs to ingest enough breast milk or formula to elevate phenylalanine levels for the screening test to identify PKU accurately, so newborn screening for PKU testing should not be performed before 24 hours of age.

Screening tests for genetic and inborn errors of metabolism require a few drops of blood taken from the newborn's heel (Fig. 18.22). These tests are usually performed shortly before discharge. Newborns that are discharged before 24 hours of age need to have repeat tests done within a week in an outpatient facility.

Be aware of which conditions your state regularly screens for at birth to ensure that the parents are taught about the tests and the importance of early treatment. Also be familiar with the optimal time frame for screening and conditions that could affect the results. Ensure that a satisfactory specimen has been obtained at the appropriate time and that circumstances that could cause false results have been minimized. Send out specimens and completed forms within 24 hours of collection to the appropriate laboratory where they are tested for several inherited metabolic disorders due to a defective gene that results in an enzyme deficiency (Korenev et al., 2019).

TABLE 18.5 Selected Conditions Screened for in the Newborn

Condition	Description	Clinical Picture/Effect If Not Treated	Treatment	Timing of Screening
PKU	Autosomal recessive inherited deficiency in one of the enzymes necessary for the metabolism of phenylalanine to tyrosine—essential amino acids found in most foods	Irritability, vomiting of protein feedings, and a musty odor to the skin or body secretions of the newborn; if not treated, mental and motor retardation, seizures, microcephaly, and poor growth and development	Lifetime diet of foods low in phenylalanine (low protein) and monitoring of blood levels; special newborn formulas available: Phenex and Lofenalac	Universally screened for in the United States; testing is done 24–48 hours after protein feeding (PKU)
Congenital hypothyroidism	Deficiency of thyroid hormone necessary for normal brain growth, calorie metabolism, and development; may result from maternal hypothyroidism	Increased risk in newborns with birth weight <2,000 g or >4,500 g, and those of Hispanic and Asian ethnic groups; feeding problems, growth and breathing problems; if not treated, irreversible brain damage and intellectual disability before age 1	Lifelong thyroid replacement therapy	Testing (measures thyroxin [T4] and TSH) is done between days 4 and 6 of life
Galactosemia	Absence of the enzyme needed for the conversion of the milk sugar galactose to glucose	Poor weight gain, vomiting, jaundice, mood changes, loss of eyesight, seizures, and intellectual disability; if untreated, galactose buildup causing permanent damage to the brain, eyes, and liver, and eventually death	Eliminate milk from diet; substitute soy milk Breastfeeding not advised	First test done on discharge from the hospital with a follow-up test within 1 month
Sickle cell anemia	Recessively inherited abnormality in hemoglobin structure, most commonly found in African American newborns	Anemia developing shortly after birth; increased risk for infection, growth restriction, vaso-occlusive crisis	Maintenance of hydration and hemodilution, rest, electrolyte replacement, pain management, blood replacement, and antibiotics	Bloodspot obtained at same time of other newborn screening tests or prior to 3 months of age

HEARING SCREENING

Hearing loss is the most common birth disorder in the United States: approximately three to five newborns out of every 1,000 live births have some degree of hearing loss. Unlike a physical deformity, hearing loss is not clinically detectable at birth and thus remains difficult to assess (CDC, 2019d). Factors associated with an increased risk of hearing loss include the following:

- Family history of hereditary childhood sensory hearing loss
- Congenital infections such as cytomegalovirus, rubella, toxoplasmosis, or herpes
- Craniofacial anomalies involving the pinna or ear canal
- Low birth weight (less than 1,500 g)
- Postnatal infections such as bacterial meningitis
- Head trauma
- Hyperbilirubinemia requiring an exchange transfusion
- Exposure to ototoxic drugs, especially aminoglycosides
- Perinatal asphyxia (Martin & Rosenfeld, 2019)

Delays in identification and intervention may affect the child's language development, academic performance, and cognitive development. Detection before 3 months greatly improves outcomes. Because of this, auditory screening programs for all newborns are recommended by the AAP (2020) and are mandated by law in all states. Screening only infants with risk factors is not enough, because as many as 50% of infants born with hearing loss have no known risk factors (CDC, 2019d). Early identification and intervention can prevent severe psychosocial, educational, and language development delays.

The current goals of *Healthy People 2030* (USDHHS, 2020) are to screen all infants by 1 month of age, confirm hearing loss with an audiologic examination by 3 months of age, and treat with comprehensive early intervention services before 6 months of age (see the *Healthy People 2030* feature earlier in this chapter and Box 18.1 for screening methods). All newborns should be screened prior to discharge to ensure that any newborn with a hearing loss is not missed. Those with suspected hearing loss should be referred for follow-up assessment. In addition, nurses should ensure that testing is accurate to facilitate early diagnosis and intervention services and

to optimize the newborn's developmental potential. The implementation of newborn hearing screenings has lowered the mean age of hearing loss identification. False results have also been minimized.

BOX 18.1 Newborn Hearing Screening Methods

Newborn hearing screening is the standard of care in hospitals nationwide. The primary purpose of newborn hearing screening is to identify newborns who are likely to have a hearing loss and who require further evaluation. A newborn's hearing can be screened in one of two ways: otoacoustic emission (OAE) or automated auditory brainstem response (ABR).

In OAE, an earphone is placed in the infant's ear canal and the sounds produced by the newborn's inner ear are measured in response to certain tones or clicks presented through the earphone. Preset parameters in the equipment decide whether the OAEs are sufficient for the newborn to pass or whether a referral is necessary for further evaluation.

In ABR, an earphone is placed in the ear canal or an earmuff is placed over the newborn's ear, and a soft, rapid tapping noise is presented. Electrodes placed around the newborn's head, neck, and shoulders record neural activity from the infant's brainstem in response to the tapping noises. The ABR tests how well the ear and the nerves leading to the brain work. Like OAEs, automated ABR screening is sensitive to more than mild degrees of hearing loss, but a "pass" does not guarantee normal hearing.

Common Concerns

During the newborn period of transition, certain conditions can develop that require intervention. These conditions, although not typically life-threatening, can be a source of anxiety for the parents. Common concerns include transient tachypnea of the newborn, physiologic jaundice, and hypoglycemia.

TRANSIENT TACHYPNEA OF THE NEWBORN

Transient tachypnea of the newborn is a benign, self-limiting condition that appears soon after birth. It occurs when the fetal liquid in the lungs is removed slowly or incompletely. This can be due to the lack of thoracic squeezing that occurs during a cesarean birth without labor or diminished respiratory effort if the mother received CNS depressant medication. Prolonged labor, birth before 39 weeks' gestation, macrosomia of the fetus, gestational diabetes, and maternal asthma also have been associated with this condition. A vaginal birth appears to be protective against transient tachypnea of the newborn (Cunningham et al., 2018).

Transient tachypnea is accompanied by retractions; expiratory grunting or cyanosis and is relieved by low-dose oxygen therapy. Mild or moderate respiratory distress typically is present at birth or within 6 hours of birth. Transient tachypnea of the newborn is generally a self-limited disorder without significant morbidity. Transient tachypnea of the newborn resolves over a 24- to 72-hour period.

Nursing interventions include providing supportive care: giving oxygen if pulse oximetry or arterial blood gas (ABG) values suggest hypoxemia, ensuring warmth, observing respiratory status frequently, and allowing time for the pulmonary capillaries and the lymphatics to remove the remaining fluid. The clinical course is relatively benign, but any newborn respiratory issue can be very frightening to the parents. Provide a thorough explanation and reassure them that the condition will resolve over time.

PHYSIOLOGIC JAUNDICE

Physiologic jaundice is very common in newborns, with the majority demonstrating yellowish skin, mucous membranes, and sclera within the first 3 days of life. In any given year, approximately 65% of the newborns in the United States will experience clinical jaundice (King et al., 2019). Jaundice is the visible manifestation of hyperbilirubinemia. It typically results from the deposition of unconjugated bilirubin pigment in the skin and mucous membranes.

Physiologic jaundice can be best understood as an imbalance between the production and elimination of bilirubin, with a multitude of factors and conditions affecting each of these processes. When an imbalance results because of an increase in circulating bilirubin (or the bilirubin load) to significantly high levels, it may go on to cause acute neurologic sequelae (acute bilirubin encephalopathy). In most infants, an increase in bilirubin production (e.g., due to hemolysis) is the primary cause of physiologic jaundice, and thus reducing bilirubin production is a rational approach for its management.

Factors that contribute to the development of physiologic jaundice in the newborn include an increased bilirubin load because of relative polycythemia, a shortened erythrocyte life span (80 days compared with the adult 120 days), and immature hepatic uptake and conjugation processes (Pace et al., 2019). Normally the liver removes bilirubin from the blood and changes it into a form that can be excreted. As the red blood cell breakdown continues at a fast pace, the newborn's liver cannot keep up with bilirubin removal. Thus, bilirubin accumulates in the blood, causing a yellowish discoloration on the skin.

AAP Guidelines for Prevention and Management of Hyperbilirubinemia in Newborns

The AAP has released guidelines for the prevention and management of hyperbilirubinemia in newborns:

- Promote and support successful breastfeeding practices to make sure the newborn is well hydrated and stooling frequently to promote elimination of bilirubin.
- Advise mothers to nurse their infants at least eight to 12 times per day for the first several days.
- Avoid routine supplementation of nondehydrated breastfed infants with water or dextrose water because that will not lower bilirubin levels.
- Ensure that all infants are routinely monitored for the development of jaundice and that nurseries have established protocols for the assessment of jaundice. Jaundice should be assessed whenever

the infant's vital signs are measured but no less than every 8 to 12 hours.
- Universal screening of all infants >35 weeks' gestation before discharge.
- Provide early and focused follow-up based on the risk assessment.
- When indicated, treat newborns with phototherapy or exchange transfusion to prevent acute bilirubin encephalopathy (Kapadia & Brion, 2017).

In newborn infants, jaundice can be detected by blanching the skin with digital pressure on the bridge of the nose, sternum, or forehead, revealing the underlying color of the skin and subcutaneous tissue. If jaundice is present, the blanched area will appear yellow before the capillary refill. The assessment of jaundice must be performed in a well-lit room or, preferably, in daylight at a window. Jaundice is usually seen first in the face and progresses caudally to the trunk and extremities (Blackburn, 2018).

Measures that parents can take to reduce the risk of jaundice include exposing the newborn to natural sunlight for short periods of time throughout the day to help oxidize the bilirubin deposits on the skin, providing breastfeeding on demand to promote elimination of bilirubin through urine and stooling, and avoiding glucose water supplementation, which hinders elimination.

If or when the levels of unconjugated serum bilirubin increase and do not return to normal levels with increased hydration, phototherapy is used. The serum level of bilirubin at which phototherapy is initiated is a matter of clinical judgment by the physician, but it is often begun when bilirubin levels reach 12 to 15 mg/dL in the first 48 hours of life in a term newborn (Pace et al., 2019). **Phototherapy** involves exposing the newborn to ultraviolet light, which converts unconjugated bilirubin into products that can be excreted through feces and urine. Phototherapy is the most common treatment for hyperbilirubinemia and has virtually eliminated the need for exchange transfusions in newborns now.

TAKE NOTE!

Exposure of newborns to sunlight represents the first documented use of phototherapy in the medical literature. Sister J. Ward, a charge nurse in Essex, England, recognized in 1956 that when jaundiced newborns were exposed to sun, they became less yellow. This observation changed the entire treatment of jaundice in newborns (Sawyer et al., 2018).

Phototherapy reduces bilirubin levels in the blood by breaking down unconjugated bilirubin into colorless compounds. These compounds can then be excreted in the bile. Phototherapy aims to curtail the increase in bilirubin blood levels; thereby preventing kernicterus, a condition in which unconjugated bilirubin enters the brain. If not treated, kernicterus can lead to brain damage and death.

During the past several decades, phototherapy has generally been administered with either banks of fluorescent lights or spotlights. Factors that determine the dosage of phototherapy include spectrum of light emitted, irradiance of light source, design of light unit, surface area of newborn exposed to the light, and distance of the newborn from the light source (Blackburn, 2018). For phototherapy to be effective, the rays must penetrate as much of the skin as possible. Thus, the newborn must be naked and turned frequently to ensure maximum exposure of the skin. Several side effects of standard phototherapy have been identified: frequent loose stools, increased insensible water loss, transient rash, and potential retinal damage if the newborn's eyes are not covered sufficiently.

Fiberoptic pads (Biliblanket or Bilivest) have been developed that can be wrapped around the newborn or on which the newborn can lie. The light is delivered from a tungsten–halogen bulb through a fiberoptic cable and is emitted from the sides and ends of the fibers inside a plastic pad (Collier, 2019). These products work on the premise that phototherapy can be improved by delivering higher-intensity therapeutic light to decrease bilirubin levels. The pads do not produce appreciable heat like the banks of lights or spotlights do, so insensible water loss is not increased. Eye patches also are not

needed; thus, parents can feed and hold their newborns continuously to promote bonding.

When caring for newborns receiving phototherapy for jaundice, nurses must do the following:

- Closely monitor body temperature and fluid and electrolyte balance.
- Document frequency, character, and consistency of stools.
- Monitor hydration status (weight, specific gravity of urine, and urine output).
- Turn frequently to increase the infant's skin exposure to phototherapy.
- Observe skin integrity (as a result of exposure to diarrhea and phototherapy lights).
- Provide eye protection to prevent corneal injury related to phototherapy exposure.
- Encourage parents to participate in their newborn's care to prevent parent–infant separation.

See Chapter 24 for a more detailed discussion of hyperbilirubinemia.

The home health nurse made a postpartum visit to Kelly to assess the situation. Kelly's son was slightly jaundiced when the home health nurse pressed gently over his sternum, but Kelly said he was nursing better compared with the previous 2 days. What home suggestions can the nurse make to Kelly to reduce the jaundice? What specific education about physiologic jaundice is needed?

HYPOGLYCEMIA

During the first 24 to 48 hours of life, as normal newborns transition from intrauterine to extrauterine life, their plasma glucose levels are typically lower than later in life. Temporary low plasma glucose concentrations are common in healthy newborns. Hypoglycemia affects as many as 40% of all full-term newborns. It is defined as a blood glucose level of less than 30 mg/dL or a plasma concentration of less than 45 mg/dL in the first 72 hours of life (Abramowski & Hamdan, 2020). From a physiologic perspective, a newborn may be said to be hypoglycemic when glucose supply is inadequate to meet

demand. In newborns, blood glucose levels fall to a low point during the first few hours of life because the source of maternal glucose is removed when the placenta is expelled. This period of transition is usually smooth, but certain newborns are at greater risk for hypoglycemia: infants of mothers who have diabetes, preterm newborns, and newborns with intrauterine growth restriction (IUGR), inadequate caloric intake, sepsis, asphyxia, hypothermia, polycythemia, glycogen storage disorders, and endocrine deficiencies (Rozance & Wolfsdorf, 2019).

Most newborns experience transient hypoglycemia and are asymptomatic. The symptoms, when present, are nonspecific and include jitteriness, lethargy, cyanosis, apnea, seizures, high-pitched or weak cry, hypothermia, and poor feeding. If hypoglycemia is prolonged or is left untreated, serious, long-term adverse neurologic sequelae such as learning disabilities and intellectual disabilities can occur (Cranmer, 2020).

Treatment of hypoglycemia in the newborn includes administration of a rapid-acting source of glucose such as dextrose gel, breastfeeding or early formula-feeding. In acute, severe cases, intravenous administration of glucose may be required. Continuous monitoring of glucose levels is not only prudent, but mandatory in high-risk newborns. Although there is no specific means of preventing hypoglycemia in newborns, it is wise and cautious to monitor for symptoms and intervene as soon as symptoms are noted. Subsequently, early diagnosis and appropriate intervention are essential for all newborns.

Nursing care of the hypoglycemic newborn includes monitoring for signs of hypoglycemia or identifying high-risk newborns prone to this disorder based on their perinatal history, physical examination, body measurements, and gestational age. Glucose screening should be performed on at-risk infants and those with clinical symptoms compatible with hypoglycemia (Martin & Rosenfeld, 2019).

Prevent hypoglycemia in newborns at risk by initiating early feedings with breast milk or formula. If hypoglycemia persists despite feeding, notify the primary health care provider for orders such as intravenous therapy with dextrose solutions. Anticipate hypoglycemia

in certain high-risk newborns and begin assessments immediately on nursery admission.

Promoting Nutrition

Several physiologic changes dictate the type and method of feeding throughout the newborn's first year. Some of these changes include the following:

- Stomach capacity is limited at birth. The emptying time is short (2 to 3 hours) and peristalsis is rapid. Therefore, small, frequent feedings are needed at first, with amounts progressively increasing with maturity.
- The immune system is immature at birth, so the baby is at a high risk for food allergies during the first 4 to 6 months of life. Introducing solid foods prior to this time increases the risk of developing food allergies.
- Pancreatic enzymes and bile to assist in digestion of fat and starch are in limited supply until about 3 to 6 months of age. Infants cannot digest cereal prior to this time.
- The kidneys are immature and unable to concentrate urine until about 4 to 6 weeks of age. Excess protein and mineral intake can place a strain on kidney function and can lead to dehydration. Infants need to consume more water per unit of body weight than adults do as a result of their high body weight from water.
- Immature muscular control at birth changes over time to assist in the feeding process by improving head and neck control, hand–eye coordination, swallowing, and ability to sit, grasp, and chew. At about 4 to 6 months, inborn reflexes disappear, head control develops, and the infant can sit to be fed, making spoon-feeding possible (Konek & Becker, 2020).

NEWBORN NUTRITIONAL NEEDS

Once the placenta no longer provides nutrition, a newborn's survival depends on the ability to take in nutrients. As newborns grow, their energy and nutrient requirements change to meet their body's changing needs. During infancy, energy, protein, vitamin, and

mineral requirements per pound of body weight are higher than at any other time of life. These high levels are needed to fuel the rapid growth and development during this stage of life. Generally, an infant's birth weight doubles in the first 4 to 6 months of life and triples within the first year (Webster et al., 2018).

A newborn's caloric needs range from 110 to 120 cal/kg body weight. Breast milk and formulas contain approximately 20 cal/oz, so the caloric needs of young infants can be met if several feedings are given throughout the day. Most term infants need a basic formula if the mother chooses not to breastfeed. These formulas are modeled after breast milk, which contains 20 cal/oz. There is no evidence to recommend one brand over the other since all of them are nutritionally interchangeable. All formulas are classified based on three parameters: caloric density, carbohydrate source, and protein composition (see Table 18.6).

Fluid requirements for the newborn and infant range from 100 to 150 mL/kg daily. This requirement can be met through breast- or bottle-feeding. Additional water supplementation is not necessary. Adequate carbohydrates, fats, protein, and vitamins are achieved through consumption of breast milk or formula. The AAP (2018) recommends that iron-fortified formula be used for all infants who are not breastfed from birth to 1 year of age. The breastfed infant draws on iron reserves for the first 6 months and then needs iron-rich foods or supplementation added at 6 months of age. The AAP (2016) also has recommended that all infants (breast- and bottle-fed) receive a daily supplement of 400 IU of vitamin D starting within the first few days of life to prevent rickets and vitamin D deficiency. It is also recommended that fluoride supplementation be given to infants not receiving fluoridated water after the age of 6 months (AAP, 2020b).

TABLE 18.6 Comparison of Breast Milk with Selected Formula Composition

Type	Brand Names	Calories per Ounce	Carbohydrate Source	Protein Source	Indications
Breast milk	None	20	Lactose	Human milk	Preferred for all infants
Term formula	Enfamil; Similac; Carnation Good Start	20	Lactose	Cow's milk	Appropriate for all term infants
Term formula with DHA and ARA	Enfamil Lipil; Good Start DHA and ARA; Similac Advance	20	Lactose	Cow's milk	Marketed to promote good vision and brain development; to make them more like breast milk.
Preterm formula	Enfamil 24 Premature; Preemie SMA 24	24	Lactose	Cow's milk	Usually given to preterm infants <34 weeks' gestation
Soy formula	Enfamil Prosobee; Good Start Soy	20	Corn based	Soy	For infants with galactosemia
Hypoallergenic formula	Similac Alimentum; Enfamil Nutramigen; Enfamil Pregestimil	20	Corn or sucrose	Extensively hydrolyzed	For infants with a milk protein allergy
Nonallergenic formula	Neocate; Nutramigen AA	20	Corn or sucrose	Amino acids	For infants with a milk protein allergy
Antireflux formula	Enfamil AR; Similac Sensitive RS	20	Lactose thickened with rice starch	Cow's milk	For infants with gastric reflux disorder

SUPPORTING THE CHOICE OF FEEDING METHOD

The benefits of breastfeeding are significant and well documented. Numerous health-related professional organizations promote breastfeeding because of the health benefits for both the mother and infant. Nurses should encourage and advocate breastfeeding for their clients and provide support for the family throughout their breastfeeding experiences. Parents typically decide about the method of feeding well before the infant is born. Prenatal and childbirth classes present information about breastfeeding versus bottle-feeding and allow the parents to make up their minds about which method is best for them. Various factors can influence their decision, including socioeconomic status, culture, sexual objectification, fear of a negative community reaction, personal inconvenience, dietary restrictions, lack of social support, lack of

self-efficacy, high frequency of violence, employment, level of education, lack of access to breast pumps, lack of time, free formula provided by government programs, range of care interventions provided during pregnancy, childbirth, and the early postpartum period, and especially partner support (American Pregnancy Association, 2019). Nurses can provide evidence-based information to assist the couple in making their decision. Regardless of which method is chosen, the nurse needs to respect and support the couple's decision.

FEEDING THE NEWBORN

The newborn can be fed at any time during the transition period if assessments are normal and a desire is demonstrated. Before the newborn can be fed, determine his or her ability to suck and swallow. Clear any mucus in the nares or mouth with a bulb syringe before initiating feeding. Auscultate bowel sounds, check for abdominal distention, and inspect the anus for patency. If these parameters are within normal limits, newborn feeding may be started. Most newborns are on demand feeding schedules and are allowed to feed when they awaken. When they go home, mothers are encouraged to feed their newborns every 2 to 4 hours during the day and only when the newborn awakens during the night for the first few days after birth.

Parents often have many questions about feeding. Generally, newborns should be fed on demand whenever they seem hungry. Most newborns will give clues about their hunger status by crying, placing their fingers or fist in their mouth, rooting around, and sucking.

Newborns differ in their feeding needs and preferences, but most breastfed ones need to be fed every 2 to 3 hours, nursing for 10 to 20 minutes on each breast. The length of feedings is up to the mother and newborn. Encourage the mother to respond to cues from her infant and not feed according to a standard or preset schedule.

Formula-fed newborns usually feed every 3 to 4 hours, finishing a bottle in 30 minutes or less. Daily formula intake for an infant should

be 1.5 to 2 oz/lb of body weight, but growth is a better measure of health than the amount of formula consumed (Konek & Becker, 2020). If the newborn seems satisfied, wets six to 10 diapers daily, produces several stools a day, sleeps well, and is gaining weight regularly, then he or she is probably receiving sufficient breast milk or formula.

Newborns swallow air during feedings, which causes discomfort and fussiness. Parents can prevent this by burping them frequently throughout the feeding. Tips about burping include:

- Hold the newborn upright with his or her head on the parent's shoulder (Fig. 18.23A).
- Support the head and neck while the parent gently pats or rubs the newborn's back (Fig. 18.23B).
- Have the newborn sit on the parent's lap, while supporting the baby's chest and head. Gently rub the newborn's back with the other hand.
- Lay the newborn on the parent's lap with the baby's back facing up.
- Support the newborn's head in the crook of the parent's arm and gently pat or rub the back.

TAKE NOTE!

It is the upright position, not the strength of the patting or rubbing that allows the newborn to release air accumulated in the stomach.

Stress to parents that feeding time is more than an opportunity to get nutrients into their newborn; it is also a time for closeness and sharing. Feedings are as much for the baby's emotional pleasure as his or her physical well-being. Encourage parents to maintain eye contact with the newborn during the feeding, hold him or her comfortably close to them, and talk softly during the feeding to promote closeness and security.

BREASTFEEDING

Breast milk is universally recognized as the unequaled, optimal form of nourishment for infants during the first 6 months to a year of life. There is consensus in the medical community that breastfeeding is ideal for all newborns. The AAP and the American Dietetic Association recommend breastfeeding exclusively for the first 6 months of life, continuing it in conjunction with other food at least until the newborn's first birthday. An estimated 83% of American mothers start out to breastfeed, but only one in four are able to exclusively do so by 6 months (CDC, 2019a). Box 18.2 highlights the advantages of breastfeeding for the mother and newborn. In addition, breastfeeding is associated with lower incidence of necrotizing enterocolitis and diarrhea during the early period of life and with lower incidence of inflammatory bowel diseases, type 2 diabetes, asthma, and obesity later in life (CDC, 2019a). Mothers should continue to breastfeed during mild illnesses such as colds or flu. However, in the United States mothers with HIV and galactosemia are advised not to breastfeed.

A

FIGURE 18.23. The nurse demonstrates (**A**) holding the newborn upright over the shoulder and (**B**) sitting the newborn upright, supporting the neck and chin.

BOX 18.2 Advantages of Breastfeeding

Advantages for the Newborn

- Contributes to the development of a strong immune system
- Stimulates growth of positive bacteria in digestive tract
- Reduces incidence of stomach upset, diarrhea, and colic
- Begins the immunization process at birth by providing passive immunity
- Promotes optimal mother–infant bonding
- Reduces risk of newborn constipation
- Promotes greater developmental gains in preterm infants
- Provides easily tolerated and digestible formula that is sterile, at proper temperature, and readily available with no artificial colorings, flavorings, or preservatives
- Is less likely to result in overfeeding, leading to obesity
- Promotes better tooth and jaw development as a result of sucking hard
- Provides protection against food allergies
- Lowers health care costs due to fewer illnesses
- Is associated with avoidance of type 1 diabetes and heart disease

Advantages for the Mother

- Can facilitate postpartum weight loss by burning extra calories
- Stimulates uterine contractions to control bleeding
- Lowers risk for ovarian and endometrial cancers
- Facilitates bonding with newborn infant
- Lowers risk of type 2 diabetes
- Breast milk is free versus formula costs
- Reduces risk of postpartum depression
- Promotes uterine involution as a result of release of oxytocin
- Lowers the risk of breast cancer and osteoporosis
- Affords some protection against conception, although it is not a reliable contraceptive method

Retrieved June 16, 2020, from https://www.cdc.gov/breastfeeding/about-breastfeeding/why-it-matters.html; and King, T. L., Brucker, M. C., Osborne, K., & Jevitt, C. M. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning.

The composition of breast milk changes over time from colostrum to transitional milk, and finally to mature milk. Colostrum is a thick, yellowish substance secreted during the first few days after birth. It is

high in protein, minerals, and fat-soluble vitamins. It is rich in immunoglobulins A, which help protect the newborn's gastrointestinal tract against infections. It is a natural laxative that helps rid the intestinal tract of meconium quickly (Bryant & Thistle, 2019).

Transitional milk occurs between colostrum and mature milk and contains all the nutrients in colostrum, but it is thinner and less yellow than colostrum. This transitional milk is replaced by true or mature milk around day 10 after birth. Mature milk appears bluish and is not as thick as colostrum. It provides 20 cal/oz and contains the following:

- *Protein*—Although the content is lower than formula, it is ideal to support growth and development for the newborn. The majority of the protein is whey, which is easy to digest.
- *Fat*—Approximately 58% of total calories are fat, but they are easy to digest. Essential fatty acid content is high, as is the level of cholesterol, which helps develop enzyme systems capable of handling cholesterol later in life.
- *Carbohydrate*—Approximately 35% to 40% of total calories are in the form of lactose, which stimulates the growth of natural defense bacteria in the gastrointestinal system and promotes calcium absorption.
- *Water*—Water, the major nutrient in breast milk, makes up 85% to 95% of the total volume. Total milk volume varies with the age of the infant and demand.
- *Minerals*—Breast milk contains calcium, phosphorus, chlorine, potassium, and sodium, with trace amounts of iron, copper, and manganese. Iron absorption is about 50%, compared with about 4% for iron-fortified formulas.
- *Vitamins*—All vitamins are present in breast milk; vitamin D is the lowest in amount. Vitamin D supplementation is recommended by the AAP now.
- *Enzymes*—Lipase and amylase are found in breast milk to assist with digestion (Konek & Becker, 2020).

Breastfeeding Assistance

Breastfeeding can be initiated immediately after birth. If the newborn is healthy and stable, wipe the newborn from head to toe with a dry cloth and place him or her skin to skin on the mother's abdomen. Then cover the newborn and mother with another warmed blanket to hold in the warmth. Immediate mother–newborn contact takes advantage of the newborn's natural alertness after a vaginal birth and fosters bonding. This immediate contact also reduces maternal bleeding and stabilizes the newborn's temperature, blood glucose level, and respiratory rate (King et al., 2019).

Left alone on the mother's abdomen, a healthy newborn scoots upward, pushing with the feet, pulling with the arms, and bobbing the head until finding and latching-on to the mother's nipple. A newborn's sense of smell is highly developed, which also helps in finding the nipple. As the newborn moves to the nipple, the mother produces high levels of oxytocin, which contracts the uterus, thereby minimizing bleeding. Oxytocin also causes the breasts to release colostrum when the newborn sucks on the nipple. Colostrum is rich in antibodies and thus provides the newborn with her "first immunization" against infection.

Keys to successful breastfeeding include:

- Initiating breastfeeding within the first hour of life if the newborn is stable
- Placing the newborn on the mother's chest/abdomen immediately after birth
- Following the newborn's feeding schedule—eight to 12 times in 24 hours
- Providing unrestricted periods of breastfeeding
- Offering no supplement unless medically indicated
- Having a lactation consultant observe a feeding session
- Avoiding artificial nipples and pacifiers except during a painful procedure
- Increasing fluid intake to encourage greater milk production
- Feeding from both breasts over each 24-hour period
- Watching for indicators of sufficient intake from infant:
  - Six to 10 wet diapers daily
  - Waking up hungry eight to 12 times in 24 hours

    - Acting content and falling asleep after feeding
- Keeping the newborn with the mother throughout the hospital stay
- The nurse or lactation consultant should be available to guide and support the breastfeeding mother while on the postpartum unit

Help position the newborn so that latching-on is effective and is not painful for the mother. Placing pillows or a folded blanket under the mother's head may help, or rolling her to one side and tucking the newborn next to her. Assess both the mother and newborn during this initial session to determine needs for assistance and education. One tool used frequently in this assessment is the LATCH scoring tool (D'Souza et al., 2018). The LATCH scoring tool is a breastfeeding charting system that provides a systematic method for gathering information about individual breastfeeding sessions. The system assigns a numerical score of 0, 1, or 2 to five key components of breastfeeding. Each letter of the acronym LATCH denotes an area of assessment: "L" is for how well the infant latches onto the breast; "A" is for the amount of audible swallowing noted; "T" is for the mother's nipple type; "C" is for the mother's level of comfort; "H" is for the amount of help the mother needs to hold her infant to the breast. The system is visually represented in the same form as the Apgar scoring grid, and the numbers are handled in the same way. With the LATCH system, the nurse can assess maternal and infant variables, define areas of needed intervention, and determine priorities in providing client care and teaching (Table 18.7). The higher the score, the lesser the nursing intervention needed by the mother and baby.

TABLE 18.7 The LATCH Scoring Tool

Parameters	0 Point	1 Point	2 Points
L: latch	Sleepy infant, no sustained latch achieved	Must hold nipple in infant's mouth to sustain latch and suck; must stimulate infant to continue to suck	Grasps nipple; tongue down; rhythmic sucking
A: audible swallowing	None	A few observed with stimulation	Spontaneous and intermittent both <24 hours old and afterward
T: type of nipple	Inverted (drawn inward into breast tissue)	Flat (not protruding)	Everted or protruding out after stimulation
C: comfort of nipple	Engorged, cracked bleeding; severe discomfort	Filling; reddened, small blisters or bruises; mild to moderate discomfort	Soft, nontender
H: hold (positioning)	Nurse must hold infant to breast	Minimal assistance; help with positioning, then mother takes over	No assistance needed by nurse

Adapted from D'Souza, G. L., D'Souza, S. R. B., Kamath, P., & Lewis, L. E. (2018). Nurse-led early initiation of breastfeeding on the LATCH scoring system. *Indian Journal of Public Health Research & Development*, *9*(1), 417–421. https://doi.org/10.5958/0976-5506.2018.00077.3; King, T. L., Brucker, M. C., Osborne, K., & Jevitt, C. M. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning.

Breastfeeding Positioning

The mother and infant must be in comfortable positions to ensure breastfeeding success. The four most common positions for breastfeeding are the football, cross cradle, across-the-lap, and side-lying holds. Each mother, on experimentation, can decide which positions feel most comfortable for her (Fig. 18.24).

- In the *football hold*, the mother holds the infant's back and shoulders in her palm and tucks the infant under her arm. Remind the mother to keep the infant's ear, shoulder, and hip in a straight line. The mother supports the breast with her hand and brings it to the infant's lips to latch on. She continues to support the breast until the infant begins to nurse. This position allows the mother to see the infant's mouth as she guides her infant to the nipple. This is a good choice for mothers who have had a cesarean birth because it avoids pressure on the incision.
- The *cross-cradling position* is the one most commonly used. The mother holds the baby in the crook of her arm, with the infant facing the mother. The mother supports the breast with her opposite hand.

FIGURE 18.24. Breastfeeding positions. **A.** Cradling position. **B.** Football hold position. **C.** Side-lying position.

- In the *across-the-lap position*, the mother places a pillow across her lap, with the infant facing the mother. The mother supports the infant's back and shoulders with her palm and supports her breast from underneath. After the infant is in position, the infant is pulled forward to latch on.
- In the *side-lying position*, the mother lies on her side with a pillow supporting her back and another pillow supporting the newborn in the front. To start, the mother props herself up on an elbow and supports the newborn with that arm, while holding her breast with the opposite hand. Once nursing is started, the mother lies down in a comfortable position.

To promote latching-on, instruct the mother to make a C or a V shape with her fingers. In the C hold, the mother places her thumb well above the areola and the other four fingers below the areola and under the breast. In the V hold, the mother places her index finger above the areola and her other three fingers below the areola and under the breast. Either method can be used as long as the mother's hand is well away from the nipple so the infant can latch on.

Breastfeeding Education

Breastfeeding is not an innate skill in human mothers. Almost all women have the potential to breastfeed successfully, but many fail because of inadequate knowledge. Nursing Care Plan 18.1 gives typical nursing analyses, outcomes, and interventions. For many mothers and newborns, breastfeeding goes smoothly from the start, but for others it is a struggle. Nurses can help throughout the experience by not being judgmental and by demonstrating techniques and offering encouragement and praise for success. Correct positioning will enhance good attachment and will ensure effective milk transfer. Nurses should emphasize that the key to successful breastfeeding is correct positioning and latching-on.

Teaching by nurses has been shown to have a significant effect on both the ability to breastfeed successfully and the duration of lactation (Sen & Kilic, 2019). During the first few breastfeeding sessions, mothers want to know how often they should be nursing, whether breastfeeding is going well, if the newborn is getting enough

nourishment, and what problems may ensue and how to cope with them. Education for the breastfeeding mother is highlighted in Teaching Guidelines 18.4.

NURSING CARE PLAN 18.1 Overview of the Mother and Newborn Having Difficulty with Breastfeeding

Baby boy James, weight 7 lb, 4 oz, was born a few hours ago. His mother is a 19-year-old gravida 1, para 1. His Apgar scores were 9 points at both 1 and 5 minutes. Labor and birth were unremarkable, and James was admitted to the nursery for assessment. After stabilization, James was brought to his mother, who had said she wished to breastfeed. The postpartum nurse assisted the new mother with positioning and latching-on and left the room for a few minutes. On returning, the mother was upset, James was crying, and she stated she wanted a bottle of formula to feed him since she didn't have milk and her nipples hurt.

Assessment reveals a young, inexperienced mother placed in an uncomfortable situation with limited knowledge of breastfeeding. Anxiety from the mother transferred to James, resulting in crying. The mother, apprehensive about breastfeeding, needs additional help.

NURSING ANALYSIS: Breastfeeding difficulty related to pain and limited skill

OUTCOME IDENTIFICATION AND EVALUATION

The mother will demonstrate understanding of breastfeeding skills as evidenced by use of correct positioning and technique, and verbalization of appropriate information related to breastfeeding.

INTERVENTIONS: *Providing Education*

- Instruct the mother on proper positioning for breastfeeding; suggest use of football hold, side-lying position, modified cradle, and across-the-lap position *to ensure comfort and to promote ease in breastfeeding*.
- Review breast anatomy and milk letdown reflex *to enhance mother's understanding of lactation*.
- Observe newborn's ability to suck and latch on to the nipple *to assess whether newborn has adequate ability*.
- Monitor sucking and newborn swallowing for several minutes *to ensure adequate latching-on and to assess intake*.
- Reinforce nipple care with water and exposure to air *to maintain nipple integrity*.

NURSING ANALYSIS: Anxiety related to breastfeeding ability and irritable, crying newborn

OUTCOME IDENTIFICATION AND EVALUATION

The mother will verbalize increased comfort with breastfeeding as evidenced by positive statements related to breastfeeding and verbalization of desire to continue to breastfeed newborn.

INTERVENTIONS: *Reducing Anxiety*

- Ensure that the environment is calm and soothing without distractions *to promote maternal and newborn relaxation*.
- Show the mother correct latching-on technique *to promote breastfeeding*.
- Assist in calming newborn by holding and talking *to ensure that the newborn is relaxed prior to latching-on*.
- Reassure the mother she can be successful at breastfeeding *to enhance her self-esteem and confidence*.
- Encourage frequent trials and attempts *to enhance confidence*.
- Encourage the mother to verbalize her anxiety/fears *to reduce anxiety*.

NURSING ANALYSIS: Pain related to breastfeeding and incorrect latching-on technique

OUTCOME IDENTIFICATION AND EVALUATION

The mother will experience a decrease in pain during breastfeeding as evidenced by statements of less nipple pain.

INTERVENTIONS: *Reducing Pain*

- Suggest several alternate positions for breastfeeding *to increase comfort*.
- Demonstrate how to break suction before removing infant from breast *to minimize trauma to nipple*.
- Inspect nipple area *to promote early identification of trauma*.
- Reinforce correct latching-on technique *to prevent nipple trauma*.
- Administer pain medication if indicated *to relieve pain*.
- Instruct about nipple care between feedings *to maintain nipple integrity*.

TAKE NOTE!

Remember that the supply of milk is equal to the demand—the more sucking, the more milk.

Remember Kelly, who was concerned about jaundice in her newborn son? At her son’s 2-week well-baby check-up at the clinic, his bilirubin level came back within normal limits. Kelly still felt he was not getting enough to eat and stated that she might switch to formula-feeding her son. What information can the nurse present to promote and reinforce breastfeeding? Should the nurse make a referral to the lactation consultant?

TEACHING GUIDELINES 18.4

Breastfeeding

- Set aside a quiet place where you can be relaxed and won't be disturbed. Relaxation promotes milk letdown.
- Sit in a comfortable chair or rocking chair or lie on a bed. Try to make each feeding calm, quiet, and leisurely. Avoid distractions.
- Listen to soothing music and sip a nutritious drink during feedings.
- Initially, nurse the newborn every few hours to stimulate milk production. Remember that the supply of milk is equal to the demand—the more sucking, the more milk.
- Watch for signals from the infant to indicate that he or she is hungry, such as:
  - Nuzzling against the mother's breasts
  - Demonstrating the rooting reflex by making sucking motions
  - Placing fist or hands in mouth to suck on
  - Crying and squirming
  - Smacking the lips
- Stimulate the rooting reflex by touching the newborn's cheek to initiate sucking.
- Look for signs indicating that the newborn has latched on correctly: wide-open mouth with the nipple and much of the areola in the mouth, lips rolled outward, and tongue over lower gum, visible jaw movement drawing milk out, rhythmic sucking with an audible swallowing (soft "ka" or "ah" sound indicates the infant is swallowing milk).
- Hold the newborn closely, facing the breast, with the newborn's ear, shoulder, and hip in direct alignment.
- Nurse the infant on demand, not on a rigid schedule. Feed every 2 to 3 hours within a 24-hour period for a total of eight to 12 feedings.
- Alternate the breast you offer first; identify with a safety pin on bra.
- Vary your position for each feeding to empty breasts and reduce soreness.
- Look for signs that the newborn is getting enough milk:

  - At least six wet diapers and two to five loose yellow stools daily
  - Steady weight gain after the first week of age
  - Pale-yellow urine, not deep yellow or orange
  - Sleeping well, yet looks alert and healthy when awake
- Wake up the newborn if he or she has nursed less than 5 minutes by unwrapping him or her.
- Before removing the baby from the breast, break the infant's suction by inserting a finger.
- Burp the infant to release air when changing breasts and at the end of the breastfeeding session.
- Avoid supplemental formula feedings unless indicated for a medical reason. Do not take drugs or medications unless approved by the health care provider.
- Avoid drinking alcohol or caffeinated drinks because they pass through milk.
- Do not smoke while breastfeeding; it increases the risk of sudden infant death syndrome.
- Always wash your hands before expressing or handling milk to store.
- Wear nursing bras and clothes that are easy to undo.

A breastfeeding algorithm to guide bedside health care practice for term newborns. *Nursing for Women's Health*, *23*(1), 49–58. https://doi.org/10.1016/j.nwh.2018.11.003; and King, T. L., Brucker, M. C., Osborne, K., & Jevitt, C. M. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning.

Breast Milk Storage and Expression

If the breastfeeding mother becomes separated from the newborn for any reason (e.g., work, travel, or illness), she needs instruction on how to express and store milk safely. Expressing milk can be done manually (hand compression of breast) or by using a breast pump. Manual or handheld pumps are inexpensive and can be used by mothers who occasionally need an extra bottle if they are going out (Fig. 18.25A). Electric breast pumps are used for mothers who

experience a lengthy separation from their infants and need to pump their breasts regularly, for example, while at the workplace (Fig. 18.25B).

To ensure the safety of expressed breast milk, instruct the mother as follows:

- Wash your hands before expressing milk or handling breast milk.
- Find a quiet, clean place to express milk if returned to workplace.
- Use clean containers to store expressed milk.
- Use sealed and chilled milk within 24 hours.
- Discard any milk that has been refrigerated for more than 24 hours.
- Use any frozen expressed milk within 3 months.
- Do not use microwave ovens to warm chilled milk.
- Discard any used milk; never refreeze it.

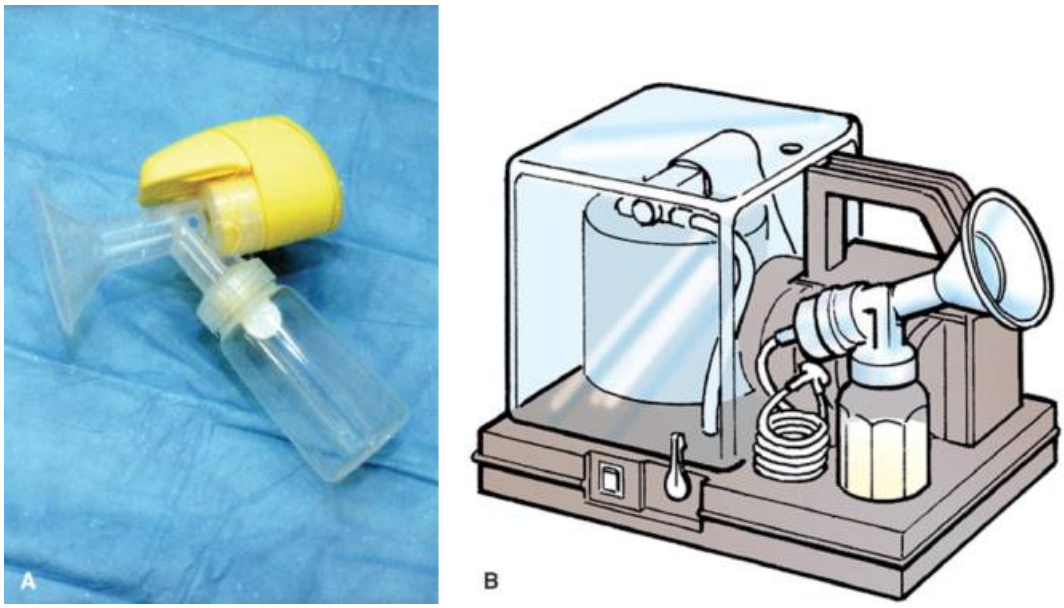

FIGURE 18.25. A. Hand-held breast pump. **B.** Electric breast pump. (Part B from Lippincott. [2015]. *Lippincott nursing procedures* [7th ed.]. Wolters Kluwer.)

- Store milk in quantities to be used for each feeding (2 to 4 oz).
- Thaw milk in warm water before using (La Leche League, 2020b).

Common Breastfeeding Concerns

Breastfeeding women may experience problems such as cracked nipples, engorgement (the painful overfilling of the breasts with milk), or mastitis (inflammation of the breast). Breastfeeding should not be painful for the mother. If she has sore, cracked nipples, the first step is to find the cause. Incorrect positioning or latching-on, removing the infant from the breast without first breaking the suction, or wearing a bra that is too tight can cause cracked or sore nipples. Cracked nipples can increase the risk of mastitis because a break in the skin may allow *Staphylococcus aureus* or other organisms to enter the body.

Sore nipples usually are caused by improper infant attachment, which traumatizes the tissue. The nurse should review techniques for proper positioning and latching-on. It is important to get this correct from the first feed to assist in the prevention of incorrect attachment and associated nipple trauma. Recommend the following to the mother:

- Use only warm water, not soap, to clean the nipples to prevent dryness.
- Express some milk before feeding to stimulate the milk ejection reflex.
- Avoid using breast pads with plastic liners, and change pads when they are wet.
- Wear a comfortable bra that is not too tight.
- Apply a few drops of breast milk to the nipples after feeding.
- Take systemic anti-inflammatory such as ibuprofen for discomfort.
- Rotate positions when feeding the infant to promote complete breast emptying.
- Leave the nursing bra flaps down after feeding to allow nipples to air-dry.
- Inspect the nipples daily for redness or cracks (La Leche League, 2020a).

To ease nipple pain and trauma, reinforce appropriate latching-on techniques and remind the woman about the need to break the suction at the breast before removing the newborn from the breast. Additional measures may include applying cold compresses over the area and massaging breast milk onto the nipple after feeding.

Engorgement may occur as the milk comes in around day 3 or 4 after birth of the newborn. Explain to the mother that engorgement, though uncomfortable, is self-limited and will resolve as the newborn continues to nurse. The mother should continue to nurse during engorgement to avoid a plugged milk duct, which could lead to mastitis. Provide the following tips for relieving engorgement:

- Take warm to hot showers to encourage milk release.
- Express some milk manually before breastfeeding.
- Lie back, which keeps breasts higher because fluids follow gravity.
- Wear a supportive nursing bra 24 hours a day to provide support.
- Feed the newborn in a variety of positions—sitting up and then lying down.
- Massage the breasts from under the axillary area down toward the nipple.
- Increase the frequency of feedings.
- Keep infant with you to facilitate frequent breastfeeding.
- Apply warm compresses to the breasts prior to nursing.
- Stay relaxed while breastfeeding.
- Stand in a shower and let hot water hit back to relax and release some milk.
- Use a breast pump if nursing or manual expression is not effective.
- Remember that this condition is temporary and resolves quickly.

Mastitis, or inflammation of the breast, causes flu-like symptoms, chills, fever, and malaise. These symptoms may occur before the development of soreness, aching, swelling, and redness in the breast (usually the upper outer quadrant). This condition usually occurs in just one breast when a milk duct becomes blocked, causing inflammation, or through a cracked or damaged nipple, allowing bacteria to infect a portion of the breast. Treatment consists of rest, warm compresses, antibiotics, breast support, and continued breastfeeding (the infection will not pass into the breast milk). Explain to the mother that it is important to keep the milk flowing in the infected breast, whether it is through nursing or manual expression or with a breast pump.

FORMULA-FEEDING

Despite the general acknowledgment that breastfeeding is the most desirable means of feeding infants; many mothers choose formula-feeding and need education about this procedure. Formula-fed infants grow more rapidly than breastfed infants not only in weight but also in length.

Formula-feeding requires more than just opening, pouring, and feeding. Parents need information about the types of formula available, preparation and storage of formula, equipment, feeding positions, and the amount to feed their newborn. The mother also needs to know how to prevent lactation (see Chapter 16 for more information).

Commercially prepared formulas are regulated by the Food and Drug Administration (FDA), which sets minimum and maximum levels of nutrients. Formulas are manufactured by numerous manufacturers in the United States. Normal full-term infants usually receive conventional cow milk–based formula, but the health care provider makes this decision. If the infant shows signs of a reaction or lactose intolerance, a switch to another formula type is recommended.

The general recommendation is for all infants to receive iron-fortified formula until the age of 1 year. The latest generation of infant formulas includes some fortification with docosahexaenoic acid (DHA) and arachidonic acid (ARA), two natural components of breast milk. Many feel the FDA does not adequately regulate the use of fatty acid additives (DHA and ARA) to infant formula before they are marketed, and there is no systematic assessment after marketing is underway. Researchers are calling for more FDA regulation over additives in infant formulas (CDC, 2020). Commercial formulas come in three forms: powder, concentrate, and easy to feed or ready to use. All are similar in terms of nutritional content but differ in expense. Powdered formula is the least expensive, with concentrated formula the next most expensive. Both must be mixed with water before using. Ready-to-feed formula is the most

expensive; it can be opened and poured into a bottle and fed directly to the infant.

Parents need information about the equipment needed for formula-feeding. Basic supplies are four to six 4-oz bottles, eight to ten 8-oz bottles, eight to ten nipple units, a bottle brush, and a nipple brush. A key area of instruction is assessing for flow of formula through the nipple and checking for any nipple damage. When the bottle is filled and turned upside down, the flow from the nipple should be approximately one drop per second. If the parents are using bottles with disposable bags, instruct them to make sure they have a tight-fitting nipple to prevent leaks. Frequent observation of the flow rate from the nipple and the condition of the nipple will prevent choking and aspiration associated with too fast a rate of delivery. Ask the parents to fill a bottle with formula and then turn it upside down and observe the rate at which the formula drips from the bottle. If it is too fast (more than one drop per second), then the nipple should be replaced.

Correct formula preparation is critical to the newborn's health and development. Mistakes in dilution may result if the parents do not understand how to prepare the formula or make measurement errors. The safety of the water supply should be considered. If well water is used, parents should sterilize the water by boiling it or should use bottled water. Many health care providers still recommend that all water used in formula preparation be brought to a rolling boil for 1 to 2 minutes and then cooled to room temperature before use.

Opened cans of ready-made or concentrated formula should be covered and refrigerated after being prepared for the day (24 hours). Instruct parents to discard any unused portions after 48 hours.

TAKE NOTE!

Any formula left in the bottle after feeding should also be discarded, because the infant's saliva has been mixed with it.

To warm refrigerated formula, advise the parents to place the bottle in a pan of hot water or an electric bottle warmer and test the temperature by letting a few drops fall on the inside of the wrist. If it is comfortably warm to the mother, it is the correct temperature.

FIGURE 18.26. Father holding his newborn securely while feeding.

Formula-Feeding Assistance

The process of feeding a newborn formula from a bottle should mirror breastfeeding as closely as possible. Although nutrition is important, so are the emotional and interactive components of feeding. Encourage parents to cuddle their newborn closely and position him or her so that the head is in a comfortable position, not

too far back or turned, which makes swallowing difficult (Fig. 18.26). Also urge parents to communicate with their newborn during the feedings by talking and singing to him or her.

Although it may seem that bottle-feeding is not a difficult task, many new parents find it awkward. At first glance, holding an infant and a bottle appears simple enough, but both the position of the baby and the angle of the bottle must be correct.

Formula-Feeding Positions

Advise mothers to feed their newborns in a relaxed and quiet setting to create a sense of calm for themselves and the baby. Make sure that comfort is a priority for both mother and newborn. The mother can sit in a comfortable chair, using a pillow to support the arm in which she is holding the baby. The mother can cradle the newborn in a semi-upright position, supporting the newborn's head in the crook of her arm. Holding the newborn close during feeding provides stimulation and helps prevent choking. Holding the newborn's head raised slightly will help prevent formula from washing backward into the eustachian tubes in the ears, which can lead to an ear infection.

Formula-Feeding Education

Parents require teaching about the correct preparation and storage of formula as well as the techniques for feeding; refer to Teaching Guidelines 18.5.

TEACHING GUIDELINES 18.5
Formula-Feeding

- Wash your hands with soap and water before preparing formula.
- Mix the formula and water amounts exactly as the label specifies.
- Always hold the newborn and bottle during feedings; never prop the bottle.
- Never freeze formula or warm it in the microwave.
- Place refrigerated formula in a pan of hot water for a few minutes to warm.
- Test the temperature of the formula by shaking a few drops on the wrist.
- Hold the bottle like a pencil, keeping it tipped to prevent air from entering. Position the bottle so that the nipple remains filled with milk.
- Burp the infant after every few ounces to allow air swallowed to escape.
- Move the nipple around in the infant's mouth to stimulate sucking.
- Always keep a bulb syringe close by to use if choking occurs.
- Avoid putting the infant to bed with a bottle to prevent "baby bottle tooth decay."
- Feed the newborn approximately every 3 to 4 hours.
- Use an iron-fortified formula for the first year.
- Prepare enough formula for the next 24 hours.
- Check nipples regularly and discard any that are sticky, cracked, or leaking.
- Store unmixed, open liquid formula in the refrigerator for up to 48 hours.
- Throw away any formula left in the bottle after each feeding.

Proper positioning makes bottle-feeding easier and more enjoyable for both the mother and newborn. As in breastfeeding, frequent burping is key. Advise the parents to hold the bottle so that formula fills the nipple, thus allowing less air to enter. Infants get

fussy when they swallow air during feedings and need to be relieved of it every 2 to 3 oz.

Emphasize to parents that an electrolyte imbalance can occur in infants who are fed formula that has been incorrectly mixed. Mixing the formula with too *little* water (i.e., too thickly) can cause hypernatremia because the high concentration of sodium is too much for the baby's immature kidneys to handle. As a result, sodium is excreted along with water, leading to dehydration. Mixing the formula with too *much* water in an effort to save money can lead to failure to thrive, diminished nutrition, fluoride overdose, and lack of weight gain (CDC, 2019c).

WEANING AND INTRODUCTION OF SOLID FOODS

Weaning

Eventually, breastfeeding or formula-feeding comes to an end. When to wean is a personal decision and will be unique to everyone. Weaning involves the transition from breast to bottle, from breast or bottle to cup, or from liquids to solids. Weaning from breastfeeding to cup has several advantages over weaning to a bottle because it eliminates the step of weaning first to a bottle and then to a cup. Another advantage is that the bottle does not become a security object for the infant.

Weaning can be done because the mother is returning to work and cannot keep breastfeeding, or because the infant is losing interest in breastfeeding and showing signs of independence. There is no "right" time to wean; it depends on the desires of the mother and infant. Weaning represents a significant change in the way the mother and infant interact, and each mother must decide for herself when she and her infant are ready to take that step. Either one can start the weaning process, but usually it occurs between 6 months and 1 year of age.

To begin weaning from the breast, instruct mothers to substitute breastfeeding with a cup or a bottle. Often the midday feeding is the

easiest feeding to replace. A trainer cup with two handles and a snap-on lid with a spout is appropriate and minimizes spilling. Because weaning is a gradual process, it may take months. Instruct parents to proceed slowly and let the infant's willingness and interest guide them.

Weaning from the bottle to the cup also needs to be timed appropriately for mother and infant. Typically, the night bottle is the last to be given up, with cup drinking substituted throughout the day. Slowly diluting the formula with water over a week can help in this process; the final result is an all-water bottle. To prevent the baby from sucking on the bottle during the night, remove it from the crib after the infant falls asleep.

Introduction of Solid Foods

The American Academy of Pediatrics recommends children be introduced to foods other than breast milk or infant formula when they are about 6 months old (CDC, 2019f). Readiness cues include:

- Consumption of 32 oz of formula or breast milk daily (estimated)
- Ability to sit up with minimal support and turn head away to indicate fullness
- Reduction of protrusion reflex so cereal can be propelled to back of throat
- Demonstration of interest in food others around them are eating
- Ability to open mouth automatically when food approaches it

When introducing solid foods, certain principles apply:

- New foods should be introduced one at a time and a week apart so that if a problem develops, the responsible item can be identified.
- Infants should be allowed to set the pace regarding how much they wish to eat.
- New foods should not be introduced more frequently than every 3 to 5 days.
- Fruits are added after cereals; then vegetables and meats are introduced; eggs are introduced last.
- A relaxed, unhurried, calm atmosphere for meals is important.
- A variety of foods are provided to ensure a balanced diet.
- Infants should never be force-fed (Konek & Becker, 2020).

Nurses can promote good feeding practices by actively listening to new mothers, helping them clarify their feelings, and discussing solutions. A warm, sincere manner and tone of voice will put an anxious mother at ease. Giving accurate information, making suggestions, and presenting options will enable the mother to decide what is best for her and her infant. Nurses should be sensitive to the individual, family, and economic and cultural differences among mothers before offering suggestions for feeding practices that may not be appropriate.

Preparing for Discharge

Preparing the parents for discharge is an essential task for the nurse. Because of today's shorter hospital stays, the nurse must identify the major teaching topics that need to be covered. Nurses should assess the parents' baseline knowledge and learning needs and plan how to meet them. Using the following principles fosters a learner-centered approach:

- Make the environment conducive to learning. Encourage the parents to feel comfortable during this stressful time by using support and praise.
- Allow the parents to provide input about the content and the process of learning. What do they want and need to learn?
- Build the parents' self-esteem by confirming that their responses to the entire birthing process and aftercare are legitimate, and others have felt the same way.
- Ensure that what the parents learn is relevant to their day-to-day home situation.
- Encourage responsibility by reinforcing that their emotional and physical responses are within the normal range.
- Respect cultural beliefs and practices that are important to the family by considering their heritage and health beliefs regarding newborn care. Examples include placing a bellyband over the newborn's navel (Hispanics and African Americans), delaying naming the newborn (Asian Americans and Haitians), and delaying breastfeeding (Native Americans; they regard colostrum as "bad") (Douglas et al., 2018).

While in the hospital, women have ready access to support and hands-on instruction regarding feeding and newborn care. When the new mother is discharged, this close supervision and support by nurses should not end abruptly. Providing the new parents with the phone number of the mother–baby unit will help them through this stressful transitional period. Giving the new family information and offering backup support via the telephone will increase parenting success.

CONSIDER THIS

I have always prided myself on being very organized and in control in most situations, but survival at home after childbirth wasn't one of them. I left the hospital 24 hours after giving birth to my son because my doctor said I could. The postpartum nurse encouraged me to stay longer, but wanting to be in control and sleeping in my own bed again won out. I thought my baby would be sleeping while I sent out birth announcements to my friends and family—wrong! What happened instead was my son didn't sleep as I imagined and my nipples became sore after breastfeeding every few hours. I was weary and tired and wanted to sleep, but I couldn't. Somehow, I thought I would be getting a full night's sleep because I was up throughout the day, but that was a fantasy too. At 2 o'clock in the morning when you are up feeding your baby, you feel you are the only one in the world up at that time and feel very much alone. My feelings of being organized and in control all the time have changed dramatically since I left the hospital. I have learned to yield to the important needs of my son and derive satisfaction from being able to bring comfort to him and to let go of my control.

Thoughts: It is interesting to see how a newborn changed this woman's need to organize and control her environment. What "tips of survival" could the nurse offer this woman to help in her transition to home with her newborn? How can friends and family help when women arrive home from the hospital with their newborns?

ENSURING FOLLOW-UP CARE

Most newborns are scheduled for their first health follow-up appointment within 2 to 4 days after discharge so they can have additional laboratory work done as part of the newborn screening series, especially if they were discharged within 48 hours. After this first visit, the typical schedule of health care visits is as follows: 2 to 4 weeks of age; 2, 4, and 6 months of age for checkups and vaccines; 9 months of age for a check-up; 12 months for a check-up and

tuberculosis testing; 15 and 18 months for check-ups and vaccines; and 2 years of age for a check-up. These appointments provide an opportunity for parents to ask questions and receive anticipatory guidance as their newborn grows and develops.

In addition to encouraging parents to keep follow-up appointments, advise parents to call their health care provider if they notice signs of illness in their newborn. They should know which over-the-counter medicines should be kept on hand. Review the following warning signs of illness with parents:

- Temperature of 101°F (38.3°C) or higher
- Forceful, persistent vomiting, not just spitting up
- Refusal to take feedings
- Two or more green, watery diarrheal stools
- Infrequent wet diapers and change in bowel movements from normal pattern
- Lethargy or excessive sleepiness
- Inconsolable crying and extreme fussiness
- Abdominal distention
- Difficult or labored breathing

PROVIDING IMMUNIZATION INFORMATION

In the last century, vaccinations have been the most effective medical intervention to reduce mortality and morbidity caused by communicable diseases. Parents also need instructions about immunizations for their newborn. **Immunization** is the process of rendering an individual immune or of becoming immune to certain communicable diseases (Blackburn, 2018). The purpose of the immune system is to identify unknown (nonself) substances in the body and develop a defense against these invaders. Disease prevention by immunization is a public health priority and is one of the leading health indicators as part of *Healthy People 2030.* Despite many advances in vaccine delivery, the goal of universal immunization has not been reached (WHO, 2020b). Nurses can help meet this national goal by educating new parents about the importance of disease prevention through immunizations.

Immunity can be provided either passively or actively. Passive immunity is protection transferred via already formed antibodies from one person to another. Passive immunity includes transplacental passage of antibodies from a mother to her newborn, immunity passed through breast milk, and immunity from immunoglobulins. Passive immunity provides limited protection and decreases over a period of weeks or months (Blackburn, 2018). Active immunity is protection produced by an individual's own immune system. It can be obtained by having the actual disease or by receiving a vaccine that produces an immunologic response by that person's body. Active immunity may be lifelong either way; see Chapter 17.

Young infants and children are susceptible to various illnesses because their immune systems are not yet mature. Many of these illnesses can be prevented by following the recommended schedule of childhood immunizations. The schedule for immunizations should be reviewed with parents, stressing the importance of continued follow-up health care to preserve their infant's health. Refer to Chapter 31 for additional information on childhood immunizations and visit thePoint to view the current CDC immunization schedule.

The newborn's first immunization (hepatitis B) is received in the hospital soon after birth. The first dose can also be given by age 2 months if the mother is HbsAg negative. If the mother is HbsAg positive, then the newborn should receive hepatitis B vaccine and hepatitis B immunoglobulin within 12 hours of birth (Cunningham et al., 2018).

Education for the parents should include the risks and benefits for each vaccine and possible adverse effects. Federal law requires a consent form to be signed before administering a vaccine. Parents have the right to refuse immunizations based on their religious beliefs and can sign a waiver noting their decision. When consent has been received, the nurse administering the vaccine must document the date and time it was given, name and manufacturer, lot number and expiration date of the vaccine given, site and route of administration, and the name and title of the nurse who administered the vaccine. Despite overwhelming evidence of vaccine safety, suspicion and misconception continues in small groups of hesitant or

resistant parents/partners/significant others, often leading to outbreaks of vaccine-preventable infections. On the front lines of vaccinations, nurses can improve vaccination rates by developing trust with parents/partners/significant others and arming them with information based on sound evidence.

KEY CONCEPTS

- The period of transition from intrauterine to extrauterine life occurs during the first several hours after birth. It is a time of stabilization for the newborn's temperature, respiration, and cardiovascular dynamics.
- The newborn's bowel is sterile at birth. It usually takes about a week for the newborn to produce vitamin K in sufficient quantities to prevent VKDB.
- It is recommended that all newborns in the United States receive an installation of a prophylactic agent (erythromycin or tetracycline ophthalmic ointment) in their eyes within an hour or two of being born.
- Nursing measures to maintain newborns' body temperature include drying them immediately after birth to prevent heat loss through evaporation, wrapping them in prewarmed blankets, putting a hat on their head, and placing them under a temperature-controlled radiant warmer.
- The specific components of a typical newborn examination include a general survey of skin color, posture, state of alertness, head size, overall behavioral state, respiratory status, gender, and any obvious congenital anomalies.
- Gestational age assessment is pertinent because it allows the nurse to plot growth parameters and to anticipate potential problems related to prematurity/postmaturity and growth abnormalities such as SGA/LGA.
- After the newborn has passed the transitional period and stabilized, the nurse needs to complete ongoing assessments, vital signs, weight and measurements, cord care, hygiene measures, newborn screening tests, and various other tasks until the newborn is discharged home from the birthing unit.
- Important topics about which to educate parents include environmental safety, newborn characteristics, feeding and bathing, circumcision and cord care, sleep and elimination patterns of newborns, safe infant car seats, holding/positioning, and follow-up care.
- Newborn screening tests consist of hearing and certain genetic and inborn errors of metabolism tests required in most states for newborns before discharge from the birth facility.

- The AAP and the American Dietetic Association recommend breastfeeding exclusively for the first 6 months of life and that it continue along with other food at least until the first birthday.
- Parents who choose not to breastfeed need to know what types of formula are available, preparation and storage of formula, equipment, feeding positions, and how much to feed their infant.
- Common problems associated with the newborn include transient tachypnea, physiologic jaundice, and hypoglycemia.
- Transient tachypnea of the newborn appears soon after birth; is accompanied by retractions, expiratory grunting, or cyanosis; and is relieved by low-dose oxygen.
- Physiologic jaundice is a very common condition in newborns, with the majority demonstrating yellowish skin, mucous membranes, and sclera within the first 3 days of life. Newborns undergoing phototherapy in the treatment of jaundice require close monitoring of their body temperature and fluid and electrolyte balance; observation of skin integrity; eye protection; and parental participation in their care.
- The newborn with hypoglycemia requires close monitoring for signs and symptoms of hypoglycemia if present. In addition, newborns at high risk need to be identified based on their perinatal history, physical examination, body measurements, and gestational age.
- The schedule for immunizations should be reviewed with parents, stressing the importance of continual follow-up health care to preserve their infant's health.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. At birth, a newborn's assessment reveals the following: heart rate of 140 bpm, loud crying, some flexion of extremities, crying when bulb syringe is introduced into the nares, and a pink body with blue extremities. The nurse would document the newborn's Apgar score as

   a. 5 points.
   b. 6 points.
   c. 7 points.
   d. 8 points.

2. The nurse is explaining phototherapy to the parents of a newborn. The nurse would include which of the following as the purpose?

   a. Increase surfactant levels
   b. Stabilize the newborn's temperature
   c. Destroy Rh-negative antibodies
   d. Oxidize bilirubin on the skin

3. The nurse administers a single dose of vitamin K intramuscularly to a newborn after birth to promote

   a. conjugation of bilirubin.
   b. blood clotting.
   c. foreman ovale closure.
   d. digestion of complex proteins.

4. A prophylactic agent is instilled in both eyes of all newborns to prevent which of the following conditions?

   a. Gonorrhea and chlamydia
   b. Thrush and enterobacter

c. *Staphylococcus* and syphilis
d. Hepatitis B and herpes

5. The AAP recommends that all newborns be placed on their backs to sleep to reduce the risk of

a. respiratory distress syndrome.
b. bottle mouth syndrome.
c. sudden infant death syndrome.
d. GI regurgitation syndrome.

6. Which one of the following immunizations is most commonly received by newborns before hospital discharge?

a. Pneumococcus
b. Varicella
c. Hepatitis A
d. Hepatitis B

7. Which condition would be missed if a newborn were screened before he had tolerated protein feedings for at least 48 hours?

a. Hypothyroidism
b. Cystic fibrosis
c. Phenylketonuria
d. Sickle cell disease

8. Which of the following findings in a newborn would the nurse document as abnormal when assessing the newborn head?

a. Two soft spots palpated between the cranial bones
b. A spongy area of edema outlined on the head
c. Head circumference 32 cm, chest 34 cm
d. Asymmetry of the head with overriding bones

9. Which of the following findings in a newborn would be considered normal?

a. Passage of meconium within the first 24 hours
b. Respiratory rate of 80 breaths/min
c. Yellow skin tones at 10 hours after birth
d. Bleeding from the umbilicus area

10. Which of the following parameters are measured in determining an APGAR score? Select all that apply

a. Blood pressure
b. Oxygen saturation
c. Skin color
d. Reflex irritability

CRITICAL THINKING EXERCISES

1. An African American mother who delivered her first baby, and is on the mother–baby unit, calls the nursery nurse into her room and expresses concern about how her daughter looks. The mother tells the nurse that her baby's head looks like a "banana" and is mushy to the touch, and she has "white spots" all over her nose. In addition, there appear to be "big bluish bruises" all over her baby's buttocks. She wants to know what is wrong with her baby and whether these problems will go away.

a. How should the nurse respond to this mother's questions?
b. What additional newborn instruction might be appropriate at this time?
c. What reassurance can be given to this new mother regarding her daughter's appearance?

2. At approximately 12:30 a.m. on a Friday, a woman enters a hospital through a busy emergency department. She is wearing a white uniform and a lab coat with a stethoscope around her neck. She identifies herself as a new nurse coming back to check on something she had left on the unit on an earlier shift. She enters a

postpartum client's room containing the mother's newborn, pushes the open crib down a hallway, and escapes through an exit. The security cameras aren't working. The infant isn't discovered missing until the 2 a.m. check by the nurse.

a. What impact does an infant abduction have on the family and the hospital?
b. What security measure was the weak link in the chain of security?
c. What can hospitals do to prevent infant abduction?

STUDY ACTIVITIES

1. Obtain a set of vital signs (temperature, pulse, and respiration) of a newborn on admission to the nursery. Repeat this procedure and compare changes in the values several hours later. Discuss what changes in the vital signs you would expect during this transitional period. The discussion of newborn changes noticed will vary from student to student, depending on the interview information obtained from the new mother.
2. Interview a new mother on the postpartum unit on her second day about the changes she has noticed in her newborn's appearance and behavior within the past 24 hours. Discuss your interview findings at postconference. This discussion will vary depending on questions asked during the bath demonstration as well as each individual mother's response to it.
3. Demonstrate a newborn bath to a new mother in her room, using the principle of bathing from the cleanest to the dirtiest body part. Discuss the questions asked by the mother and her reaction to the demonstration in postconference.
4. Go to the La Leche League website (refer to thePoint website). Review the information it provides on breastfeeding. How helpful would it be to a new mother?

The La Leche League website is filled with helpful information with pictures to assist new mothers with breastfeeding. Each student will have his or her own opinion about how helpful the website is and what educational level it addresses.

5. Debate the risks and benefits of neonatal circumcision within your nursing group at postconference. Did either side present a stronger position? What is your opinion, and why? The risks of neonatal circumcision include hemorrhage, infection, adhesions, dehiscence, urethral fistula, meatal stenosis, and pain. The benefits of neonatal circumcision include prevention of penile cancer, decreased incidence of UTIs and STIs, and preservation of male body consistent with father and peers where the procedure is common. Students will express their own opinions about their thoughts based on their value systems and cultural backgrounds.

BRINGING IT ALL TOGETHER: A CASE STUDY

Two days after having a difficult birth of her first child at 37 weeks' gestation, 25-year-old Molly and her partner took their son home from the hospital. That evening while she was breastfeeding him, Molly noticed that the whites of her son's eyes seemed slightly yellow, a condition that worsened noticeably by the next day. Molly called the *Healthy Start* Home Health nurse and requested a visit to evaluate her newborn.

ASSESSMENT

Upon examining the 3-day-old newborn, the nurse noted that there were a few areas of bruising on the newborn's head and a yellow hue on the infant's skin when she pressed on boney prominent areas. When questioning the mother about her breastfeeding, the mother stated that her son didn't seem all that interested at times, so she let him sleep instead.

Go to thePoint to find questions to consider about this case.

UNIT VII

Childbearing at Risk

19

Nursing Management of Pregnancy at Risk: Pregnancy-Related Complications

WOW

WORDS OF WISDOM

Detours and bumps along the road of life can be managed, but many cannot be entirely cured.

KEY TERMS

abortion

eclampsia (ek-lamp´sē-ă)

ectopic pregnancy

gestational hypertension

gestational trophoblastic disease (GTD) (jes-tā´shŭn-ŭl trof´ō-blas´tik di-zēz)

high-risk pregnancy

hyperemesis gravidarum (hī´pĕr-em´ĕ-sis grav´i-dăr´ŭm)

multiple gestation

oligohydramnios (ol´i-gō-hī-dram´nē-os)

placental abruption

placenta accreta spectrum

placenta previa

polyhydramnios (pol´ē-hī-dram´nē-os)

preeclampsia

prelabor rupture of membranes (PROM)

preterm prelabor rupture of membranes (PPROM)

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Compare and contrast a normal pregnancy to a high-risk one. Determine the common factors that might place a pregnancy at high risk.
2. Detect the causes of vaginal bleeding during early and late pregnancy.
3. Outline nursing assessment and management for the pregnant woman experiencing vaginal bleeding.
4. Identify current evidence-based guidelines used to effectively screen, diagnose, and manage placenta accreta spectrum disorders.

5. Develop plans of care for women experiencing preeclampsia, eclampsia, and HELLP syndrome.
6. Describe Rh incompatibility and hemolytic disease of the newborn.
7. Examine the pathophysiology of imbalances in amniotic fluid and subsequent management.
8. Explore multiple gestation and possible complications for both the mother and fetus.
9. Evaluate factors in a woman's prenatal history that place her at risk for prelabor rupture of membranes (PROM).
10. Formulate a teaching plan for maintaining the health of pregnant women experiencing a high-risk pregnancy.

Helen, a 35-year-old G5P4, presents to the labor and birth suite with severe abdominal pain. She reports that the pain began suddenly about an hour ago while she was resting. She has had two prior cesarean births and thus far has had an uneventful past 32 weeks. Helen appears distressed and is moaning. What additional assessments do you need to do to care for Helen? What might be your immediate nursing action?

INTRODUCTION

Our society views pregnancy as a natural process with a positive outcome—the birth of a healthy newborn. Unfortunately, conditions can occur that may result in negative outcomes for the fetus, mother, or both. A **high-risk pregnancy** is one in which a condition exists that jeopardizes the health of the mother, her fetus, or both. The condition may result from the pregnancy, or it may be a condition that was present before the woman became pregnant.

Approximately, one in four pregnant women is considered to be at high risk or diagnosed with complications (Jordan et al., 2019). Women who are considered to be at high risk have a higher morbidity and mortality compared with mothers in the general population. The risk status of a woman and her fetus can change

during the pregnancy due to a number of problems occurring during labor, birth, or afterward, even in women without any known previous prenatal risk. Examples of high-risk conditions include gestational diabetes, hypertension, polycystic ovary syndrome, autoimmune disease, obesity, HIV/AIDS, Zika infection, older or younger age, substance abuse, tobacco use, birth defects, previous preterm birth, multiple gestation, and ectopic pregnancy (National Institute of Child Health and Human Development [NICHD], 2019). Many obstetric complications and conditions are life-threatening emergencies with high morbidity and mortality rates. It is essential that these be identified early to ensure the best possible outcome for the mother and infant. These conditions are specifically addressed in *Healthy People 2030* (U.S. Department of Health and Human Services, 2020). See *Healthy People 2030* 19.1. Early identification of the woman at risk is essential to ensuring that appropriate interventions are instituted promptly, increasing the opportunity to change the course of events and provide a positive outcome.

The term “risk” may mean different things to different groups. For example, health care providers may focus on disease processes and treatments to prevent complications. Nurses may focus on nursing care and on the psychosocial impact on the woman and her family. Health insurance companies may focus on the economic issues related to the high-risk status. The woman’s attention may be focused on her own needs and those of her family. Together, working as a collaborative team, the goal of care is to ensure the best possible outcome for the woman, her fetus, and her family.

HEALTHY PEOPLE 2030 • 19.1

Objective	Nursing Significance
MICH-2030-05 Reduce severe maternal complications of pregnancy identified during labor and delivery hospitalizations.	Will reduce perinatal morbidity and mortality and optimize pregnancy outcomes
MICH-2030-07 Reduce preterm births.	Will help preserve the health and well-being of the growing fetus if the pregnancy goes to term

Adapted from USDHHS. (2020). *Proposed objectives for inclusion in Healthy People 2030*. https://www.healthypeople.gov/sites/default/files/ObjectivesPublicComment508.pdf

Risk assessment begins at the first prenatal visit and continues with each subsequent visit because factors may be identified in later visits that were not apparent during earlier visits. For example, as the nurse and client develop a trusting relationship, previously unidentified or unsuspected factors (such as drug abuse or intimate partner violence) may be revealed. Through education and support, the nurse can encourage the client to inform her health care provider of these concerns, and necessary interventions or referrals can be made.

Various factors must be considered when determining a woman's risk for adverse pregnancy outcomes, and a comprehensive approach to high-risk pregnancy is needed. For example, prenatal stress and distress have been shown to have significant consequences for the mother, child, and family. Pregnancy-specific stress such as depression, anxiety, and perceived stress may increase the risk for adverse birth outcomes and is associated with preterm births and intrauterine fetal growth restriction (Brooks & Wilson, 2019). Risks are grouped into broad categories based on threats to health and pregnancy outcomes. Current categories of risk are biophysical, psychosocial, sociodemographic, and environmental (Box 19.1) (Cunningham et al., 2018).

This chapter describes the major conditions directly related to pregnancy that can complicate a pregnancy, possibly affecting maternal and fetal outcomes. These include bleeding during

pregnancy (spontaneous abortion, ectopic pregnancy, gestational trophoblastic disease, cervical insufficiency, placenta previa, placental abruption, and placenta accreta), hyperemesis gravidarum, gestational hypertension, HELLP syndrome, gestational diabetes, blood incompatibility, amniotic fluid imbalances (polyhydramnios and oligohydramnios), multiple gestation, and prelabor rupture of membranes. Chapter 20 addresses preexisting conditions that can complicate a woman's pregnancy as well as populations that are considered to be at high risk.

BLEEDING DURING PREGNANCY

Bleeding at any time during pregnancy is potentially life threatening. Every minute of every day, a woman dies in pregnancy or childbirth. The biggest killer is obstetric hemorrhage, the successful treatment of which is a challenge for both developed and developing countries. The presence of an attendant at every birth and access to emergency obstetric care are helpful in reducing maternal morbidity and mortality (World Health Organization [WHO], 2019). Management of obstetric hemorrhage involves early recognition, assessment, and resuscitation. Various methods are available to try to stop the bleeding, ranging from pharmacologic methods to aid uterine contraction (e.g., oxytocin, ergometrine, and prostaglandins) to surgical methods to stem the bleeding (e.g., balloon tamponade, compression sutures, or arterial ligation). Bleeding can occur early or late in the pregnancy and may result from numerous conditions. Bleeding is experienced by approximately 25% of women during the first trimester of pregnancy (American Family Physician, 2019). Conditions commonly associated with early bleeding (first half of pregnancy) include spontaneous abortion, uterine fibroids, ectopic pregnancy, gestational trophoblastic disease, and cervical insufficiency. Conditions associated with late bleeding include placenta previa, placental abruption, and placenta accreta, which usually occur after the 20th week of gestation.

BOX 19.1 Factors Placing a Woman at Risk During Pregnancy

Biophysical Factors

- Genetic conditions
- Chromosomal abnormalities
- Multiple pregnancy
- Defective genes
- Inherited disorders
- ABO incompatibility
- Large fetal size
- Medical and obstetric conditions
- Preterm labor and birth
- Cardiovascular disease
- Chronic hypertension
- Cervical insufficiency
- Placental abnormalities
- Infection
- Diabetes
- Maternal collagen diseases
- Thyroid disease
- Asthma
- Post-term pregnancy
- Hemoglobinopathies
- Nutritional status
- Inadequate dietary intake
- Food fads
- Excessive food intake
- Underweight or overweight status
- Hematocrit value less than 33%
- Eating disorder

Psychosocial Factors

- Smoking
- Caffeine
- Alcohol and substance abuse
- Maternal obesity
- Inadequate support system
- Situational crisis
- History of violence
- Emotional distress
- Unsafe cultural practices

Sociodemographic Factors

- Poverty status

- Lack of prenatal care
- Age younger than 15 years or older than 35 years
- Parity—All first pregnancies and more than five pregnancies
- Marital status—Increased risk for unmarried women
- Accessibility to health care
- Ethnicity—Increased risk in non-White women

Environmental Factors

- Infections
- Radiation
- Pesticides
- Illicit drugs
- Industrial pollutants
- Second-hand cigarette smoke
- Personal stress

L., & Grace, K. T. (2019). *Prenatal and postnatal care: A woman-centered approach* (2nd ed.). John Wiley & Sons, Inc.; and King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning.

Spontaneous Abortion

Abortion is considered not only a major reproductive health matter, but also a health risk factor for a woman's well-being. Spontaneous abortion is the most common complication of early pregnancy (Tulandi & Al-Fozan, 2019). An **abortion** is the loss of an early pregnancy, usually before week 20 of gestation. Abortion can be spontaneous or induced. A spontaneous abortion refers to the loss of a fetus resulting from natural causes, that is, not elective or therapeutically induced by a procedure. A stillbirth is the loss of a fetus after the 20th week of development, while a miscarriage is a loss before the 20th week. Nonmedical people often use the term "miscarriage" to denote an abortion that has occurred spontaneously. A miscarriage can occur during early pregnancy, and many women who miscarry may not even be aware that they are pregnant. About 80% of spontaneous abortions occur within the first trimester. The terms "stillbirth" and "miscarriage" can sometimes be confusing. Both

refer to the loss of an early pregnancy; however, stillbirth occurs later in pregnancy. Some stillbirths can occur right up to the time of labor and delivery. Stillbirths are much less common than miscarriages, occurring in one out of every 100 pregnancies in the United States (March of Dimes, 2019f).

The overall rate for spontaneous abortion in the United States is reported to be 10% to 15% of recognized pregnancies in the United States and 50% of miscarriages are attributed to chromosomal abnormalities. However, with the development of highly sensitive assays for human chorionic gonadotropin (hCG) levels that detect pregnancies prior to the expected next menses, the incidence of pregnancy loss increases significantly—to about 60% to 70% (King et al., 2019). The frequency of spontaneous abortion increases further with maternal age.

Pathophysiology

The causes of spontaneous abortion are varied and often unknown. The most common cause for first-trimester abortions is fetal genetic abnormalities, usually unrelated to the mother. Chromosomal abnormalities are more likely causes in the first trimester and maternal disease is more likely in the second trimester. Those occurring during the second trimester are more likely related to maternal conditions, such as cervical insufficiency, congenital or acquired anomaly of the uterine cavity (uterine septum or fibroids), hypothyroidism, diabetes mellitus, chronic nephritis, use of cocaine, inherited and acquired thrombophilias, lupus, polycystic ovary syndrome, severe hypertension, and acute infection such as that of rubella virus, cytomegalovirus, herpes simplex virus, bacterial vaginosis, and toxoplasmosis (Resnik et al., 2019).

Women experiencing a first-trimester abortion at home without a dilation and curettage (D&C) to resolve it require frequent monitoring of hCG levels to validate that all the conceptus tissues have been expelled. Women going through a second-trimester abortion are admitted to the hospital to have an augmented labor and delivery. Nursing care would focus on care of the laboring women with

tremendous attention paid to providing emotional support to the woman and her family.

Nursing Assessment

When a pregnant woman calls and reports vaginal bleeding, she must be seen as soon as possible by a health care professional to ascertain the etiology. Varying degrees of vaginal bleeding, low back pain, abdominal cramping, and passage of products of conception tissue may be reported. Ask the woman about the color of the vaginal bleeding (bright red is significant) and the amount—for example, question her about the frequency with which she is changing her peripads (saturation of one peripad hourly is significant) and the passage of any clots or tissue. Instruct her to save any tissue or clots passed and bring them with her to the health care facility. Also, obtain a description of any other signs and symptoms the woman may be experiencing, along with a description of their severity and duration. It is important to remain calm and listen to the woman's description.

When the woman arrives at the health care facility, assess her vital signs and observe the amount, color, and characteristics of the bleeding. Ask her to rate her current pain level, using an appropriate pain assessment tool. Also evaluate the amount and intensity of the woman's abdominal cramping or contractions, and assess the woman's level of understanding about what is happening to her. A thorough assessment helps in determining the type of spontaneous abortion, such as threatened abortion, inevitable abortion, incomplete abortion, complete abortion, missed abortion, and habitual abortion, that the woman may be experiencing (Table 19.1).

Nursing Management

Nursing management of the woman with a spontaneous abortion focuses on providing continued monitoring and psychological support because the family is experiencing acute loss and grief. An important component of this support is reassuring the woman that

spontaneous abortions usually result from an abnormality and that her actions did not cause the abortion.

PROVIDING CONTINUED MONITORING

Continued monitoring and ongoing assessments are essential for the woman experiencing a spontaneous abortion. Monitor the amount of vaginal bleeding through pad counts and observe for passage of products of conception tissue. Assess the woman's pain and provide appropriate pain management to address the cramping discomfort.

Assist in preparing the woman for procedures and treatments such as surgery to evacuate the uterus or medications such as misoprostol or prostaglandin E2 (PGE2). If the woman is Rh-negative and not sensitized, expect to administer RhoGAM within 72 hours after the abortion is complete. Drug Guide 19.1 provides more information about these medications.

PROVIDING SUPPORT

Pregnancy loss subjects parents to a multitude of emotions and may have significant consequences on their mental health. A woman's emotional reaction may vary depending on her desire for the pregnancy and her available support network. Provide both physical and emotional support. In addition, prepare the woman and her family for the assessment process and answer their questions.

Explaining some of the causes of spontaneous abortions can help the woman understand what is happening and may allay her fears and guilt that she did something to cause the pregnancy loss. Many women experience an acute sense of loss and go through a grieving process with a spontaneous abortion. Providing sensitive listening, counseling, and anticipatory guidance to the woman and her family will allow them to verbalize their feelings and ask questions about future pregnancies.

The grieving period may last years after a pregnancy loss, with each person grieving in their own way. Encourage friends and family to be supportive but give the family space and time to work through

their loss. Referral to a community support group for parents who have experienced a loss can be helpful during this grief process.

Ectopic Pregnancy

An **ectopic pregnancy** is any pregnancy in which the fertilized ovum implants outside the uterine cavity. The term “ectopic” is derived from the Greek word *ektopos,* meaning “out of place,” and refers to the implantation of a fertilized egg in a location outside of the uterine cavity, including the fallopian tubes, cervix, ovary, and the abdominal cavity. This abnormally implanted embryo grows and draws its blood supply from the site of abnormal implantation. As the embryo enlarges, it creates the potential for organ rupture because only the uterine cavity is designed to expand and accommodate fetal development. Ectopic pregnancy can lead to massive hemorrhage, infertility, or death.

TABLE 19.1 Categories of Abortion

Category	Assessment Findings	Diagnosis	Therapeutic Management
Threatened abortion	Vaginal bleeding (often slight) early in a pregnancy No cervical dilation or change in cervical consistency Mild abdominal cramping Closed cervical os No passage of fetal tissue	Vaginal ultrasound to confirm if sac is empty Declining maternal serum hCG and progesterone levels to provide additional information about viability of pregnancy	Conservative supportive treatment Possible reduction in activity in conjunction with nutritious diet and adequate hydration
Inevitable abortion	Vaginal bleeding (greater than that associated with threatened abortion) Rupture of membranes Cervical dilation Strong abdominal cramping Possible passage of products of conception	Ultrasound and hCG levels to indicate pregnancy loss	Vacuum curettage if products of conception are not passed to reduce risk of excessive bleeding and infection Prostaglandin analogs such as misoprostol to empty uterus of retained tissue (only used if fragments are not completely passed)
Incomplete abortion (passage of some of the products of conception)	Intense abdominal cramping Heavy vaginal bleeding Cervical dilation	Ultrasound confirmation that products of conception still in uterus	Client stabilization Evacuation of uterus via D&C or prostaglandin analog

Complete abortion (passage of all products of conception)	History of vaginal bleeding and abdominal pain Passage of tissue with subsequent decrease in pain and significant decrease in vaginal bleeding	Ultrasound demonstrating an empty uterus	No medical or surgical intervention necessary Follow-up appointment to discuss family planning
Missed abortion (nonviable embryo retained in utero for at least 6 weeks)	Absent uterine contractions Irregular spotting Possible progression to inevitable abortion	Ultrasound to identify products of conception in uterus	Evacuation of uterus (if inevitable abortion does not occur): suction curettage during first trimester, dilation and evacuation during second trimester Induction of labor with intravaginal PGE2 suppository to empty uterus without surgical intervention
Recurrent abortion	History of three or more consecutive spontaneous abortions Not carrying the pregnancy to viability or term	Validation via client's history No diagnostic ultrasound findings	Identification and treatment of underlying cause (possible causes such as genetic or chromosomal abnormalities, reproductive tract

	abnormalities, chronic diseases or immunologic problems) Cervical cerclage in second trimester if incompetent cervix is the cause

Ectopic pregnancies occur in one in every 50 pregnancies in the United States or roughly 2% of pregnancies. The incidence of ectopic pregnancy has increased fourfold in the past 30 years and accounts for 10% of maternal mortality in the United States (March of Dimes, 2019b). It is a major health concern for women of reproductive age and is the primary cause of death during the first trimester of pregnancy in the United States (Wong & Kitsantas, 2019). The discovery of ectopic pregnancies prior to rupture has increased dramatically in the past few decades as a result of improved diagnostic techniques such as the development of sensitive and specific radioimmunoassays for hCG, high-resolution ultrasonography, and the widespread availability of laparoscopy (Norwitz et al., 2019).

With an ectopic pregnancy, rupture and hemorrhage may occur due to the growth of the embryo. A ruptured ectopic pregnancy is a medical emergency; therefore, prediction of any tubal rupture before its occurrence is extremely important. It is a potentially life-threatening condition and involves pregnancy loss.

DRUG GUIDE 19.1 Medications Related to Abortions

Medication	Action/Indications	Nursing Implications
Misoprostol (Cytotec)	Stimulates uterine contractions to terminate a pregnancy and to evacuate the uterus after abortion to ensure passage of all the products of conception	• Monitor for side effects such as diarrhea, abdominal pain, nausea, vomiting, and dyspepsia. • Assess vaginal bleeding, and report any increased bleeding, pain, or fever. • Monitor for signs and symptoms of shock, such as tachycardia, hypotension, and anxiety.
Mifepristone (RU-486)	Acts as progesterone antagonist, allowing prostaglandins to stimulate uterine contractions; causes the endometrium to slough; may be followed by administration of misoprostol within 48 hours	• Monitor for headache, vomiting, diarrhea, and heavy bleeding. • Anticipate administration of antiemetic prior to use to reduce nausea and vomiting. • Encourage client to use acetaminophen to reduce discomfort from cramping.
PGE2, dinoprostone (Cervidil, Prepidil Gel, Prostin E2)	Stimulates uterine contractions, causing expulsion	• Bring gel to room temperature before administering.

	of uterine contents; expels uterine contents in fetal death or missed abortion during second trimester; effaces and dilates the cervix in pregnancy at term	• Avoid contact with skin. • Use sterile technique to administer. • Keep client supine for 30 minutes after administering. • Document time of insertion and dosing intervals. • Remove insert with retrieval system after 12 hours or at the onset of labor. • Explain purpose and expected response to client.
Rh(D) immunoglobulin (Gamulin, HydroRho-D, RhoGAM, MICRhoGAM)	Suppresses immune response of nonsensitized Rh-negative clients who are exposed to Rh-positive blood to prevent isoimmunization in Rh-negative women exposed to Rh-positive blood after abortions, miscarriages, and pregnancies.	• Administer intramuscularly in deltoid area. • Give only MICRhoGAM for abortions and miscarriages <12 weeks unless fetus or father is Rh-negative (unless client is Rh-positive, Rh antibodies are present). • Educate woman that she will need this after subsequent deliveries if fetuses are Rh-positive; also

	check lab study results prior to administering the drug.

King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning; Skidmore-Roth, L. (2020). *Mosby's 2020 nursing drug reference* (33rd ed.). Mosby Elsevier.

Pathophysiology

Normally, the fertilized ovum implants in the uterus. In ectopic pregnancy, the journey along the fallopian tube is arrested or altered in some way. With an ectopic pregnancy, the ovum implants outside the uterus. The most common site for implantation is the fallopian tubes (96%), but some ova may implant in the ovary, the intestine, the cervix, or the abdominal cavity (Fig. 19.1) (Stevens, 2019). None of these anatomic sites can accommodate placental attachment or a growing embryo.

Risk Factors

Ectopic pregnancies usually result from conditions that obstruct or slow the passage of the fertilized ovum through the fallopian tube to the uterus. This may be a physical blockage in the tube or failure of the tubal epithelium to move the zygote (the cell formed after the egg is fertilized) down the tube into the uterus. In the general population, most cases are the result of tubal scarring secondary to pelvic inflammatory disease (PID). Organisms such as *Neisseria gonorrhea* and *Chlamydia trachomatis* preferentially attack the fallopian tubes, producing silent infections. A recent study reported a twofold increased risk for ectopic pregnancy in women with a history of a chlamydia infection resulting in tubal damage (Reekie et al., 2019). Other associated risk factors for ectopic pregnancy include previous tubal surgery, infertility, PID, previous pregnancy loss (induced or spontaneous), use of an intrauterine contraceptive system, previous ectopic pregnancy, uterine fibroids, sterilization, smoking (which alters tubal motility), history of multiple sexual partners, use of

progestin-only oral contraceptives, douching, and exposure to diethylstilbestrol (DES) (Tulandi, 2019b).

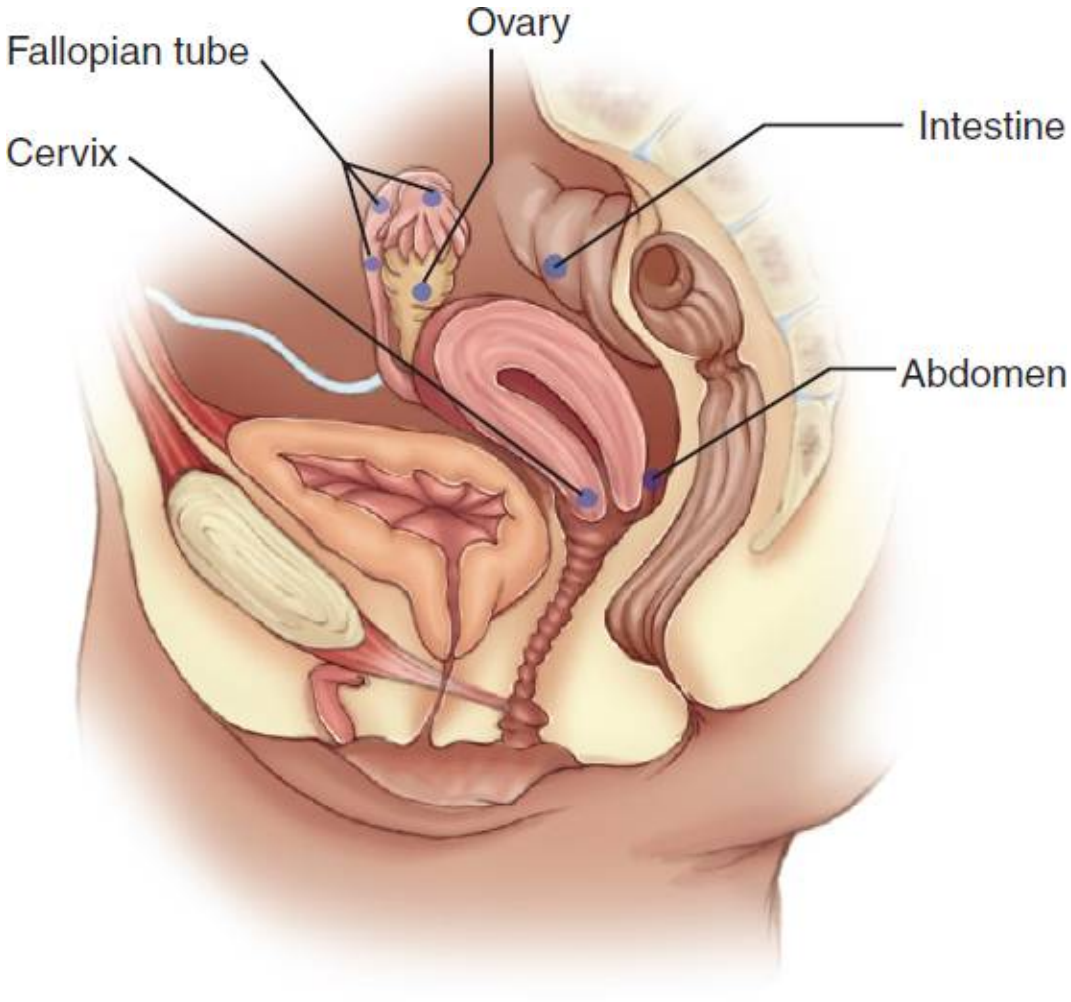

FIGURE 19.1. Possible sites for implantation with an ectopic pregnancy.

Therapeutic Management

In clinically stable women who have been diagnosed with nonruptured ectopic pregnancies, laparoscopic surgery or intramuscular (IM) methotrexate administration are safe and effective treatments. The diagnosis of ectopic pregnancy can be challenging because many women are asymptomatic before tubal rupture. The classic clinical triad of ectopic pregnancy includes abdominal pain, amenorrhea, and vaginal bleeding. However, only about half of women present with all three symptoms. Physical exam findings

include a tender abdomen, painful vaginal exam, cervical motion tenderness, and a possible adnexal mass (King et al., 2019).

Diagnostic procedures used for a suspected ectopic pregnancy include a urine pregnancy test to confirm the pregnancy, beta-hCG concentrations to exclude a false-negative urine test, and a transvaginal ultrasound to visualize the misplaced pregnancy (Tulandi, 2019a).

Historically, the treatment of ectopic pregnancy was limited to surgery. The therapeutic management of ectopic pregnancy depends on whether the tube is intact or has ruptured, creating a medical emergency. In the event of a surgical intervention, preservation of the affected fallopian tube is attempted (King et al., 2019).

MEDICAL INTERVENTION

With early diagnosis, most women with ectopic pregnancy could be treated with methotrexate. To be eligible for medical therapy, the client must be hemodynamically stable, with no signs of active bleeding in the peritoneal cavity, low beta-hCG levels (lower than 5,000 mIU/mL), and the mass (which must measure less than 4 cm as determined by ultrasound) must be unruptured.

Contraindications to medical treatment include an unstable client, severe persistent abdominal pain, renal or liver disease, immunodeficiency, active pulmonary disease, peptic ulcer, suspected intrauterine pregnancy, and poor client compliance (ACOG, 2018a). The potential advantages include avoidance of surgery, the preservation of tubal patency and function, and a lower cost.

The medical approach today for an unruptured tubal pregnancy most often consists of a single-dose IM injection of methotrexate (Rheumatrex, Trexall) with outpatient follow-up. Medical management with methotrexate, though not approved by the Food and Drug Administration (FDA) for this purpose, has been endorsed by the American College of Obstetricians and Gynecologists (ACOG). Prostaglandins, misoprostol, and actinomycin have also been used in the medical nonsurgical management of ectopic pregnancy with a reported success rate of approximately 90%.

Methotrexate is a folic acid antagonist that inhibits cell division in the developing embryo. It typically has been used as a chemotherapeutic agent in the treatment of leukemia, lymphomas, and carcinomas. It has been shown to produce results similar to that for surgical therapy in terms of high success rate, low complication rate, and good reproductive potential (ACOG, 2018a). Adverse effects associated with methotrexate include nausea, vomiting, stomatitis, diarrhea, gastric upset, increased abdominal pain, and dizziness. Methotrexate for an ectopic pregnancy is ordered based on the client's body surface area. The administration of methotrexate should be limited to people who have had education and training in the handling and administration of hazardous drugs. Prior to receiving the single-dose IM injection to treat unruptured pregnancies, the woman needs to be counseled on the risks, benefits, adverse effects, and the possibility of failure of medical therapy, which would result in tubal rupture, necessitating surgery (ACOG, 2018a). The woman is then instructed to return weekly for follow-up laboratory studies for the next several weeks until beta-hCG titers decrease. Beta-hCG level changes between days 0 and 4 after methotrexate therapy have clinical significance and predictive value. A decreasing beta-hCG level is highly predictive of treatment success (Jordan et al., 2019).

SURGICAL INTERVENTION

Surgical management for the unruptured fallopian tube might involve a linear salpingostomy to preserve the tube—an important consideration for the woman who wants to preserve her future fertility. It may also be considered when medical treatment is considered unsuitable.

With a ruptured ectopic pregnancy, surgery is necessary as a result of possible uncontrolled hemorrhage. A laparotomy with a removal of the tube (salpingectomy) may be necessary. With earlier diagnosis and medical management, the focus has changed from preventing maternal death to facilitating rapid recovery and preserving fertility.

Regardless of the treatment approach (medical or surgical), the woman's beta-hCG level is monitored until it is undetectable to ensure that any residual trophoblastic tissue that forms the placenta is gone. Also, all Rh-negative unsensitized clients are given Rh immunoglobulin to prevent isoimmunization in future pregnancies.

Nursing Assessment

Nursing assessment focuses on determining the existence of an ectopic pregnancy and whether or not it has ruptured. A woman with a suspected ectopic pregnancy may have to undergo several diagnostic tests, some of which are invasive. Consider how she might feel during all of these tests, anticipate her questions, and offer her thorough explanations and reassurances.

HEALTH HISTORY AND PHYSICAL EXAMINATION

Assess the client thoroughly for signs and symptoms that may suggest an ectopic pregnancy. The onset of signs and symptoms varies, but they usually begin at about the 7th or 8th week of gestation. A missed menstrual period, adnexal fullness, and tenderness may indicate an unruptured tubal pregnancy. As the tube stretches, the pain increases. Pain may be unilateral, bilateral, or diffuse over the abdomen.

TAKE NOTE!

The hallmark of ectopic pregnancy is abdominal pain with spotting within 6 to 8 weeks after a missed menstrual period. Although this is the classic triad, all three of these signs and symptoms occur in only about 50% of cases. Many women have symptoms typical of early pregnancy, such as breast tenderness, nausea, fatigue, shoulder pain, and low back pain.

In addition, review the client's history for possible contributing factors. These may include:

- Previous ectopic pregnancy
- History of sexually transmitted infections (STIs)

- Fallopian tube scarring from PID
- In utero exposure to DES
- Endometriosis
- Previous tubal or pelvic surgery
- Infertility and infertility treatments, including use of fertility drugs
- Uterine abnormalities such as fibroids
- Presence of intrauterine contraception
- Use of progestin-only mini pill (slows ovum transport)
- Postpartum or postabortion infection
- Altered estrogen and progesterone levels (interferes with tubal motility)
- Age older than 35 years
- Cigarette smoking (ACOG, 2018a)

If rupture or hemorrhage occurs before treatment begins, symptoms may worsen and include severe, sharp, and sudden pain in the lower abdomen as the tube tears open and the embryo is expelled into the pelvic cavity; feelings of faintness; referred pain to the shoulder area, indicating bleeding into the abdomen caused by phrenic nerve irritation; hypotension; marked abdominal tenderness with distention; and hypovolemic shock (Cunningham et al., 2018).

LABORATORY AND DIAGNOSTIC TESTING

The use of transvaginal ultrasound to visualize the misplaced pregnancy and low levels of serum beta-hCG assist in diagnosing an ectopic pregnancy. The ultrasound determines whether the pregnancy is intrauterine, assesses the size of the uterus, and provides evidence of fetal viability. The visualization of an adnexal mass and the absence of an intrauterine gestational sac are diagnostic of ectopic pregnancy (Baker, 2019). In a normal intrauterine pregnancy, beta-hCG levels typically double every 2 to 4 days until peak values are reached 60 to 90 days after conception. Concentrations of hCG decrease after 10 to 11 weeks and reach a plateau at low levels by 100 to 130 days (Norwitz et al., 2019). Therefore, low beta-hCG levels are suggestive of an ectopic pregnancy or impending abortion. Additional tests may be done to

rule out other conditions such as spontaneous abortion, ruptured ovarian cyst, appendicitis, and salpingitis.

Nursing Management

Nursing management for the woman with an ectopic pregnancy focuses on preparing the woman for treatment, providing support, and providing education about preventive measures.

PREPARING THE WOMAN FOR TREATMENT

Administer analgesics as ordered to promote comfort and relieve discomfort from abdominal pain. Although the intensity of the pain can vary, women often report a great deal of pain. If the woman is treated medically, educate the woman about the medication that will be used and what she can expect. Also review signs and symptoms of possible adverse effects. If treatment will occur on an outpatient basis, outline the signs and symptoms of ectopic rupture (severe, sharp, stabbing, unilateral abdominal pain; vertigo/fainting; hypotension; and increased pulse) and advise the woman to seek medical help immediately if they occur.

If surgery is needed, close assessment and monitoring of the client's vital signs, bleeding (peritoneal or vaginal), and pain status are critical to identify hypovolemic shock, which may occur with tubal rupture. Prepare the client physiologically and psychologically for surgery or any procedure. Provide a clear explanation of the expected outcome. Astute vigilance and early referral will help reduce short- and long-term morbidity.

PROVIDING EMOTIONAL SUPPORT

The woman with an ectopic pregnancy requires support throughout diagnosis, treatment, and aftercare. A woman's psychological reaction to an ectopic pregnancy is unpredictable. However, it is important to recognize she has experienced a pregnancy loss in addition to undergoing treatment for a potentially life-threatening condition. The woman may find it difficult to comprehend what has

happened to her because events occur so quickly. In the woman's mind, she had just started a pregnancy and now it has ended abruptly. Bleeding during any pregnancy is traumatic because of the uncertainty of the outcome. Help her make this experience more "real" by encouraging her and her family to express their feelings and concerns openly and by validating that this is a loss of pregnancy and that it is OK to grieve over the loss. Although the woman may have physically recovered from an ectopic pregnancy, she may still experience significant emotional distress for a long time.

Provide emotional support, spiritual care, and information about community support groups (such as Resolve through Sharing) as the client grieves for the loss of her unborn child and comes to terms with the medical complications of the situation. Acknowledge the client's pregnancy and allow her to discuss her feelings about what the pregnancy means. Also stress the need for follow-up blood testing for several weeks to monitor hCG titers until they return to zero, indicating resolution of the ectopic pregnancy. Ask about her feelings and concerns about her future fertility, and provide teaching about the need to use contraceptives for at least three menstrual cycles to allow her reproductive tract to heal and the tissue to be repaired. Include the woman's partner in this discussion to make sure both parties understand what has happened, what intervention is needed, and what the future holds regarding childbearing.

EDUCATING THE CLIENT

Preventing ectopic pregnancies through screening and client education is essential. Many can be prevented by avoiding conditions that might cause scarring of the fallopian tubes. In addition, a contributing factor to the development of ectopic pregnancy is a previous ectopic pregnancy. Therefore, educating the woman is crucial. Prevention education may include:

- Reduce risk factors such as sexual intercourse with multiple partners or intercourse without a condom.
- Avoid contracting STIs that lead to PID.
- Obtain early diagnosis and adequate treatment of STIs.

- If an intrauterine contraceptive system is chosen, descriptions of the signs of PID should be included to reduce the risk of repeat ascending infections, which can be responsible for tubal scarring.
- Avoid smoking during childbearing years since a correlation with an increase in risk exists.
- Use condoms to decrease the risk of infections that cause tubal scarring.
- Seek prenatal care early to confirm the location of pregnancy.

Gestational Trophoblastic Disease

The WHO classification of **gestational trophoblastic disease (GTD)** includes disorders of placental development (hydatidiform mole) and neoplasms of the trophoblast (choriocarcinoma). A common feature of all trophoblastic lesions is that they produce hCG, which serves as a clinical marker for the presence of persistent or progressive trophoblastic disease (Murdock et al., 2019). With GTD, there is abnormal hyperproliferation of trophoblastic cells that would normally develop into the placenta during pregnancy. Gestational tissue is present, but the pregnancy is not viable. The incidence is hard to determine due to uncommon diagnosis and inaccuracy of documentation of pregnancy loss, but it is thought to occur in about 110 to 120 per 100,000 pregnancies in the United States; in Asian countries, the rate is five to 10 times higher (National Cancer Institute [NCI], 2019).

Pathophysiology

The pathogenesis is unique because the maternal tumor arises from gestational rather than maternal tissue. Hydatidiform mole is a benign neoplasm of the chorion in which the chorionic villi degenerate and become transparent vesicles containing clear, viscid fluid. Hydatidiform mole is classified as complete or partial, distinguished by differences in clinical presentation, pathology, genetics, and epidemiology (Blackburn, 2018). The complete mole contains no fetal tissue and develops from an “empty egg,” which is

fertilized by a normal sperm (the paternal chromosomes replicate, resulting in 46 all-paternal chromosomes) (Fig. 19.2). The embryo is not viable and dies. No circulation is established, and no embryonic tissue is found. The complete mole is associated with the development of choriocarcinoma. Surgery can totally remove most complete moles, but as many as one in five women will have some persistent molar tissue and require further treatment (ACS, 2019). Most women with a classic complete mole present with vaginal bleeding, anemia, excessively enlarged uterus, preeclampsia, and hyperemesis.

The partial mole has a triploid karyotype (69 chromosomes) because two sperm cells have provided a double contribution by fertilizing the ovum. Women with a partial mole usually present with the clinical features of a missed or incomplete abortion, including vaginal bleeding and a small- or normal-sized-for-date uterus. A complete mole presents with uterine enlargement greater than expected for gestational dates, hyperemesis, and preeclamptic symptoms (Lurain, 2019).

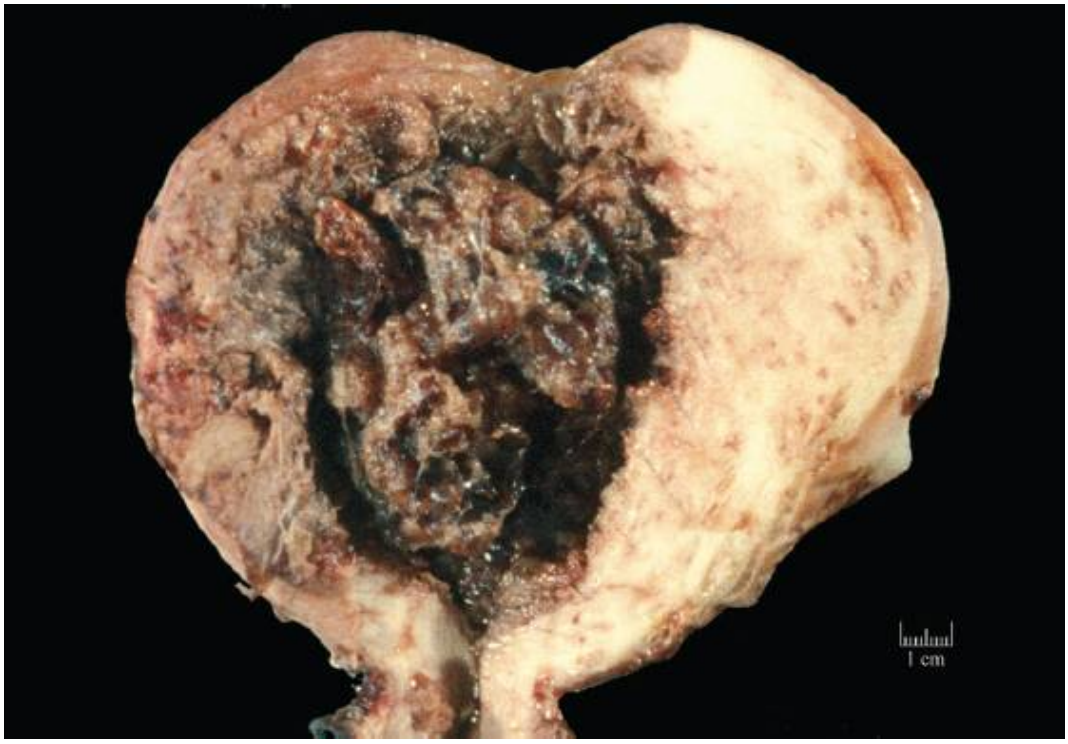

FIGURE 19.2. Complete hydatidiform mole as seen in a cutaway of a uterus. The chorionic villi degenerate and become filled with a viscid fluid, forming transparent vesicles. (From Reichert [2011]. *Diagnostic Gynecologic and Obstetric Pathology*. Courtesy of Dr. Enrique Higa. LWW.)

The exact cause of molar pregnancy is unknown, but researchers are looking into a genetic basis. Other theories include an ovular defect, stress, or a nutritional deficiency (carotene). Although the etiology remains uncertain, at some point in the pregnancy, trophoblastic cells that normally would form the placenta proliferate and the chorionic villi become edematous. The latter changes become the grape-like clusters that characterize the molar pregnancy (King et al., 2019). Studies have revealed some remarkable features about molar pregnancies, including:

- Ability to invade into the wall of the uterus
- Tendency to recur in subsequent pregnancies
- Possible development into choriocarcinoma, a virulent cancer with metastasis to other organs
- Influence of nutritional factors, such as protein deficiency
- Tendency to affect older women more often than younger women

Having a molar pregnancy (either partial or complete) results in the loss of the pregnancy and the possibility of developing choriocarcinoma, a chorionic malignancy from the trophoblastic tissue. Typically, asymptomatic, the first symptoms of choriocarcinoma in 80% of cases are shortness of breath, indicative of metastasis to the lungs because the lung is the most common site of metastases (94%) (Darwich & Guy, 2020). Choriocarcinoma affects women of all ages and can occur during pregnancy, after childbirth, or even years remote from the antecedent pregnancy. Asian American, Native American, and African American women are at increased risk for developing choriocarcinoma after a molar pregnancy (Berkowitz et al., 2020). The most frequent sites of metastases are the lungs, lower genital tract, brain, and liver. Choriocarcinoma is highly responsive to chemotherapy with an overall remission rate greater than 90% (Bishop & Edemekong, 2019). Partial moles rarely transform into choriocarcinoma.

Therapeutic Management

Treatment consists of immediate evacuation of the uterine contents as soon as the diagnosis is made and long-term follow-up of the client to detect any remaining trophoblastic tissue that might become malignant. D&C is used to empty the uterus. The tissue obtained is sent to the laboratory for analysis to evaluate for choriocarcinoma. Serial levels of hCG are used to detect residual trophoblastic tissue for 1 year. If any tissue remains, hCG levels will not regress. In 80% of women with a benign hydatidiform mole, serum hCG titers steadily drop to normal within 8 to 12 weeks after evacuation of the molar pregnancy. In the other 20% of women with a malignant hydatidiform mole, serum hCG levels begin to rise (Resnik et al., 2019).

As a result of the increased risk for cancer, the client is advised to receive extensive follow-up therapy for the next 12 months. The follow-up protocol may include:

- Baseline hCG level, chest radiograph, and pelvic ultrasound
- Quantitative hCG levels every week until undetectable for three consecutive weeks; then serial hCG levels monthly for 1 year

- Chest radiograph every 6 months to detect pulmonary metastasis
- Regular pelvic examinations to assess uterine and ovarian regression
- Systemic assessments for symptoms indicative of lung, brain, liver, or vaginal metastasis
- Strong recommendation to avoid pregnancy for 1 year because the pregnancy can interfere with the monitoring of hCG levels
- Use of a reliable contraceptive for at least 1 year (Cunningham et al., 2018)

Nursing Assessment

The nurse plays a crucial role in identifying and bringing this condition to the attention of the health care provider based on sound knowledge of the typical clinical manifestations and astute prenatal assessments.

Clinical manifestations of GTD are similar to those of spontaneous abortion at about 12 weeks of pregnancy. Assess the woman for potential clinical manifestations at each prenatal visit. Be alert for the following:

- Report of early signs of pregnancy, such as amenorrhea, breast tenderness, fatigue
- Brownish vaginal bleeding/spotting
- Anemia
- Inability to detect a fetal heart rate after 10 to 12 weeks' gestation
- Fetal parts not evident with palpation
- Bilateral ovarian enlargement caused by cysts and elevated levels of hCG
- Persistent, often severe nausea and vomiting (due to high hCG levels)
- Fluid retention and swelling
- Uterine size larger than expected for pregnancy dates
- Extremely high hCG levels present; no single value considered diagnostic
- Early development of preeclampsia (usually not present until after 24 weeks)
- Absence of fetal heart rate or fetal activity

- Expulsion of grape-like vesicles (possible in some women)

The diagnosis is made by high hCG levels and the characteristic appearance of the vesicular molar pattern in the uterus via transvaginal ultrasound.

Nursing Management

Nursing management of the woman with GTD focuses on preparing her for a D&C, providing emotional support to deal with the loss and potential risks, and educating her about the risk that cancer may develop after a molar pregnancy and the strict adherence needed with the follow-up program. The woman must understand the need for the continued follow-up care regimen to improve her chances of future pregnancies and to ensure her continued quality of life.

PREPARING THE CLIENT

Upon diagnosis, the client will need an immediate evacuation of the uterus. Perform preoperative care, preparing the client physically and psychologically for the procedure.

PROVIDING EMOTIONAL SUPPORT

To aid the client and her family in coping with the loss of the pregnancy and the possibility of a cancer diagnosis, use the following interventions:

- Listen to their concerns and fears.
- Allow them time to grieve for the pregnancy loss.
- Acknowledge their loss and sad feelings.
- Encourage them to express their grief; allow them to cry.
- Provide them with as much factual information as possible to help them make sense of what is happening.
- Enlist support from additional family and friends as appropriate and with the client's permission.

EDUCATING THE CLIENT

After GTD is diagnosed, teach the client about the condition and appropriate interventions that may be necessary to save her life. Explain each phase of treatment accurately and provide support for the woman and her family as they go through the grieving process.

As with any facet of health care, be aware of the latest research and new therapies. Inform the client about her follow-up care, which will probably involve close clinical surveillance for approximately 1 year, and reinforce its importance in monitoring the client's condition. Tell the client that serial serum beta-hCG levels are used to detect residual trophoblastic tissue. Continued high or increasing hCG titers are abnormal and need further evaluation.

Inform the client about the possible use of chemotherapy, such as methotrexate, which may be started prophylactically. Strongly urge the client to use a reliable contraceptive to prevent pregnancy for 1 year, because a pregnancy would interfere with tracking the serial beta-hCG levels used to identify a potential malignancy. Stress the need for the client to adhere to the plan of therapy throughout this year-long follow-up period.

CONSIDER THIS

We had lived across the dorm hall from each other during nursing school but really did not get to know each other except for a casual hello in passing. When we graduated, Rose went to work in the emergency room, and I worked in OB. We saw each other occasionally in the employee cafeteria, but a quick hello was all that we usually exchanged. I heard she married one of the paramedics who worked in the ER and was soon pregnant. I finally got to say more than hello when she was admitted to the OB unit bleeding during her fourth month of pregnancy. Gestational trophoblastic disease was discovered instead of a normal pregnancy. I remember holding her in my arms as she wept. She was told she had a complete molar pregnancy after surgery, and she would need extensive follow-up for the next year. I lost track of her that summer as my life became busier. Around Thanksgiving time, I heard she had died from choriocarcinoma. I attended her funeral, finally, to get the time to say a final hello and good-bye, but this time with sadness and tears.

Thoughts: Rose was only 26 years old when she succumbed to this very virulent cancer. I think back and realize I missed knowing this brave young woman and wished that I had taken the time to say more than hello. Could her outcome have been different? Why wasn't it recognized earlier? Did she not follow up after her diagnosis? I can only speculate regarding these questions. She lived a short but purposeful life, and hopefully continued research will change other women's outcomes in the future.

Cervical Insufficiency

Cervical insufficiency, also called premature dilation of the cervix, describes a weak, structurally defective cervix that spontaneously dilates in the absence of uterine contractions in the second trimester or early third trimester, resulting in the loss of the pregnancy. Since this typically occurs in the fourth or fifth month of gestation before the point of fetal viability, the fetus dies unless the dilation can be

arrested. The incidence of cervical insufficiency is less than 1% in the obstetric population (Pandey & Gupta, 2019).

Pathophysiology

The exact mechanism contributing to cervical insufficiency is not known. The cervix may have less elastin, less collagen, and greater amounts of smooth muscle than the normal cervix and thus results in loss of sphincter tone (Brown et al., 2019). Several theories have been proposed that focus on damage to the cervix as a key component of hormonal factors, such as increased amounts of relaxin. When the pressure of the expanding uterine contents becomes greater than the ability of the cervical sphincter to remain closed, the cervix suddenly relaxes, allowing effacement and dilation to proceed. The cervical dilation is typically rapid, relatively painless, and accompanied by minimal bleeding (Norwitz et al., 2019).

Structural cervical weakness is the likely cause of many recurrent second-trimester losses, but not the only etiology. Cervical insufficiency is likely the clinical end point of many pathologic processes, such as congenital cervical hypoplasia, in utero DES exposure that caused cervical hypoplasia, or trauma to the cervix (conization, amputation, obstetric laceration, or forced cervical dilation that may occur during elective pregnancy termination). Other conditions such as previous precipitous birth, a prolonged second stage of labor, increased amounts of relaxin and progesterone, or increased uterine volume (multiple gestation, hydramnios) are associated with cervical insufficiency (Berghella, 2019). However, the exact etiology of cervical insufficiency is not known.

Cervical length has also been associated with cervical insufficiency and subsequently preterm birth. Recent studies have examined the association between a short cervical length and the risk of preterm birth. Some have demonstrated a continuum of risk between a shorter cervix on ultrasound and a higher risk of preterm birth, leading to the hypothetical argument that women with a short cervix on ultrasound might benefit from cervical cerclage (the sewing closed of the cervix). The ACOG does not recommend cerclage

placement for women with short cervixes who do not have a history of preterm birth, as it has not been shown to be beneficial in this population (2019a).

Therapeutic Management

Cervical insufficiency may be treated with bed rest; pelvic rest; avoidance of heavy lifting; progesterone supplementation in women at risk for preterm birth; placement of a cervical pessary (a round, silicone device at the mouth of the cervix); or surgically via a cervical cerclage procedure in the second trimester. Cerclage was created more than 50 years ago based on the hypothesis that for some women, weakness or malfunction of the cervix has a causative role in the pathway to preterm birth. It can either be performed transvaginally or transabdominally. Cervical cerclage involves using a heavy purse-string suture to secure and reinforce the internal os of the cervix (Fig. 19.3).

According to the ACOG (2019a), if a short cervix is identified at or after 20 weeks and no infection (chorioamnionitis) is present, the decision to proceed with cerclage should be made with caution. ACOG recommends the following indications for cervical cerclage: history of second-trimester pregnancy loss with painless dilatation; prior cerclage placement for cervical insufficiency; history of spontaneous preterm birth prior to 34 weeks' gestation; and painless cervical dilatation on physical examination in the second trimester (2019a). Complications associated with cerclage placement are suture displacement, rupture of membranes, and chorioamnionitis, and their incidences vary widely in relation to the timing and indications for the cerclage (Jazayeri, 2019a). The optimal timing for cerclage removal is unclear, but ACOG (2019a) supports cerclage placement up to 28 weeks' gestation. A recent study concluded that vaginal progesterone with cerclage is efficacious in the prevention of preterm birth in women with a short cervix in the mid-trimester with decreased overall neonatal morbidity and mortality (Enakpene et al., 2018).

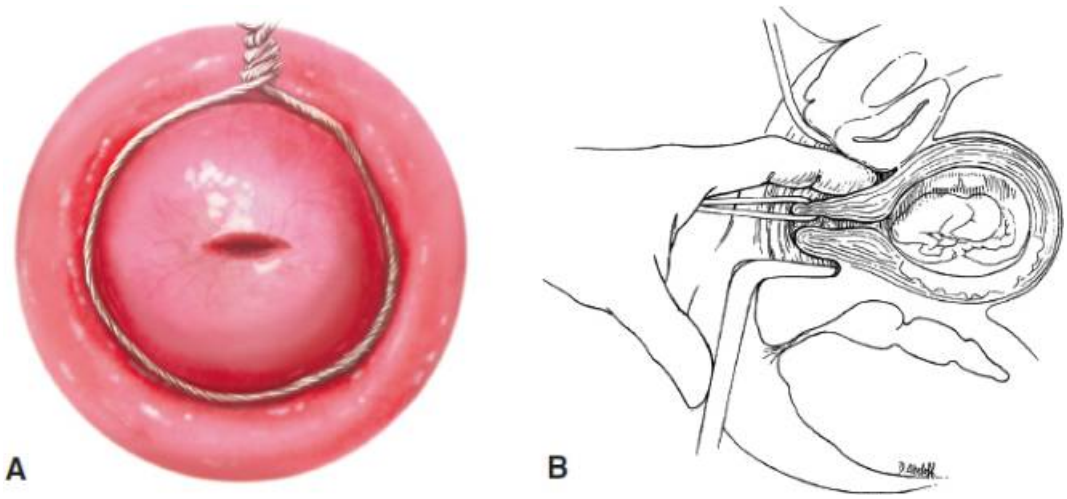

FIGURE 19.3. A. Cervical cerclage. **B.** Suturing the cervix for cervical insufficiency.

Nursing Assessment

RISK FACTORS

Nursing assessment focuses on obtaining a thorough history to determine any risk factors that might have a bearing on the pregnancy, including previous cervical trauma, preterm labor, fetal loss in the second trimester, and previous surgeries or procedures involving the cervix. History may reveal a previous loss of pregnancy around 20 weeks.

Also be alert for complaints of vaginal discharge or pelvic pressure. With cervical insufficiency, the woman will often report a pink-tinged vaginal discharge or an increase in low pelvic pressure, cramping with vaginal bleeding, and loss of amniotic fluid. Cervical dilation also occurs. If this continues, rupture of the membranes, release of amniotic fluid, and uterine contractions occur, subsequently resulting in delivery of the fetus, often before it is viable.

TAKE NOTE!

The diagnosis of cervical insufficiency remains difficult in many circumstances. The cornerstone of diagnosis is a history of a pregnancy loss during the second or early third trimester associated with painless cervical dilation without evidence of uterine activity.

DIAGNOSTIC TESTS

Transvaginal ultrasound is typically done between 16 and 24 weeks' gestation to determine cervical length, evaluate for shortening, and attempt to predict an early preterm birth. Cervical shortening occurs from the internal os outward and can be viewed on ultrasound as funneling. The amount of funneling can be determined by dividing funnel length by cervical length. The most common time at which a short cervix or funneling develops is 16 to 24 weeks, so ultrasound screening should be performed during this interval (Cunningham et al., 2018). A cervical length of less than 25 mm is abnormal between 16 and 24 weeks and may increase the risk of preterm labor. Among clients with short cervixes, provide education concerning the signs and symptoms of preterm labor, especially as the pregnancy approaches potential viability. Prenatal visits or contacts may be scheduled at more frequent intervals to increase client interaction with the care provider, especially between 20 and 34 weeks' gestation, which may decrease the rate of extremely early preterm births.

Expect the woman (particularly a woman with pelvic pressure, backache, or increased mucoid discharge) to undergo serial transvaginal ultrasound evaluations every few days to avoid missing rapid changes in cervical dilation or until the trend in cervical length can be characterized (Cunningham et al., 2018).

Nursing Management

Nursing management focuses on monitoring the woman closely for signs of preterm labor: backache, increase in vaginal discharge, rupture of membranes, and uterine contractions. Provide emotional

support and education to allay the couple's anxiety about the well-being of the fetus. Provide preoperative care and teaching as indicated if the woman will be undergoing cerclage. Teach the client and her family about the signs and symptoms of preterm labor and the need to report any changes immediately. Also reinforce the need for activity restrictions (if appropriate) and continued regular follow-up. Continuing surveillance throughout the pregnancy is important to promote a positive outcome for the family. The nurse can play a pivotal role in identifying preterm labor through risk assessment, physical examination, and client advocacy.

Placenta Previa

Placenta previa (meaning "afterbirth first") exists when the placenta is inserted wholly or partly into the lower uterine segment of the uterus, partially or completely covering the internal cervical opening. It is a bleeding condition that occurs during the last two trimesters of pregnancy. It poses a high risk of prenatal and postpartum hemorrhage as well as perinatal mortality. Placenta previa affects about one out of every 200 pregnancies (Resnik et al., 2019). Over the last 30 years, the incidence of placenta previa has increased 10-fold (Abu-Rustum, 2019). The risk of placenta previa in a first pregnancy is one in 400, but it rises to one in 160 after one cesarean section; one in 60 after two; one in 30 after three; and one in 10 after four and is associated with potentially serious consequences from hemorrhage, abruption (separation) of the placenta, or emergency cesarean birth (Lockwood & Russo-Stieglitz, 2020). With the rising incidence of cesarean section operations combined with increasing maternal age and more infertility treatments, the number of cases of placenta previa is increasing dramatically. The cesarean section rate must be reduced to decrease maternal morbidity and mortality. Comprehensive risk assessment combined with advances in ultrasound and color Doppler can provide earlier detection of this impaired placental implantation (Lu, 2019).

Pathophysiology

The exact cause of placenta previa is unknown. It is initiated by implantation of the embryo in the lower uterus, perhaps due to uterine endometrial scarring or damage in the upper segment, which may incite placental growth in the unscarred lower uterine segment. Uteroplacental underperfusion may also be present, which may increase the surface area required for placental attachment and may cause the placenta to encroach on the lower uterine segment. With placental attachment and growth, the cervical os may become covered by the developing placenta. Placental vascularization is defective, allowing the placenta to attach directly to the myometrium (accreta), deeply attach to the myometrium (increta), or infiltrate the myometrium (percreta).

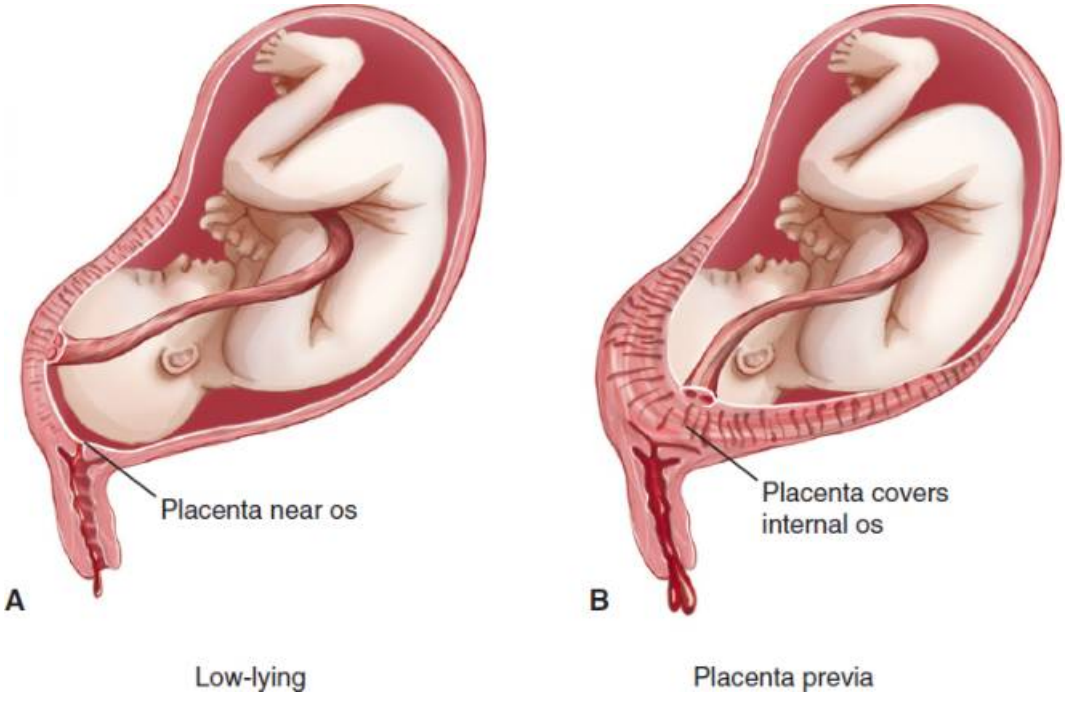

FIGURE 19.4. Classification of placenta previa. **A.** Low-lying. **B.** Placenta previa.

Placenta previa is currently classified with two terms: “placenta previa” and “low-lying placenta.” If the placental edge is less than 2 cm from the internal os but does not cover it, the placenta is reported as low-lying. If the placental edge covers the internal os, it is labeled

as a placenta previa. Both should have follow-up ultrasounds at 36 weeks' gestation if the woman is asymptomatic without bleeding (Resnik et al., 2019) (Fig. 19.4).

Therapeutic Management

Therapeutic management depends on the extent of bleeding, the closeness of the placenta to the cervical os, whether the fetus is developed enough to survive outside the uterus, the position of the fetus, the mother's parity, and the presence or absence of labor (Cunningham et al., 2018). With the increase in the rate of previous cesarean sections, the frequency of placenta previa has increased. Most women continue to present in emergency departments, therefore the associated morbidity due to hemorrhage remains high. Efforts should be made to avoid primary cesarean section where possible. In addition, prenatal care and timely diagnosis of placenta previa on ultrasound can decrease the associated morbidity.

If the mother and fetus are both stable, therapeutic management may involve expectant ("wait-and-see" or watchful waiting) care. This care can be carried out at home or on a prenatal unit in the health care facility. If there is no active bleeding and the client has ready access to reliable transportation, can maintain bed rest at home, and can comprehend instructions, expectant care at home is appropriate. However, if the client requires continuous care and monitoring and cannot meet the home care requirements, the prenatal unit is the best environment.

Nursing Assessment

Nursing assessment involves a thorough history including possible risk factors and a physical examination. Evaluate the client closely for these risk factors:

- Maternal age over 35 years
- Previous cesarean birth
- Multiparity
- Uterine insult or injury
- Cocaine use

- Previous D&C
- Endometrial ablation
- Prior placenta previa
- Infertility treatment
- Multiple gestations
- Previous induced surgical abortion
- Smoking
- Previous myomectomy to remove fibroids
- Short interval between pregnancies
- Hypertension or diabetes (Blackburn, 2018)

HEALTH HISTORY AND PHYSICAL EXAMINATION

Ask the client if she has any problems associated with bleeding now or in the recent past. The classical clinical presentation is painless, bright red vaginal bleeding occurring during the second or third trimester. The initial bleeding is usually not profuse and it ceases spontaneously, only to recur again. The first episode of bleeding occurs (on average) at 27 to 32 weeks' gestation. The bleeding is thought to arise secondary to the thinning of the lower uterine segment in preparation for the onset of labor. When the bleeding occurs at the implantation site in the lower uterus, the uterus cannot contract adequately and stop the flow of blood from the open vessels. Typically, with normal placental implantation in the upper uterus, minor disruptive placental attachment is not a problem because there is a larger volume of myometrial tissue able to contract and constrict bleeding vessels.

Assess the client for uterine contractions, which may or may not occur with the bleeding. Palpate the uterus; typically, it is soft and nontender upon examination. Auscultate the fetal heart rate; it is commonly within normal parameters. Fetal distress is usually absent but may occur when cord problems arise, such as umbilical cord prolapse or cord compression, or when the client has experienced blood loss to the extent that maternal shock or placental abruption has occurred (King et al., 2019).

LABORATORY AND DIAGNOSTIC TESTING

To validate the position of the placenta, a transvaginal ultrasound is done. In addition, magnetic resonance imaging (MRI) may be ordered when preparing for childbirth because it allows identification of placenta accreta (placenta abnormally adherent to the myometrium), increta (placenta accreta with penetration of the myometrium), or percreta (placenta accreta with invasion of the myometrium to the peritoneal covering, causing rupture of the uterus) in addition to placenta previa. These placental abnormalities, though rare, carry a high morbidity and mortality rate, possibly necessitating a hysterectomy at delivery.

Nursing Management

Whether the care setting is in the client's home or in the health care facility, the nurse focuses on monitoring the maternal–fetal status, including assessing for signs and symptoms of vaginal bleeding and fetal distress and providing support and education to the client and her family, including providing information about the diagnostic studies and procedures that are performed. For the majority of women, a cesarean birth will be planned. Nursing Care Plan 19.1 discusses the nursing process for the woman with placenta previa.

MONITORING MATERNAL–FETAL STATUS

Assess the degree of vaginal bleeding; inspect the perineal area for blood that may be pooled underneath the woman. Estimate and document the amount of bleeding. Perform a peripad count on an ongoing basis, making sure to report any changes in amount or frequency to the health care provider. If the woman is experiencing active bleeding, prepare for blood typing and cross-matching in the event a blood transfusion is needed.

TAKE NOTE!

Avoid doing vaginal examinations in the woman with placenta previa because they may disrupt the placenta and cause hemorrhage.

Monitor maternal vital signs and uterine contractility frequently for changes. Have the client rate her level of pain using an appropriate pain rating scale. Assess fetal heart rates via Doppler or electronic monitoring to detect fetal distress. Monitor the woman's cardiopulmonary status, reporting any difficulties in respirations, changes in skin color, or complaints of difficulty in breathing. Have oxygen equipment readily available should fetal or maternal distress develop. Encourage the client to lie on her side to enhance placental perfusion.

If the woman has an intravenous (IV) line inserted, inspect the IV site frequently. Alternately, anticipate the insertion of an intermittent IV access device such as a saline lock, which can be used if quick access is needed for fluid restoration and infusion of blood products. Obtain laboratory tests as ordered, including complete blood count (CBC), coagulation studies, and Rh status if appropriate.

Administer pharmacologic agents as necessary. Give Rh immunoglobulin if the client is Rh-negative at 28 weeks' gestation. Monitor tocolytic (anticontraction) medication if prevention of preterm labor is needed.

PROVIDING SUPPORT AND EDUCATION

Determine the woman's level of understanding about placenta previa and the associated procedures and treatment plan. Doing so is important to prevent confusion and gain her cooperation. Provide information about the condition, and make sure that all information related is consistent with information from the primary care provider. Explain all assessments and treatment measures as needed.

Act as a client advocate in obtaining information for the family. Teach the woman how to perform and record daily fetal movement. This action serves two purposes: (1) It provides valuable information

about the fetus, and (2) it is an activity in which the client can participate, thereby fostering some feeling of control over the situation.

If the woman will require prolonged hospitalization or home bed rest, assess the physical and emotional impact that this may have on her. Evaluate her coping mechanisms to help determine how well she will be able to adjust and adhere to the treatment plan. Allow the client to verbalize her feelings and fears, and provide emotional support. Also provide opportunities for distraction—educational videos, arts and crafts, computer games, reading books—and evaluate the client's response.

NURSING CARE PLAN 19.1 Overview of the Woman with Placenta Previa

A 39-year-old G5P4 multigravida client at 32 weeks' gestation was admitted to the labor and birth suite with sudden vaginal bleeding. She had no further active bleeding and did not complain of any abdominal discomfort or tenderness. She did complain of occasional "tightening" in her stomach. Her abdomen palpated soft. Fetal heart rates were in the 140s with accelerations with movement. She was placed on bed rest with bathroom privileges. Ultrasound identified a low-lying placenta with a viable, normal-growth fetus. She was diagnosed with placenta previa and admitted for observation and surveillance of fetal well-being. Her history revealed two previous cesarean births, smoking half a pack of cigarettes per day, and endometritis infection after birth of her last newborn. Additional assessment findings included painless, bright red vaginal bleeding with initial bleeding ceasing spontaneously; irregular, mild, and sporadic uterine contractions; fetal heart rate and maternal vital signs within normal range; fetus in transverse lie; anxiety related to the outcome of pregnancy; and expression of feelings of helplessness.

Nursing ANALYSIS: Injury (fetal and maternal) risk related to threat to uteroplacental perfusion and hemorrhage

OUTCOME IDENTIFICATION AND EVALUATION

The client will maintain adequate tissue perfusion as evidenced by stable vital signs, decreased blood loss, few or no uterine contractions, normal fetal heart rate patterns and variability, and positive fetal movement.

INTERVENTIONS: *Maintaining Adequate Tissue Perfusion*

- Establish IV access *to allow for administration of fluids, blood, and medications as necessary*.
- Obtain type and cross-match for at least 2 units of blood products *to ensure availability should bleeding continues*.
- Obtain specimens as ordered for blood studies, such as CBC and clotting studies, *to establish a baseline and use for future comparison*.
- Monitor output *to evaluate adequacy of renal perfusion*.
- Administer IV fluid replacement therapy as ordered *to maintain blood pressure and blood volume*.
- Palpate for abdominal tenderness and rigidity *to determine bleeding and evidence of uterine contractions*.
- Institute bed rest *to reduce oxygen demands*.

- Assess for rupture of membranes *to evaluate for possible onset of labor*.
- Avoid vaginal examinations *to prevent further bleeding episodes*.
- Complete an Rh titer *to identify the need for RhoGAM*.
- Avoid nipple stimulation *to prevent uterine contractions*.
- Continuously monitor for contractions or PROM *to allow for prompt intervention*.
- Administer tocolytic agents as ordered *to stall preterm labor*.
- Monitor vital signs frequently *to identify possible hypovolemia and infection*.
- Assess frequently for active vaginal bleeding *to minimize risk of hemorrhage*.
- Continuously monitor fetal heart rate with electronic fetal monitor *to evaluate fetal status*.
- Assist with fetal surveillance tests as ordered *to aid in determining fetal well-being*.
- Observe for abnormal fetal heart rate patterns, such as loss of variability, decelerations, tachycardia, *to identify fetal distress*.
- Position client in side-lying position with wedge for support *to maximize placental perfusion*.
- Assess fetal movement *to evaluate for possible fetal hypoxia*.
- Teach woman to monitor fetal movement *to evaluate fetal well-being*.
- Administer oxygen as ordered *to increase oxygenation to mother and fetus*.

Nursing ANALYSIS: Acute anxiety related to threat to self and fetus, unknown future

OUTCOME IDENTIFICATION AND EVALUATION

The client will experience a decrease in anxiety as evidenced by verbal reports of less anxiety, use of effective coping measures, and calm demeanor.

INTERVENTIONS: *Minimizing Anxiety*

- Provide factual information about diagnosis and treatment, and explain interventions and the rationale behind them *to provide client with understanding of her condition.*
- Answer questions about health status honestly *to establish a trusting relationship.*
- Speak calmly to client and family members *to minimize environmental stress.*
- Encourage the use of past effective techniques for coping *to promote relaxation and feelings of control.*
- Acknowledge and facilitate the woman's spiritual needs *to promote effective coping.*
- Involve the woman and family in the decision-making process *to foster self-confidence and control over situation.*

- Maintain a presence during stressful periods *to allay anxiety.*
- Use the sense of touch if appropriate *to convey caring and concern.*
- Encourage talking as a means *to release tension.*

In addition to the emotional impact of prolonged bed rest, thoroughly assess the woman's skin to prevent skin breakdown and to help alleviate her discomfort secondary to limited physical activity. Instruct the woman in appropriate skin care measures. Encourage her to eat a balanced diet with adequate fluid intake to ensure adequate nutrition and hydration and prevent complications associated with urinary and bowel elimination secondary to bed rest.

Teach the client and family about any signs and symptoms that should be reported immediately. In addition, prepare the woman for the possibility of a cesarean birth. The woman must notify her health care provider about any bleeding episodes or backaches (may indicate preterm labor contractions) and must adhere to the prescribed bed rest regimen. To ensure adherence to the plan and a positive outcome, the client needs to be aware of and understand the rationales for the ongoing observations.

Placental Abruption

Placental abruption is the early separation of a normally implanted placenta after the 20th week of gestation prior to birth, which leads to hemorrhage. Abruption results from bleeding between the decidua and placenta. It is a significant cause of second- or third-trimester bleeding with a high mortality rate. It occurs in about 1% of all pregnancies throughout the world, or approximately one in 100 pregnancies. There is about a 20-fold increase in risk of reoccurrence in a subsequent pregnancy (Resnik et al., 2019). It typically peaks between 24 and 26 weeks' gestation.

Maternal risks include obstetric hemorrhage, need for blood transfusions, emergency hysterectomy, disseminated intravascular coagulopathy (DIC), Sheehan syndrome or postpartum gland necrosis, and renal failure. Perinatal consequences include low birth weight, preterm birth, asphyxia, stillbirth, and perinatal death. In

developed countries, approximately 10% of all preterm births and 10% to 20% of all perinatal deaths are caused by placental abruption (Schmidt et al., 2019). The overall fetal mortality rate for placental abruption is up to 40% depending on the extent of the abruption. Maternal mortality is approximately 5% in placental abruption and is related to cesarean birth and/or hemorrhage or coagulopathy (Kitchens et al., 2019).

Pathophysiology

Abruption occurs when the maternal vessels tear away from the placenta and bleeding occurs between the uterine lining and the maternal side of the placenta. As the blood accumulates, it pushes the uterine wall and placenta apart. If the abruption continues, loss of placental function results in fetal hypoxia and possibly fetal death. The etiology of this condition is unknown; however, it has been proposed that abruption starts with degenerative changes in the small maternal blood vessels, resulting in blood clotting, degeneration of the decidua (uterine lining), and possible rupture of a vessel. Bleeding from the blood vessel forms a blood clot between the placenta and the uterine wall. Most of the cases of abruption originate from maternal hypertension and preeclampsia. Fetal blood supply is compromised, and fetal distress develops in proportion to the degree of placental separation. This is caused by the insult of the abruption itself and by issues related to prematurity when early birth is required to alleviate maternal or fetal distress. Placental abruption is classified according to the extent of separation and the amount of blood loss from the maternal circulation. Classifications include:

- Grade 0: Clinically unrecognized before birth, diagnosis is made retrospectively after birth
- Mild (grade 1): No sign of vaginal bleeding or minimal bleeding (less than 500 mL), marginal separation (10% to 20%), tender uterus, no coagulopathy, no signs of shock, no fetal distress
- Moderate (grade 2): No sign of bleeding or moderate bleeding (1,000 to 1,500 mL), moderate separation (20% to 50%),

continuous abdominal pain, mild shock, normal maternal blood pressure, maternal tachycardia, evidence of fetal distress
- Severe (grade 3): Absent to moderate bleeding (more than 1,500 mL), severe separation (more than 50%), profound shock, dark vaginal bleeding, agonizing abdominal pain, decreased maternal blood pressure, significant maternal tachycardia and the development of DIC
- Classification of 0 or 1 is typically associated with a partial or marginal separation, whereas classification of 2 or 3 is associated with a complete or central separation (Norwitz et al., 2019; Schmidt et al., 2019).

Placental abruption also may be classified as partial or complete, depending on the degree of separation. Alternately, it can be classified as concealed or apparent by the type of bleeding (Fig. 19.5).

Remember Helen, the pregnant woman with severe abdominal pain? Electronic fetal monitoring revealed uterine hypertonicity with absent fetal heart sounds. Palpation of her abdomen revealed rigidity and extreme tenderness in all four quadrants. Her vital signs were as follows: temperature, afebrile; pulse, 94; respirations, 22; blood pressure, 130/90 mm Hg. What might you suspect as the cause of Helen's abdominal pain? What course of action would you anticipate for Helen?

Therapeutic Management

The onset of placental abruption is often unexpected, sudden, and intense, and it requires immediate treatment. Management of placental abruption is guided by fetal viability, severity of the abruption, and maternal status. Treatment of placental abruption is designed to assess, control, and restore the amount of blood lost; provide a positive outcome for both mother and newborn; and prevent coagulation disorders, such as DIC (Box 19.2). Emergency measures include starting two large-bore IV lines with normal saline or lactated Ringer's solution to combat hypovolemia, obtaining blood specimens for evaluating hemodynamic status values and for typing and cross-matching, and frequently monitoring fetal and maternal

well-being. After the severity of abruption is determined and appropriate blood and fluid replacement is given, cesarean birth is done immediately if fetal distress is evident. If the fetus is not in distress, close monitoring continues with birth planned at the earliest signs of fetal distress. Because of the possibility of fetal blood loss through the placenta, a neonatal intensive care team should be available during the birth process to assess and treat the newborn immediately for shock, blood loss, and hypoxia.

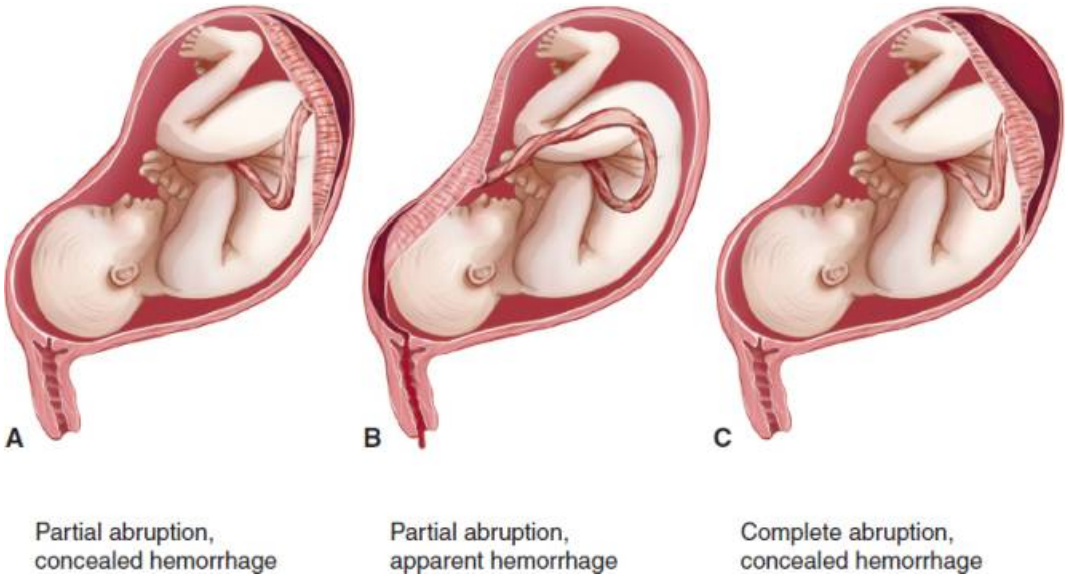

FIGURE 19.5. Classifications of placental abruption. **A.** Partial abruption with concealed hemorrhage. **B.** Partial abruption with apparent hemorrhage. **C.** Complete abruption with concealed hemorrhage.

The acute hemorrhage associated with the abruption activates the coagulation cascade, and with ongoing bleeding, disseminated intravascular coagulation (DIC)may result. Coagulopathy develops in about 10% of abruptions (Resnik et al., 2019). If the woman develops DIC, treatment focuses on determining the underlying cause of DIC and correcting it. Replacement therapy of the coagulation factors is achieved by transfusion of fresh-frozen plasma along with cryoprecipitate to maintain the circulating volume and provide oxygen to the cells of the body. Anticoagulant therapy (low–molecular-weight heparin), packed red cells, platelet concentrates,

antithrombin concentrates, and nonclotting protein-containing volume expanders, such as plasma protein fraction or albumin, are also used to combat this serious condition. Prompt identification and early intervention are essential for a woman with acute DIC associated with placental abruption to treat DIC and possibly save her life.

Nursing Assessment

Initial assessment should focus on maternal hemodynamic status and fetal well-being. Placental abruption is usually a medical emergency. If the bleeding is not arrested, then the lives of the mother and fetus are in jeopardy. The nurse plays a critical role in assessing the pregnant woman presenting with abdominal pain and/or experiencing vaginal bleeding, especially in a concealed hemorrhage, in which the extent of bleeding is not recognized. Rapid assessment is essential to ensure prompt, effective interventions to prevent maternal and fetal morbidity and mortality. Comparison Chart 19.1 compares placenta previa with placental abruption.

BOX 19.2 Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a bleeding disorder characterized by an abnormal reduction in the elements involved in blood clotting resulting from their widespread intravascular clotting (Belfort, 2019). This disorder can occur secondary to placental abruption, amniotic fluid embolism, endotoxin sepsis after an abortion, retained dead fetus, posthemorrhagic shock, hydatidiform mole, HELLP syndrome, and gynecologic malignancies.

The clinical and pathologic manifestations of DIC can be described as a loss of balance between the clot-forming activity of thrombin and the clot-lysing activity of plasmin. Therefore, too much thrombin tips the balance toward the prothrombic state, and the client develops clots. Alternately, too much clot lysis (fibrinolysis) results from plasmin formation, and the client hemorrhages. Small clots form throughout the body, and eventually the blood clotting factors are used up, rendering them unavailable to form clots at sites of tissue injury. Clot-dissolving mechanisms are also increased, resulting in potentially severe bleeding.

Complications of DIC include acute kidney failure, hepatic dysfunction, cardiac tamponade, gangrene and loss of digits, shock, and death (Levi, 2019). DIC is associated with high mortality and morbidity rates. No single laboratory test is sensitive or specific enough to diagnose DIC definitively, but it can be diagnosed by using a combination of multiple clinical and laboratory tests that reflect the pathophysiology of the syndrome.

Laboratory studies that assist in the diagnosis include:

- Decreased fibrinogen and platelets
- Prolonged PT and aPTT
- Positive D-dimer tests and fibrin (split) degradation products (objective evidence of the simultaneous formation of thrombin and plasmin) (Levi, 2019)

COMPARISON CHART 19.1 Placenta Previa versus Placental Abruption

Manifestation	Placenta Previa	Placental Abruption
Onset	Insidious	Sudden
Type of bleeding	Always visible; slight, then more profuse	Can be concealed or visible
Blood description	Bright red	Dark
Discomfort/pain	None (painless)	Constant; uterine tenderness on palpation
Uterine tone	Soft and relaxed	Firm to rigid
Fetal heart rate	Usually in normal range	Fetal distress or absent
Fetal presentation	May be breech or transverse lie; engagement is absent	No relationship

HEALTH HISTORY AND PHYSICAL EXAMINATION

Placental abruption produces a wide range of clinical effects, depending on the extent of placental separation and the amount of maternal blood loss. Begin the health history by assessing the woman for risk factors that may predispose her to placental abruption, such as maternal age over 35 years old, poor nutrition, multiple gestation, excessive intrauterine pressure caused by hydramnios, multifetal pregnancy, recent trauma to the abdomen, chronic hypertension, fetal growth restriction, cigarette smoking, severe trauma (e.g., auto accident, intimate partner violence), history of abruption in a previous pregnancy, placental abnormalities, cocaine or methamphetamine abuse, thrombophilia, alcohol ingestion, and multiparity (Jordan et al., 2019). In addition, be alert for other notable risk factors, such as male fetal gender, chorioamnionitis, prolonged prelabor ruptured membranes (more

than 24 hours), oligohydramnios, preeclampsia, and low socioeconomic status (Li et al., 2019).

Assess the woman for bleeding. As the placenta separates from the uterus, hemorrhage ensues. It can be apparent, appearing as vaginal bleeding, or it can be concealed. Vaginal bleeding is present in 80% of women diagnosed with placental abruption and may be significant enough to jeopardize both maternal and fetal health within a short time frame. The remaining 20% of abruptions are associated with a concealed hemorrhage and the absence of vaginal bleeding (Moses, 2020). Monitor the woman's level of consciousness, noting any signs or symptoms that may suggest shock.

TAKE NOTE!

Vital signs can be within normal range, even with significant blood loss, because a pregnant woman can lose up to 40% of her total blood volume without showing signs of shock (Resnik et al., 2019).

Assess the woman for complaints of pain, including the type, onset, and location. Ask if she has had any contractions. Palpate the abdomen, noting any contractions, uterine tenderness, tenseness, or rigidity. Ask if she has noticed any changes in fetal movement and activity. Decreased fetal movement may be the presenting complaint, resulting from fetal jeopardy or fetal death (Cunningham et al., 2018). Assess fetal heart rate and continue to monitor it electronically.

TAKE NOTE!

Classic manifestations of placental abruption include painful, dark red vaginal bleeding (port-wine color) because the bleeding comes from the clot that was formed behind the placenta; "knife-like" abdominal pain; uterine tenderness; contractions; and decreased fetal movement. Rapid assessment is essential to ensuring prompt, effective interventions to prevent maternal and fetal morbidity and mortality.

LABORATORY AND DIAGNOSTIC TESTING

Laboratory and diagnostic tests may be helpful in diagnosing the condition and guiding management. These studies may include:

- *CBC:* Determines the current hemodynamic status; however, it is not reliable for estimating acute blood loss.
- *Fibrinogen levels:* Typically, are increased in pregnancy (hyperfibrinogenemia); thus, a moderate dip in fibrinogen levels might suggest DIC, and if profuse bleeding occurs, the clotting cascade might be compromised.
- *Prothrombin time (PT)/activated partial thromboplastin time (aPTT):* Determines the client's coagulation status, especially if surgery is planned.
- *Type and cross-match:* Determines blood type if a transfusion is needed.
- *Nonstress test:* Demonstrates findings of fetal jeopardy manifested by late decelerations or bradycardia.
- *Biophysical profile:* Aids in evaluating clients with chronic abruption; a low score (less than 6 points) suggests possible fetal compromise (Resnik et al., 2019).

Nursing Management

Nursing management of the woman with placental abruption warrants immediate care to provide the best outcome for both mother and fetus.

ENSURING ADEQUATE TISSUE PERFUSION

When the woman arrives at the facility, place her on strict bed rest and in a left lateral position to prevent pressure on the vena cava. This position provides uninterrupted perfusion to the fetus. Expect to administer oxygen therapy via nasal cannula to ensure adequate tissue perfusion. Monitor oxygen saturation levels via pulse oximetry to evaluate the effectiveness of interventions.

Obtain maternal vital signs frequently, as often as every 15 minutes as indicated, depending on the woman's status and amount of blood loss. Observe for changes in vital signs suggesting

hypovolemic shock and report them immediately. Also expect to insert an indwelling urinary (Foley) catheter to assess hourly urine output and initiate an IV infusion for fluid replacement using a large-bore catheter.

Assess fundal height for changes. An increase in size would indicate bleeding. Monitor the amount and characteristics of any vaginal bleeding as frequently as every 15 to 30 minutes. Be alert for signs and symptoms of DIC, such as bleeding gums, tachycardia, oozing from the IV insertion site, and petechiae, and administer blood products as ordered if DIC occurs.

Institute continuous electronic fetal monitoring. Assess uterine contractions, and report any increased uterine tenseness or rigidity. Also observe the tracing for tetanic uterine contractions or changes in fetal heart rate patterns suggesting that the fetus has been compromised.

PROVIDING SUPPORT AND EDUCATION

A woman diagnosed with placental abruption may be filled with a sense of heightened anxiety and apprehension for her own health as well as for the health of her fetus. Communicate empathy and understanding of the client's experience, and provide emotional support throughout this frightening time. Remain with the woman and her partner, acknowledge their emotions and fears, and address their spiritual and cultural needs. Answer their questions about the status of their fetus openly and honestly, being sure to explain indicators of fetal well-being. Provide information about the various diagnostic tests, treatments, and procedures that may be done, including the possible need for a cesarean birth. Depending on the client's status, extent of bleeding, and length of gestation, the fetus may not survive. If the fetus does survive, he or she most likely will require neonatal intensive care. Assist the client and family in dealing with the loss or with the birth of a newborn in the neonatal intensive care unit.

Although placental abruption is not a preventable condition, client education is important to help reduce the risk for a recurrence of this condition. Encourage the woman to avoid drinking, smoking, or using

drugs during pregnancy. Urge her to seek early and continuous prenatal care and to receive prompt health care if any signs and symptoms occur in future pregnancies.

Think back to Helen, the pregnant woman described at the beginning of the chapter. She was diagnosed with placental abruption and was prepared for an emergency cesarean birth. Upon exploration, there was almost a 75% abruption, with approximately 800 mL of concealed blood between the uterus and the placenta. In addition, she lost an additional 500 mL during surgery. What factors in Helen's history may have placed her at increased risk for abruption? What assessments and interventions would be essential during her postpartum recovery secondary to her significant blood loss? What psychosocial interventions would be necessary due to her fetal loss?

Placenta Accreta Spectrum

Placenta accreta spectrum refers to a full range of accrete diagnoses, including placenta accreta (adherent placenta), as well as increta and percreta (invasive placentas). They are potentially life-threatening obstetric hemorrhagic conditions that require a multidisciplinary approach to management. The incidence of placenta accreta has increased and seems to parallel the increasing cesarean birth rate or intrauterine procedures. **Placenta accreta spectrum** includes three conditions. Accreta is the most common and is a condition in which the placenta attaches itself too deeply into the wall of the uterus but does not penetrate the uterine muscle. *Placenta increta*, occurs when the placenta invades the myometrium, and *placenta percreta*, when it has extended through the myometrium and uterine serosa and adjacent tissue. A common risk associated with placenta accreta when unsuspected at the time of birth is the possibility of hemorrhaging during manual attempts to detach the placenta. According to the March of Dimes (2019d), placenta accreta occurs in as many as one in 272 pregnancies. The specific cause of placenta accreta is unknown, but it can be related to placenta previa, advanced maternal age, multiparity, in vitro fertilization, smoking, and previous cesarean births or uterine surgery. According to the National Accreta Foundation (2020) a

cesarean birth increases the possibility of a future placenta accreta; the more cesarean births that are done, the greater the incidence.

According to ACOG (2018b), postpartum hemorrhage is a complication associated with placenta accreta. The severity of hemorrhage and associated complications are related to the type of accretas. Of accretas, 90% have postpartum hemorrhage, and 50% of these will result in a hysterectomy (ACOG, 2018b). Women at highest risk of emergency hysterectomy are those who are multiparous, had a cesarean birth in either a previous or the present pregnancy, or had abnormal placentation. The essential management issues are early detection and immediate and appropriate intervention. If a placenta accreta diagnosis is made, the client should be counseled that a cesarean section and possible hysterectomy may be necessary interventions (Resnik et al., 2019).

Placenta accreta is typically diagnosed after birth when the placenta fails to normally separate from the uterine wall. A prenatal screening diagnosis via ultrasound is not able to diagnose these conditions in all cases. MRI can aid in determining the diagnosis and staging of placenta accreta spectrum disorders. A profuse hemorrhage may result because the uterus cannot contract to close off the open blood vessels. Management will depend on the severity of the bleeding and frequently necessitates a prompt hysterectomy (Jauniaux et al., 2019). Nurses need to be prepared to assist in this emergency situation as dictated by the health care provider.

HYPEREMESIS GRAVIDARUM

Hyperemesis gravidarum is a severe form of nausea and vomiting of pregnancy associated with significant costs and psychosocial impacts. At least 70% of women experience nausea and vomiting during their pregnancies (Cunningham et al., 2018). The term “morning sickness” is often used to describe this condition when symptoms are relatively mild. Studies have shown that nausea and vomiting during pregnancy is associated with improved fetal outcomes, such as lower rates of miscarriage (Smith et al., 2020).

Such symptoms usually disappear after the first trimester. This mild form mostly affects the quality of life of the woman and her family, while the severe form—hyperemesis gravidarum—results in dehydration, weight loss, electrolyte imbalance, and the need for hospitalization (Austin et al., 2019).

Unlike morning sickness, hyperemesis gravidarum is a complication of pregnancy characterized by persistent, uncontrollable nausea and vomiting that begins before 9 weeks' gestation and causes dehydration, nutritional deficiencies, ketosis, electrolyte imbalances, and weight loss of more than 5% of prepregnancy body weight. Risk factors for hyperemesis include previous pregnancy complicated by hyperemesis, molar pregnancies, history of *Helicobacter pylori* infection, multiple gestation, prepregnancy history of genitourinary disorders, clinical hyperthyroid disorders, and prepregnancy psychiatric diagnosis (King et al., 2019).

Hyperemesis (uncontrollable vomiting) is estimated to occur in up to 3% of pregnant women, is likely to recur in subsequent pregnancies, and is the second leading cause of hospitalization in pregnancy (following preterm labor). The prevalence increases in molar pregnancies and multiple gestations. The peak incidence is at 8 to 12 weeks of pregnancy, and symptoms usually resolve by week 20 (Havner et al., 2019).

TAKE NOTE!

Every pregnant woman needs to be instructed to report any episodes of severe nausea and vomiting or episodes that extend beyond the first trimester.

Pathophysiology

Although the exact cause of nausea and vomiting is unknown, its effects—decreased placental blood flow, decreased maternal blood flow, and acidosis—can threaten the health of the mother and fetus. Hyperemesis gravidarium is a multifactorial condition involving

gastrointestinal, hormonal, and genetic factors. Dehydration can also lead to preterm labor (Norwitz et al., 2019). Numerous theories abound, but few studies have produced scientific evidence to identify the precise etiology of this condition. It is likely that multiple factors contribute to it.

Elevated levels of hCG are present in all pregnant women during early pregnancy, usually declining after 12 weeks. This corresponds to the usual duration of morning sickness. In hyperemesis gravidarum, the hCG levels are often higher and extend beyond the first trimester. Symptoms exacerbate the disease. Decreased fluid intake and prolonged vomiting cause dehydration; dehydration increases the serum concentration of hCG, which in turn exacerbates the nausea and vomiting. A few other theories that have been proposed to contribute to its etiology include:

- *Endocrine theory*: High levels of hCG and estrogen during pregnancy
- *Metabolic theory*: Vitamin B6 deficiency
- *Genetic factors*: May predispose the woman to this condition
- *Psychological theory*: Psychological stress increases the symptoms

Therapeutic Management

Hyperemesis gravidarum is a diagnosis of exclusion. Careful consideration of other conditions must be assessed when a client experiences nausea and vomiting for the first time after 9 weeks' gestation.

Conservative management in the home is the first line of treatment for the woman with hyperemesis gravidarum. This usually focuses on dietary and lifestyle changes. If conservative management fails to alleviate the client's symptoms and nausea and vomiting continue, hospitalization is necessary to reverse the effects of severe nausea and vomiting.

Upon admission to the hospital, blood tests are ordered to assess the severity of the client's dehydration, electrolyte imbalance, ketosis, and malnutrition. Parenteral fluids and drugs are ordered to

rehydrate the woman and reduce the symptoms. The first choice for fluid replacement is generally normal saline, which aids in preventing hyponatremia, with vitamins (pyridoxine, or vitamin B6) and electrolytes added. Oral food and fluids are withheld for the first 24 to 36 hours to allow the gastrointestinal tract to rest. Antiemetics may be administered rectally or intravenously to control the nausea and vomiting initially because the woman is considered NPO (not able to ingest anything by mouth). Once her condition stabilizes and she is allowed oral intake, medications may be administered orally.

If the client does not improve after several days of bed rest, "gut rest," IV fluids, and antiemetics, total parenteral nutrition or feeding through a percutaneous endoscopic gastrostomy tube is instituted to prevent malnutrition. Administering antiemetics IV or IM is typically the second pillar of treatment for hyperemesis gravidarum. Finding a drug that works for any given client is largely a matter of trial and error. If one drug is ineffective, another class of drugs with a different mechanism of action may help. Diclegis is a first-line therapy that may be sufficient in controlling symptoms. In addition, vitamin B6 (pyridoxine) and doxylamine should be given. Second-line therapies may include dimenhydrinate (Dramine), diphenhydramine (Benadryl), and promethazine (Phenergan). If they fail to relieve symptoms, newer drugs such as ondansetron (Zofran) may be tried. Most drugs are given IV or IM. There is no evidence that any antiemetic class is superior to another with respect to effectiveness (King et al., 2019) (Drug Guide 19.2).

Few women receive complete relief of symptoms from any one therapy. Complementary and alternative medicine therapies appeal to many women as supplements to traditional ones. Some popular therapies include acupressure, hypnosis, massage, therapeutic touch, ginger, and the wearing of Sea-Bands to prevent nausea and vomiting. Recent research has reported a positive effect of using acupressure (provided by Sea-Bands) over the *nei guan* acupoint on the wrist to control nausea and vomiting associated with pregnancy (Norwitz et al., 2019).

Concept Mastery Alert

Priority Interventions in Hyperemesis Gravidarum

Hyperemesis gravidarum is nausea and vomiting in early pregnancy that prevents the woman from ingesting adequate nutrition. IV fluids may be required for rehydration, but the priority is to stop all intake of food and fluid for a period of time until vomiting has stopped.

Nursing Assessment

Nursing assessment of the woman with hyperemesis gravidarum requires a thorough history and physical examination to identify signs and symptoms associated with this disorder. The client is extremely uncomfortable. She may experience many hours of lost work productivity and sleep, and hyperemesis may damage family relationships. If hyperemesis progresses untreated, it may cause neurologic disturbances, renal damage, dehydration, ketosis, alkalosis from loss of hydrochloric acid, hypokalemia, retinal hemorrhage, and/or death (Jordan et al., 2019). Laboratory and diagnostic tests aid in determining the severity of the disorder.

DRUG GUIDE 19.2 Medications Used for Hyperemesis Gravidarum

Medication	Action/Indications	Nursing Implications
Promethazine (Phenergan)	Diminishes vestibular stimulation and acts on the chemoreceptor trigger zone (CTZ) Symptomatic relief of nausea, vomiting, and motion sickness	Be alert for urinary retention, dizziness, hypotension, and involuntary movements. Institute safety measures to prevent injury secondary to sedative effects. Offer hard candy and frequent rinsing of mouth for dryness.
Pyridoxine and doxylamine (Diclegis)	Delayed-release medication containing a combination of an antihistamine and vitamin B6 Symptomatic relief of nausea and vomiting during pregnancy	Be alert for drowsiness, dizziness, headache, irritability. Do not administer with any central nervous system depressants or sleeping medications. It must be taken daily, not as needed. It should be taken on an empty stomach with a full glass of water.
Ondansetron (Zofran)	Blocks serotonin release, which stimulates the	Monitor for possible side effects such as diarrhea,

	vagal afferent nerves, thus stimulating the vomiting reflex	constipation, abdominal pain, headache, dizziness, drowsiness, and fatigue. Monitor liver function studies as ordered.

Jennings, L. K., & Krywko, D. M. (2019). Hyperemesis gravidarium. *StatPearls*. Retrieved April 27, 2020, from https://www.ncbi.nlm.nih.gov/books/NBK532917/; King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning.

Health History and Physical Examination

Begin the history by asking the client about the onset, duration, and course of her nausea and vomiting. Ask her about any medications or treatments she used and how effective they were in relieving her nausea and vomiting. Obtain a diet history from the client, including a dietary recall for the past week. Note the client's knowledge of nutrition and need for appropriate nutritional intake. Be alert for patterns that may contribute to or trigger her distress. Also ask about any complaints of ptyalism (excessive salivation), anorexia, indigestion, and abdominal pain or distention. Ask if she has noticed any blood or mucus in her stool.

Review the client's history for possible risk factors, such as young age, nausea and vomiting with previous pregnancy, history of intolerance of oral contraceptives, nulliparity, trophoblastic disease, multiple gestation, emotional or psychological stress, gastroesophageal reflux disease, primigravida status, obesity, hyperthyroidism, and *Helicobacter pylori* seropositivity (Stevens, 2019). Weigh the client and compare this weight with her weight before she began experiencing symptoms and to her prepregnancy weight to estimate the degree of loss. With hyperemesis, weight loss usually exceeds 5% of body mass.

Inspect the mucous membranes for dryness and check skin turgor for evidence of fluid loss and dehydration. Assess blood pressure for changes, such as hypotension, that may suggest a fluid volume deficit. Also note any complaints of weakness, fatigue, activity intolerance, dizziness, or sleep disturbances.

Assess the client's perception of the situation. Note any evidence of depression, anxiety, irritability, mood changes, and decreased ability to concentrate, which can add to her emotional distress. Much of the psychological distress is self-limiting in this condition and probably in the causal pathway (Jennings & Krywko, 2019). Determine the woman's support systems who are available to help.

Laboratory and Diagnostic Testing

The results of laboratory and diagnostic tests may provide clues to the severity or etiology of the disorder. These may include:

- *Liver enzymes:* To rule out hepatitis, pancreatitis, and cholestasis; elevations of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are usually present
- *CBC:* Elevated levels of red blood cells and hematocrit, indicating dehydration
- *Urine ketones:* Positive when the body breaks down fat to provide energy in the absence of adequate intake
- *TSH and T4*: To rule out thyroid disease
- *Blood urea nitrogen:* Increased in the presence of salt and water depletion
- *Urine specific gravity*: Greater than 1.025, possibly indicating concentrated urine linked to inadequate fluid intake or excessive fluid loss; ketonuria
- *Serum electrolytes:* Decreased levels of potassium, sodium, and chloride resulting from excessive vomiting and loss of hydrochloric acid in stomach
- *Ultrasound:* Evaluation for molar pregnancy or multiple gestation (Cunningham et al., 2018)

Nursing Management

Nursing management for the client with hyperemesis gravidarum focuses on promoting comfort by controlling the client's nausea and vomiting and promoting adequate nutrition. In addition, the nurse plays a major role in supporting and educating the client and her family.

Promoting Comfort and Nutrition

During the initial period, expect to withhold all oral food and fluids, maintaining NPO status to allow the gastrointestinal tract to rest. In addition, administer prescribed antiemetics to relieve the nausea and vomiting and IV fluids to replace fluid losses. Monitor the rate of infusion to prevent overload and assess the IV insertion site to prevent infiltration or infection. Also administer electrolyte replacement therapy as ordered to correct any imbalances, and periodically check serum electrolyte levels to evaluate the effectiveness of therapy.

Provide physical comfort measures such as hygiene measures and oral care. Pay special attention to the environment, making sure to keep the area free of pungent odors. As the client's nausea and vomiting subside, gradually introduce oral fluids and foods in small amounts. Monitor intake and output and assess the client's tolerance to the increase in intake.

Providing Support and Education

Women with hyperemesis gravidarum are often fatigued physically and emotionally. Many are exhausted, frustrated, and anxious. Offer reassurance that all interventions are directed toward promoting positive pregnancy outcomes for both the woman and her fetus. Providing information about the expected plan of care may help alleviate the client's anxiety. Listen to her concerns and feelings, answering all questions honestly. Educate the woman and her family about the condition and its treatment options (Teaching Guidelines 19.1). Teach the client about therapeutic lifestyle changes, such as avoiding stressors and fatigue that may trigger nausea and vomiting. Offer ongoing support and encouragement and promote active

participation in care decisions, thereby empowering the client and her family. Attempting to provide the client with a sense of control may help her overcome the feeling that she has lost control. If necessary, refer the client to a spiritual advisor or counseling. Also suggest possible local or national support groups that the client may contact for additional information. Arrange for possible home care follow-up for the client and reinforce discharge instructions to promote understanding. Timely counseling, balanced nutrition, pharmacotherapy, and emotional support are associated with favorable outcomes for the woman with this condition. Collaborate with community resources to ensure continuity of care.

TEACHING GUIDELINES 19.1
Teaching to Minimize Nausea and Vomiting

- Avoid noxious stimuli, such as strong flavors, perfumes, or strong odors like frying bacon, that might trigger nausea and vomiting.
- Avoid tight waistbands to minimize pressure on abdomen.
- Eat small, frequent meals throughout the day.
- Separate fluids from solids by consuming fluids in between meals.
- Avoid lying down or reclining for at least 2 hours after eating.
- Use high-protein supplement drinks.
- Avoid foods high in fat.
- Increase your intake of carbonated beverages.
- Increase your exposure to fresh air to improve symptoms.
- Eat when you are hungry, regardless of normal mealtimes.
- Drink herbal teas containing peppermint or ginger.
- Avoid fatigue, and learn how to manage stress in life.
- Schedule daily rest periods to avoid becoming overtired.
- Eat foods that settle the stomach, such as dry crackers, toast, or soda.

HYPERTENSIVE DISORDERS OF PREGNANCY

Hypertensive disorders of pregnancy, an umbrella term, includes chronic hypertension, preeclampsia–eclampsia, superimposed preeclampsia in the setting of chronic hypertension, and gestational hypertension (ACOG, 2019c). Hypertensive disorders of pregnancy are among the leading causes of maternal mortality, along with thromboembolism, hemorrhage, and injuries. Hypertension remains the most commonly encountered medical condition in pregnant women, complicating up to 10% of all pregnancies and are on the rise. Worldwide, between 80 and 120 women with a pregnancy complicated by hypertension die daily. Hypertension becomes more prevalent as age increases (Wilkerson & Ogunbodede, 2019). It results in frequent hospital admissions, maternal morbidity and mortality, and preterm births with concomitant neonatal morbidity and mortality. Hypertensive disorders of pregnancy comprise a spectrum of severity ranging from a mild elevation of blood pressure to severe preeclampsia and hemolysis. Recent data show that hypertensive disorders of pregnancy are associated with long-term cardiovascular risks and diabetes in women (Troiano et al., 2019).

Risk factors for women during pregnancy, prenatal, and postpartum periods include chronic hypertension, diabetes, history of preterm birth, moderate to severe obstructive sleep apnea, non-Hispanic black ethnicity, obesity, older than 40 years, and strong family history of cardiovascular disease (August, 2020). Hypertensive disorders are associated with higher rates of maternal, fetal, and infant mortality and with severe morbidity, especially in cases of severe preeclampsia, eclampsia, and HELLP syndrome (ACOG, 2019d). Regardless of its onset or subclassification, hypertension jeopardizes the well-being of the mother as well as the fetus.

Although not accepted globally, specific hypertensive disorders of pregnancy are named based on the context in which the hypertension was first identified. The classification of hypertensive disorders in pregnancy currently consists of four categories:

I. *Chronic hypertension*: Hypertension that exists prior to pregnancy or that develops before 20 weeks' gestation with blood pressure readings greater than 140/90 mm Hg

2. *Gestational hypertension*: A new-onset blood pressure elevation (140/90 mm Hg) identified after 20 weeks' gestation without proteinuria; blood pressure returns to normal by 12 weeks' postpartum
3. *Preeclampsia/eclampsia and HELLP*: Most common hypertensive disorder of pregnancy, which develops with proteinuria after 20 weeks' gestation; a multisystem disease process, which is accompanied by at least one of the following: proteinuria, elevated creatinine, liver involvement, epigastric or abdominal pain, neurologic complications, hematologic complications, and uteroplacental dysfunction; eclampsia occurs when seizure activity develops
4. *Chronic hypertension with superimposed preeclampsia*: develops after 20 weeks' gestation and occurs in approximately 25% of pregnant women with increased maternal and fetal morbidity rates (Braunthal & Brateanu, 2019)

Chronic Hypertension

Chronic hypertension is defined as blood pressure exceeding 140/90 mm Hg before pregnancy or before 20 weeks' gestation. ACOG classifies chronic hypertension in pregnancy as mild/moderate 140 to 159 mm Hg systolic and diastolic 90 to 109 mm Hg or severe higher than 160 mm Hg systolic or diastolic higher than 110 mm Hg (2019c). When hypertension is first identified during a woman's pregnancy and she is less than 20 weeks' gestation, blood pressure elevations usually represent chronic hypertension. Chronic hypertension occurs in about 20% of women of childbearing age with the prevalence varying according to age, race, and body mass index (BMI). As the U.S. obesity rate rises, more women will start pregnancies with elevated blood pressures. About 25% of women with chronic hypertension develop preeclampsia during pregnancy (King et al., 2019). Women with chronic hypertension in pregnancy should be monitored for the development of worsening hypertension and/or the development of superimposed preeclampsia.

ACOG recommends antihypertensive therapy be initiated if chronic hypertension is severe because of the long-term sequelae of stroke or acute renal failure (2019c). Women with mild to moderate chronic hypertension do not require antihypertensive therapy during most of pregnancy. Pharmacologic treatment of mild hypertension does not reduce the likelihood of developing preeclampsia later in gestation and increases the likelihood of intrauterine growth restriction. If maternal blood pressure exceeds 160/100 mm Hg, however, drug treatment is recommended (Jordan et al., 2019). Nurses can play a large role in educating their hypertensive clients to help them understand potential complications and how simple changes in their lifestyles might be helpful in influencing the pregnancy outcome positively.

Gestational Hypertension

The gestational hypertension category is used in women with nonproteinuric hypertension of pregnancy, in which the pathophysiologic disturbances of the preeclampsia syndrome do not develop before giving birth. Gestational hypertension is a temporary diagnosis for hypertensive pregnant women who do not meet the criteria for preeclampsia (both hypertension and possibly proteinuria) or chronic hypertension (hypertension first detected before the 20th week of pregnancy).

Gestational hypertension is characterized by hypertension (higher than 140/90 mm Hg) in a previously normotensive woman without proteinuria after 20 weeks' gestation resolving by 12 weeks' postpartum (Carson, 2019). Gestational hypertension is diagnosed when systolic blood pressure is over 140 mm Hg and/or diastolic pressure is over 90 mm Hg on at least two occasions at least 4 to 6 hours apart after the 20th week of gestation in women known to be normotensive prior to this time and prior to pregnancy (King et al., 2019). Gestational hypertension can be differentiated from chronic hypertension, which appears before the 20th week of gestation, or hypertension before the current pregnancy, which continues after the woman gives birth.

Preeclampsia/Eclampsia

Preeclampsia currently remains one of the leading causes of death and severe maternal morbidity worldwide. Normal physiologic adaptations to pregnancy are altered in the woman who develops preeclampsia. **Preeclampsia** can be described as new-onset hypertension accompanied by proteinuria and/or maternal organ dysfunction that targets the cardiovascular, hepatic, renal, and central nervous systems (CNS). Preeclampsia can present with severe features, or it may not. Each is associated with specific criteria. Comparison Chart 19.2 highlights these.

Pathophysiology

Preeclampsia remains a challenge. The condition can be devastating to both the mother and fetus, yet the etiology still remains a mystery to medical science despite decades of research. Many theories exist, but none has truly explained the widespread pathologic changes that result in pulmonary edema, oliguria, seizures, thrombocytopenia, and abnormal liver enzymes (Cunningham et al., 2018). Despite the results of several research studies, the use of aspirin or supplementation with calcium, magnesium, zinc, or antioxidant therapy (vitamins C and E), salt restriction, diuretic therapy, or fish oils have not been proven to prevent this destructive condition.

Preeclampsia is a two-stage event; the underlying mechanisms involved are vasospasm and hypoperfusion. In the first stage, the key feature is widespread vasospasm. In addition, endothelial injury occurs, leading to platelet adherence, fibrin deposition, and the presence of schistocytes (fragments of erythrocytes). The second stage of preeclampsia is the woman's response to abnormal placentation, when symptoms appear (i.e., hypertension, proteinuria, headache, nausea and vomiting, retinal vascular changes causing blurred vision, and hyperreflexia due to hypoperfusion).

The first stage of generalized vasospasm results in elevation of blood pressure and reduced blood flow to the brain, liver, kidneys, placenta, and lungs. Decreased liver perfusion leads to impaired

liver function and subcapsular hemorrhage. This is demonstrated by epigastric pain and elevated liver enzymes in the maternal serum. Decreased brain perfusion leads to small cerebral hemorrhages and symptoms of arterial vasospasm such as headaches, visual disturbances, blurred vision, and hyperactive deep tendon reflexes (DTRs). A thromboxane/prostacyclin imbalance leads to increased thromboxane (potent vasoconstrictor and stimulator of platelet aggregation) and decreased prostacyclin (potent vasodilator and inhibitor of platelet aggregation), which contribute to the hypertensive state. Decreased kidney perfusion reduces the glomerular filtration rate, resulting in decreased urine output and increased serum levels of sodium, blood urea nitrogen (BUN), uric acid, and creatinine, further increasing extracellular fluid and edema. Increased capillary permeability in the kidneys allows albumin to escape, which reduces plasma colloid osmotic pressure and moves more fluid into extracellular spaces; this leads to pulmonary edema and generalized edema. Poor placental perfusion resulting from prolonged vasoconstriction contributes to intrauterine growth restriction, placental abruption, persistent fetal hypoxia, and acidosis. In addition, hemoconcentration (resulting from decreased intravascular volume) causes increased blood viscosity and elevated hematocrit (ACOG, 2019b).

COMPARISON CHART 19.2 Preeclampsia Versus Eclampsia

	Preeclampsia without Severe Features	Preeclampsia with Severe Features	Eclampsia
Blood pressure	>140/90 mm Hg after 20 weeks' gestation	≥160/110 mm Hg on two occasions at least 6 hours apart while on bed rest	>160/110 mm Hg
Seizures/coma	No	No	Yes
Hyperreflexia	No	Yes	Yes
Other signs and symptoms		Headache Oliguria Blurred vision, scotomata (blind spots) Pulmonary edema Thrombocytopenia (platelet count <100,000 platelets/mm^3) Cerebral disturbances Persistent epigastric or right upper quadrant pain HELLP Progressive renal insufficiency	Severe headache Generalized edema right upper quadrant or epigastric pain Visual disturbances Cerebral hemorrhage Renal failure HELLP

Therapeutic Management

Management of the woman with preeclampsia varies depending upon the severity of her condition and its effects on the fetus. Typically, the woman is conservatively managed if she is not experiencing severe features. However, if the condition progresses, management becomes more aggressive. The "cure" for preeclampsia/eclampsia is always delivery of the placenta. The

resolution following expulsion of the placenta supports theories related to the placental influence on the disease (Lim, 2019). According to recent studies, prevention of preeclampsia should be considered with daily low-dose aspirin (75 to 150 mg) from 12 weeks' gestation until delivery for women considered high risk (see Evidence-Based Practice 19.1). Risk factors for the development of preeclampsia include multifetal gestation, a previous pregnancy with preeclampsia, renal disease, autoimmune disease, diabetes, first pregnancy, periodontal disease, chronic hypertension, and obesity (ACOG, 2019d).

MANAGEMENT FOR PREECLAMPSIA WITHOUT SEVERE FEATURES

Conservative strategies for preeclampsia without severe features are used if the woman exhibits no signs of renal or hepatic dysfunction or coagulopathy. A woman with mild elevation in blood pressure may be placed on bed rest at home. She is encouraged to rest as much as possible in the lateral recumbent position to improve uteroplacental blood flow, reduce her blood pressure, and promote diuresis. In addition, prenatal visits and diagnostic testing—such as CBC, clotting studies, liver enzymes, and platelet levels—increase in frequency. The woman will be asked to monitor her blood pressure daily (every 4 to 6 hours while awake) and report any increased readings; she will be counseled on taking daily kick counts and report any decrease in fetal movements; and she will see her health care provider weekly for ongoing evaluations. She should record daily fetal movement counts, and if there is any decrease in movement, she needs to be evaluated by her health care provider that day. A balanced, nutritional diet with no sodium restriction is advised. In addition, she is encouraged to drink six to eight 8-oz glasses of water daily. If home management fails to lower the blood pressure, admission to the hospital is warranted and the treatment strategy is individualized based on the severity of the condition and the gestational age at the time of diagnosis.

During hospitalization, the woman with preeclampsia without severe features is monitored closely for signs and symptoms of severe preeclampsia or impending eclampsia (e.g., persistent headache, hyperreflexia). Blood pressure measurements are frequently recorded. Fetal surveillance is instituted in the form of daily fetal movement counts, nonstress testing, and serial ultrasounds to evaluate fetal growth and amniotic fluid volume to confirm fetal well-being. Expectant management (watchful waiting) usually continues until the pregnancy reaches at least 37 weeks' gestation, fetal lung maturity is documented, or complications develop that warrant immediate birth. Women with preeclampsia without severe features are at greatest risk for postpartum hypertension (King et al., 2019).

EVIDENCE-BASED PRACTICE 19.1 Clinical Characteristics of Pregnant Women on the Use of Daily Low-Dose Aspirin in Different Hypertensive Pregnancy Disorders: A Retrospective Comparative Study

STUDY

Hypertensive disorders are major causes of maternal and fetal complications worldwide, most notably preeclampsia. Aspirin has been a well-accepted therapy for prevention of cardiovascular events, so why not during pregnancy? It is thought that aspirin, an antiplatelet agent, taken in early pregnancy may reduce pathologic coagulation and vasoconstriction in the placental circulation and promote placental growth, thus reducing the incidence of cardiovascular conditions in pregnant women. This study aimed to assess the clinical characteristics from the benefits of daily low-dose aspirin along with antihypertensive agents in pregnant women with hypertensive disorders.

Findings

The study was designed as a retrospective study which included 100 pregnant women with various hypertensive disorders. They were divided into two groups: Group A took low-dose aspirin along with their antihypertensive medications and Group B took their antihypertensive medications without low-dose aspirin. The study provided intriguing evidence for the benefits of daily low-dose aspirin use during pregnancy as a protective measure from serious maternal complications of hypertensive disorders, particularly those at risk for preeclampsia. Aspirin could be considered for reducing the risk of preeclampsia and in turn eclampsia and other adverse maternal and fetal outcomes.

Nursing Implications

Based on the study's findings, nurses can be instrumental in prenatal assessments of high-risk mothers to identify them early so that prophylactic low-dose aspirin can be prescribed in early pregnancy if deemed appropriate by the health care provider. The nurse can provide instruction and rationales for the use and timing of this therapy to the clients. Numerous studies and professional health organizations have recommended this therapy to prevent preeclampsia, so nurses can view this therapy as an evidence-based intervention to promote better outcomes for mothers and their infants.

Adapted from Al-Taie, A., Albasry, Z., & Mohammed, N. H. (2019). Clinical characteristics of pregnant women on the use of low-dose aspirin in different hypertensive pregnancy disorders: A retrospective comparative study. Journal of Pharmacy & BioAllied Sciences, 11(1), 77–82.

Prevention of disease progression is the focus of treatment during labor. Blood pressure is monitored frequently, and a quiet environment is important to minimize the risk of stimulation and to promote rest. ACOG does not recommend routine use of magnesium sulfate for all women with preeclampsia without severe features (2019c). Continued close monitoring of neurologic status is warranted to detect any signs or symptoms of hypoxemia, impending seizure activity, or increased intracranial pressure. An indwelling urinary catheter is usually inserted to allow for accurate measurement of urine output.

MANAGEMENT OF PREECLAMPSIA WITH SEVERE FEATURES

Current management of preeclampsia for high-risk women includes preconception counseling, perinatal blood pressure control and monitoring, prenatal aspirin therapy, betamethasone for women prior to 34 weeks' gestation, parenteral magnesium sulfate prophylaxis, and follow-up of postpartum blood pressures. Before 37 weeks'

gestation, expectant management may be appropriate unless the disease progresses and symptoms worsen. Preeclampsia with severe features may develop suddenly or within days and bring with it high blood pressure of more than 160/110 mm Hg, cerebral and visual symptoms, pulmonary edema, epigastric pain, impaired liver function, thrombocytopenia, and progressive renal insufficiency (Resnik et al., 2019). This clinical picture signals preeclampsia with severe features, and immediate hospitalization is needed.

Treatment is highly individualized and based on disease severity and fetal age. Birth of the infant is the only cure because preeclampsia depends on the presence of trophoblastic tissue. Therefore, the exact age of the fetus is assessed to determine viability.

Preeclampsia with severe features is treated aggressively because hypertension poses a serious threat to mother and fetus. The goal of care is to stabilize the mother–fetus dyad and prepare for birth. Therapy focuses on controlling hypertension, preventing seizures, preventing long-term morbidity, and preventing maternal, fetal, or newborn death (Lim, 2019). Intense maternal and fetal surveillance starts when the mother enters the hospital and continues throughout her stay.

The woman in labor with preeclampsia with severe features typically receives oxytocin to stimulate uterine contractions, antihypertensive drugs to control blood pressure, and magnesium sulfate to prevent seizure activity. Oxytocin and magnesium sulfate can be given simultaneously via infusion pumps to ensure both are administered at the prescribed rate. Magnesium sulfate is given IV via an infusion pump. A loading dose of 4 to 6 g is given over 15 to 30 minutes, followed by an infusion of 1 to 2 g/hr as a continuous infusion. If overdosage occurs, calcium gluconate (10 mL of a 10% solution injected intravenously over 3 minutes) is an effective antidote.

The client is evaluated closely for magnesium toxicity. If overdose occurs, calcium gluconate (10 mL of a 10% solution injected IV over 3 minutes) is an effective antidote. If at all possible, a vaginal delivery is preferable to a cesarean birth for better maternal

outcomes and less risk associated with a surgical birth. PGE2 gel may be used to ripen the cervix. A cesarean birth may be performed if the client is seriously ill. A pediatrician, neonatologist, and/or neonatal nurse practitioner should be available in the birthing room to care for the newborn. A newborn whose mother received high doses of magnesium sulfate needs to be monitored for respiratory depression, hypocalcemia, and hypotonia. Decreased fetal heart rate variability may occur, but in general, magnesium sulfate does not pose a risk to the fetus. The newborn may exhibit respiratory depression, loss of reflexes, muscle weakness, and neurologic depression (Martin & Rosenfeld, 2019).

MANAGEMENT OF ECLAMPSIA

Eclampsia is the hallmark neurologic complication of preeclampsia, the onset of seizure activity. Eclamptic seizures are a medical emergency and require immediate treatment to prevent mortality in both the mother and fetus (Magley & Hinson, 2020). In the woman who develops an eclamptic seizure, the convulsive activity begins with facial twitching followed by generalized muscle rigidity. The woman's face initially may become distorted with protrusion of the eyes, and foaming at the mouth may occur. Respirations cease for the duration of the seizure, resulting from muscle spasms, thus compromising fetal oxygenation. Seizure complications can include tongue biting, head trauma, broken bones, and aspiration. Coma usually follows the seizure activity, with respiration resuming.

The basic principles of airway, breathing, and circulation should always be followed as a general rule in seizure management. As with any seizure, the initial management is to clear the airway and administer adequate oxygen. Positioning the woman on her left side and protecting her from injury during the seizure are the key. Suction equipment must be readily available to remove secretions from her mouth after the seizure is over. IV fluids are administered after the seizure at a rate to replace urine output and additional insensible losses. Fetal heart rate is monitored closely. Magnesium sulfate is administered IV to prevent further seizures and continued for at least

24 hours after the woman's last seizure. Serum magnesium levels, respiratory rate, reflexes, and urine output in women receiving magnesium sulfate are closely monitored to avoid magnesium toxicity and prevent cardiac arrest. Hypertension is controlled with antihypertensive medications. After the woman's seizures are controlled, her stability is assessed. If she is found stable, birth via induction or cesarean birth is performed (August & Sibai, 2019). If the woman's condition remains stable, she will be transferred to the postpartum unit for care. If she becomes unstable after giving birth, she may be transferred to the critical care unit for closer observation.

Nursing Assessment

Preventing complications related to preeclampsia requires the use of assessment, advocacy, and counseling skills. Assessment begins with the accurate measurement of the client's blood pressure at each encounter. In addition, nurses need to assess for subjective complaints that may indicate progression of the disease—visual changes, severe headaches, unusual bleeding or bruising, or epigastric pain (Troiano et al., 2019). The significant signs of preeclampsia—proteinuria and hypertension—occur without the woman's awareness. Unfortunately, by the time symptoms are noticed, gestational hypertension can be severe.

TAKE NOTE!

The absolute blood pressure (value that validates elevation) of 140/90 mm Hg should be obtained on two occasions 4 to 6 hours apart to be diagnostic of preeclampsia. Proteinuria is defined as 300 mg or more of urinary protein per 24 hours or more than 1+ protein by chemical reagent strip or dipstick of at least two random urine samples collected at least 4 to 6 hours apart with no evidence of urinary tract infection (UTI) (ACOG, 2019b).

HEALTH HISTORY AND PHYSICAL EXAMINATION

Take a thorough history during the first prenatal visit to identify whether the woman is at risk for preeclampsia. Risk factors include:

- Primigravida status
- Chromosomal abnormalities
- Structural congenital anomalies
- Multiple gestation
- History of preeclampsia in a previous pregnancy
- Excessive placental tissue as seen in women with GTD
- Chronic stress
- In vitro fertilization
- Lupus (autoimmune disease)
- Use of ovulation drugs
- Family history of preeclampsia (mother or sister)
- Lower socioeconomic status
- History of diabetes, hypertension, or renal disease
- Poor nutrition
- African American ethnicity
- Age younger than 20 or older than 35
- Obesity (CDC, 2019)

In addition, complete a nutritional assessment that includes the woman's usual intake of protein, calcium, daily calories, and fluids.

Women at risk for preeclampsia require more frequent prenatal visits throughout their pregnancy, and they require teaching about problems so that they can report them promptly.

Blood pressure must be measured carefully and consistently. Obtain all measurements with the woman in the same position (blood pressure is highest in the sitting position and lowest in the side-lying position) and by using the same technique (automated versus manual). This standardization in position and technique will yield the most accurate readings (Norwitz et al., 2019).

TAKE NOTE!

Although edema is not a cardinal sign of preeclampsia, weight should be monitored frequently to identify sudden gains in a short time span. Current research relies on decreased organ perfusion, endothelial dysfunction (capillary leaking and proteinuria), and elevated blood pressure as key indicators (Carson, 2019).

At every prenatal visit, assess the fetal heart rate with a Doppler device. Also check a clean-catch urine specimen for protein using a dipstick.

LABORATORY AND DIAGNOSTIC TESTING

Various laboratory tests may be performed to evaluate the woman's status. Typically, these include a CBC, serum electrolytes, BUN, creatinine, and hepatic enzyme levels. Urine specimens are checked for protein; if levels are 1 to 2+ or greater, a 24-hour urine collection is completed.

Nursing Management

Nursing management of the woman with preeclampsia focuses on close monitoring of blood pressure and ongoing assessment for evidence of disease progression. Throughout the client's pregnancy, fetal surveillance is essential.

INTERVENING FOR PREECLAMPSIA WITHOUT SEVERE FEATURES

The woman with preeclampsia without severe features requires frequent monitoring to detect changes because preeclampsia can progress to eclampsia rapidly. Instruct all women to know the signs and symptoms of preeclampsia, and urge them to contact their health care professionals for immediate evaluation should any occur.

Typically, women with preeclampsia without severe features can be managed at home if they have a good understanding of the disease process, blood pressure and vital signs are stable, there are no abnormal laboratory test results, and good fetal movement is demonstrated (Teaching Guidelines 19.2). The home care nurse makes frequent visits and follow-up phone calls to assess the woman's condition, assist with scheduling periodic evaluations of the fetus (such as nonstress tests), and evaluate any changes that might suggest a worsening of the woman's condition.

TEACHING GUIDELINES 19.2

Teaching for the Woman with Preeclampsia without Severe Features

- Rest in a quiet environment to prevent cerebral disturbances.
- Drink eight to 10 glasses of water daily.
- Consume a balanced, high-protein diet including high-fiber foods.
- Obtain intermittent bed rest to improve circulation to the heart and uterus.
- Limit your physical activity to promote urination and subsequent decrease in blood pressure.
- Enlist the aid of your family so that you can obtain adequate rest time.
- Perform self-monitoring as instructed, including:
  - Taking your own blood pressure twice daily
  - Recording the number of fetal kicks daily
- Contact the home health nurse if any of the following occurs:
  - Increase in blood pressure
  - Burning or frequency when urinating
  - Decrease in fetal activity or movement
  - Headache (forehead or posterior neck region)
  - Dizziness or visual disturbances
  - Stomach pain, excessive heartburn, or epigastric pain
  - Decreased or infrequent urination
  - Contractions or low back pain
  - Easy or excessive bruising
  - Sudden onset of abdominal pain
  - Nausea and vomiting

Early detection and management of preeclampsia is associated with the greatest success in reducing progression of this condition. As long as the client carries out the guidelines of care as outlined by the health care provider and remains stable, home care can continue to maintain the pregnancy until the fetus is mature. If disease progression occurs, hospitalization is required.

INTERVENING FOR PREECLAMPSIA WITH SEVERE FEATURES

The woman with preeclampsia with severe features usually requires hospitalization. Keep the client on complete bed rest in the left lateral lying position. Ensure that the room is dark and quiet to reduce stimulation. Give sedatives as ordered to encourage quiet bed rest. The client is at risk for seizures if the condition progresses. Therefore, institute and maintain seizure precautions, such as padding the side rails and having oxygen, suction equipment, and a call light readily available to protect the client from injury.

TAKE NOTE!

Preeclampsia increases the risk of placental abruption, preterm birth, intrauterine growth restriction, and fetal distress during childbirth. Always be prepared if you see symptoms of preeclampsia!

Closely monitor the client's blood pressure. Administer antihypertensives as ordered to reduce blood pressure (Drug Guide 19.3). Assess the client's vision and level of consciousness. Report any changes and any complaints of headache or visual disturbances. Offer a high-protein diet with eight to 10 glasses of water daily. Monitor the client's intake and output every hour, and administer fluid and electrolyte replacements as ordered. Assess the woman for signs and symptoms of pulmonary edema, such as crackles and wheezing heard on auscultation, dyspnea, decreased oxygen saturation levels, cough, neck vein distention, anxiety, and restlessness. The treatment of acute pulmonary edema is symptomatic and includes the administration of vasodilating agents and of diuretics. The development of acute pulmonary edema in women with hypertension during pregnancy is associated with high levels of IV fluid administration (Pretorius et al., 2019).

DRUG GUIDE 19.3 Medications Used with Preeclampsia and Eclampsia

Medication	Action/Indications	Nursing Implications
Magnesium sulfate	Blockage of neuromuscular transmission, vasodilation Prevention and treatment of eclamptic seizures	Administer loading dose of 4 to 6 g by IV in 100 mL of fluid administered over 15 to 30 minutes followed by a maintenance dose of 1 to 2 g as a continuous IV infusion. Monitor serum magnesium levels closely. Assess DTRs, and check for ankle clonus. Have calcium gluconate available in case of toxicity. Monitor for signs and symptoms of toxicity, such as flushing, sweating, hypotension, and cardiac and CNS depression.
Hydralazine hydrochloride (Apresoline)	Vascular smooth muscle relaxant, thus improving perfusion to renal, uterine, and cerebral areas Reduction in blood pressure	Administer 5 to 10 mg by slow IV bolus every 20 minutes as needed. Use parenteral form immediately after opening ampule.

		Withdraw drug slowly to prevent possible rebound hypertension. Monitor for adverse effects such as palpitations, headache, tachycardia, anorexia, nausea, vomiting, and diarrhea.
Labetalol hydrochloride (Normodyne)	Alpha-1 and beta blocker Reduction in blood pressure	Be aware that drug lowers blood pressure without decreasing maternal heart rate or cardiac output. Administer IV dose of 20 to 40 mg every 15 minutes as needed and then administer IV infusion of 2 mg/min until desired blood pressure value achieved. Monitor for possible adverse effects such as gastric pain, flatulence, constipation, dizziness, vertigo, and fatigue.
Nifedipine (Procardia)	Calcium channel blocker/dilation of	Administer 10 to 20 mg orally for three

	coronary arteries, arterioles, and peripheral arterioles Reduction in blood pressure, stoppage of preterm labor	doses and then every 4 to 8 hours. Monitor for possible adverse effects such as dizziness, peripheral edema, angina, diarrhea, nasal congestions, cough.
Sodium nitroprusside (Nitropress)	Rapid vasodilation (arterial and venous) Severe hypertension requiring rapid reduction in blood pressure	Administer via continuous IV infusion with dose titrated according to blood pressure levels. Wrap IV infusion solution in foil or opaque material to protect from light. Monitor for possible adverse effects, such as apprehension, restlessness, retrosternal pressure, palpitations, diaphoresis, and abdominal pain.
Furosemide (Lasix)	Diuretic action, inhibiting the reabsorption of sodium and chloride from the ascending loop of Henle Pulmonary edema (used only if condition	Administer via slow IV bolus at a dose of 10 to 40 mg over 1 to 2 minutes. Monitor urine output hourly. Assess for possible adverse effects such

	is present)	as dizziness, vertigo, orthostatic hypotension, anorexia, vomiting, electrolyte imbalances, muscle cramps, and muscle spasms.

King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning; Skidmore-Roth, L. (2020). *Mosby's 2020 nursing drug reference* (33rd ed.). Mosby Elsevier.

To achieve a safe outcome for the fetus, prepare the woman for possible testing to evaluate fetal status as preeclampsia progresses. Testing may include the nonstress test, serial ultrasounds to track fetal growth, amniocentesis to determine fetal lung maturity, Doppler velocimetry to screen for fetal compromise, and biophysical profile to evaluate ongoing fetal well-being (Rana et al., 2019).

Other laboratory tests may be performed to monitor the disease process and to determine if it is progressing into HELLP syndrome. These include liver enzymes such as lactic dehydrogenase (LDH), ALT, and AST; chemistry panel, such as creatinine, BUN, uric acid, and glucose; CBC including platelet count; coagulation studies, such as PT, PTT, fibrinogen, and bleeding time; and a 24-hour urine collection for protein and creatinine clearance.

Administer parenteral magnesium sulfate as ordered to prevent seizures. Assess DTRs to evaluate the effectiveness of therapy. Clients with preeclampsia with severe features commonly present with hyperreflexia. Preeclampsia with severe features causes changes in the cortex, which disrupts the equilibrium of impulses between the cerebral cortex and the spinal cord. Brisk reflexes (hyperreflexia) are the result of an irritable cortex and indicate CNS involvement (Resnik et al., 2019). Diminished or absent reflexes occur when the client develops magnesium toxicity. Because magnesium is a potent neuromuscular blockade, the afferent and efferent nerve pathways do not relay messages properly and

hyporeflexia develops. Common sites used to assess DTRs are biceps reflex, triceps reflex, patellar reflex, Achilles reflex, and plantar reflex. Nursing Procedure 19.1 highlights the steps for assessing the patellar reflex.

The National Institute of Neurological Disorders and Stroke, a division of the National Institutes of Health, published a scale in the early 1990s that, though subjective, is used widely today. It grades reflexes from 0 to 4+. Grades 2+ and 3+ are considered normal, and grades 0 and 4 may indicate pathology (Table 19.2). Because these are subjective assessments, to improve communication of reflex results, condensed descriptor categories such as absent, average, brisk, or clonus should be used rather than numeric codes (Wilkerson & Ogunbodede, 2019).

NURSING PROCEDURE 19.1 Assessing the Patellar Reflex

Purpose: To Evaluate for Nervous System Irritability Related to Preeclampsia

1. Place the woman in the supine position (or sitting upright with the legs dangling freely over the side of the bed or examination table).
2. If lying supine, have the woman flex her knee slightly.
3. Place a hand under the knee to support the leg and locate the patellar tendon. It should be midline just below the knee cap.
4. Using a reflex hammer or the side of your hand, strike the area of the patellar tendon firmly and quickly.
5. Note the movement of the leg and foot. A patellar reflex occurs when the leg and foot move (documented as 2+).
6. Repeat the procedure on the opposite leg.

Clonus is the presence of rhythmic involuntary contractions, most often at the foot or ankle. Sustained clonus confirms CNS involvement. Nursing Procedure 19.2 highlights the steps when testing for ankle clonus.

With magnesium sulfate administration, the client is at risk for magnesium toxicity. Closely assess the client for signs of toxicity, which include a respiratory rate of less than 12 breaths per minute, absence of DTRs, and a decrease in urinary output (less than 30

mL/hr). Also monitor serum magnesium levels. Although exact levels may vary among agencies, serum magnesium levels ranging from 4 to 7 mEq/L are considered therapeutic, while levels more than 8 mEq/dL are generally considered toxic. As levels increase, the woman is at risk for severe problems:

TABLE 19.2 Grading Deep Tendon Reflexes

Description of Finding	Grade
Reflex absent, none elicited	0
Hypoactive response, sluggish	1
Reflex in lower half of normal range	2
Reflex in upper half of normal range	3
Hyperactive, brisk, clonus present	4

Cunningham, F. G., Leveno, K. J., Bloom, S. L., Dashe, J. S., Hoffman, B. L., Casey, B. M., & Spong, C. Y. (2018). *William's obstetrics* (25th ed.). McGraw-Hill Education; King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning; and Norwitz, E., Zelop, C., Miller, D., & Keefe, D. (2019). *Evidence-based obstetrics and gynecology*. Wiley Blackwell.

- 10 mEq/L: Possible loss of DTRs
- 15 mEq/L: Possible respiratory depression
- 25 mEq/L: Possible cardiac arrest (Skidmore-Roth, 2020)

If signs and symptoms of magnesium toxicity develop, expect to administer calcium gluconate as the antidote.

Throughout the client's stay, closely monitor her for signs and symptoms of labor. Perform continuous electronic fetal monitoring to assess fetal well-being. Note trends in baseline rate and presence or absence of accelerations or decelerations. Also observe for signs of fetal distress and report them immediately. Administer glucocorticoid treatment as ordered to enhance fetal lung maturity and prepare for labor induction if the mother's condition warrants.

Keep the client and family informed of the woman's condition and educate them about the course of treatment. Provide emotional support for the client and family. Severe preeclampsia is frightening for the client and her family, and most expectant mothers are anxious about their own health as well as that of the fetus. To allay anxiety, use light touch to comfort and reassure the client that the necessary actions are being taken. Actively listening to her concerns and fears and communicating them to the health care provider are important to keep the lines of communication open. Offering praise for small accomplishments can provide positive reinforcement for effective behaviors.

INTERVENING FOR ECLAMPSIA

The onset of seizure activity identifies eclampsia. Typically, eclamptic seizures are generalized and start with facial twitching. The body then becomes rigid in a state of tonic muscular contraction. The clonic phase of the seizure involves alternating contraction and relaxation of all body muscles. Respirations stop during seizure activity and resume shortly after it ends. Client safety is the primary concern during eclamptic seizures. If possible, turn the client to her side and remain with her. Make sure that the side rails are up and padded. Dim the lights and keep the room quiet.

NURSING PROCEDURE 19.2 Testing for Ankle Clonus

Purpose: To Evaluate for Nervous System Irritability Related to Preeclampsia

1. Place the woman in the supine position.
2. Have the client slightly bend her knee, and place a hand under the knee to support it.
3. Dorsiflex the foot briskly and then quickly release it.
4. Watch for the foot to rebound smoothly against your hand. If the movement is smooth without any rapid contractions of the ankle or calf muscle, then clonus is not present; if the movement is jerky and rapid, clonus is present.
5. Repeat on the opposite side.

Document the time and sequence of events as soon as possible. After the seizure activity has ceased, suction the nasopharynx as necessary and administer oxygen. Continue the magnesium sulfate infusion to prevent further seizures. Ensure continuous electronic fetal monitoring, evaluating fetal status for changes. Also assess the client for uterine contractions. After the client is stabilized, prepare her for the birthing process as soon as possible to reduce the risk of perinatal mortality.

PROVIDING FOLLOW-UP CARE

After birth of the newborn, continue to monitor the client for signs and symptoms of preeclampsia/eclampsia for at least 48 hours. Expect to continue to administer magnesium sulfate infusion for 24 hours to prevent seizure activity, and monitor serum magnesium levels for toxicity.

Assess vital signs at least every 4 hours, along with routine postpartum assessments: fundus, lochia, breasts, bladder, bowels, and the woman's emotional state. Monitor urine output closely. Diuresis is a positive sign that, along with a decrease in proteinuria, signals resolution of the disease.

HELLP Syndrome

HELLP syndrome is an acronym for hemolysis, elevated liver enzymes, and low platelet count. It is a variant of the preeclampsia/eclampsia syndrome that occurs in up to 20% of clients whose conditions are labeled as preeclampsia with severe features. Similar to preeclampsia, the essential phenomenon in HELLP's development is an abnormal trophoblastic invasion due to inadequate maternal immune tolerance (Jordan et al., 2019). Women with HELLP syndrome are at increased risk for complications such as cerebral hemorrhage, retinal detachment, hematoma/liver rupture, DIC, placental abruption, eclampsia, acute renal failure, pulmonary edema, and maternal death (Jordan et al., 2019). It is a life-threatening obstetric complication considered by many to be a severe form of preeclampsia involving hemolysis, thrombocytopenia, and liver dysfunction.

Both HELLP and preeclampsia occur during the later stages of pregnancy and sometimes after childbirth. HELLP syndrome is a clinically progressive condition. Early diagnosis is critical to prevent liver distention, rupture, and hemorrhage and the onset of DIC. If the condition presents prenatally, morbidity and mortality can affect both mother and baby.

HELLP syndrome occurs in up to 20% of pregnant women diagnosed with preeclampsia with severe features. Misdiagnosis and delayed recognition of HELLP syndrome are common due to vague and varying presentation. It is unique, as it is a laboratory value-specific diagnosis. Women with HELLP usually have fewer signs of abnormalities consistent with the metabolic syndrome and a lower prevalence of thrombophilia as compared with women who have preeclampsia without HELLP (Sibai, 2019). Although it has been

reported as early as 17 weeks' gestation, most of the time it is diagnosed between 22 and 36 weeks' gestation (Cunningham et al., 2018). It can present prior to the presence of an elevated blood pressure. HELLP syndrome leads to an increased maternal risk for developing liver hematoma or rupture, stroke, cardiac arrest, seizure, pulmonary edema, DIC, subendocardial hemorrhage, adult respiratory distress syndrome, renal damage, sepsis, hypoxic encephalopathy, and maternal or fetal death (Sibai, 2019). The recognition of HELLP syndrome and an aggressive multidisciplinary approach and prompt transfer of these women to obstetric centers with expertise in this field are required for the improvement of maternal–fetal prognosis.

Pathophysiology

HELLP syndrome is characterized by abnormal vascular tone, vasospasm, and coagulation defects. The hemolysis that occurs is called microangiopathic hemolytic anemia. This cascade of events is thought to happen when red blood cells become fragmented as they pass through small, damaged blood vessels. Elevated liver enzymes are the result of reduced blood flow to the liver secondary to obstruction from fibrin deposits. At the same time, endothelial damage and fibrin deposition in the liver may lead to liver impairment and can result in hemorrhagic necrosis, indicated by right upper quadrant tenderness, nausea, and vomiting. Hyperbilirubinemia and jaundice result from liver impairment. Low platelets result from vascular damage, the result of vasospasm, and platelets aggregate at sites of damage, resulting in thrombocytopenia in multiple sites (Stevens, 2019).

Therapeutic Management

Management focuses on stabilization of blood pressure and assessment of fetal well-being to determine the optimal time for birth. The treatment for HELLP syndrome is based on the severity of the disease, the gestational age of the fetus, and the condition of the mother and fetus. The mainstay of treatment is lowering of high

blood pressure with rapid-acting antihypertensive agents, prevention of convulsions or further seizures with magnesium sulfate, and use of steroids for fetal lung maturity if necessary, followed by the birth of the infant and placenta (King et al., 2019). The client should be admitted or transferred to a tertiary center with a neonatal intensive care unit. Additional treatment includes correction of the coagulopathies that accompany HELLP syndrome. After this syndrome is diagnosed and the woman's condition is stable, birth of the infant is indicated.

Magnesium sulfate is used prophylactically to prevent seizures. Antihypertensives such as hydralazine or labetalol are given to control blood pressure. Blood component therapy—such as fresh-frozen plasma, packed red blood cells, or platelets—is transfused to address the microangiopathic hemolytic anemia. Birth may be delayed up to 96 hours so that betamethasone or dexamethasone can be given to stimulate lung maturation in the preterm fetus.

Nursing Assessment

Nursing assessment of the woman with HELLP is similar to that for the woman with preeclampsia with severe features. Be alert for complaints of nausea (with or without vomiting), malaise, epigastric or right upper quadrant pain, headache, and changes in vision. Perform systematic assessments frequently as indicated by the woman's condition and response to therapy.

A diagnosis of HELLP syndrome is made based on laboratory test results, including:

- Low hematocrit that is not explained by any blood loss
- Elevated LDH (liver impairment)
- Elevated AST (liver impairment)
- Elevated ALT (liver impairment)
- Elevated BUN (renal impairment)
- Elevated bilirubin level (liver impairment)
- Elevated uric acid and creatinine levels (renal involvement)
- Low platelet count (less than 100,000 cells/mm^3) (ARUP Laboratories, 2020)

Nursing Management

Nursing management of the woman diagnosed with HELLP syndrome is the same as that for the woman with preeclampsia with severe features. If possible, the woman with HELLP syndrome should be transferred to a tertiary care center once she has been assessed and stabilized. Closely monitor the client for changes and provide ongoing support throughout this experience.

GESTATIONAL DIABETES

Gestational diabetes is a condition involving glucose intolerance that occurs during pregnancy. It is discussed in greater detail in Chapter 20.

BLOOD INCOMPATIBILITY

Blood incompatibility most commonly involves one of two issues: blood type or Rh factor. Blood type incompatibility, also known as ABO incompatibility, arises when a mother with blood type O becomes pregnant with a fetus with a different blood type (type A, B, or AB). The mother's serum contains naturally occurring anti-A and anti-B, which can cross the placenta and hemolyze fetal red blood cells. It is usually less severe than Rh incompatibility. One reason is that fetal red blood cells express less of the ABO blood group antigens when compared to adult levels. In addition, in contrast to the Rh antigens, the ABO blood group antigens are expressed by a variety of fetal (and adult) tissues, reducing the chances of anti-A and anti-B binding their target antigens on the fetal red blood cells. ABO incompatibility rarely causes significant hemolysis, and prenatal treatment is not warranted.

Rh isoimmunization occurs when a pregnant woman's immune system creates antibodies against fetal Rh blood factors. Although the mother will exhibit no symptoms of Rh incompatibility, Rh antibodies adversely affect fetal health. Rh antibodies can cause fetal heart problems, breathing difficulties, jaundice, and a form of

anemia known as hemolytic disease of the newborn. Rh sensitization occurs in approximately one in 1,000 births to Rh-negative women (March of Dimes, 2019e). Today, RH isoimmunization in pregnant women and hemolytic disease of the newborn are rarely seen, primarily because women who are Rh-negative are given anti-D immune globulin prophylaxis (RhoGAM) in the third trimester of pregnancy and after childbirth if the newborn is Rh-positive.

Pathophysiology

Rhesus (Rh) incompatibility refers to the discordant pairing of maternal and fetal Rh type. This discordance becomes clinically significant if a mother who is Rh-negative becomes sensitized to the D antigen and subsequently produces anti-D antibodies that can bind to and destroy Rh-positive red blood cells in the fetus (Costumbrado & Mansour, 2020).

ABO Incompatibility

Hemolysis associated with ABO incompatibility is limited to type O mothers with fetuses who have type A or B blood. In mothers with type A and B blood, naturally occurring antibodies are of the IgM class, which do not cross the placenta, while in type O mothers, the antibodies are predominantly IgG in nature. Because A and B antigens are widely expressed in a variety of tissues besides red blood cells, only a small portion of the antibodies crossing the placenta is available to bind to fetal red cells. In addition, fetal red cells appear to have less surface expression of A or B antigen, resulting in few reactive sites—hence the low incidence of significant hemolysis in affected neonates.

With ABO incompatibility, usually the mother is blood type O with anti-A and anti-B antibodies in her serum; the infant is blood type A, B, or AB. The incompatibility arises as a result of the interaction of antibodies present in maternal serum and the antigen sites on the fetal red cells.

Rh Incompatibility (Hemolytic Disease of the Newborn)

Rh incompatibility is a condition that develops when a woman with Rh-negative blood type is exposed to Rh-positive blood cells and subsequently develops circulating titers of Rh antibodies. Individuals with Rh-positive blood type have the D antigen present on their red cells, while individuals with an Rh-negative blood type do not. The presence or absence of the Rh antigen on the red blood cell membrane is genetically controlled.

In the United States, about 15% of the White population, 5% to 8% of the African American and Hispanic populations, and 1% to 2% of the Asian and Native American populations are Rh-negative. The vast majority (85%) of individuals is Rh-positive (March of Dimes, 2019e).

Rh incompatibility most commonly arises with exposure of an Rh-negative mother to Rh-positive fetal blood during pregnancy or birth; isoimmunization can also occur during an amniocentesis, ectopic pregnancy, placenta previa, placenta abruption, in utero fetal death, and small placental accidents (transplacental bleeds secondary to minor separation, trophoblastic disease, spontaneous abortion, or abdominal/pelvic trauma). After a significant exposure, alloimmunization or sensitization occurs. As a result, maternal antibodies are produced against the foreign Rh antigen. The amount of fetal blood necessary to produce Rh incompatibility varies. In one study, less than 1 mL of Rh-positive blood was shown to result in sensitization of women who are Rh-negative (Moise, 2019).

Once sensitized, it takes approximately a month for Rh antibodies in the maternal circulation to cross over into fetal circulation. In 90% of cases, sensitization occurs during childbirth (Cunningham et al., 2018). Thus, most firstborn infants with Rh-positive blood type are not affected because the short period from first exposure of Rh-positive fetal erythrocytes to the birth of the infant is insufficient to produce a significant maternal IgG antibody response.

The risk and severity of alloimmune response increase with each subsequent pregnancy involving a fetus with Rh-positive blood. A second pregnancy with an Rh-positive fetus often produces a mildly

anemic infant, while succeeding pregnancies produce infants with more serious hemolytic anemia.

Nursing Assessment

At the first prenatal visit, determine the woman's blood type and Rh status. Also obtain a thorough health history, noting any reports of previous events involving hemorrhage to delineate the risk for prior sensitization. When the client's history reveals an Rh-negative mother who may be pregnant with an Rh-positive fetus, prepare the client for an antibody screen (indirect Coombs test) to determine whether she has developed isoimmunity to the Rh antigen. This test detects unexpected circulating antibodies in a woman's serum that could be harmful to the fetus (Blackburn, 2018).

Nursing Management

If the indirect Coombs test is negative (meaning no antibodies are present), then the woman is a candidate for RhoGAM. If the test is positive, RhoGAM is of no value because isoimmunization has occurred. In this case, the fetus is carefully monitored for hemolytic disease.

The incidence of isoimmunization has declined dramatically as a result of prenatal and postnatal RhoGAM administration after any event in which blood transfer may occur. The standard dose is 300 mcg, which is effective for 15 mL of fetal blood cells. Rh immunoglobulin helps destroy any fetal cells in the maternal circulation before sensitization occurs, thus inhibiting maternal antibody production. This provides temporary passive immunity, thereby preventing maternal sensitization.

The current recommendation is for every Rh-negative nonimmunized woman to receive RhoGAM at some point between 28 and 32 weeks' gestation and again within 72 hours after giving birth. Other indications for RhoGAM include:

- Ectopic pregnancy
- Chorionic villus sampling

- Amniocentesis
- Prenatal hemorrhage
- Molar pregnancy
- Maternal trauma
- Percutaneous umbilical sampling
- Therapeutic or spontaneous abortion
- Fetal death
- Fetal surgery (King et al., 2019)

Despite the availability of RhoGAM and laboratory tests to identify women and newborns at risk, isoimmunization remains a serious clinical reality that continues to contribute to perinatal and neonatal mortality. As client advocates, nurses are in a unique position to make sure test results are brought to the health care provider's attention so appropriate interventions can be initiated. In addition, nurses must stay abreast of current literature and research regarding isoimmunization and its management. Stress to all women that early prenatal care can help identify and prevent this condition. Because Rh incompatibility is preventable with the use of RhoGAM, prevention remains the best treatment. Nurses can make a tremendous impact to ensure positive outcomes for the greatest possible number of pregnancies through education.

AMNIOTIC FLUID IMBALANCES

Amniotic fluid develops from several maternal and fetal structures, including the amnion, chorion, maternal blood, fetal lungs, gastrointestinal tract, kidneys, and skin. Any alteration in one or more of the various sources will alter the amount of amniotic fluid. Polyhydramnios and oligohydramnios are two imbalances associated with amniotic fluid.

Polyhydramnios

Polyhydramnios, also called hydramnios, is a condition in which there is too much amniotic fluid (more than 2,000 mL) surrounding

the fetus between 32 and 36 weeks. It occurs in approximately 2% of all pregnancies and is associated with maternal diabetes mellitus and fetal anomalies of development such as upper gastrointestinal obstruction or atresias, neural tube defects, and anterior abdominal wall defects, together with impaired swallowing in fetuses with chromosomal anomalies, such as trisomies 13 and 18 and anencephaly (Norwitz et al., 2019). Approximately 18% of all women with diabetes will develop polyhydramnios during their pregnancy. There is an increase in cesarean births for fetal labor intolerance, low 5-minute Apgar scores, increased neonatal birth weight, congenital anomalies, and newborn intensive care unit admissions for women with too much amniotic fluid at term (Beloosesky & Ross, 2019). Overall, it is associated with poorer fetal outcomes because of the increased incidence of preterm births, fetal malpresentation, and cord prolapse.

There are several causes of polyhydramnios. Generally, too much fluid is being produced, there is a problem with the fluid being taken up, or both. It can be associated with maternal disease and fetal anomalies, but it can also be idiopathic (of unknown cause) in nature.

Therapeutic Management

Treatment may include close monitoring and frequent follow-up visits with the health care provider if the polyhydramnios is mild to moderate. In severe cases in which the woman is in pain and experiencing shortness of breath, an amniocentesis or artificial rupture of the membranes is done to reduce the fluid and the pressure. Removal of fluid by amniocentesis is only transiently effective. A noninvasive treatment may involve the use of a prostaglandin synthesis inhibitor (indomethacin) to decrease amniotic fluid volume by decreasing fetal urinary output, but this may cause premature closure of the fetal ductus arteriosus (King et al., 2019).

Nursing Assessment

Begin the assessment with a thorough history, staying alert to risk factors such as maternal diabetes or multiple gestations. Review the maternal history for information about possible fetal anomalies including fetal esophageal or intestinal atresia, neural tube defects, chromosomal deviations, fetal hydrops, CNS or cardiovascular anomalies, and hydrocephaly.

Polyhydramnios is initially suspected when uterine enlargement, maternal abdominal girth, and fundal height are larger than expected for the fetus's gestational age. Determine the gestational age of the fetus, and measure the woman's fundal height. With polyhydramnios, there is a discrepancy between fundal height and gestational age, or a rapid growth of the uterus is noted. Assess the woman for complaints of discomfort in her abdomen, such as being severely stretched and tight. Also note any reports of uterine contractions, which may result from overstretching of the uterus. Assess for shortness of breath resulting from pressure on her diaphragm and inspect her lower extremities for edema, which results from increased pressure on the vena cava. Palpate the abdomen and obtain fetal heart rate. Often the fetal parts and heart rate are difficult to obtain because of the excess fluid present.

Prepare the woman for possible diagnostic testing to evaluate for the presence of possible fetal anomalies. An ultrasound is usually done to measure the pockets of amniotic fluid to estimate the total volume. In some cases, ultrasound is also helpful in finding the etiology of polyhydramnios, such as multiple pregnancy or a fetal structural anomaly.

Nursing Management

Nursing management of the woman with polyhydramnios focuses on ongoing assessment and monitoring for symptoms of abdominal pain, dyspnea, uterine contractions, and edema of the lower extremities. Explain to the woman and her family that this condition can cause her uterus to become overdistended and may lead to preterm labor and prelabor rupture of membranes. Outline the signs and symptoms of both conditions, and instruct the woman to contact

her health care provider if they occur. If a therapeutic amniocentesis is performed, assist the health care provider and monitor maternal and fetal status throughout for any changes.

Oligohydramnios

Oligohydramnios is a decreased amount of amniotic fluid (less than 500 mL) between 32 and 36 weeks' gestation that is associated with poor pregnancy outcomes. The volume of amniotic fluid increases in a linear fashion until 38 weeks' gestation to a mean volume of 1,000 mL and then starts to decrease. It occurs in approximately 4% of all pregnancies. Oligohydramnios may result from any condition that prevents the fetus from making urine or blocks it from going into the amniotic sac. Oligohydramnios occurs in about four out of every 100 pregnancies. It is most common in the last trimester of pregnancy, but it can develop at any time in the pregnancy. About one in eight women whose pregnancies last 2 weeks past the due date develops oligohydramnios. This happens as amniotic fluid levels naturally decline. This condition puts the fetus at an increased risk of perinatal morbidity and mortality (March of Dimes, 2019c). Reduction in amniotic fluid reduces the ability of the fetus to move freely without risk of cord compression, which increases the risk for fetal death and intrapartal hypoxia.

Therapeutic Management

The woman with oligohydramnios can be managed on an outpatient basis with serial ultrasounds and fetal surveillance through nonstress testing and biophysical profiles. As long as fetal well-being is demonstrated with frequent testing, no intervention is necessary. If fetal well-being is compromised, however, birth may be planned along with amnioinfusion (the transvaginal infusion of crystalloid fluid to compensate for the lost amniotic fluid). The fluid is introduced into the uterus through an intrauterine pressure catheter. The infusion is administered in a controlled fashion to prevent overdistention of the uterus. Amnioinfusion is thought to improve abnormal fetal heart rate

patterns, decrease cesarean births, and possibly minimize the risk of neonatal meconium aspiration syndrome, but more studies need to be done to validate this (Jordan et al., 2019).

Nursing Assessment

Review the maternal history for factors associated with oligohydramnios, including:

- Uteroplacental insufficiency
- Rupture of membranes prior to labor onset
- Hypertension of pregnancy
- Maternal diabetes
- Intrauterine growth restriction
- Post-term pregnancy
- Fetal renal agenesis
- Polycystic kidneys
- Urinary tract obstructions

Assess the client for complaints of fluid leaking from the vagina. Leaking of amniotic fluid from the vagina occurs with rupture of the amniotic sac. Leaking in conjunction with a uterus that is small for expected dates of gestation also suggests oligohydramnios. However, the woman may not present with any symptoms. Typically, the reduced volume of amniotic fluid is identified on ultrasound.

Nursing Management

Nursing management of the woman with oligohydramnios involves continuous monitoring of fetal well-being during nonstress testing or during labor and birth by identifying category II and III patterns on the fetal monitor. Variable decelerations indicating cord compression are common. Changing the woman's position might be therapeutic in altering this fetal heart rate pattern. After the birth, evaluate the newborn for signs of postmaturity, congenital anomalies, and respiratory difficulty.

Continue to assess the woman's vital signs and contraction status and the fetal heart rate. Provide comfort measures such as changing the bed linens and the woman's bed clothes frequently because of

the constant leakage of fluid from the vagina. Also provide frequent perineal care during the infusion.

MULTIPLE GESTATION

Multiple gestation is defined as a pregnancy with two or more fetuses. This includes twins, triplets, and higher-order multiples such as quadruplets. The incidence of multiple gestations in the United States continues to increase because of the widespread use of fertility drugs, older age of women having babies, and the development of assisted reproductive technologies to treat infertility. About one third of live births from assisted reproductive technology result in more than one infant, and twins represent 85% of those multiple-birth children (Norwitz et al., 2019).

In the United States, the overall prevalence of twins is approximately 33 per 1,000, now accounting for 3% of all live births in the United States (NICE, 2019). About two thirds are dizygotic (derived from two separate ova) (March of Dimes, 2019a). The increasing number of multiple gestations is a concern because women who are expecting more than one infant are at high risk for preterm labor, polyhydramnios, hyperemesis gravidarum, anemia, preeclampsia, and antepartum hemorrhage. Fetal/newborn risks or complications include prematurity, respiratory distress syndrome, birth asphyxia/perinatal depression, congenital anomalies (CNS, cardiovascular, and gastrointestinal defects), twin-to-twin transfusion syndrome (transfusion of blood from one twin [i.e., donor] to the other twin [i.e., recipient]), intrauterine growth restriction, and becoming conjoined twins (Mandy, 2019).

Twins are either monozygotic (identical) or dizygotic (Fig. 19.6). Monozygotic twins develop when a single, fertilized ovum splits during the first 2 weeks after conception. Monozygotic twins also are called identical twins. Two sperm fertilizing two ova produce dizygotic twins, which are called fraternal twins. Separate amnions, chorions, and placentas are formed in dizygotic twins (fraternal). Triplets can be monozygotic, dizygotic, or trizygotic.

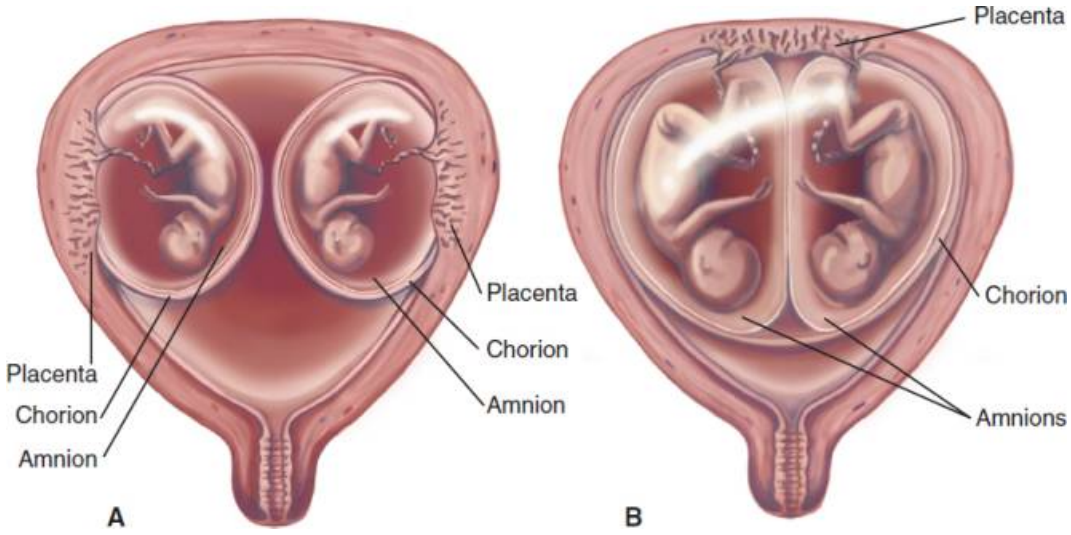

FIGURE 19.6. Multiple gestation with twins. **A.** Dizygotic twins; each fetus has its own placenta, amnion, and chorion. **B.** Monozygotic twins; the fetuses share one placenta, two amnions, and one chorion.

Therapeutic Management

When a multiple gestation is confirmed, the woman is followed with serial ultrasounds to assess fetal growth patterns and development. Biophysical profiles along with nonstress tests are ordered to determine fetal well-being. Many women are hospitalized in late pregnancy to prevent preterm labor and receive closer surveillance. During the intrapartum period, the woman is closely monitored with a perinatal team available to assist after birth. Operative delivery is frequently needed due to fetal malpresentation.

Nursing Assessment

Obtain a health history and perform a physical examination. Be alert for complaints of fatigue and severe nausea and vomiting. Assess the woman's abdomen and fundal height. Typically, with a multiple gestation the uterus is larger than expected based on the estimated date of birth. Laboratory test results may reveal anemia. Prepare the woman for ultrasound, which typically confirms the diagnosis of a multiple gestation.

Nursing Management

During the prenatal period, provide education and support for the woman regarding nutrition, increased rest periods, and close observation for pregnancy complications such as anemia, excessive weight gain, proteinuria, edema, vaginal bleeding, and hypertension. Prevention of preterm labor is a major priority in caring for women with a multifetal gestation. Instruct the woman to be alert for and immediately report any signs and symptoms of preterm labor, including contractions, uterine cramping, low backache, an increase in vaginal discharge, loss of mucus plug, pelvic pain, and pressure.

With the onset of labor, expect to monitor fetal heart rates continuously. Prepare the woman for an ultrasound to assess the presentation of each fetus to determine the best delivery approach. Ensure that extra nursing staff and the perinatal team are available for any birth or newborn complications.

After the babies are born, closely assess the woman for hemorrhage by frequently assessing uterine involution. Palpate the uterine fundus and monitor the amount and characteristics of lochia.

Throughout the entire pregnancy, birth, and hospital stay, inform and support the woman and her family. Encourage them to ask questions and verbalize any fears and concerns.

PRELABOR RUPTURE OF MEMBRANES

Prelabor rupture of membranes (PROM) is the spontaneous rupture of the amniotic sac, sometimes called the bag of waters, before the onset of true labor. There are a number of associated conditions and complications, such as infection, prolapsed cord, placental abruption, and preterm labor. High-risk factors associated with PROM include low socioeconomic status, multiple gestation, low BMI, tobacco use, history of preterm labor, placenta previa, placental abruption, UTI, vaginal bleeding at any time in pregnancy, illicit drug use, cerclage, and amniocentesis (Jazayeri, 2019b). At term, it complicates approximately 8% of pregnancies (Duff, 2020).

If prolonged (greater than 24 hours), the woman's risk for infection (chorioamnionitis, endometritis, sepsis, and neonatal infections) increases and continues to increase the longer the time since the amniotic sac ruptured. The time interval from rupture of membranes to the onset of regular contractions is termed the latent period. Fetal complications include intrauterine infection, umbilical cord compression, and placental abruption.

Women with PROM present with leakage of fluid, vaginal discharge, vaginal bleeding, and pelvic pressure, but they are not having contractions. PROM is diagnosed by speculum vaginal examination of the cervix and vaginal cavity. Pooling of fluid in the vagina or leakage of fluid from the cervix, ferning of the dried fluid under microscopic examination, and alkalinity of the fluid as determined by nitrazine paper (pH indicator) confirm the diagnosis.

The terminology of PROM can be confusing. PROM is rupture of the membranes prior to the onset of labor and is used appropriately when referring to a woman who is beyond 37 weeks' gestation, has presented with spontaneous rupture of the membranes, and is not in labor. A related term is **preterm prelabor rupture of membranes (PPROM)**, which is defined as rupture of membranes prior to the onset of labor in a woman who is *less* than 37 weeks' gestation. Perinatal risks associated with PPROM may stem from immaturity, including respiratory distress syndrome, intraventricular hemorrhage, patent ductus arteriosus, and necrotizing enterocolitis. Of neonatal morbidity and mortality, 85% is a result of prematurity. PPROM is associated with 30% to 40% of preterm deliveries and is the leading identifiable cause of preterm delivery. PPROM complicates 3% of all pregnancies and occurs in approximately 150,000 pregnancies yearly in the United States (Jazayeri, 2019b).

The exact cause of PROM is not known but may be associated with vaginal bleeding, placental abruption, microbial invasion of the amniotic cavity, and defective placentation. In many cases, PROM occurs spontaneously. Increasing evidence associates abnormalities in vaginal flora during pregnancy with preterm labor and birth with potential neonatal sequelae due to prematurity and poor perinatal outcome (Dayal & Hong, 2019).

Therapeutic Management

Treatment of PROM typically depends on the gestational age. Under no circumstances is an unsterile digital cervical examination done until the woman enters active labor to minimize infection exposure. If the fetal lungs are mature, induction of labor is initiated. PROM is not a lone indicator for surgical birth. If the fetal lungs are immature, expectant management is carried out with adequate hydration, reduced physical activity, pelvic rest, and close observation for possible infection, such as with frequent monitoring of vital signs and laboratory test results (e.g., white blood cell count). Corticosteroids may be given to enhance fetal lung maturity if lungs are immature, though this remains controversial. Recent studies have shown clear benefits of antibiotics to decrease neonatal morbidity associated with PPROM (Resnik et al., 2019).

Nursing Assessment

Nursing assessment focuses on obtaining a complete health history and performing a physical examination to determine maternal and fetal status. An accurate assessment of the gestational age and knowledge of the maternal, fetal, and neonatal risks are essential to appropriate evaluation, counseling, and management of women with PROM and PPROM. Nurses need to be aware that the risk of infection increases with the duration of PPROM.

Health History and Physical Examination

Review the maternal history for risk factors such as infection, increased uterine size (potential polyhydramnios, macrosomia, and multiple gestation), uterine and fetal anomalies, lower socioeconomic status, STIs, cervical insufficiency, vaginal bleeding, and cigarette smoking during pregnancy. Ask about any history or current symptoms of UTI (frequency, urgency, dysuria, or flank pain) or pelvic or vaginal infection (pain or vaginal discharge).

Assess for signs and symptoms of labor, such as cramping, pelvic pressure, or back pain. Also assess vital signs, noting any signs indicative of infection such as fever and elevated white blood cell count (more than 18,000 cells/mm^3) (Duff, 2020).

Institute continuous electronic fetal heart rate monitoring to evaluate fetal well-being. Conduct a vaginal examination to ascertain the cervical status in PROM. If PPROM exists, a sterile speculum examination (during which the examiner inspects the cervix but does not palpate it) is done rather than a digital cervical examination because it may diminish latency (period of time from rupture of membranes to birth) and increase newborn morbidity (Cunningham et al., 2018).

Observe the characteristics of the amniotic fluid. Note any evidence of meconium, or a foul odor. When meconium is present in the amniotic fluid, it typically indicates fetal distress related to hypoxia. Meconium stains the fluid yellow to greenish brown, depending on the amount present. A foul odor of amniotic fluid indicates infection. Also observe the amount of fluid. A decreased amount of amniotic fluid reduces the cushioning effect, thereby making cord compression a possibility. Key assessments are summarized in Box 19.3.

Laboratory and Diagnostic Testing

To diagnose PROM or PPROM, several procedures may be used: the nitrazine test, fern test, or ultrasound. After the insertion of a sterile speculum, a sample of the fluid in the vaginal area is obtained. With a nitrazine test, the pH of the fluid is tested; amniotic fluid is more basic (7.0) than normal vaginal secretions (4.5). Nitrazine paper turns blue in the presence of amniotic fluid. However, false-positive results can occur if blood, urine, semen, or antiseptic chemicals are also present; all will increase the pH.

BOX 19.3 Key Assessments with Prelabor Rupture of Membranes

For the woman with PROM, the following assessments are essential:

- Determining the date, time, and duration of membrane rupture by client interview
- Ascertaining gestational age of the fetus based on date of mother's last menstrual period, fundal height, and ultrasound dating
- Visualizing clear fluid pooled in the vaginal vault
- Questioning the woman about possible history of or recent UTI or vaginal infection that might have contributed to PROM
- Assessing for any associated labor symptoms, such as back pain or pelvic pressure
- Assisting with or performing diagnostic tests to validate leakage of fluid, such as nitrazine test, "ferning" on slide, and ultrasound; contamination of nitrazine tape with lubricant or insufficient fluid will render the assessment unreliable
- Continually assessing for signs of infection including:
  - Elevation of maternal temperature and pulse rate
  - Abdominal/uterine tenderness
  - Fetal tachycardia more than 160 bpm
  - Elevated white blood cell count and C-reactive protein
  - Cloudy, foul-smelling amniotic fluid

Cunningham, F. G., Leveno, K. J., Bloom, S. L., Dashe, J. S., Hoffman, B. L., Casey, B. M., & Spong, C. Y. (2018). *William's obstetrics* (25th ed.). McGraw-Hill Education; Dayal, S., & Hong, P. L. (2019). Premature rupture of membranes. StatPearls. Retrieved December 16, 2019, from https://www.ncbi.nlm.nih.gov/books/NBK532888/; Duff, P. (2020). Preterm prelabor rupture of membranes: Clinical manifestations and diagnosis. UpToDate. Retrieved May 29, 2020, from https://www.uptodate.com/contents/preterm-prelabor-rupture-of-membranes.

For the fern test, a sample of vaginal fluid is placed on a slide to be viewed directly under a microscope. Amniotic fluid will develop a fern-like pattern when it dries because of sodium chloride crystallization. If both of these tests are inconclusive, a transvaginal ultrasound can also be used to determine whether membranes have ruptured by demonstrating a decreased amount of amniotic fluid (oligohydramnios) in the uterus (Jazayeri, 2019b).

Other laboratory and diagnostic tests that may be used include:

- Urinalysis and urine culture for UTI or asymptomatic bacteriuria
- Cervical test or culture for chlamydia or gonorrhea

- Vaginal culture for bacterial vaginosis and trichomoniasis
- Vaginal introital/rectal culture for group B streptococcus

Nursing Management

Nursing management for the woman with PROM or PPROM focuses on preventing infection and identifying uterine contractions. The risk for infection is great because of the break in the amniotic fluid membrane and its proximity to vaginal bacteria. Therefore, maternal vital signs must be monitored closely. Be alert for a temperature elevation or an increase in pulse, which could indicate infection. Also monitor the fetal heart rate continuously, reporting any fetal tachycardia (which could indicate a maternal infection) or variable decelerations (suggesting cord compression). If variable decelerations are present, amnioinfusion may be used based on agency policy. Evaluate the results of laboratory tests such as a CBC. An elevation in white blood cells would suggest infection. Administer antibiotics if ordered.

Encourage the woman and her partner to verbalize their feelings and concerns. Educate them about the purpose of the protective membranes and the implications of early rupture. Keep them informed about planned interventions, including potential complications and required therapy. As appropriate, prepare the woman for induction or augmentation of labor as appropriate if she is near term.

If labor does not start within 48 hours, the woman with PPROM may be discharged home on expectant management, which may include:

- Antibiotics if cervicovaginal cultures are positive
- Activity restrictions
- Education about signs and symptoms of infection and when to call with problems or concerns (Teaching Guidelines 19.3)
- Frequent fetal testing for well-being
- Ultrasound every 3 to 4 weeks to assess amniotic fluid levels
- Possible corticosteroid treatment depending on gestational age
- Daily kick counts to assess fetal well-being

TEACHING GUIDELINES 19.3
Teaching for the Woman with PPROM

- Monitor your baby's activity by performing fetal kick counts daily.
- Check your temperature daily, and report any temperature increases to your health care provider.
- Watch for signs related to the beginning of labor. Report any tightening of the abdomen or contractions.
- Avoid any touching or manipulating of your breasts, which could stimulate labor.
- Do not insert anything into your vagina or vaginal area; do not use tampons, and avoid vaginal intercourse.
- Do not swim in pools or in the ocean or sit in a hot tub or Jacuzzi.
- Take showers for daily hygiene needs; avoid sitting in a tub bath.
- Maintain any specific activity restrictions as recommended.
- Wash your hands thoroughly after using the bathroom and make sure to wipe from front to back each time.
- Keep your perineal area clean and dry.
- Take your antibiotics as directed if your health care provider has prescribed them.
- Call your health care provider with changes in your condition, including fever, uterine tenderness, feeling like your heart is racing, and foul-smelling vaginal discharge.

KEY CONCEPTS

- Identifying risk factors early on and throughout the pregnancy is important to ensure the best outcome for every pregnancy. Risk assessment should start with the first prenatal visit and continue with subsequent visits.
- The three most common causes of hemorrhage early in pregnancy (first half of pregnancy) are spontaneous abortion, ectopic pregnancy, and GTD.
- Ectopic pregnancies occur in about one in 50 pregnancies and have increased dramatically during the past few decades.
- Having a molar pregnancy results in the loss of the pregnancy and the possibility of developing choriocarcinoma, a chronic malignancy from the trophoblastic tissue.
- The classic clinical picture presentation for placenta previa is painless, bright red vaginal bleeding occurring during the third trimester.
- Treatment of placental abruption is designed to assess, control, and restore the amount of blood lost; to provide a positive outcome for both mother and infant; and to prevent coagulation disorders.
- DIC can be described in simplest terms as a loss of balance between the clot-forming activity of thrombin and the clot-lysing activity of plasmin.
- Hyperemesis gravidarum is a complication of pregnancy characterized by persistent, uncontrollable nausea and vomiting before the 20th week of gestation.
- Gestational hypertension is the leading cause of maternal death in the United States and the most common complication reported during pregnancy.
- HELLP is an acronym for hemolysis, elevated liver enzymes, and low platelets.
- Rh incompatibility is a condition that develops when a woman with Rh-negative blood is exposed to Rh-positive fetal blood cells and subsequently develops circulating titers of Rh antibodies.
- Polyhydramnios occurs in approximately 3% to 4% of all pregnancies and is associated with fetal anomalies of development.

- Nursing care related to the woman with oligohydramnios involves continuous monitoring of fetal well-being during nonstress testing or during labor and birth by identifying category II and III patterns on the fetal monitor.
- The increasing number of multiple gestations is a concern because women who are expecting more than one infant are at high risk for preterm labor, hydramnios, hyperemesis gravidarum, anemia, preeclampsia, and antepartum hemorrhage.
- Nursing care related to PROM centers on infection prevention and identification of preterm labor contractions.
- Monitoring maternal vital signs for changes and the fetal heart rate once PPROM occurs is essential to increasing the changes of a good outcome.
- It is essential that nurses educate all pregnant women about how to detect the early signs of PROM and what action is needed if it happens.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. Which woman should receive RhoGAM postpartum?
   a. Nonsensitized Rh-negative mother with an Rh-negative newborn
   b. Nonsensitized Rh-negative mother with an Rh-positive newborn
   c. Sensitized Rh-negative mother with an Rh-positive newborn
   d. Sensitized Rh-negative mother with an Rh-negative newborn

2. A woman is suspected of having placental abruption. Which finding would the nurse expect to assess as a classic symptom?
   a. Painless, bright red bleeding
   b. “Knife-like” abdominal pain
   c. Excessive nausea and vomiting
   d. Hypertension and headache

3. RhoGAM is given to Rh-negative women to prevent maternal sensitization. In addition to pregnancy, Rh-negative women would also receive this medication after which occurrence?
   a. Therapeutic or spontaneous abortion
   b. Head injury from a car accident
   c. Blood transfusion after a hemorrhage
   d. Unsuccessful artificial insemination procedure

4. After teaching a woman about hyperemesis gravidarum and how it differs from the typical nausea and vomiting of

pregnancy, which statement by the woman indicates that the teaching was successful?

a. “I can expect the nausea to last through my second trimester.”
b. “I should drink fluids with my meals instead of in between them.”
c. “I need to avoid strong odors, perfumes, or flavors.”
d. “I should lie down after I eat for about 2 hours.”

5. A pregnant woman who is at approximately 12 weeks’ gestation comes to the emergency department after calling her health care provider’s office and reporting moderate vaginal bleeding. Assessment reveals cervical dilation and moderately strong abdominal cramps. She reports that she has passed some tissue with the bleeding. The nurse interprets these findings to suggest which of the following?

a. Threatened abortion
b. Inevitable abortion
c. Incomplete abortion
d. Missed abortion

6. When administering magnesium sulfate to a client with preeclampsia, the nurse explains to her that this drug is given to

a. reduce blood pressure.
b. increase the progress of labor.
c. prevent seizures.
d. lower blood glucose levels.

7. A woman is being discharged after receiving treatment for a hydatidiform molar pregnancy. The nurse should include which information in the discharge teaching?

a. Do not become pregnant for at least a year; use contraceptives to prevent it.

b. Have your blood pressure checked weekly in the clinic.
c. RhoGAM must be given within the next month at the clinic.
d. An amniocentesis can detect a recurrence of this disorder in the future.

CRITICAL THINKING EXERCISES

1. A 16-year-old primigravida presents to the maternity clinic complaining of continual nausea and vomiting for the past 3 days. She states she is approximately 15 weeks pregnant and has been unable to keep anything she eats down or take any fluids in without throwing up for the past 3 days. She reports she is dizzy and weak. Upon examination, she appears pale and anxious. Her mucous membranes are dry, skin turgor is poor, and her lips are dry and cracked.

   a. What is your impression of this condition?
   b. What risk factors does the client have?
   c. What intervention is appropriate for this woman?

2. An obese 39-year-old primigravida of African American descent is diagnosed with gestational hypertension. Her history reveals that her sister developed preeclampsia during her pregnancy. When describing her diet to the nurse, the client mentions that she tends to eat a lot of fast food.

   a. What risk factors does this client have that increase her risk for gestational hypertension?
   b. When assessing this client, what assessment findings would lead the nurse to suspect that this client has developed severe preeclampsia?

STUDY ACTIVITIES

1. Ask a community health maternity nurse how the signs and symptoms of gestational hypertension (including preeclampsia and eclampsia) are taught and how effective efforts have been to reduce the incidence in the area.
2. Find a website designed to help parents who have suffered a pregnancy loss secondary to a spontaneous abortion. What is its audience level? Is the information up to date?
3. A pregnancy in which the blastocyst implants outside the uterus is a(n) _____ pregnancy.
4. The most serious complication of hydatidiform mole is the development of _____ afterward.
5. Discuss various activities a woman with a multiple gestation could engage in to help pass the time when ordered to be on bed rest at home for 2 months.

BRINGING IT ALL TOGETHER: A CASE STUDY

A 21-year-old woman presented to the local public health maternity clinic with a chief complaint of intermittent vaginal bleeding, abdominal cramping, and nausea. She stated her last menstrual period was 8 weeks ago, and prior to coming in, she had taken a home pregnancy test which was positive. She was taking no medications and had no known drug allergies. She reports smoking half a pack of cigarettes a day but says she had been trying to quit.

ASSESSMENT

The nurse started to take the client's history, which reveals she had been taking oral contraceptives until approximately 3 months ago when her copayment went up and she did not get her prescription filled because she did not have the money. She also reported that she had a D&C for dysfunctional bleeding about a year ago because she did not respond to medications. Her sexual history reveals she had five sexual partners in the past with inconsistent use of

condoms with those partners. She had tested positive for gonorrhea and chlamydia and was treated for these about 6 months ago. Her retest was negative. Her vital signs were within normal range, and the remainder of her physical examination was unremarkable.

Go to thePoint to find questions to consider about this case.

20

Nursing Management of the Pregnancy at Risk: Selected Health Conditions and Vulnerable Populations

WOW

WORDS OF WISDOM

As the sun sets each day, nurses should make sure they have done something for others, and should try to be understanding even under the most difficult of conditions.

KEY TERMS

acquired immunodeficiency syndrome (AIDS) (ă-kwīrd´ im´yū-nō-dē-fish´en-sē sin´drōm)

adolescence

anemia

fetal alcohol spectrum disorder (FASD)

gestational diabetes mellitus

glycosylated hemoglobin (HbA1c) level (glī´kō-si-lā´tĕd hē´mō-glō´bin lev´ĕl)

human immunodeficiency virus (HIV)

multiple sclerosis (MS)

neonatal abstinence syndrome (NAS) (nē´ō-nā´tăl ab´sti-nents sin´drōm)

perinatal drug abuse

pica

pregestational diabetes

rheumatoid arthritis (RA)

systemic lupus erythematosus (SLE)

teratogen

type 1 diabetes

type 2 diabetes

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Identify conditions present before pregnancy that can have negative effects on a pregnancy.
2. Examine how a condition present before pregnancy can affect the woman physiologically and psychologically when she becomes pregnant.
3. Evaluate the nursing assessment and management for a pregnant woman with diabetes from that of a pregnant woman without diabetes.
4. Explore how congenital and acquired heart conditions can affect a woman's pregnancy.
5. Design the nursing assessment and management of a pregnant woman with cardiovascular disorders and respiratory conditions.
6. Differentiate the types of anemia affecting pregnant women in terms of prevention and management.
7. Relate the nursing care needed for the pregnant woman with an autoimmune disorder.
8. Compare the most common infections that can jeopardize a pregnancy, and propose possible preventive strategies.
9. Develop a plan of care for the pregnant woman who is HIV-positive.
10. Outline the nurse's role in the prevention and management of adolescent pregnancy.
11. Determine the impact of pregnancy on a woman over the age of 35.
12. Analyze the effects of substance abuse during pregnancy.

Rose, a thin 16-year-old who appears far along in her pregnancy, came into the clinic wheezing and having difficulty catching her breath. She had missed several previous prenatal visits but arrived at the clinic today in distress. Rose has a history of asthma since she was 5 years old. How might Rose's current condition affect her pregnancy? Is this picture typical of the pregnant woman with asthma?

INTRODUCTION

Pregnancy can be a special time in a woman's life, but it can also be anxiety-producing if it is accompanied by a medical condition that might complicate the pregnancy and jeopardize the fetal outcome. Ideally the pregnant woman is free of any conditions that can affect a pregnancy, but in reality, many women enter pregnancy with a multitude of health-related or psychosocial issues that can have a negative impact on the outcome. Currently, because of the obesity epidemic in the United States and women postponing their pregnancies until later in their lives, nurses will increasingly see more women with medical conditions that affect their pregnancies.

Many pregnant women express hopes that their babies are born healthy. Nurses can play a major role in helping this become a reality by educating women about health promotion before they become pregnant. Conditions such as diabetes, cardiac and respiratory disorders, anemia, autoimmune disorders, and specific infections can frequently be controlled through close prenatal management so that the impact on pregnancy is minimized. Nurses can provide pregnancy prevention strategies when counseling teenagers. Meeting the developmental needs of pregnant adolescents is a challenge. Finally, lifestyle choices can place many women at risk during pregnancy, and nurses need to remain nonjudgmental when working with these special populations. Lifestyle choices such as the use of alcohol, nicotine, and illicit substances during pregnancy are addressed in *Healthy People 2030* as outlined in *Health People 2030* 20.1.

Chapter 19 described pregnancy-related conditions that place the woman at risk. This chapter addresses common conditions that can have a negative impact on the pregnancy and special populations at risk, outlining appropriate nursing assessment and management for each condition or situation. The unique skills of nurses, in conjunction with the other members of the health care team, can increase the potential for a positive outcome in many high-risk pregnancies.

HEALTHY PEOPLE 2030 • 20.1

Objective	Nursing Significance
MICH-2030-09 Increase abstinence from alcohol among pregnant women. **MICH-2030-10** Increase abstinence from cigarette smoking among pregnant women. **MICH-2030-11** Increase abstinence from illicit drugs among pregnant women.	Will help focus attention on measures for reducing substance exposure and use, thereby minimizing the effects of these substances on the fetus and newborn.

DIABETES MELLITUS

Diabetes is a global public health concern with potential implications for the health of diabetic mothers and their offspring. Up to 9% of pregnancies are affected with prevalence rates up to 25% in high-risk groups, including African Americans, Latina Americans, Asian Americans, Pacific Islanders, and Native Americans. Additional risk factors for gestational diabetes include advanced maternal age, having a first-degree relative with diabetes, engaging in minimal physical activity, being overweight or obese, and having hypertension and/or cardiac disease (Trout, 2019). Diabetes mellitus is a chronic disease characterized by a relative lack of insulin or absence of the hormone that is necessary for glucose metabolism. The chronic hyperglycemia of diabetes is associated with long-term damage, dysfunction, and failure of the eyes, kidneys, nerves, heart, and blood vessels. The prevalence of diabetes in the United States is increasing at an alarming rate, already reaching epidemic proportions. Contributing factors to these increasing rates are more sedentary lifestyles, dietary changes, continued immigration by high-risk populations, and the growing epidemic of childhood and adolescent obesity. Approximately every 21 seconds, someone in

the United States is diagnosed with diabetes. Nearly half of the adult population has diabetes or prediabetes. Current estimates project that by 2030, one in three adults in the United States will have diabetes mellitus. Currently, one in seven people have it (American Diabetes Association [ADA], 2019a). The Institute for Alternative Futures estimates that the number of Americans living with diabetes (diagnosed and undiagnosed) will increase 54% by 2030 to more than 60 million Americans. The resulting medical and societal cost of diabetes will be approximately $622 billion (Institute for Alternative Futures, 2019).

Diabetes is commonly classified based on disease etiology (ADA, 2019b). These groups include:

- **Type 1 diabetes**: Absolute insulin deficiency due to autoimmune beta cell destruction.
- **Type 2 diabetes:** Insulin resistance or deficiency due to a progressive loss of beta cell insulin secretion frequently on the background of insulin resistance. This type is related to obesity and sedentary lifestyle. It is diagnosed primarily in adults older than 30 but is now being seen in children. It is the most common type of diabetes and is diagnosed more frequently in African Americans, Latino Americans, Native Americans, Asian Americans, and Pacific Islanders, as well as older adults.
- **Specific types of diabetes due to other causes:** Monogenic diabetes syndromes, such as neonatal diabetes and maturity-onset diabetes of the young (MONDY); diseases of the exocrine pancreas, such as cystic fibrosis and pancreatitis; and drug or chemical-induced diabetes, such as that caused by glucocorticoid use, the treatment of HIV/AIDS, or after organ transplantation.
- **Gestational diabetes mellitus**: Glucose intolerance with its onset during pregnancy usually diagnosed in the second or third trimester of pregnancy that was not clearly overt prior to gestation. The prevalence of gestational diabetes has been increasing in the United States and is as high as 10%.

TABLE 20.1 Recommendations for Diagnosing and Classifying Hyperglycemia in Pregnancy

When	Diagnosis	Test	Cutoff for Diagnosis
First prenatal visit	Overt (pregestational) diabetes or high-risk history—physical inactivity, first-degree relative with diabetes, hypertension, high-risk race/ethnicity, obesity, polycystic ovary syndrome, hypercholesterolemia, previous large infant >9 lb; and smoker	Fasting HbA1c Random	126 mg/dL <7% 200 mg/dL
24–28 weeks	Gestational diabetes	Fasting	<95 mg/dL
		75 g OGTT–1 hr	>180 mg/dL
		75 g OGTT–2 hr	>153 mg/dL

OGTT, oral glucose tolerance test.

Pregnancy outcomes of women additionally diagnosed as gestational diabetes by the International Association of the Diabetes and Pregnancy Study Group's criteria. *Diabetes & Metabolism Journal*, *43*(6), 766–775. https://doi.org/10.4093/dmj.2018.0192; and Durnwald, C. (2019). Diabetes mellitus in pregnancy: Screening and diagnosis. *UpToDate*. Retrieved June 5, 2020, from https://www.uptodate.com/contents/diabetes-mellitus-in-pregnancy-screening-and-diagnosis.

During pregnancy, diabetes typically is categorized into two groups: **pregestational diabetes** (alteration in carbohydrate metabolism identified before conception), which includes women

with type 1 or type 2 disease, and gestational diabetes, which develops during pregnancy.

The International Association of Diabetes and Pregnancy Study Group has issued recommendations for diagnosing and classifying hyperglycemia in pregnancy (Table 20.1).

Gestational diabetes occurs in up to 10% of pregnancies in the United States (Dickens & Thomas, 2019). It is associated with neonatal complications such as macrosomia, hypoglycemia, and birth trauma due to shoulder dystocia, and maternal complications such as preeclampsia and cesarean birth. All women of childbearing age with diabetes should be counseled about the importance of strict glycemic control prior to conception. A recent study found that women diagnosed with gestational diabetes have a twofold higher risk of developing cardiovascular disease compared to those women without gestational diabetes (Kramer et al., 2019). Before the discovery of insulin in 1922, most women with diabetes were infertile or experienced spontaneous abortion (March of Dimes, 2019a). During the past several decades, great strides have been made in improving the outcomes of pregnancy in women with diabetes, but this chronic metabolic disorder remains a high-risk condition during pregnancy. A favorable outcome requires commitment on the woman's part to adhere to frequent prenatal visits, dietary restrictions, self-monitoring of blood glucose levels, frequent laboratory tests, intensive fetal surveillance, and perhaps hospitalization.

Pathophysiology

Pregnancy is characterized by a series of metabolic changes that promote accumulation of adipose tissue in early pregnancy followed by insulin resistance later in gestation. Diabetes is a complex and progressive disease that has major societal and economic impacts. It is a multifactorial disease, the pathophysiology of which involves not only the pancreas but also the liver, skeletal muscle, adipose tissue, gastrointestinal tract, brain, and kidney. Reduced sensitivity to insulin in the liver, muscle, and adipose tissue, and a progressive decline in

pancreatic beta cell function leads to impaired insulin secretion, eventually resulting in hyperglycemia, the hallmark of diabetes (Moore, 2019). Current understanding of the pathophysiology of gestational diabetes includes two key components. These are the existence of pancreatic beta cell dysfunction prior to pregnancy and the unmasking of this problem by the development of insulin resistance during pregnancy, which requires enhanced insulin production to maintain normal blood glucose ranges.

Normal pregnancy is characterized by increasing peripheral resistance to insulin and a compensatory increase in insulin secretion. Therefore, pregnancy might be viewed as a stress test for the glucose homeostasis mechanisms. That is, women who have some degree of chronic insulin resistance and compensatory increased insulin production resulting in beta cell dysfunction before pregnancy may be unable to mount a sufficiently robust beta cell response to pregnancy-mediated insulin resistance. Pregnancy is accompanied by insulin resistance mediated by placental secretion of diabetogenic hormones. These and other metabolic changes that occur during pregnancy ensure that the fetus has an ample supply of nutrients.

With diabetes, there is a deficiency of or resistance to insulin. This interferes with the body's ability to obtain essential nutrients for fuel and storage. If a pregnant woman has pregestational diabetes or develops gestational diabetes, the profound metabolic alterations that occur during pregnancy and that are necessary to support the growth and development of the fetus are greatly affected.

Maternal metabolism is directed toward supplying adequate nutrition for the fetus. In pregnancy, placental hormones cause insulin resistance at a level that tends to parallel the growth of the fetoplacental unit. As the placenta grows, more placental hormones are secreted. Human placental lactogen (hPL), progesterone, cortisol, prolactin, and growth hormone (somatotropin) increase in direct correlation with the growth of placental tissue, rising throughout the last 20 weeks of pregnancy and causing insulin resistance. Subsequently, insulin secretion increases to overcome the resistance of these two hormones. In the pregnant woman

without diabetes, the pancreas can respond to the demands for increased insulin production to maintain normal glucose levels throughout the pregnancy (Blackburn, 2018). However, the woman with glucose intolerance or diabetes during pregnancy cannot cope with changes in metabolism resulting from insufficient insulin to meet the needs during gestation.

Over the course of pregnancy, insulin resistance changes. It peaks in the last trimester to provide more nutrients to the fetus. The insulin resistance typically results in postprandial hyperglycemia, though some women also have an elevated fasting blood glucose level (King et al., 2019). With this increased demand on the pancreas in late pregnancy, women with diabetes or glucose intolerance cannot accommodate the increased insulin demand; glucose levels rise as a result of insulin deficiency, leading to hyperglycemia. Subsequently, the mother and her fetus can experience major problems, as outlined in Table 20.2.

Screening

Currently, there are inconsistent standards around the world for how women are tested for gestational diabetes as well cut-off values to diagnose it, even after six decades of research in an effort to reach global consensus of how and when to screen for it. The American College of Obstetricians and Gynecologists (ACOG) and the ADA currently recommend a risk analysis of all pregnant women at their first prenatal visit and additional screening of all high-risk pregnant women again at 24 to 28 weeks or earlier if risk factors are present. If the initial screening risk assessment is low, additional screening may not be necessary. Pregnant women who fulfill all of the following criteria do not need to be screened at their first prenatal visit:

TABLE 20.2 Diabetes and Pregnancy: Effects on the Mother and Fetus

Effects on the Mother	Effects on the Fetus/Neonate
• Hydramnios due to fetal diuresis caused by hyperglycemia • Gestational hypertension of unknown etiology • Ketoacidosis due to uncontrolled hyperglycemia • Preterm labor secondary to premature membrane rupture • Stillbirth in pregnancies complicated by ketoacidosis and poor glucose control • Hypoglycemia as glucose is diverted to the fetus (occurring in first trimester) • Urinary tract infections resulting from excess glucose in the urine (glucosuria), which promotes bacterial growth • Chronic monilial vaginitis due to glucosuria, which promotes growth of yeast • Difficult labor, cesarean birth, postpartum hemorrhage secondary to an overdistended uterus to accommodate a macrosomic infant	• Cord prolapse secondary to polyhydramnios and abnormal fetal presentation • Congenital anomaly due to hyperglycemia in the first trimester (cardiac problems, neural tube defects, skeletal deformities, and genitourinary problems) • Macrosomia resulting from hyperinsulinemia stimulated by fetal hyperglycemia • Birth trauma due to increased size of fetus, which complicates the birthing process (shoulder dystocia) • Preterm birth secondary to polyhydramnios and an aging placenta, which places the fetus in jeopardy if the pregnancy continues • Fetal asphyxia secondary to fetal hyperglycemia and hyperinsulinemia • Intrauterine growth restriction secondary to maternal vascular impairment and decreased placental perfusion, which restricts growth • Perinatal death due to poor placental perfusion and hypoxia • Respiratory distress syndrome resulting from poor surfactant production secondary to hyperinsulinemia inhibiting the production of phospholipids, which make up surfactant • Polycythemia due to excessive red blood cell (RBC) production in response to hypoxia • Hyperbilirubinemia due to excessive RBC breakdown from hypoxia and an immature liver unable to break down bilirubin • Neonatal hypoglycemia resulting from ongoing hyperinsulinemia after the placenta is removed

- Subsequent childhood obesity and carbohydrate intolerance

American College of Obstetricians and Gynecologists (ACOG). (2018a). ACOG Practice Bulletin No. 190: Gestational diabetes mellitus. *Obstetrics and Gynecology*, *131*(2), 49–64; Cunningham, F. G., Leveno, K. J., Bloom, S. L., Dashe, J. S., Hoffman, B. L., Casey, B. M., & Spong, C. Y. (2018). *William's obstetrics* (25th ed.). McGraw-Hill Education; and Durnwald, C. (2019). Diabetes mellitus in pregnancy: Screening and diagnosis. *UpToDate*. Retrieved June 5, 2020, from https://www.uptodate.com/contents/diabetes-mellitus-in-pregnancy-screening-and-diagnosis.

- No history of glucose intolerance
- Younger than 25 years old
- Normal body weight
- No family history (first-degree relative) of diabetes
- No history of poor obstetric outcomes
- Not from an ethnic/racial group with a high prevalence of diabetes (ADA, 2019b)

If the initial risk assessment is high, rescreening should take place between 24 and 28 weeks. A woman with abnormal early results may have had diabetes before the pregnancy, and her fetus is at great risk for congenital anomalies. An elevated glycosylated hemoglobin (HbA1c) supports the likelihood of gestational diabetes. Combining the use of HbA1c and plasma glucose measurements for the diagnosis of diabetes offers the benefits of each test and reduces the risk of systematic bias inherent in HbA1c testing alone (Farahvar et al., 2019).

There is little consensus regarding the appropriate screening method. Typically, a one-step screening protocol for gestation diabetes is based on a 75-g, 2-hour glucose tolerance test, usually performed between 24 and 28 weeks' gestation (Jordan et al., 2019). A 75-g oral glucose load is given without regard to the timing or content of the last meal. Blood glucose is measured 2 hours later; a level above 120 mg/dL is abnormal. If the result is abnormal, a 3-hour glucose tolerance test is done. ADA and ACOG glucose targets (Durnwald, 2020) are:

- Fasting blood glucose level: Less than 95 mg/dL

- At 1 hour: Less than 140 mg/dL
- At 2 hours: Less than 120 mg/dL
- At 3 hours: Less than 95 mg/dL

A diagnosis of gestational diabetes can be made only after an abnormal result is obtained on the glucose tolerance test. One or more abnormal values confirm a diagnosis of gestational diabetes (Norwitz et al., 2019). HbA1c screening has been adopted by ADA and ACOG because of mounting evidence that diagnosing and treating even mild gestational diabetes reduces morbidity for both mother and infant (ADA, 2019b). If adopted universally, these guidelines are expected to have immediate, widespread clinical implications.

Therapeutic Management

Care for the Woman with Pregestational Diabetes

Pregestational diabetes is a significant public health problem that increases the risk for structural birth defects affecting both maternal and neonatal pregnancy outcomes. Women who have pregestational diabetes need comprehensive prenatal care. Achieving good metabolic control during the period prior to conception is essential to reducing congenital malformations that can occur in pregnancies complicated by diabetes. The primary goals of care are to maintain glycemic control and minimize the risks of the disease on the fetus. Key aspects of treatment include nutritional management, exercise, insulin regimens, and close maternal and fetal surveillance (Fig. 20.1).

Preconception counseling is essential for the woman with pregestational diabetes to ensure that her disease state is stable. The problem is that as many as half of all pregnancies in the United States are unplanned. Thus, women with chronic medical conditions such as diabetes might not have the opportunity to take steps to optimize management of the diabetes before becoming pregnant. When preconception care is possible, women with pregestational

diabetes should be taught how to improve their metabolic control prior to conception to reduce the risk of birth defects. Nurses caring for women of reproductive age can contribute to preconception care by helping counsel someone who is prediabetic to avoid progression to diabetes and its attendant risks during pregnancy. The goals of preconception care are to:

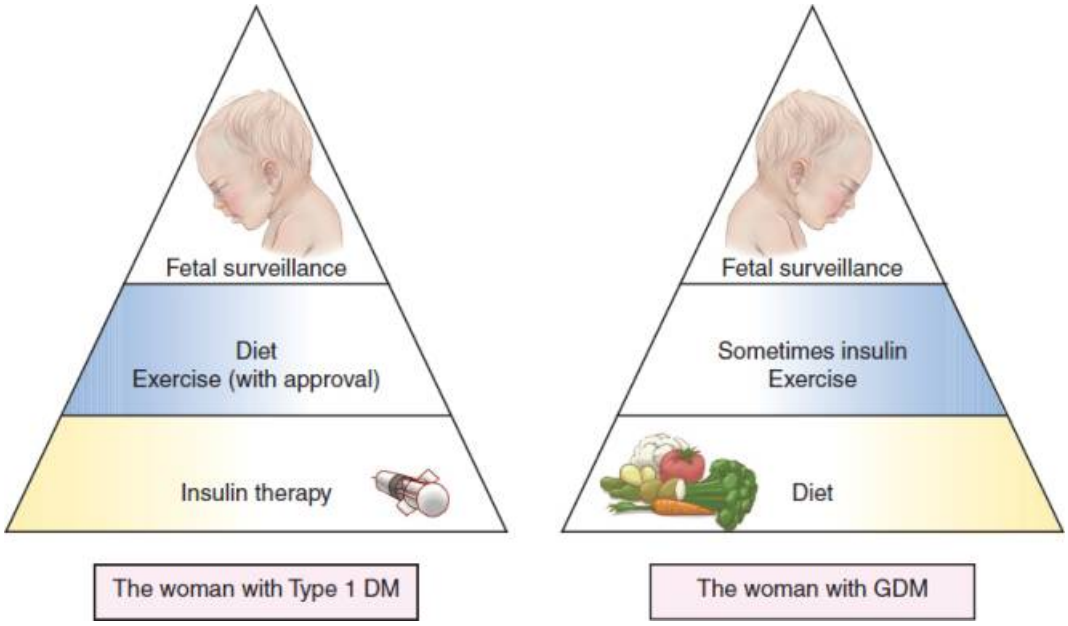

FIGURE 20.1. Treatment overview for diabetes in pregnancy. For women with pregestational type 1 diabetes mellitus, the foundation of glycemic management is insulin therapy along with dietary management, exercise, and fetal surveillance. For the woman who develops gestational diabetes, dietary modification is generally the foundation of treatment. Some women may require insulin along with dietary modifications, while others will not require insulin therapy. Exercise and fetal surveillance are also important facets of care.

- integrate the woman into the management of her diabetes.
- achieve the lowest glycosylated hemoglobin A1c test results without excessive hypoglycemia.
- ensure effective contraception until stable glycemia is achieved.
- identify and evaluate long-term diabetic complications such as retinopathy, nephropathy, neuropathy, cardiovascular disease (CVD), and hypertension (ASRM, 2019).

Excellent control of blood glucose as evidenced by normal fasting blood glucose levels and a **glycosylated hemoglobin (HbA1c) level** (measurement of the average glucose levels during the past 100 to 120 days), is crucial to achieve the best pregnancy outcome. A glycosylated hemoglobin level of less than 7% indicates good control; a value of more than 8% indicates poor control and warrants intervention. A pregestational diabetic pregnant woman has up to a ninefold increase in birth defects, shoulder dystocia, bone fracture, and nerve palsies compared with the rates among nondiabetic pregnancies if the pregestational diabetic pregnant woman does not have glycemic control (Pyeritz et al., 2019).

Preconception counseling is also important in reducing the risk of congenital malformation. The most common malformations associated with diabetes occur in the renal, cardiac, skeletal, and central nervous systems. Since these defects occur by the eighth week of gestation, preconception counseling is critical. The rate of congenital anomalies in women with pregestational diabetes can be reduced if excellent glycemic control is achieved at the time of conception (Cunningham et al., 2018). This information needs to be stressed to all women with diabetes who are contemplating a pregnancy. In addition, the woman with pregestational diabetes needs to be evaluated for complications of diabetes. This evaluation should be part of baseline screening and continuing assessment during pregnancy.

Care during Pregnancy for the Woman with Gestational Diabetes

Lifestyle modification, nutritional changes, and encouragement of physical activities form the primary mode of therapy for diabetes during pregnancy. Therapeutic management for the woman with gestational diabetes mellitus focuses on tight glucose control. The ADA (2019b) recommends maintaining a fasting blood glucose level below 92 mg/dL with postprandial levels below 180 mg/dL and 1-hour and 2-hour postprandial levels below 153 mg/dL. In comparison, for pregnant women without diabetes, near-normal

glucose values include a fasting value between 60 and 90 mg/dL, a 1-hour postprandial value of 100 to 120 mg/dL, and a 2-hour postprandial value of 60 to 120 mg/dL. Such tight control has been advocated because it is associated with a reduction in macrosomia. In addition, maternal prepregnancy weight and weight gain during pregnancy appear to be significant and independent risk factors for macrosomia in women with gestational diabetes (ACOG, 2020a).

Nutritional management focuses on maintaining balanced glucose levels and providing enough energy and nutrients for the pregnant woman while avoiding ketosis and minimizing the risk of hypoglycemia in women treated with insulin. Nutrition therapy is the cornerstone of therapy for women with gestational diabetes. Women should receive culturally appropriate nutritional advice on how to change their dietary habits from a dietitian. The diet counseling must be in keeping with the mother's present cultural dietary patterns and not radically different to become adopted and followed. If rice is a staple of a client's diet, then it should be incorporated into the diet counseling plan and not eliminated (Andrews & Boyle, 2019). A low glycemic index diet is considered safe and has positive effects on the glycemic control and pregnancy outcomes for healthy women, those with type 2 diabetes, and those with gestational diabetes. A moderately low-carbohydrate diet with a carbohydrate content of 40% of the calories results in good glycemic control for most (Opara & Dagogo-Jack, 2019). "Eating for two" during pregnancy for a woman who has diabetes does not mean eating volume for two but rather focusing on quality and timing to support both mother and fetus. Women who receive dietary instruction and follow it have been shown to have better pregnancy outcomes than those who do not receive dietary advice (ADA, 2019c).

PHARMACOLOGIC THERAPY FOR GESTATIONAL DIABETES

For the woman with gestational diabetes, nutritional management and exercise may be all that is necessary. Pharmacologic therapy is considered if nutrition and exercise fail to maintain target glucose

levels. Blood glucose levels in the woman can be controlled by nutritional therapy and exercise, but in uncontrolled cases in which target glycemic levels cannot be reached, insulin is also required. ACOG affirms the use of insulin as the first-line pharmacotherapy for gestational diabetes when medication is necessary to control blood glucose levels (2018a). Insulin, which does not cross the placenta, has historically been the medication of choice for treating hyperglycemia in pregnancy. Insulin is calculated based on the woman's weight. Combining intermediate- and short-acting insulin yields the best result for most women. Two insulin doses are given daily with two thirds of the total insulin in the morning to cover energy needs of the active day and one third at night.

Oral Medications for Management of Gestational Diabetes.

People tend to manage oral medications better than insulin, so the standard of care may be moving toward the oral route (King et al., 2019). Recent studies have examined the use of oral hypoglycemic medications in pregnancy with much success. Several studies have used glyburide (DiaBeta) with promising results. Many health care providers are using glyburide and metformin as an alternative to insulin therapy because they do not cross the placenta and therefore do not cause fetal or neonatal hypoglycemia. Some oral hypoglycemic medications are considered safe and may be used if nutrition and exercise are not adequate alone. Maternal and newborn outcomes are similar to those seen in women who are treated with insulin. Currently, there is a growing acceptance of oral antidiabetic agents as therapy for gestational diabetes, but this remains controversial. ACOG still recommends insulin be used as a first-line therapy to control glucose levels rather than oral agents (Kilgore, 2020). Gestational diabetes offers a window of opportunity for prevention of diabetes in future life (Stevens, 2019).

The ADA (2019b) recommends that women diagnosed with gestational diabetes with a 3-hour glucose tolerance test receive nutritional counseling from a registered dietitian. The ADA also recommends insulin therapy or oral diabetic medications if diet is unsuccessful in achieving a fasting glucose level below 95 mg/dL, a

1-hour postprandial level below 140 mg/dL, or 2-hour postprandial level below 120 mg/dL (ADA, 2019b).

ACOG (2018a) recommends the use of diet or insulin (first-line therapy) or oral diabetic medications (second-line therapy) to achieve a 1-hour postprandial blood glucose level of 140 mg/dL or lower. Randomized studies show that glyburide and insulin are equally effective in achieving glycemic control. Glycemic control—regardless of whether it involves diet, insulin, or oral agents—leads to fewer cases of shoulder dystocia, hyperbilirubinemia requiring phototherapy, nerve palsy, bone fracture, large-for-gestational-age (LGA) status, and fetal macrosomia (ACOG, 2018a).

Exercise is another important component of comprehensive prenatal care for the pregnant woman with glucose intolerance. Regular exercise helps maintain glucose control by increasing the uptake of glucose into the cells and decreasing central obesity, hypertension, and dyslipidemia, which will ultimately decrease the woman's insulin requirements (Jordan et al., 2019). Regular physical activity has been proven to result in marked benefits for mother and fetus. Maternal benefits include improved cardiovascular function, limited pregnancy weight gain, decreased musculoskeletal discomfort, reduced incidence of muscle cramps and lower limb edema, mood stability, and reduction of gestational diabetes mellitus and gestational hypertension. Fetal benefits include decreased fat mass, improved stress tolerance, and advanced neurobehavioral maturation.

Insulin for Management of Gestational Diabetes.

Insulin remains the medication of choice for glycemic control if oral medications, diet, or exercise fail to yield results in pregnant and lactating women with any type of diabetes (Norwitz et al., 2019). Generally, insulin doses are reduced in the first trimester to prevent hypoglycemia resulting from increased insulin sensitivity as well as from nausea and vomiting. Short-acting insulins such as lispro (Humalog) and aspart (NovoLog), which do not cross the placenta, may help reduce postprandial hyperglycemia, episodes of hypoglycemia between meals. Target fasting glucose values of 60 to

90 mg/dL and 1-hour postprandial values lower than 140 mg/dL are necessary to provide good glycemic control and good pregnancy outcomes (Feghali et al., 2019). Changes in diet and activity level add to the need for changes in insulin dosages throughout pregnancy. If the glycemic target is not reached, the use of metformin with lifestyle interventions appears to be a safe alternative to insulin. It remains an option as a second-line treatment in women who refuse insulin or who are unable to administer insulin safely (Pantea-Stoian et al., 2019).

Insulin regimens vary, and controversy remains over the best strategy for insulin delivery during pregnancy. Many health care providers use a split-dose therapy (two thirds of the daily dose in the morning and the remaining one third in the evening). Others advocate the use of an insulin pump to deliver a continuous subcutaneous insulin infusion. Regardless of which protocol is used, frequent blood glucose measurements are necessary, and the insulin dosage is adjusted on the basis of daily glucose levels. Insulin therapy or oral hypoglycemic agents in addition to diet and exercise are main elements of achieving glycemic control. See Evidence-Based Practice 20.1.

Close maternal and fetal surveillance is also essential. Frequent laboratory tests are done during pregnancy to monitor the woman's status and glucose control. Fetal surveillance via diagnostic testing aids in evaluating fetal well-being and assisting in determining the best time for birth.

Care during and after Labor for the Woman with Gestational Diabetes

For the laboring woman with diabetes, intravenous (IV) saline or lactated Ringer's is given, and blood glucose levels are monitored every 1 to 2 hours. Glucose levels are maintained below 110 mg/dL throughout labor to reduce the likelihood of neonatal hypoglycemia. If necessary, an infusion of regular insulin may be given to maintain this level (King et al., 2019). If the woman was receiving insulin during her pregnancy, adjustments in dosage may be necessary

after birth since glucose diversion across the placenta to supply the growing fetus is no longer present and insulin resistance is now removed. Insulin requirements drop quickly after birth, exposing women to hypoglycemia. Frequently, the woman can control gestational diabetes through diet and weight management; the woman with type 1 diabetes usually returns to prepregnant levels of insulin administration (Norwitz et al., 2019).

EVIDENCE-BASED PRACTICE 20.1 Exercise during Pregnancy Has a Preventative Effect on Excessive Maternal Weight Gain and Gestational Diabetes: A Randomized Controlled Trial

STUDY

Excessive gestational weight gain is associated with several adverse events and pathology during pregnancy for both the mother and the fetus. Physical activity is an essential component for women with gestational diabetes. Exercise increases glucose uptake and increases insulin sensitivity, thus decreasing insulin resistance. The purpose of this study was to examine the effects of an exercise program throughout pregnancy on maternal weight gain and prevalence of gestational diabetes.

A randomized controlled trial included an exercise intervention group and a standard control group without exercise, including 594 women divided into the two groups. The exercise group included moderate aerobic exercise performed 3 days per week (50 to 55 minutes per session) for 8 to 10 weeks to 38 to 39 weeks' gestation.

Findings

The results showed a higher percentage of women gained excessive weight in the control group than in the exercise group. In addition, the prevalence of gestational diabetes was significantly higher in the control group without exercise versus in the exercise group.

Nursing Implications

The result of this study indicates that exercise throughout pregnancy can reduce the risk of excessive maternal weight gain and gestational diabetes. Nurses should inform women about the benefits of exercise and provide literature and resources about specific exercises such as daily walking, biking, and swimming. Writing out a “prescription” for the type and amount of exercise may help women recognize the importance of this intervention and encourage them to do it. Encourage them to keep a daily log to track their regimen, and ask about it at every prenatal visit.

Adapted from Barakat, R., Refoyo, I., Coteron, J., & Franco, E. (2019). Exercise during pregnancy has a preventative effect on excessive maternal weight gain and gestational diabetes. A randomized controlled trial. Brazilian Journal of Physical Therapy, 23(2), 148–155.

After giving birth, the overt glycemic abnormalities of gestational diabetes usually resolve. This phenomenon suggests that the diabetes is transient and that the consequences of gestational diabetes end with the birth of the infant. However, for the woman, childbirth is not the end of the story. The diagnosis of gestational diabetes heralds future health risks. Knowledge of this “failed” stress test conveys new information about her future risk for type 2 diabetes, which warrants further screening and prevention efforts during the postpartum period and beyond.

Nursing Assessment

Nursing assessment begins at the first prenatal visit. A thorough history and physical examination in conjunction with specific laboratory and diagnostic testing aids in developing an individualized plan of care for the woman with diabetes. Early screening, ideally before 13 weeks’ gestation, is important to identify pregestational diabetes. If glucose levels are abnormal in the first half of pregnancy, the woman would be diagnosed with pregestational diabetes, not gestational diabetes (Trout, 2019).

Health History and Physical Examination

For the woman with pregestational diabetes, obtain a thorough history of the preexisting diabetic condition. Ask about her duration of disease, management of glucose levels (insulin injections, insulin pump, or oral hypoglycemic agents), dietary adjustments, presence of vascular complications and current vascular status, current insulin regimen, and technique used for glucose testing. Review any information that she may have received as part of her preconception counseling and measures that were implemented during this time.

Be knowledgeable about the woman's nutritional requirements and assess the adequacy and pattern of her dietary intake. Assess her blood glucose self-monitoring in terms of technique, frequency, and her ability to adjust the insulin dose based on the changing patterns. Ask about the frequency of episodes of hypoglycemia or hyperglycemia to ascertain the woman's ability to recognize and treat them. Continue to assess her for signs and symptoms of hypoglycemia and hyperglycemia.

During antepartum visits, assess the client's knowledge about her disease, including the signs and symptoms of hypoglycemia, hyperglycemia, and diabetic ketoacidosis, insulin administration techniques, and the impact of pregnancy on her chronic condition. If possible, have the woman demonstrate her technique for blood glucose monitoring and insulin administration if appropriate. It is essential that the nurse remembers there is a huge learning curve for women with diabetes concerning the need for dietary changes, frequency of blood glucose monitoring, exercise, and insulin or oral medication administration. Suddenly, the woman is expected to make rapid changes in her life, which can be overwhelming. The nurse can help facilitate these changes by exercising patience and understanding and reinforcing all verbal instructions with written material. Frequent encouragement is also needed to assist the woman with her lifestyle changes. Although the client may have had diabetes for some time, do not assume that she has a firm knowledge base about her disease process or management of it (Fig. 20.2).

FIGURE 20.2. The nurse is demonstrating the technique for self-blood glucose monitoring with a pregnant client who has diabetes.

Assess the woman's risk for gestational diabetes at the first prenatal visit. The clinical presentation of diabetes mellitus in pregnancy may be quite varied, but the classical triad of the symptoms of polydipsia, polyphagia, and polyuria may not be reported by most women during pregnancy. Instead, the women may present with previous history of medical complications of diabetes (chronic hypertension or chronic renal disease) and obesity. All of these conditions can influence pregnancy outcome. The ADA (2019b) recommends assessing all women for risk factors and then determining the need for additional testing based on the findings. Factors that place a woman at high risk include:

- Previous infant with congenital anomaly (skeletal, renal, central nervous system, cardiac)
- History of gestational diabetes or polyhydramnios in a previous pregnancy
- Family history of diabetes
- Medications like corticosteroids or antipsychotics
- Age 35 years or older

- Polycystic ovary syndrome
- Multiple pregnancy (twins, triplets)
- Previous infant weighing more than 9 lb (4,000 g)
- Previous unexplained fetal demise or neonatal death
- Maternal obesity (body mass index [BMI] over 30)
- Hypertension before pregnancy or in early pregnancy
- Hispanic, Native American, Pacific Islander, or African American ethnicity
- Recurrent monilia infections that do not respond to treatment
- Signs and symptoms of glucose intolerance (polyuria, polyphagia, polydipsia, fatigue)
- Presence of glycosuria or proteinuria (Farahvar et al., 2019).

Women with clinical characteristics consistent with a high risk for gestational diabetes should undergo glucose testing as soon as feasible.

Provide close ongoing assessment throughout the prenatal period. Women with gestational diabetes mellitus are at increased risk for preeclampsia and glucose control–related complications such as hypoglycemia, hyperglycemia, and ketoacidosis. Gestational diabetes of any severity increases the risk of fetal macrosomia, as noted earlier. It is also associated with an increased frequency of maternal hypertensive disorders and operative births. This may be the result of fetal growth disorders (ADA, 2019b). Even though gestational diabetes is diagnosed during pregnancy, the woman may have had glucose intolerance before the pregnancy. Therefore, monitor the woman closely for signs and symptoms of possible complications.

Also assess the woman's psychosocial adaptation to her condition. This assessment is critical to gain her cooperation for a change in regimen or the addition of a new regimen throughout pregnancy. Identify her support systems and note any financial constraints, because she will need intense monitoring and frequent fetal surveillance.

Laboratory and Diagnostic Testing

The results of laboratory and diagnostic tests provide valuable information about maternal and fetal well-being. Women with pregestational diabetes and those diagnosed with gestational diabetes require ongoing maternal and fetal surveillance to promote the best outcome.

SURVEILLANCE

Maternal surveillance may include:

- Urine check for protein (may indicate the need for further evaluation for preeclampsia) and for nitrates and leukocyte esterase (may indicate a urinary tract infection)
- Urine check for ketones (may indicate the need for evaluation of eating habits)
- Kidney function evaluation every trimester for creatinine clearance and protein levels
- Eye examination in the first trimester to evaluate the retina for vascular changes
- HbA1c every 4 to 6 weeks to monitor glucose trends (Jordan et al., 2019)

Fetal surveillance may include ultrasound to provide information about fetal growth, activity, and amniotic fluid volume and to validate gestational age. Alpha-fetoprotein (AFP) levels may be obtained to detect congenital anomalies such as an open neural tube or ventral wall defects of omphalocele or gastroschisis, and a fetal echocardiogram may be necessary to rule out cardiac anomalies. A biophysical profile helps monitor fetal well-being and uteroplacental profusion, and nonstress tests are commonly performed weekly after 28 weeks' gestation to evaluate fetal well-being. As the pregnancy progresses, an amniocentesis may be done to determine the lecithin/sphingomyelin (L/S) ratio and the presence of phosphatidyl glycerol (PG) to evaluate whether the fetal lung is mature enough for birth (Wilmott et al., 2019).

Nursing Management

The ideal outcome of every pregnancy is a healthy newborn and mother. Nurses can be pivotal in realizing this positive outcome for women with pregestational or gestational diabetes by implementing measures to minimize risks and complications. Since the woman with diabetes is considered to be at high risk, prenatal visits occur more frequently (every 2 weeks up to 28 weeks and then twice a week until birth), providing the nurse with numerous opportunities for ongoing assessment, education, and counseling (Nursing Care Plan 20.1).

Promoting Optimal Glucose Control

At each visit, review the mother's blood glucose levels, including any laboratory tests and self-monitoring results. Reinforce with the woman the need to perform blood glucose monitoring (usually four times a day, before meals and at bedtime) and to keep a record of the results. If appropriate, obtain a fingerstick blood glucose level to evaluate the accuracy of self-monitoring results. Also assess the woman's techniques for monitoring blood glucose levels and for administering insulin if ordered, and offer support and guidance. If the woman is receiving insulin therapy, assist with any changes needed if glucose levels are not controlled. Obtain a urine specimen and check for glucose, protein, and ketones. Ask the woman if she has had any episodes of hypoglycemia and what she did to alleviate them. Discuss dietary measures related to blood glucose control (Fig. 20.3). In addition, recommend the following:

- Avoid weight loss and dieting during pregnancy.
- Ensure that food intake is adequate to prevent ketone formation and promote weight gain.
- Be physically active daily.
- Eat three meals a day plus three snacks to promote glycemic control:
  - 40% of calories from good-quality complex carbohydrates
  - 35% of calories from protein sources
  - 25% of calories from unsaturated fats
- Small frequent feedings throughout the day are recommended.
- Bedtime snacks are recommended for all women.

- Include protein and fat at each meal (National Institute of Diabetes, Digestive and Kidney Diseases, 2019).

TAKE NOTE!

Nutrient requirements and recommendations for weight gain for the pregnant woman with diabetes are the same as those for the pregnant nondiabetic woman.

If necessary, arrange for consultation with a dietitian or nutritionist to individualize the dietary plan. Also encourage the woman to participate in an exercise program that includes at least three sessions which last at least 30 minutes daily. Exercise may lessen the need for insulin or dosage adjustments.

When caring for the laboring woman with pregestational or gestational diabetes, adjust the IV flow rate and the rate of supplemental regular insulin based on the blood glucose levels as ordered. Monitor blood glucose levels every 1 to 2 hours or more frequently if necessary. Keep a syringe with 50% dextrose solution at the bedside to treat profound hypoglycemia. Monitor fetal heart rate patterns throughout labor to detect abnormal patterns. Assess maternal vital signs every hour in addition to assessing the woman's urinary output with an indwelling catheter. If a cesarean birth is scheduled, monitor the woman's blood glucose levels hourly and administer short-acting insulin or glucose based on the blood glucose levels as ordered.

FIGURE 20.3. The pregnant client with diabetes eating a nutritious meal to ensure adequate glucose control.

NURSING CARE PLAN 20.1 Overview of the Pregnant Woman with Type 1 Diabetes

Patty, a 30-year-old woman with type 1 diabetes, presents to the maternity clinic for preconception care. She has had diabetes for 8 years and takes insulin twice daily by injection. She does blood glucose self-monitoring four times daily. She reports that her disease is fairly well controlled, but "I'm worried about how my diabetes will affect a pregnancy and my baby. Will I need to make changes in my routine? Will my baby be normal?" She reports that she recently had a foot infection and needed to go to the emergency department because it led to an episode of ketoacidosis. She states that her last glycosylated hemoglobin A1c test results were abnormal.

Nursing ANALYSIS: Altered health maintenance: Maternal related to lack of knowledge regarding care in diabetic condition in pregnancy as evidenced by questions about effect on pregnancy, possible changes in regimen, and pregnancy outcome

OUTCOME IDENTIFICATION AND EVALUATION

The client will demonstrate increased knowledge of type 1 diabetes and effects on pregnancy as evidenced by proper techniques for blood glucose monitoring and insulin administration, ability to modify insulin doses and dietary intake to achieve control, and verbalization of need for glycemic control prior to pregnancy with blood glucose levels remaining within normal range.

INTERVENTIONS: *Providing Client Teaching*

- Assess client's knowledge of diabetes and pregnancy *to establish a baseline from which to develop an individualized teaching plan*.
- Review the underlying problems associated with diabetes and how pregnancy affects glucose control *to provide client with a firm knowledge base for decision-making*.
- Review signs and symptoms of hypoglycemia and hyperglycemia and prevention and management measures *to ensure client can deal with them should they occur*.
- Provide written materials describing diabetes and care needed for control *to provide opportunity for client's review and promote retention of learning*.
- Observe client administering insulin and self-glucose testing for technique and offer suggestions for improvement if needed *to ensure adequate self-care ability*.
- Discuss proper foot care *to prevent future infections*.

- Teach home treatment for symptomatic hypoglycemia *to minimize risk to client and fetus*.
- Outline acute and chronic diabetic complications *to reinforce the importance of glucose control*.
- Discuss use of contraceptives until blood glucose levels can be optimized before conception occurs *to promote best possible health status before conception*.
- Explain the rationale for good glucose control and the importance of achieving excellent glycemic control before pregnancy *to promote a positive pregnancy outcome*.
- Review self-care practices (blood glucose monitoring and frequency of testing; insulin administration; adjustment of insulin dosages based on blood glucose levels) *to foster independence in self-care and feelings of control over the situation*.
- Refer client for dietary counseling *to ensure optimal diet for glycemic control*.
- Outline obstetric management and fetal surveillance needed for pregnancy *to provide client with information on what to expect*.
- Discuss strategies for maintaining optimal glycemic control during pregnancy *to minimize risks to client and fetus*.

NURSING ANALYSIS: Acute anxiety related to threat to self and fetus as evidenced by questions about her condition's effect on the baby and baby being healthy

OUTCOME IDENTIFICATION AND EVALUATION

The client will openly express her feelings related to her diabetes and pregnancy as evidenced by statements of feeling better about her preexisting condition and pregnancy outlook, and statements of understanding related to future childbearing by linking good glucose control with positive outcomes for both her and offspring.

INTERVENTIONS: ***Minimizing Anxiety***

- Review the need for a physical examination *to evaluate for any effects of diabetes on the client's health status*.
- Explain the rationale for assessing client's blood pressure, vision, and peripheral pulses at each visit *to provide information related to possible effects of diabetes on health status*.
- Identify any alterations in present diabetic condition that need intervention *to aid in minimizing risks that may increase client's anxiety level*.
- Review potential effects of diabetes on pregnancy *to promote client understanding of risks and ways to control or minimize them*.

- Encourage active participation in decision-making and planning pregnancy *to promote feelings of control over the situation and foster self-confidence*.
- Discuss feelings about future childbearing and managing pregnancy *to help reduce anxiety related to uncertainties*.
- Encourage client to ask questions or voice concerns *to help decrease anxiety related to the unknown*.
- Emphasize the use of frequent and continued surveillance of client and fetal status during pregnancy *to reduce the risk of complications and aid in alleviating anxieties related to the unknown*.
- Provide positive reinforcement for healthy behaviors and actions *to foster continued use and enhancement of self-esteem*.

After birth, monitor blood glucose levels every 2 to 4 hours for the first 48 hours to determine the woman's insulin need, and continue IV fluid administration as ordered. Encourage breastfeeding to assist in maintaining good glucose control. For the woman with pregestational diabetes and type 1 or 2 diabetes, expect insulin needs to decrease rapidly after birth; they may be reduced by half of the antepartum dose as meals are started (King et al., 2019). Some women may return to their prepregnancy insulin dosage. In addition, the nurse must monitor the infant of the diabetic mother for common problems like macrosomia, respiratory distress syndrome, transitional hypoglycemia, polycythemia, hypocalcemia, hyperbilirubinemia, and a variety of congenital anomalies (Martin & Rosenfeld, 2019). Frequently, admission to the neonatal intensive care unit (NICU) for close observation and glucose control is needed.

The therapy plan after childbirth is individualized. If recommended dietary modifications are carried out along with weight loss, the woman with gestational diabetes may return to her normal glucose levels. This is also true for the woman with pregestational diabetes except that she will return to her prepregnancy insulin administration levels. This provides the nurse with an opportunity to reinforce healthy lifestyle interventions on the postpartum unit. Nurses can also become involved with community-based education to continue to offer their expertise.

Preventing Complications

Assess the woman closely for signs and symptoms of complications at each visit. Anticipate possible complications and plan appropriate interventions or referrals. Check the woman's blood pressure for changes, and evaluate for proteinuria when obtaining a urine specimen. These might suggest the development of preeclampsia. Measure fundal height and review gestational age. Note any discrepancies between fundal height and gestational age or a sudden increase in uterine growth. These may suggest hydramnios.

Encourage the woman to perform daily fetal movement counts to monitor fetal well-being. Tell her specifically when she should notify her health care provider. Also prepare the woman for the need for frequent laboratory and diagnostic testing to evaluate fetal status. Assist with serial ultrasounds to monitor fetal growth and with nonstress tests and biophysical profiles to assess fetal well-being.

CONSIDER THIS

Scott and I had been busy all day setting up the new crib in our nursery, and we finally sat down to rest. I was due any day, and we had been putting this off until we had a long weekend to complete the task. I was excited to think about decorating my new daughter's room. I was sure that she would love it as much as I loved her already. A few days later, I barely noticed any fetal movement, but I thought that she must be as tired as I was by this point.

That night I went into labor and kept looking at the worried faces of the nurses and the midwife in attendance. I had been diagnosed with gestational diabetes a few months ago and had tried to follow the instructions regarding diet and exercise, but old habits are hard to change when you are 38 years old. I was finally told after a short time in the labor unit that they couldn't pick up a fetal heartbeat and an ultrasound was to be done; still no heartbeat was detected. Scott and I were finally told that our daughter was stillborn. All I could think about was that she would never get to see all the colors in the nursery.

Providing Client Education and Counseling

The pregnant woman with diabetes requires counseling and education about the need for strict glucose monitoring, diet and exercise, and signs and symptoms of complications. Encourage the client and her family to make any lifestyle changes needed to optimize the pregnancy outcome. Providing dietary education, weight control measures, and lifestyle advice that extends beyond pregnancy may lower the risk that the woman will have gestational diabetes in subsequent pregnancies as well as type 2 diabetes (Jordan et al., 2019). At each visit, stress the importance of performing blood glucose screening and documenting the results. With proper instruction, the client and her family will be able to cope with all the changes in her body during pregnancy (Teaching Guidelines 20.1).

TEACHING GUIDELINES 20.1

Teaching for the Pregnant Woman with Diabetes

- Be sure to keep your appointments for frequent prenatal visits and tests for fetal well-being.
- Perform blood glucose self-monitoring as directed, usually before each meal and at bedtime. Keep a record of your results and call your health care provider with any levels outside the established range. Bring your results to each prenatal visit.
- Perform daily fetal kick counts. Document them, and report any decrease in activity.
- Drink eight to 10 8-oz glasses of water each day to prevent bladder infections and maintain hydration.
- Wear proper, well-fitted footwear when walking to prevent injury.
- Engage in a regular exercise program such as walking to aid in glucose control, but avoid exercising in temperature extremes.
- Consider breastfeeding your infant to lower your blood glucose levels.
- If you are taking insulin:
  - Administer the correct dose of insulin at the correct time every day.
  - Eat breakfast within 30 minutes after injecting regular insulin to prevent a reaction.
  - Plan meals at a fixed time and snacks to prevent extremes in glucose levels.
- Avoid simple sugars (cake, candy, cookies), which raise blood glucose levels.
- Know the signs and symptoms of hypoglycemia and treatment needed:
  - Sweating, tremors, cold, clammy skin, headache
  - Feeling hungry, blurred vision, disorientation, irritability
  - Treatment: Drink 8 oz of milk and eat two crackers or take two glucose tablets.
  - Treatment: Carry “glucose boosters” (such as hard candies) to treat hypoglycemia.

- Know the signs and symptoms of hyperglycemia and treatment needed:
  - Dry mouth, frequent urination, excessive thirst, rapid breathing
  - Feeling tired, flushed, hot skin, headache, drowsiness
  - Treatment: Notify health care provider, because hospitalization may be needed.
- Wear a diabetic identification bracelet at all times.
- Wash your hands frequently to prevent infections.
- Report any signs and symptoms of illness, infection, and dehydration to your health care provider, because these can affect blood glucose control.

Review discussions about the timing of birth and the rationale. Counsel the client about the possibility of cesarean birth for an LGA infant, or inform the woman who will be giving birth vaginally about the possible need for augmentation with oxytocin (Pitocin).

TAKE NOTE!

In the woman with well-controlled diabetes, birth is typically not induced before term unless complications arise, such as preeclampsia or fetal compromise. An early delivery date might be set for the woman with poorly controlled diabetes or a large fetus who is having complications.

Instruct the client about the benefits of breastfeeding related to blood glucose control. Breastfeeding helps normalize blood glucose levels. Therefore, encourage the woman to breastfeed her newborn. Also teach the woman receiving insulin for diabetes that her insulin needs after birth will drastically decrease. Women with gestational diabetes are at risk of developing type 2 diabetes and prediabetes in the postpartum period. Lactation is considered beneficial for maternal postpartum weight loss and control of glycemic metabolism, so it should be encouraged (Shen et al., 2019).

For the woman with gestational diabetes, the focus is on lifestyle education. Women with gestational diabetes have a greater than

50% increased risk of developing type 2 diabetes (ADA, 2019b). Inform the woman that screening most likely will be done at the postpartum follow-up appointment in 6 weeks. Teach her how to maintain an optimal weight to reduce her risk of developing diabetes. If necessary, refer the woman to a dietitian to help outline a balanced, nutritious diet.

CARDIOVASCULAR DISORDERS

Despite an increase in awareness of a wide range of health concerns, the myth persists that CVD is a man's disease, and women do not need to be concerned about it. Every minute, an American woman dies of CVD and more than one in three women is living with a cardiovascular disorder, including nearly half of all African American women and 35% of White women. CVD is now a leading cause of maternal death (American Heart Association [AHA], 2019). CVD is the leading cause of death for women in the United States. It kills nearly 400,000 women each year. Despite the prominent reduction in cardiovascular mortality among men, the rate has not declined for women. CVD has killed more women than men since 1984 (Ying et al., 2018). In addition to being the top killer of women, at the time of diagnosis, women have both a poorer overall prognosis and a higher risk of death than men diagnosed with heart disease. Women represent 50% of deaths from CVD than the next three causes of death combined, including all forms of cancer (ACOG 2019h). In both men and women, risk factors such as hypertension, diabetes, high blood cholesterol level, smoking, lack of physical activity, and obesity increase the probability of developing CVD.

Maternal heart disease has emerged as a major threat to safe motherhood and women's long-term cardiovascular health. More women die of heart disease, stroke, and other CVDs than men, yet many women do not realize they are at risk. Pregnancy can be viewed as a cardiovascular stress test in that the development of certain complications (gestational hypertension, gestational diabetes

mellitus, preterm birth, intrauterine growth restriction [IUGR] of the newborn, or placental abruption) has the potential to reveal a woman's susceptibility to future vascular or metabolic diseases (Graves et al., 2019). Approximately 4% of pregnant women have cardiac disease, which is responsible for 10% to 25% of maternal deaths (Cunningham et al., 2018). The prevalence of cardiac disease is increasing as a result of lifestyle patterns, including cigarette smoking, diabetes, and stress. As women are delaying childbearing, the incidence of cardiac disease in pregnancy will continue to increase. The cardiovascular adaptations during pregnancy are well tolerated by the normal heart but may unveil undiagnosed underlying heart disease or tip the hemodynamic balance and lead to decompensation in those with existing heart disease. Pregnancy is a predictor of future cardiovascular health in women (ACOG, 2019h).

Rheumatic heart disease used to represent the majority of cardiac conditions during pregnancy, but congenital heart disease now constitutes nearly half of all cases of heart disease encountered during pregnancy. Classic symptoms of heart disease mimic common symptoms of late pregnancy, such as palpitations, shortness of breath with exertion, and occasional chest pain. Few women with heart disease die during pregnancy, but they are at risk for other complications, such as heart failure, arrhythmias, and stroke. Their offspring are also at risk of complications, such as premature birth, low birth weight for gestational age, respiratory distress syndrome, intraventricular hemorrhage, and death (Troiano et al., 2019).

Congenital and Acquired Heart Disease

Congenital heart disease often involves structural defects that are present at birth but may not be discovered at that time (Table 20.3). Until recently, women with congenital heart disease did not live long enough to bear children. Today, due to new surgical techniques to correct these defects, many of these women can complete a successful pregnancy at relatively low risk when appropriate

counseling and optimal care are provided. Increasing numbers of women with complex congenital heart disease are reaching childbearing age. Complications such as growth restriction, preterm and premature birth, and fetal and neonatal mortality are more common among children of women with congenital heart disease. The risk of complications is determined by the severity of the cardiac lesion, the functional abnormality produced by the lesion, and the development of complications such as hemorrhage, preeclampsia, or infection (Troiano et al., 2019).

Women with certain congenital conditions should avoid pregnancy. These include uncorrected tetralogy of Fallot or transposition of the great arteries, severe pulmonary hypertension, aortic valve stenosis, Marfan syndrome, peripartum cardiomyopathy, and Eisenmenger syndrome, a defect with both cyanosis and pulmonary hypertension (Resnik et al., 2019).

Acquired heart diseases are conditions affecting the heart and its associated blood vessels that develop during a person's lifetime in contrast with congenital heart diseases, which are present at birth. Acquired heart diseases include coronary artery disease, coronary heart disease, rheumatic heart disease, diseases of the pulmonary vessels and the aorta, diseases of the tissues of the heart, and diseases of the heart valves. The incidence of rheumatic heart disease has declined dramatically in the past several decades because of prompt identification of streptococcal throat infections and treatment with antibiotics. When the heart is involved, valvular lesions, such as mitral stenosis, prolapse, or aortic stenosis, are common (see Table 20.3).

TABLE 20.3 Selected Heart Conditions Affecting Pregnancy

Condition	Description	Management
Congenital		
Tetralogy of Fallot	Congenital defect involving four structural anomalies: obstruction to pulmonary flow; ventricular septal defect (abnormal opening between the right and left ventricles); dextroposition of the aorta (aortic opening overriding the septum and receiving blood from both ventricles); and right ventricular hypertrophy (increase in volume of the myocardium of the right ventricle)	Hospitalization and bed rest possible after the 20th week with hemodynamic monitoring via a pulmonary artery catheter to monitor volume status Oxygen therapy may be necessary during labor and birth.
Atrial septal defect (ASD)	Congenital heart defect involving a communication or opening between the atria with left-to-right shunting due to greater left-sided pressure Arrhythmias present in some women	Treatment with atrioventricular nodal blocking agents, and at times with electrical cardioversion
Ventricular septal defect (VSD)	Congenital heart defect involving an opening in the ventricular septum, permitting blood flow from the left to the right ventricle Complications include arrhythmias, heart failure, and pulmonary hypertension	Rest with limited activity if symptomatic
Patent ductus arteriosus	Abnormal persistence of an open lumen in the ductus arteriosus between the aorta and the pulmonary	Surgical ligation of the open ductus during infancy; subsequent problems

	artery after birth; results in increased pulmonary blood flow and redistribution of flow to other organs	minimal after surgical correction
Acquired		
Mitral valve prolapse	Very common in the general population, occurring most often in younger women Leaflets of the mitral valve prolapse into the left atrium during ventricular contraction The most common cause of mitral valve regurgitation if present during pregnancy Usually improvements in mitral valve function due to increased blood volume and decreased systemic vascular resistance of pregnancy; most women are able to tolerate pregnancy well	Most women are asymptomatic; diagnosis is made incidentally Occasional palpitations, chest pain, or arrhythmias in some women, possibly requiring beta-blockers Usually no special precautions are necessary during pregnancy.
Mitral valve stenosis	Most common chronic rheumatic valvular lesion in pregnancy Causes obstruction of blood flow from the atria to the ventricle, thereby decreasing ventricular filling and causing a fixed cardiac output Resultant pulmonary edema, pulmonary hypertension, and right ventricular failure Most pregnant women with this condition can be managed medically.	General symptomatic improvement with medical management involving diuretics, beta-blockers, and anticoagulant therapy Activity restriction, reduction in sodium, and potentially bed rest if condition severe

Aortic stenosis	Narrowing of the opening of the aortic valve, leading to an obstruction to left ventricular ejection Women with mild disease can tolerate hypervolemia of pregnancy; with progressive narrowing of the opening, cardiac output becomes fixed. Diagnosis can be confirmed with echocardiography. Most women can be managed with medical therapy, bed rest, and close monitoring.	Diagnosis confirmed with echocardiography Pharmacologic treatment with beta-blockers and/or antiarrhythmic agents to reduce risk of heart failure and/or dysrhythmias Bed rest/limited activity and close monitoring
Peripartum cardiomyopathy	Rare congestive cardiomyopathy that may arise during pregnancy Multiparity, age, multiple fetuses, hypertension, an infectious agent, autoimmune disease, or cocaine use may contribute to its presence Development of heart failure in the last month of pregnancy or within 5 months of giving birth without any preexisting heart disease or any identifiable cause	Preload reduction with diuretic therapy Afterload reduction with vasodilators Improvement in contractility with inotropic agents Nonpharmacologic approaches include salt restriction and daily exercise such as walking or biking The question of whether another pregnancy should be attempted is controversial due to the high risk of repeat complications
Myocardial infarction (MI)	Rare during pregnancy, but incidence is expected to increase as older women are becoming pregnant and the risk factors for coronary artery disease become more prevalent	Usual treatment modalities for any acute MI along with consideration for the fetus Anticoagulant therapy, rest, and lifestyle changes to preserve the health of both parties

	Factors contributing to MI include family history, stress, smoking, age, obesity, multiple fetuses, hypercholesterolemia, and cocaine use.
	Increased plasma volume and cardiac output during pregnancy increase the cardiac workload as well as the myocardial oxygen demands; imbalance in supply and demand may contribute to myocardial ischemia.

Cunningham, F. G., Leveno, K. J., Bloom, S. L., Dashe, J. S., Hoffman, B. L., Casey, B. M., & Spong, C. Y. (2018). *William's obstetrics* (25th ed.). McGraw-Hill Education; Iftikhar, S. F., & Biswas, M. (2019). Cardiac disease in pregnancy. *StatPearls*. Retrieved March 21, 2020, from https://www.ncbi.nlm.nih.gov/books/NBK537261/; and King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning.

Many women are postponing childbearing until their 30s and 40s. With advancing maternal age, underlying medical conditions such as hypertension, diabetes, and hypercholesterolemia contributing to ischemic heart disease become more common and increase the incidence of acquired heart disease complicating pregnancy. Coronary artery disease and myocardial infarction may result.

A woman's ability to function during the pregnancy is often more important than the actual diagnosis of the cardiac condition. The following is the modified World Health Organization (WHO) classification of maternal cardiovascular risk. It provides a simple way of classifying the extent of heart failure by placing people in one of four categories based on how much they are limited during physical activity, normal breathing, and varying degrees of shortness of breath and/or chest pain:

- *Risk Class I:* No detectable increased risk of maternal mortality and no increase or a mild increase in morbidity; prepregnancy/pregnancy counseling suggested. Select conditions

under this classification might include pulmonary stenosis, patent ductus arteriosus, and mitral valve prolapse.

- *Risk Class II:* Small increased risk of maternal mortality or moderate increase in morbidity; prepregnancy/pregnancy counseling and cardiac consult every trimester. Select conditions under this classification include atrial or ventricular septal defect, repaired tetralogy of Fallot defects, and most arrhythmias.
- *Risk Classes II and III:* Intermediate increased risk of maternal mortality or moderate to severe increase in morbidity; prepregnancy/pregnancy counseling with cardiologist consult every trimester. Delivery at appropriate level hospital. Select conditions include mild left ventricular impairment or hypertrophic cardiomyopathy.
- *Risk Class III*: Significantly increased risk of maternal mortality or severe morbidity; prepregnancy/pregnancy counseling, cardiologist consult every other month, prenatal care and delivery at appropriate level hospital. Select conditions in this classification include moderate left ventricular impairment, mechanical valve, moderate mitral stenosis, and ventricular tachycardia.
- *Class IV*: Pregnancy contraindicated. Extremely high risk of maternal mortality or severe morbidity. Cardiac team consult and follow-up monthly. Select conditions include pulmonary arterial hypertension, severe ventricular dysfunction, severe mitral stenosis, and severe aortic dilation (ACOG, 2019h).

The classification may change as the pregnancy progresses and the woman's body must cope with the increasing stress on the cardiovascular system resulting from the numerous physiologic changes taking place. Typically, a woman with class I or II cardiac disease can go through a pregnancy without major complications. A woman with class III disease needs frequent visits with the cardiac care team throughout pregnancy. A woman with class IV disease should typically be advised to avoid pregnancy (Dumitru, 2019). Women with cardiac disease may benefit from preconception counseling so that they know the risks before deciding to become pregnant.

BOX 20.1 Classification of Maternal Mortality Risk

Group I (minimal risk) has a 2% to 5% risk of maternal cardiac event and comprises women with:

- Patent ductus arteriosus
- Tetralogy of Fallot, corrected
- Atrial septal defect
- Ventricular septal defect
- Mitral stenosis, classes I and II

Group II (moderate risk) has a 6% to 10% risk of maternal cardiac event and comprises women with:

- Tetralogy of Fallot, uncorrected
- Mitral stenosis with atrial fibrillation
- Aortic stenosis, classes III and IV
- Aortic coarctation without valvular involvement
- Artificial valve replacement

Group III (major risk) has a 20% to 27% risk of maternal cardiac event and comprises women with:

- Pulmonary hypertension
- Complicated aortic coarctation
- Previous myocardial infarction

Group IV has >27% maternal risk of a cardiac event and pregnancy should be avoided in this risk group.

Iftikhar, S. F., & Biswas, M. (2019). Cardiac disease in pregnancy. StatPearls. Retrieved March 21, 2020, from https://www.ncbi.nlm.nih.gov/books/NBK537261/; American College of Obstetricians and Gynecologists (ACOG). (2019h). ACOG Practice Bulletin No. 212: Pregnancy and heart disease. Obstetrics & Gynecology, 133(5), 320–356; and Malin, G. L., & Wallace, S. V. (2019). Cardiac disease in pregnancy. Obstetrics, Gynecology & Reproductive Medicine, 29(2), 51–55.

Maternal mortality varies directly with the functional class at pregnancy onset. ACOG has adopted a three-tiered classification according to the risk of death during pregnancy (Box 20.1).

Pathophysiology

Numerous hemodynamic changes occur in all pregnant women. These normal physiologic changes can overstress the woman's cardiovascular system, increasing her risk for problems. Increased cardiac workload and greater myocardial oxygen demand during

pregnancy place the woman's cardiovascular system at high risk for morbidity and mortality.

Pregnancy causes cardiac output to rise as early as the first trimester, reaching peak values at 20 to 24 weeks, and continues to increase until it plateaus between 28 and 34 weeks' gestation. This rise in cardiac output is due to a 30% to 50% increase in blood volume (stroke volume) and a 30% increase in heart rate. A normal resting heart rate for any pregnant woman can be on average 20 beats per minute (bpm) above her normal values.

TAKE NOTE!

Uterine blood flow increases by at least 1 L per minute, requiring the body to produce more blood during pregnancy. This results in a 25% increase in red blood cells, a 50% expansion of plasma volume during pregnancy, and an overall hemodilution. In addition, the increase in total red blood cellular volume includes an increase in clotting factors and platelets, defining the hypercoagulable state of pregnancy (Blackburn, 2018). These changes start as early as the second month of gestation.

Similarly, cardiac output increases steadily during pregnancy by 30% to 50% over prepregnancy levels. Stroke volume increases 20% to 30% from prepregnant levels, and the maternal heart rate increases by 10 to 20 bpm. The increase is due to both the expansion in blood volume and the augmentation of stroke volume and heart rate. Other hemodynamic changes associated with pregnancy include a decrease in both the systemic vascular resistance and pulmonary vascular resistance, thereby lowering the systolic and diastolic blood pressure. In addition, the hypercoagulability associated with pregnancy might increase the risk of arterial thrombosis and embolization. These normal physiologic changes are important for a successful adaptation to pregnancy but create unique physiologic challenges for the woman with cardiac disease (Comparison Chart 20.1).

Therapeutic Management

Ideally, a woman with a history of congenital or acquired heart disease should consult her health care provider and undergo a risk assessment before becoming pregnant. This risk assessment must consider the woman's functional capacity, exercise tolerance, degree of cyanosis, medication needs, and history of arrhythmias. Data needed for risk assessment can be acquired from a thorough cardiovascular history and examination, a 12-lead electrocardiogram (ECG), and evaluation of oxygen saturation levels by pulse oximetry. The impact of heart disease on a woman's childbearing potential needs to be clearly explained, and providing information on how pregnancy may affect her and the fetus is important. This allows women to make an informed choice about whether they wish to accept the risks associated with pregnancy. When possible, any surgical procedures, such as valve replacement, should be done before pregnancy to improve fetal and maternal outcomes (Cunningham et al., 2018).

If the woman presents for care after she has become pregnant, prenatal counseling focuses on the impact of the hemodynamic changes of pregnancy, the signs and symptoms of cardiac compromise, and dietary and lifestyle changes needed. More frequent prenatal visits (every 2 weeks until the last month and then weekly) are usually needed to ensure the health and safety of the mother and fetus.

Nursing Assessment

There are four key risk factors linked to CVD-related maternal mortality: race/ethnicity (higher risk of death in non-Hispanic black women versus non-Hispanic White women); age (older than 40 years); hypertension/preeclampsia (especially during pregnancy); and obesity (ACOG, 2019h). Frequent and thorough assessments are crucial during the antepartum period to ensure early detection of and prompt intervention for problems. Assess the woman's vital signs, noting any changes. Auscultate the apical heart rate and heart sounds, being especially alert for abnormalities, including irregularities in rhythm or murmurs. Check the client's weight and

compare with baseline and weights obtained on previous visits. Report any weight gain outside recommended parameters. Inspect the extremities for edema and note any pitting.

COMPARISON CHART 20.1 CARDIOVASCULAR CHANGES: PREPREGNANCY VERSUS PREGNANCY

Measurement	Prepregnancy	Pregnancy
Heart rate	72 (±10 bpm)	+10–20%
Cardiac output	4.3 (±0.9 L/min)	+30–50%
Blood volume	5 L	+20–50%
Stroke volume	73.3 (±9 mL)	+30%
Systemic vascular resistance	1,530 (±520 dyne/cm/sec)	–20%
Oxygen consumption	250 mL/min	+20–30%

King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning; Blackburn, S. T. (2018). *Maternal, fetal, & neonatal physiology: A clinical perspective* (5th ed.). Elsevier; and Norwitz, E., Zelop, C., Miller, D., & Keefe, D. (2019). *Evidence-based obstetrics and gynecology*. Wiley Blackwell.

Question the woman about fetal activity, and ask if she has noticed any changes. Report any changes such as a decrease in fetal movements. Ask the woman about any symptoms of preterm labor, such as low back pain, uterine contractions, and increased pelvic pressure and vaginal discharge, and report them immediately. Assess the fetal heart rate and review serial ultrasound results to monitor fetal growth.

Assess the client's lifestyle and her ability to cope with the changes of pregnancy and its effect on her cardiac status and ability to function. Evaluate the client's understanding of her condition and what restrictions and lifestyle changes may be needed to provide the best outcome for her and her fetus. A healthy infant and mother at the end of pregnancy is the ultimate goal. As the client's pregnancy

advances, expect her functional class to be revised based on her level of disability. Suggest realistic modifications.

The nurse plays a major role in recognizing the signs and symptoms of cardiac decompensation. Decompensation refers to the heart's inability to maintain adequate circulation. As a result, tissue perfusion in the mother and the fetus is impaired. Common complaints of normal pregnancy, such as dyspnea, fatigue, palpitations, orthopnea, and pedal edema, mimic symptoms of worsening cardiac disease and create challenges when trying to evaluate pregnant women with cardiac disease. The pregnant woman is most vulnerable for this complication from 28 to 32 weeks' gestation and in the first 48 hours postpartum (Malin & Wallace, 2019). Assess the woman for the following signs and symptoms:

- Shortness of breath on exertion, dyspnea
- Cyanosis of lips and nail beds
- Swelling of face, hands, and feet
- Jugular vein engorgement
- Rapid respirations
- Abnormal heartbeats, reports of heart racing or palpitations
- Chest pain with effort or emotion
- Syncope with exertion
- Increasing fatigue
- Moist, frequent cough

TAKE NOTE!

Assessing the pregnant woman with heart disease for cardiac decompensation is vital because the mother's hemodynamic status determines the health of the fetus.

Nursing Management

Nursing management of the pregnant woman with heart disease focuses on assisting with measures to stabilize the mother's hemodynamic status, because a decrease in maternal blood pressure or volume will cause blood to be shunted away from the uterus, thus reducing placental perfusion. Pregnant women with

cardiac disease also need assistance in reducing risks that would lead to complications or further cardiac compromise; therefore, education and counseling are critical. Collaboration between the cardiologist, obstetrician, perinatologist, and nurse is needed to promote the best possible outcome.

Drug therapy may be indicated for the pregnant woman with a cardiac disorder. Possible drugs include diuretics, such as Lasix, to prevent heart failure; digitalis to increase contractility and decrease heart rates; antiarrhythmic agents (lidocaine); beta-blockers (labetalol); calcium channel blockers (nifedipine) to treat hypertension; and anticoagulants (low–molecular-weight heparin). Warfarin (Coumadin) is not recommended because it crosses the placenta and may have teratogenic effects. It has been associated with spontaneous abortion, multiple birth defects, fetal growth restriction, and stillbirth (Skidmore-Roth, 2021).

The U.S. Food and Drug Administration (FDA) is no longer using drug categories A, B, C, D, and X. The package inserts include three separate categories that provide information in a narrative format. The goal of this labeling is to provide information about the drug to the consumer. They now use specific subheadings under each of the three categories: pregnancy; lactation; and females and males of reproductive potential. For specific changes under each category, please visit the FDA website.

Encourage the woman to continue taking her cardiac medications as prescribed. Review the indications, actions, and potential side effects of the medications. Reinforce the importance of frequent prenatal visits and close medical supervision throughout the pregnancy.

Discuss the need to conserve energy. Help the client prioritize household chores and child care to allow rest periods. Encourage the client to rest in the side-lying position, which enhances placental perfusion.

Encourage the client to eat nutritious foods and consume a high-fiber diet to prevent straining and constipation. Discuss limiting sodium intake if indicated to reduce fluid retention. Contact a dietitian to assist the woman in planning nutritionally appropriate meals.

Assist the woman in preparing for diagnostic tests to evaluate fetal well-being. Describe the tests that may be done, such as ECG and echocardiogram, and explain the need for serial nonstress testing, usually beginning at approximately 32 weeks' gestation. Instruct the woman in how to monitor fetal activity and movements. Urge her to do this daily and report any changes in activity immediately.

Although the morbidity and mortality rates of pregnant women with cardiac disease have decreased greatly, hemodynamic changes during pregnancy (increased heart rate, stroke volume, cardiac output, and blood volume) have a profound effect, which may increase cardiac work and might exceed the functional capacity of the diseased heart. These changes may result in pulmonary hypertension, pulmonary edema, heart failure, or maternal death (Iftikhar & Biswas, 2019). Explain the signs and symptoms of these complications and review the signs and symptoms of cardiac decompensation, encouraging the woman to notify her health care provider if any occur.

Provide support and encouragement throughout the prenatal period. Assess the support systems available to the client and her family, and encourage her to use them. If necessary, assist with referrals to community services for additional support.

During labor, anticipate the need for invasive hemodynamic monitoring, and make sure the woman has been prepared for this beforehand. Monitor her fluid volume carefully to prevent overload. Anticipate the use of epidural anesthesia if a vaginal birth is planned. After birth, assess the client for fluid overload as peripheral fluids mobilize. This fluid shift from the periphery to the central circulation taxes the heart, and signs of heart failure such as cough, progressive dyspnea, edema, palpitations, and crackles in the lung bases may ensue before postpartum diuresis begins. Because hemodynamics do not return to baseline for several days after childbirth, women at intermediate or high risk require monitoring for at least 48 hours postpartum (Cunningham et al., 2018).

Pregnancy offers a unique window through which women at risk of future CVD may be identified. Nurses have the opportunity to implement health monitoring, lifestyle modifications, and other

needed interventions to reduce the burden of future CVD in all of their pregnant clients. Dispelling the myths surrounding CVD in women versus men are important in promoting awareness.

Hypertension in Pregnancy

In the United States, one out of every nine pregnancies are complicated by a hypertensive disorder, and up to 5% are complicated by preeclampsia (Wilkerson & Ogunbodede, 2019). ACOG has recently published revised guidelines for management of hypertension in pregnancy. They have outlined four categories to describe hypertension in pregnancy: preeclampsia/eclampsia, chronic hypertension, chronic hypertension with superimposed preeclampsia, and gestational hypertension. The woman has it or not, with or without severe features (thrombocytopenia, renal insufficiency, impaired liver function, pulmonary edema, and visual or cerebral changes). Proteinuria and edema are no longer required to diagnose preeclampsia. ACOG recommends women with preeclampsia without severe features should give birth at 37 0/7 weeks; women with preeclampsia with severe features give birth at 34 0/7 weeks (ACOG, 2019a).

Chronic Hypertension

Entering pregnancy with chronic hypertension is increasingly common. It is an important risk factor for pregnancy complications, including for the fetus or newborn, poor fetal growth, preterm birth, low birth weight, admission to the NICU, and death, and for the mother, superimposed preeclampsia/eclampsia, acute renal failure, pulmonary edema, surgical birth, placental abruption, stroke, postpartum cardiomyopathy, and mortality (ACOG, 2019b). Chronic hypertension exists when the woman has high blood pressure before pregnancy or before the 20th week of gestation, or when hypertension persists for more than 12 weeks postpartum. The *Eighth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure* (Joint

National Committee [JNC 8], 2018) recently updated blood pressure guidelines:

- *Normal:* Systolic less than 120/80 mm Hg
- *Elevated:* Systolic between 120 and 129 mm Hg and diastolic less than 80 mm Hg
- *Stage 1:* Systolic between 130 and 139 mm Hg or diastolic between 80 and 89 mm Hg
- *Stage 2:* Systolic at least 140 mm Hg or diastolic at least 90 mm Hg
- *Hypertensive crisis:* Systolic over 180 mm Hg and/or diastolic over 120 mm Hg (Alexander, 2019; Bakris, 2019)

Chronic hypertension occurs in up to 22% of women of childbearing age with the prevalence varying according to age, race, and BMI. It complicates at least 5% of pregnancies, with one in four women developing preeclampsia during pregnancy (Bakris, 2019). Chronic hypertension is typically seen in older, obese women with glucose intolerance. The most common complication is preeclampsia, which is seen in approximately 25% of women who enter the pregnancy with hypertension. Worldwide, about 76,000 women die from preeclampsia each year, corresponding to 15% of all maternal deaths (WHO, 2019a). (See Chapter 19 for more information about preeclampsia.)

Therapeutic Management

Preconception counseling is important in fostering positive outcomes. Typically, it involves lifestyle changes such as diet, exercise, weight loss, and smoking cessation. Treatment for women with chronic hypertension focuses on maintaining normal blood pressure, preventing superimposed preeclampsia/eclampsia, and ensuring normal fetal development.

Once the woman is pregnant, antihypertensive agents are considered, but when to start those remains controversial. ACOG recommends treatment only for severe hypertension. Medications used most often to treat hypertension include labetalol hydrochloride

(Trandate), hydralazine hydrochloride (Apresoline), and nifedipine (Procardia) (Troiano et al., 2019).

The U.S. Preventive Services Task Force (USPSTF) recommends daily low-dose aspirin (81 mg/day) after 12 weeks of pregnancy in women with chronic hypertension and other risk factors and for those who are at high risk for preeclampsia to reduce its occurrence (2018).

Lifestyle changes are needed and should continue throughout gestation. The woman with chronic hypertension will be seen more frequently (every 2 weeks until 28 weeks and then weekly until birth) to monitor her blood pressure and to assess for any signs of preeclampsia. At approximately 24 weeks' gestation, the woman will be instructed to document fetal movement. At this same time, serial ultrasounds will be ordered to monitor fetal growth and amniotic fluid volume. Additional tests will be included if the client's status changes.

Nursing Assessment

Nursing assessment of the woman with chronic hypertension involves a thorough history and physical examination. Review the woman's history closely for risk factors. The pathogenesis of hypertension is multifactorial and includes many modifiable risk factors such as smoking, obesity, caffeine intake, excessive alcohol intake, excessive salt intake, and use of nonsteroidal antiinflammatory drugs (NSAIDs). Also be alert for nonmodifiable risk factors such as increasing age and African American race (Stevens, 2019). Ask if the woman has received any preconception counseling and what measures have been used to prevent or control hypertension.

Assess the woman's vital signs, in particular her blood pressure. Evaluate her blood pressure in all three positions (sitting, lying, and standing), and note any major differences in the readings. Assess her for orthostatic hypertension when she changes her position from sitting to standing. Document your findings.

Ask the woman if she monitors her blood pressure at home; if so, inquire about the typical readings. Ask the woman if she uses any medications for blood pressure control, including the drug, dosage, and frequency of administration, as well as any side effects. Ask the woman about lifestyle modifications that she has used to address any modifiable risk factors and their effectiveness.

Hypertension during pregnancy decreases uteroplacental perfusion. Therefore, fetal well-being must be assessed and closely monitored. Anticipate serial ultrasounds to assess fetal growth and amniotic fluid volume. Question the woman about fetal movement and evaluate her report of daily kick counts. Assess fetal heart rate at every visit.

Nursing Management

Preconception counseling is the ideal time to discuss lifestyle changes to prevent or control hypertension. One area to cover during this visit would be the dietary approaches to stop hypertension (DASH) diet, which contains an adequate intake of potassium, magnesium, and calcium. Sodium is usually limited to 2.4 g a day. Suggest aerobic exercise as tolerated. Encourage smoking cessation and avoidance of alcohol. If the woman is overweight, encourage her to lose weight before becoming pregnant, not during the pregnancy (Jordan et al., 2019). Stressing the positive benefits of a healthy lifestyle might help motivate the woman to make the necessary modifications and change unhealthy habits.

Assist the woman with scheduling appointments for prenatal visits every 2 weeks until 28 weeks' gestation and then weekly. Prepare the woman for frequent fetal assessments. Explaining the rationale for the need to monitor fetal growth is important to gain the woman's cooperation. Carefully monitor the woman for signs and symptoms of placental abruption (abdominal pain, rigid abdomen, vaginal bleeding) as well as superimposed preeclampsia (elevation in blood pressure, weight gain, edema, proteinuria). Alerting the woman to these risks can mean early identification and prompt intervention.

Stress the importance of daily periods of rest (1 hour) in the left lateral recumbent position to maximize placental perfusion. Encourage women with chronic hypertension to use home blood pressure monitoring devices. Urge the woman to report any elevations. As necessary, instruct the woman and her family how to take and record a daily blood pressure, and reinforce the need for her to take her medications as prescribed to control her blood pressure and to ensure the well-being of her unborn child. Praising her for her efforts at each prenatal visit may motivate her to continue the regimen throughout her pregnancy.

The close monitoring of the woman with chronic hypertension continues during labor and birth and during the postpartum period to prevent or identify the onset of preeclampsia. Accurate and frequent blood pressure readings and careful administration of antihypertensive medications, if prescribed, are essential components of care. Stressing the need for continued medical supervision after childbirth is vital to motivate the woman to maintain or initiate lifestyle changes and dietary habits and stay compliant with her medication regimen.

RESPIRATORY CONDITIONS

Awareness of pregnancy-associated changes in respiratory physiology is essential in the management of respiratory conditions in pregnancy. During pregnancy, the respiratory system is affected by hormonal changes, mechanical changes, and prior respiratory conditions. These changes can cause a woman with a history of compromised respiration to decompensate during pregnancy. Although upper respiratory infections are typically self-limiting, chronic respiratory conditions, such as asthma or tuberculosis (TB), can have a negative effect on the growing fetus when alterations in oxygenation occur in the mother. The outcome of pregnancy in a woman with a respiratory condition depends on the severity of the oxygen alteration as well as the degree and duration of hypoxia on the fetus.

Asthma

Worldwide, the prevalence of asthma among pregnant women is on the rise; pregnancy leads to a worsening of asthma for many women (CDC, 2019a). Asthma affects up to 8% of pregnancies. One in 13 people have asthma. It is one of the most common and potentially serious medical conditions to complicate pregnancy (Jordan et al., 2019). Maternal asthma is associated with an increased risk of infant death, preeclampsia, IUGR, preterm birth, and low birth weight. These risks are linked to the severity of the asthma; more severe asthma increases these risks (National Asthma Education and Prevention Program [NAEPP], 2019).

Remember Rose, the pregnant teenager with asthma in acute distress described at the beginning of the chapter? What therapies might be offered to control her symptoms? Should she be treated differently than someone who is not pregnant? Why or why not?

Pathophysiology

Asthma is an allergic-type inflammatory response of the respiratory tract to various stimuli such as allergens (pollen and animal dander), irritants (cigarette smoke and chemicals), stress, infections (colds or flu), and physical exertion. It is also known as reactive airway disease because the bronchioles constrict in response to these stimuli. Asthma is characterized by paroxysmal or persistent symptoms of bronchoconstriction including breathlessness, wheezing, chest tightness, cough, and sputum production. In addition to bronchoconstriction, inflammation of the airways produces thick mucus that further limits the movement of air and makes breathing difficult. Insight into the pathogenesis of asthma has changed with the recognition that airway inflammation occurs in almost all cases. The management of asthma focuses on treatment of airway inflammation to decrease airway responsiveness and prevent asthma symptoms (Resnik et al., 2019).

The normal physiologic changes of pregnancy affect the respiratory system. Although the respiratory rate does not change,

hyperventilation increases at term by 48% due to high progesterone levels. Diaphragmatic elevation and a decrease in functional lung residual capacity occur late in pregnancy, which may reduce the woman's ability to inspire deeply to take in more oxygen. Oxygen consumption and the metabolic rate both increases, placing additional stress on the woman's respiratory system (American Academy of Allergy, Asthma, and Immunology [AAAAI], 2019).

Both the woman and her fetus are at risk if asthma is not well managed during pregnancy. When a pregnant woman has trouble breathing, her fetus also has trouble getting the oxygen it needs for adequate growth and development. Severe persistent asthma has been linked to the development of maternal hypertension, low birth weight, preterm birth, preeclampsia, placenta previa, uterine hemorrhage, and oligohydramnios. A woman whose asthma is poorly controlled during pregnancy is at increased risk of preterm birth, low birth weight, and stillbirth (Shebl & Chakraborty, 2019).

The severity of the condition improves in one third of pregnant women, remains unchanged in one third, and worsens in one third (Cunningham et al., 2018). However, the effect of pregnancy on asthma is unpredictable. The greatest increase in asthma attacks usually occurs between 24 and 36 weeks' gestation; flare-ups are rare during the last 4 weeks of pregnancy and during labor (AAAAI, 2019).

Therapeutic Management

The primary goal of management during pregnancy is to maintain adequate oxygenation of the fetus by preventing hypoxic episodes in the mother. Asthma should be treated as aggressively in pregnant women as in nonpregnant women because the benefits of averting an asthma attack outweigh the risks of medications. The ultimate goal of asthma therapy is to prevent hypoxic episodes to preserve continuous fetal oxygenation; improved maternal and perinatal outcomes are achieved with optimal control of asthma. One third of women with asthma develop worsening of control during pregnancy; therefore, close monitoring and reevaluation are essential. Four

important aspects of asthma treatment ensure optimal control: close monitoring, education of clients, avoidance of asthma triggers, and pharmacologic therapy.

Many women with asthma have positive skin tests to allergens, the most common being animal dander, dust mites, cockroach antigens, pollens, and molds. There are nonimmune triggers as well, including strong odors, tobacco smoke, air pollutants, and drugs such as aspirin and beta-blockers. For exercise-triggered asthma, the use of a bronchodilator 5 to 60 minutes before exercise may reduce symptoms. Avoidance of these allergens and triggers can significantly reduce the need for medication and the occurrence of exacerbations during and after pregnancy. All women should be strongly encouraged to stop smoking, but especially those with asthma because they are at increased risk for worsening chronic and acute asthma sequelae.

Allergy injections may benefit those with allergies and asthma, called allergic asthma. Also called immunotherapy, allergy shots do not “cure” asthma in the manner in which, for example, an injection of antibiotics might cure an infection. Instead, allergy shots work a bit more like a vaccine. Allergy injections for asthma contain a very small amount of an allergen (substance causing allergy). Over time, the dosage is increased. Exposure to progressive amounts of the allergen is likely to help the body develop a tolerance to it. If the allergen buildup is effective, the allergic reaction will become much less severe. Allergy injections can reduce the symptoms of allergies and prevent the development of asthma.

Medical therapy includes a stepwise approach in an attempt to use the least amount of medication necessary to control a woman’s asthma and keep her severity in the mild range. When asthma symptoms worsen or are poorly controlled, treatment is stepped up to the next level. Goals of therapy include having normal or near-normal pulmonary function and minimal or no chronic symptoms, exacerbations, or limitations on activities. The final goal is to minimize the adverse effects of treatment. Pharmacologic agents used to treat asthma in pregnancy fall into two categories: rescue agents and maintenance agents. Rescue agents provide immediate

symptomatic relief by reducing acute bronchospasm. Agents used in this category include albuterol and ipratropium. Maintenance agents, by contrast, reduce the inflammation that leads to bronchospasm. Agents used in this category are inhaled steroids. Common ones prescribed include beclomethasone and salmeterol (Troiano et al., 2019).

Nursing Assessment

Obtain a thorough history of the disease, including the woman's usual therapy and control measures. Question the woman about asthma triggers and strategies used to reduce exposure to them (Box 20.2). Review the client's medication therapy regimen.

BOX 20.2 Common Asthma Triggers

- Smoke and chemical irritants
- Air pollution
- Dust mites
- Animal dander
- Seasonal changes with pollen, molds, and spores
- Upper respiratory infections
- Esophageal reflux
- Medications, such as aspirin and NSAIDs
- Exercise
- Cold air
- Emotional stress

American Academy of Allergy, Asthma, & Immunology (AAAAI). (2019). *Asthma and pregnancy*. Retrieved June 16, 2020, from https://www.aaaai.org/conditions-and-treatments/library/asthma-library/asthma-and-pregnancy; King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning; and Shebl, E., & Chakraborty, R. K. (2019). Asthma in pregnancy. StatPearls. Retrieved March 28, 2020, from https://www.ncbi.nlm.nih.gov/books/NBK532283/.

Auscultate the lungs and assess respiratory and heart rates. Include the rate, rhythm, and depth of respirations; skin color; blood pressure and pulse rate; and signs of fatigue. Clients with an acute asthma attack often present with wheezing, chest tightness, tachypnea, nonproductive coughing, shortness of breath, and

dyspnea. Lung auscultation findings might include diffuse wheezes and rhonchi, bronchovesicular sounds, and a more prominent expiratory phase of respiration compared to the inspiratory phase (Jarvis & Eckhardt, 2020). If the pregnancy is far enough along, the fetal heart rate is measured and routine prenatal assessments (weight, blood pressure, fundal height, urine for protein) are completed.

Laboratory studies usually include a complete blood count with differential (to assess the degree of nonspecific inflammation and identify anemia) and pulmonary function tests (to assess the severity of an attack and to provide a baseline to evaluate the client's response to treatment).

Nursing Management

Nursing management focuses on client education about the condition and the skills necessary to manage it: self-monitoring, correct use of inhalers, identifying and limiting exposure to asthma triggers, and following a long-term plan for managing asthma and for promptly handling signs and symptoms of worsening asthma. Client education fosters adherence to the treatment regimen, thereby promoting an optimal environment for fetal growth and development.

Client education should begin at the first prenatal visit. The importance of optimal asthma control and the risks of poor control for the woman and her fetus should be discussed early in pregnancy. Clients should be taught signs and symptoms and which of these should be of concern, as well as who to contact in emergent situations. Women should be observed using their inhalers and correct use reinforced. Frank discussion about the importance of continuing asthma medications and the possible severe consequences for the woman and her fetus with discontinuation is vital.

Ensure that the woman understands drug actions and interactions, the uses and potential abuses of asthma medications, and the signs and symptoms that require medical evaluation. Reviewing potential perinatal complications with the woman is helpful in motivating her to

adhere to the prescribed regimen. At each antepartum visit, reassess the efficacy of the treatment plan to determine whether adjustments are needed.

Taking control of asthma in pregnancy is the responsibility of the client along with her health care team. Providing the client with the knowledge and tools to monitor her condition, control triggers and her environment (Teaching Guidelines 20.2), and use medications to prevent acute exacerbations. Assist the client in taking control. Facilitating a partnership with the woman will improve perinatal outcomes.

TEACHING GUIDELINES 20.2

Teaching to Control Asthma Linked to Environmental Triggers

- Remove any carpeting in the house, especially the bedroom, to reduce dust mites.
- Use allergen-proof encasing on the mattress, box spring, and pillows.
- Wash all bedding in hot water.
- Remove dust collectors in the house, such as stuffed animals, books, and knick knacks.
- Avoid pets in the house to reduce exposure to pet dander.
- Keep humidity <50% to reduce dust mites.
- Use a high-efficiency particulate air (HEPA) filtering system in the bedroom.
- Do not smoke, and avoid places where you can be exposed to passive cigarette smoke from others.
- Dust and vacuum frequently using vacuum with a high-efficiency HEPA filter.
- Avoid use of wood stove heaters within the house.
- Stay indoors, and use air conditioning when the pollen or mold count is high or air quality is poor.
- Wear a covering over your nose and mouth when going outside in the cold weather.
- Avoid exposure to persons with colds, flu, or viruses.

When teaching the pregnant woman with asthma, cover the following topics:

- Signs and symptoms of asthma progression and exacerbation
- Importance and safety of medication to the fetus and to herself
- Warning signs that indicate the need to contact the health care provider
- Potential harm to the fetus and to herself by undertreatment or delay in seeking help
- Prevention and avoidance of known triggers
- Home use of metered-dose inhalers
- Adverse effects of medications

Nurses should instruct and strongly urge women to remain on asthma medications during pregnancy because one third of clients have worsening of their asthma, including those women with mild asthma. There are proven negative effects from exacerbations and poor control on pregnancy outcome, while there are clear benefits of good control. Client education about the importance of good asthma control is essential for improving pregnancy outcomes.

During labor, monitor the client's oxygenation saturation by pulse oximetry and provide pain management through epidural analgesia to reduce stress, which may trigger an acute attack. Continuously monitor the fetus for distress during labor and assess fetal heart rate patterns for hypoxia. Assess the newborn for signs and symptoms of hypoxia.

Rose, the pregnant client described earlier, is concerned about passing her asthma on to her baby. What should the nurse discuss with her? What questions should the nurse ask to help in identifying triggers in Rose's environment to prevent future asthma attacks?

TAKE NOTE!

Successful asthma management can reduce adverse perinatal outcomes: preeclampsia, preterm birth, and low birth weight.

Tuberculosis

TB is a multisystem disease with myriad presentations and manifestations, and it is now the most common cause of infectious disease–related mortality worldwide (WHO, 2020a). Manifestation of the disease can be vague and widespread. It is a disease that has been around for years but never seems to go away completely. Annually, 10 million people fall ill with TB. Despite it being a preventable and curable disease, 1.5 million people die from it each year (WHO, 2020a). Someone in the world is newly infected with TB every second. Overall, one third of the world's population is currently infected with TB (WHO, 2019b).

Although it is not prevalent in the United States, a resurgence was noted starting in the mid-1980s secondary to the AIDS epidemic and immigration. Left undiagnosed and untreated, each person with active TB will infect on average between 10 and 15 people each year (WHO, 2019b). With large numbers of immigrants coming to the United States, all nurses must be skilled in screening for and managing this condition.

In many cultures, the social consequences associated with the diagnosis of TB fall most heavily on women. Difficulties finding a marriage partner and divorce or abandonment among those already married are significant consequences for women from Pakistan, Vietnam, and India (Aggarwal, 2019). Fear of social consequences can translate into delayed or absent health-seeking behavior. In pregnancy, TB that is treated early and adequately has outcomes equivalent to those in nonpregnant women. By contrast, studies have reported an increase in obstetric mortality with increased incidence of spontaneous abortion, stillbirth, low birth weight, congenital anomalies, preterm labor, and preeclampsia in cases in which TB was diagnosed late (Friedman & Tanoue, 2020).

A person becomes infected by inhaling the infectious organism *Mycobacterium tuberculosis,* which is carried on droplet nuclei and spread by airborne transmission. The lung is the major site of involvement, but the lymph glands, meninges, bones, joints, and kidneys can become infected. Women can remain asymptomatic for long periods of time as the organism lies dormant. Pregnant women with untreated TB are more likely to have an underweight infant, an infant with a low Apgar score, and perinatal death (Herchline, 2020). The newborn is at risk of postnatally acquired TB if the mother still has active TB at the time of birth. Therefore, prenatal diagnosis and effective treatment of the mother are essential.

Therapeutic Management

The WHO recommends that the treatment of TB in pregnant women should be the same as that in nonpregnant women and the rest of

the general population. The only exception is that streptomycin should be avoided in pregnancy because it is ototoxic to the fetus.

Medications are the cornerstone of treatment to prevent infection from progressing. The safety of the first-line drugs (isoniazid, rifampin, and ethambutol) for the management of active TB in pregnancy has been established, and therapy improves both maternal and neonatal outcomes.

Pregnant women should start treatment as soon as TB is suspected. The woman with active TB should be treated with isoniazid (INH) (300 mg/day) combined with rifampin (600 mg/day) for 9 months. In addition, pyridoxine (vitamin B6) (50 mg/day) should be given to prevent the peripheral neuropathy that is associated with INH treatment. Women who are being treated with antituberculosis drugs may breastfeed (Resnik et al., 2019).

Nursing Assessment

Review the woman's history for risk factors such as immunocompromised status, recent immigration status, homelessness or overcrowded living conditions, and injectable drug use. Women emigrating from developing countries such as Latin America, Asia, the Indian subcontinent, Eastern Europe, Russia, China, Mexico, Haiti, and Africa with high rates of TB are also at risk.

At prenatal visits, be alert for clinical manifestations of TB, including fatigue, fever or night sweats, nonproductive cough, weakness, slow weight loss, anemia, hemoptysis, fatigue, and anorexia (Macias & Monedero-Recuero, 2019). If TB is suspected or the woman is at risk for developing TB, anticipate screening with purified protein derivative (PPD) administered by intradermal injection. If the client has been exposed to TB, a reddened induration will appear within 72 hours. If the test is positive, anticipate a follow-up chest x-ray with lead shielding over the abdomen, as well as sputum cultures to confirm the diagnosis.

Nursing Management

Adherence to the multidrug therapy is critical to protect the woman and her fetus from progression of TB. Provide education about the disease process, the mode of transmission, prevention, potential complications, and the importance of adhering to the treatment regimen.

Stressing the importance of health promotion activities throughout the pregnancy is important. Some suggestions might include avoiding crowded living conditions, avoiding sick people, maintaining adequate hydration, eating a nutritious, well-balanced diet, keeping all prenatal appointments to evaluate fetal growth and well-being, and getting plenty of fresh air outside. Determining the woman's understanding of her condition and treatment plan is important for adherence. A language interpreter may be needed to validate and reinforce her understanding if she does not speak English.

Breastfeeding is not contraindicated during the time the mother is on the medication regimen and should in fact be encouraged. If the mother is untreated for TB at the time of childbirth, she should not breastfeed or be in direct contact with the newborn until at least 2 weeks after starting antitubercular medications. Untreated mothers can be encouraged to pump their milk to feed their newborns until they can breastfeed directly (American Academy of Pediatrics [AAP], 2019a). Nurses should consult their hospital policies regarding mothers with tuberculosis for guidance. Management of the newborn of a mother with TB involves preventing transmission by teaching the parents not to cough, sneeze, or talk directly into the newborn's face. Nurses need to stay current about new therapies and screening techniques to treat this disease.

HEMATOLOGIC CONDITIONS

Anemia, a reduction in red blood cell volume, is measured by hematocrit (Hct) or a decrease in the concentration of hemoglobin (Hgb) in the peripheral blood. This results in reduced capacity of the blood to carry oxygen to the vital organs of the mother and fetus. Anemia is a sign of an underlying problem but does not indicate its

origin. Anemia during pregnancy is generally defined as an Hgb below 11 g/dL in the first and third trimesters, and below 10.5 g/dL in the second trimester (Blackburn, 2018).

Iron-Deficiency Anemia

Anemia in pregnancy is a global health problem. Iron deficiency is the most common pathologic cause of anemia in pregnancy. Increased risk during pregnancy is due to increased maternal iron needs and demands from the growing fetus, increased erythrocyte mass, and in the third trimester, expanded maternal blood volume (FIGO Working Group, 2019). Anemia affects one fourth of the world's population, and iron deficiency is the predominant cause. Iron-deficiency anemia mainly reflects poor nutrition, principally attributed to poor economic status worldwide. A recent study indicates iron-deficiency anemia is strongly associated with low socioeconomic status, which affects women's knowledge and health-seeking behaviors. The study concludes that empowering women with education and economic status is the key factor in combating anemia in pregnancy to prevent the cycle of associated problems (Habeeb, 2018).

Iron-deficiency anemia accounts for 75% to 95% of the cases of anemia in pregnant women (affecting one in four pregnancies), and is usually related to an iron-deficient diet, gastrointestinal issues affecting absorption, or a short pregnancy interval (Auerbach & Landy, 2020). A woman who is pregnant often has insufficient iron stores to meet the demands of pregnancy. A cohort study of more than half a million pregnant women suggests that maternal anemia in early pregnancy has a negative impact on the fetus's neurodevelopment related to iron deficiency in the developing brain (Orvos, 2019).

The clinical consequences of iron-deficiency anemia include preterm delivery, perinatal mortality, and postpartum depression. Fetal and neonatal consequences include low birth weight, cardiovascular strain, and intellectual disability with poor mental and psychomotor performance (Auerbach & Landy, 2020). With

significant maternal iron depletion, the fetus will attempt to store iron, but at a cost to the mother. Anemia early and at term increases the perinatal risk for both the mother and newborn. The risks of hemorrhage (impaired platelet function) and infection during and after birth also are increased. Clinical symptoms of iron-deficiency anemia include fatigue, diminished quality of life, impaired cognitive function, increased risk for thromboembolic events, diabetes, headache, hypertension, placental abruption, restless legs syndrome, and **pica** (consuming nonfood substances) eating behaviors (Beckert et al., 2019).

Therapeutic Management

The goals of treatment for iron-deficiency anemia in pregnancy are to eliminate symptoms, correct the deficiency, and replenish iron stores. The Office on Women's Health (OWH) recommends iron supplementation for all pregnant women with ferrous sulfate, 325 mg one to three times daily along with 500 mg of ascorbic acid to enhance absorption of the iron (2019). Side effects of iron supplementation are nausea, abdominal pain, constipation, and black stool. Attempting to meet maternal iron requirements solely through diet in the face of diminished iron stores is difficult.

Nursing Assessment

Review the mother's history for factors that may contribute to the development of iron-deficiency anemia, including poor nutrition, hemolysis, pica, multiple gestation, limited intervals between pregnancies, and blood loss. Assess the woman's dietary intake as well as the quantity and timing of ingestion of substances that interfere with iron absorption, such as tea, coffee, chocolate, and high-fiber foods. Ask the woman if she has fatigue, weakness, malaise, anorexia, or increased susceptibility to infection, such as frequent colds. Inspect the skin and mucous membranes, noting any pallor. Obtain vital signs and report any tachycardia.

Prepare the woman for laboratory testing. Laboratory tests usually reveal low Hgb (less than 11 g/dL), low Hct (less than 35%), low

serum iron (less than 30 mcg/dL), microcytic and hypochromic cells, and low serum ferritin (less than 100 mg/dL).

TAKE NOTE!

Hemoglobin and hematocrit decrease normally during pregnancy in response to an increase in blood plasma in comparison to red blood cells. This hemodilution can lead to physiologic anemia of pregnancy, which does not indicate a decrease in oxygen-carrying capacity or true anemia.

Nursing Management

Nursing management of the woman with iron-deficiency anemia focuses on encouraging adherence to iron drug therapy and providing dietary instruction about the intake of iron-rich foods. Although iron constitutes a minimal percentage of the body's total weight, it has several major roles: it assists in the transport of oxygen and carbon dioxide throughout the body, it aids in the production of red blood cells, and it plays a role in the body's immune response.

Stress the importance of taking prenatal vitamins, which contain 27 mg/day of iron, and an iron supplement consistently. Encourage the woman to take the iron supplement with vitamin C–containing fluids such as orange juice, which will promote absorption, rather than milk, which can inhibit iron absorption. Taking iron on an empty stomach improves its absorption, but many women cannot tolerate the gastrointestinal discomfort it causes. In such cases, advise the woman to take it with meals. Instruct the woman about adverse effects, which are predominantly gastrointestinal and include gastric discomfort, nausea, vomiting, anorexia, diarrhea, metallic taste, and constipation. Suggest that the woman take the iron supplement with meals and increase her intake of fiber and fluids to help overcome the most common side effects.

Provide dietary counseling. Recommend foods high in iron, such as dried fruits, whole grains, green leafy vegetables, lean meats, peanut butter, and iron-fortified cereals (Brown, 2020). Anticipate the

need for a referral to a dietitian. Teaching Guidelines 20.3 highlights instructions for the pregnant woman with iron-deficiency anemia.

TEACHING GUIDELINES 20.3
Teaching for the Woman with Iron-Deficiency Anemia

- Take your prenatal vitamin daily; if you miss a dose, take it as soon as you remember.
- For best absorption, take iron supplements between meals and with vitamin C.
- Be aware of the side effects of iron supplementation.
- Avoid taking iron supplements with coffee, tea, chocolate, and high-fiber foods.
- Eat foods rich in iron, such as:
  - Meats, green leafy vegetables, legumes, dried fruits, whole grains
  - Peanut butter, bean dip, whole-wheat fortified breads and cereals
- For best iron absorption from foods, consume the food along with a food high in vitamin C.
- Increase your exercise, fluids, and high-fiber foods to reduce constipation.
- Plan frequent rest periods during the day.

Thalassemia

Thalassemia is a group of hereditary anemias in which synthesis of one or both chains of the hemoglobin molecule (alpha and beta) is defective. Inheritance is autosomal recessive. A low Hgb and a microcytic, hypochromic anemia results. The prevalence and severity of thalassemia depend on the woman's ancestry; individuals of Mediterranean, Asian, Italian, Greek, or African American descent are most frequently affected. Beta-thalassemia is the most common form found in the United States (March of Dimes, 2019b).

Thalassemia occurs in two forms: alpha-thalassemia and beta-thalassemia. Alpha-thalassemia (minor), the heterozygous form, results from the inheritance of one abnormal gene from either parent, placing the offspring in a carrier trait state. Women with alpha-thalassemia have little or no hematologic disease and are clinically asymptomatic (silent carrier state). Beta-thalassemia (major) is the form involving inheritance of the gene from both parents. Beta-thalassemia major can be severe. Genetic counseling might be necessary when decisions about childbearing are being made.

Thalassemia minor has little effect on pregnancy, though the woman will have mild, persistent anemia. This anemia does not respond to iron therapy, and iron supplements should not be prescribed. Several recent studies suggest that pregnancy appears safe for a woman with well-treated beta-thalassemia major who does not have heart disease (Origa & Comitini, 2019).

Management of thalassemia during pregnancy depends on the severity of the disease. Apart from the routine prenatal visit schedule, thalassemic pregnant women need additional care, including regular and periodic evaluation of cardiac function by a cardiologist to prevent fluid overload. Additionally, frequent hemoglobin and ferritin levels should be monitored to avoid iron overload. Identification and screening are important to plan care. The woman's ethnic background, medical history, and blood studies are analyzed. If the woman is determined to be a carrier, screening of the father of the child is indicated. Knowledge of the carrier state of each parent provides the genetic counselor with knowledge about the risk that the fetus will be a carrier or will have the disease (Knutzen & Stoll, 2019). Mild anemia may be present, and instructions to rest and avoid infections are helpful. Nurses should provide supportive care and expectant management throughout the pregnancy.

Sickle Cell Anemia

Sickle cell anemia is an autosomal recessive inherited condition that results from a defective hemoglobin molecule (hemoglobin S). The

typical lifespan of sickled red blood cells (RBCs) is approximately 15 days compared to the 120-day lifespan of normal RBCs. Consequently, women with sickle cell anemia suffer from moderate to severe anemia. Sickle cell disease is no longer a life-threatening disease of childhood but now a chronic disease of adults (James, 2019). It is found most commonly in African American, Southeast Asian, and Middle Eastern populations. Sickle cell disease affects about 1 million individuals worldwide, two thirds of whom live in West Africa. In the United States, approximately 100,000 Americans have the disease, and 2 million have the sickle cell trait. Sickle cell disease occurs once in every 365 African American births. One in 13 African Americans has the sickle cell trait (CDC, 2019b).

Women with sickle cell disease can have more adverse maternal outcomes such as preeclampsia, eclampsia, preterm labor and birth, urinary tract infections, placental abruption, IUGR, low birth weight, and maternal mortalities (Jordan et al., 2019). The gene offers protection against malaria but can be a cause of chronic pain and early death. Life expectancy is shortened as a consequence of renal damage, cardiac damage, and infection (March of Dimes, 2019c). People with only one gene for the trait (heterozygous) will have sickle cell trait without obvious symptoms of the disease and with little effect on the pregnancy.

Pathophysiology

In the human body, the hemoglobin molecule serves as the oxygen-carrying component of the RBCs. Most people have several types of circulating hemoglobin (HbA and HbA2) that make up the majority of their circulatory system. In sickle cell disease, the abnormal hemoglobin S (HbS) replaces HbA and HbA2. This abnormal hemoglobin (HbS) becomes sickle-shaped as a result of any stress or trauma such as infection, fever, acidosis, dehydration, physical exertion, excessive cold exposure, or hypoxia. Signs and symptoms of sickle cell anemia result from hemolysis, vaso-occlusion of vessels, and/or an increased susceptibility to infection. The sickle

shape of the hemoglobin causes clumping together, which blocks the microvasculature. Significant anemia usually results.

Sickle cell anemia during pregnancy is associated with more severe anemia and frequent vaso-occlusive crises with increased maternal and perinatal morbidity and mortality. In pregnant women with sickle cell anemia, complications can occur at any time during gestation, labor and birth, or postpartum. This is believed to be secondary to hormonal modifications, hypercoagulable state, and increased susceptibility to infection. Microvascular sickling in the placental circulation is associated with miscarriages, stillbirth, placental abruption, preeclampsia, preterm labor and birth, IUGR, fetal distress, and low birth weight (Rogers et al., 2019).

Therapeutic Management

Ideally, women with hemoglobinopathies are screened before conception and are made aware of the risks of sickle cell anemia to themselves and to the fetus. A blood hemoglobin electrophoresis (lab study used for both DNA and RNA analysis) is done for all women from high-risk ancestry at their first prenatal visit to determine the types and percentages of hemoglobin present. This information should help them in making reproductive decisions.

Treatment depends on the health status of the woman. The effect of sickle cell disease on pregnancy depends on which manifestations the woman is experiencing. For example, sickle cell anemia combined with the increased blood volume in pregnancy increases the risks for heart failure should fluid overload occur in therapy for the anemia (Cunningham et al., 2018).

Early and continuous prenatal care is needed to safeguard the fetus or newborn from potential complications during the antepartum, intrapartum, and postpartum periods. Toward this end, prenatal visits for the first and second trimesters should be scheduled more frequently. During pregnancy, only supportive therapy is used: blood transfusions for severe anemia, analgesics for pain, and antibiotics for infection.

Nursing Assessment

Assess the woman for signs and symptoms of sickle cell anemia. Ask the woman if she has anorexia, dyspnea, or malaise. Inspect the color of the skin and mucous membranes, noting any pallor. Be alert for indicators of sickle cell crisis, including severe abdominal pain, muscle spasms, leg pains, joint pain, fever, stiff neck, nausea and vomiting, and seizures (Jordan et al., 2019).

Nursing Management

Clients require emotional support, education, and follow-up care to deal with this chronic condition, which can have a great impact on the woman and her family. Monitor vital signs, fetal heart rate, weight gain, and fetal growth. Assess hydration status at each visit and urge the client to drink eight to 10 glasses of fluid daily to prevent dehydration. Iron supplementation is not recommended for women with sickle cell disease (Norwitz et al., 2019). Teach the client about the need to avoid infections (including meticulous hand hygiene), cigarette smoking, alcohol consumption, and temperature extremes.

Assist the woman in scheduling frequent fetal well-being assessments, such as biophysical profiles, nonstress tests, and contraction stress tests, and monitor laboratory test results for changes. Throughout the prenatal period, be alert for early signs and symptoms of crisis.

During labor, encourage rest and provide pain management. Oxygen supplementation is typically used throughout labor, along with IV fluids to maintain hydration. The fetal heart rate is monitored closely. After giving birth, the woman is fitted with antiembolism stockings to prevent blood clot formation. Before discharge from the facility after birth of the newborn, discuss family planning options.

The ability to predict the clinical course of sickle cell anemia during pregnancy is difficult. Outcomes have improved for pregnant women with the disease, and currently, the majority can achieve a successful live birth. However, pregnancy is associated with an increased incidence of morbidity and mortality. Optimal management during pregnancy should be directed at preventing pain crises,

chronic organ damage, and early mortality using a multidisciplinary team approach and prompt, effective, and safe relief of acute pain episodes. Although these measures do not remove the risk of maternal and fetal complications, they are thought to minimize them, promoting a successful pregnancy outcome. As part of the obstetric health care team, the nurse provides nursing interventions for the labor and postpartum client aimed at pain management, maternal/fetal safety, and client education. The overall objective is a healthy outcome for the childbearing family. The nurse has a vital role in making this happen.

AUTOIMMUNE DISORDERS

Autoimmune disorders are a group of more than 80 distinct diseases that emerge when the immune system launches an immune response against its own cells and tissues. It is thought that a genetic predisposition, environmental triggers, and hormones all contribute disease development and activity. Two distinct types of autoimmune disease are prevalent:

1. Localized disorders target specific organs such as the thyroid gland in Hashimoto thyroiditis and Graves disease.
2. Systemic disorders affect multiple organs. For example, in systemic lupus erythematosus (SLE), the immune system can target the lungs, hearts, joints, kidneys, brain, and RBCs.

Autoimmune disorders may cause mild insidious symptoms that come and go or debilitating conditions with high mortality.

Women suffer from autoimmune disease more often than men. According to the Centers for Disease Control and Prevention (CDC, 2019c), autoimmune diseases affect approximately 8% of the population, 90% of whom are women. Autoimmune diseases are the third most common category of disease in the United States after cancer and heart disease; they affect approximately 5% to 8% of the population or 14 to 22 million people (CDC, 2019c). Previously, the general advice to women with autoimmune diseases, especially SLE, multiple sclerosis, or rheumatoid syndromes, was to avoid

pregnancy because there was a high risk of maternal and fetal morbidity and mortality. However, it is now clear that these risks can generally be reduced by avoiding pregnancy when the diseases are active and continuing appropriate medication to reduce the chances of disease flare during pregnancy.

Systemic Lupus Erythematosus

Lupus disease, also known as **systemic lupus erythematosus (SLE)**, is diagnosed based on laboratory values, symptoms, and signs. SLE is a chronic, relapsing autoimmune disease of the connective tissues that can affect various organs, such as the skin, joints, kidneys, and serosal membranes. Lupus is of unknown etiology, but it is thought to be a failure of the regulatory mechanisms of the autoimmune system. It is usually managed with antiinflammatory and antirheumatic medications. Several triggers that cause the disease to activate include estrogen; cigarette smoking; infections, especially Epstein–Barr virus; physical or psychological stress; exposure to ultraviolet light; and pregnancy. Lupus symptoms may include swollen joints, extreme fatigue, oral ulcers, skin rashes, and sensitivity to sunlight (Bermas & Smith, 2019). Lupus is a complex disorder characterized by periods of relative inactivity and periods of disease exacerbation (flare-ups). To be diagnosed with SLE, a woman must have at least four out of 11 positive American College of Rheumatology criteria, which include red rash on face, photosensitivity, oral ulcers, arthritis, serositis, renal disease, seizures, fatigue, weight changes, anemia, and a positive antinuclear antibody test (Fava & Petri, 2019).

The overall incidence of lupus in the United States is approximately 130 per 100,000 individuals. The peak onset occurs between ages 15 and 45 with the majority of cases diagnosed in women who are in their childbearing years. SLE is more common among those of African American, African Caribbean, Asian, Native American, and Hispanic descent (Bartels, 2019).

Pathophysiology

The autoimmune responses in SLE prevent the body from recognizing the self from the nonself, thus allowing antibodies to be formed that attack the body's own cells and proteins. This activity causes suppression of the body's normal immunity and damage to the body tissue. The autoimmune response may initially involve one organ or several. The most common organs and organ systems involved are the cardiovascular, integumentary, musculoskeletal, and nervous systems and the kidneys and lungs. In pregnancy, inflammation of the connective tissue of the decidua can result in placental implantation problems and poor functioning (King et al., 2019).

Women with SLE are at increased risk for adverse pregnancy outcomes and CVD. A pregnancy with lupus is prone to complications, including flares of disease activity during pregnancy or in the postpartum period, preeclampsia, pregnancy loss, miscarriage, stillbirth, fetal growth restriction, lupus nephritis, and preterm birth. Active lupus nephritis poses the greatest risk. The recognition of a lupus flare during pregnancy may be difficult because the signs and symptoms may mimic those of normal pregnancy (De Carolis et al., 2019).

Therapeutic Management

The focus of therapy is to control disease flare-ups, suppress symptoms, and prevent organ damage. Treatment decisions are based on the severity of the condition and organ involvement. Treatment of SLE in pregnancy is generally limited to NSAIDs like ibuprofen (Advil), prednisone (Deltasone), and an antimalarial agent, hydroxychloroquine (Plaquenil). During pregnancy in the woman with SLE, the goal is to keep drug therapy to a minimum (King et al., 2019).

Nursing Assessment

The time at which the nurse comes in contact with the woman in her childbearing life cycle will determine the focus of the assessment. If the woman is considering pregnancy, it is recommended that she postpone conception until the disease has been stable or in remission for 6 months. Active disease at time of conception and history of renal disease increase the likelihood of a poor pregnancy outcome (Cunningham et al., 2018). In particular, if pregnancy is planned during periods of inactive or stable disease, the result is often giving birth to healthy full-term babies without increased risks of pregnancy complications. Nonetheless, pregnancies with most autoimmune diseases are still classified as high risk because of the potential for major complications. Preconception counseling should include the medical and obstetric risks of spontaneous abortion, stillbirth, fetal death, fetal growth restriction, preeclampsia, preterm labor, and neonatal death and the need for more frequent visits for monitoring the condition (Do & Druzin, 2019).

If the woman is already pregnant when the nurse encounters her, the nurse needs to assess for:

- Duration and presence of SLE signs and symptoms (fatigue, fever, malaise, polyarthritis, skin rashes, and multiorgan involvement)
- Evidence of anemia, thrombocytopenia, and thrombophilia
- Underlying renal disease (check the urine for protein and specific gravity)
- Signs of flare-ups
- Abnormalities in laboratory tests
- Signs of infection (check at each prenatal visit especially urinary tract infections and upper respiratory infections since prednisone can mask signs of infection and lower resistance)
- Fetal well-being and growth (check using ultrasound, fundal height measurements, nonstress tests, and biophysical profiles)

Nursing Management

The nurse should discuss with the woman the importance of having good control over her SLE condition throughout the pregnancy. Discussions should focus on the effects of SLE during the pregnancy and possible risk for exacerbations. Emphasize the importance of

frequent prenatal visits to detect early preeclampsia, preterm labor, or infections. Instruction should cover the implications and potential side effects of all drug therapies prescribed. Teach energy conservation techniques to prevent fatigue, signs and symptoms to report (extreme fatigue, edema, confusion, abdominal pain, weight loss, leg pain, anorexia), and the need for frequent and close monitoring for fetal well-being.

After childbirth, a discussion of birth control and the effects of the various methods on the disease is essential. Referral to self-help groups and local and national SLE organizations is important for further education of the woman and her family.

SLE can greatly complicate a pregnancy if close supervision is not maintained. The keys to a successful outcome for the mother and her infant include an accurate assessment of the disease and of the various systems involved, and vigilance during the pregnancy for disease progression, effects on the fetus, and development of complications. Nursing care should be directed at early detection of problematic signs and symptoms, education of the mother and family, careful evaluation of the fetal status, and providing support to assist the mother in strengthening her coping strategies.

Multiple Sclerosis

Multiple sclerosis (MS) is a chronic inflammatory, demyelinating autoimmune disorder of the central nervous system. The Multiple Sclerosis Association of America (MSAA) estimates that approximately 1 million people in the United States have MS (2020). It is more commonly seen in women than in men, and the mean age of onset is 30 years. Globally, approximately 2.5 million are affected. There is no cure for the disease, and the disease usually becomes a chronic condition.

In the early inflammatory course of MS, autoreactive T-cells cross the blood–brain barrier, attacking myelin proteins and leading to inflammation and demyelination. As the inflammatory process continues, repeated injury results of the myelin membrane with progressive neurodegeneration. The pathologic hallmark of MS can

be described as multicentric, multiphasic central nervous system inflammation with resultant demyelination (Olek & Mowry, 2019).

Uncomplicated MS does not have adverse effects on fertility, labor, or birth. Rates of spontaneous abortion, congenital anomalies, and fetal mortality are no higher among women with MS when compared with women in the general population. While there is ample evidence that the disease doesn't impact pregnancy, many women living with MS still question their ability to have children and how it will impact their disease in the future (Coyle et al.,2019). There is no indication that women with MS require different care or management during the labor and birth process. Pregnant women with MS tend to have fewer relapses during gestation with a subsequent increase in disease activity in the first 3 months postpartum. Breastfeeding does not seem to have an influence on severity or frequency of exacerbations or the health of mothers and has been shown to decrease MS relapse rates during the first 6 months postpartum (Kaplan, 2019). Breastfeeding should be encouraged as long as the woman is not being treated with disease-modifying agents.

The clinical presentation of MS can be similar to common pregnancy-related symptoms, especially fatigue, weakness, constipation, urinary frequency, balance problems, back pain, and visual changes. The similarity of the symptoms makes it difficult to attribute any symptoms that may develop during an established pregnancy to the disease process. These symptoms should be assessed carefully to assess MS exacerbations (Toscano & Thornburg, 2019).

The focus of therapy for MS is to prevent clinical relapse and postpone neurodegeneration and the subsequent disability. Current medications include antiinflammatory drugs, immunosuppressants, immunomodulators/biologic agents, and a variety of complementary and alternative therapies such as vitamin/mineral supplementation, homeopathy, botanical products, and antioxidants. Complementary and alternative therapies have not been proven to reduce relapse rates or disease progression, but many people with MS turn to them (King et al., 2019). Most medications used in MS treatment are not

FDA-approved during pregnancy, but many have been used and have not been shown to have adverse effects.

Nursing care is similar to that outlined previously under SLE. The need for support at this life-changing time is crucial. Continuity of care, access to information tailored to the woman's needs, and having a point of contact are all important aspects of nursing care.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is characterized by joint inflammation and progressive disability and is one of the most common chronic autoimmune disorders. It is predominant in women, commonly affecting women of childbearing age and may complicate pregnancy. RA primarily affects synovial joints and tissues of the hands and feet, but any joint can be involved. Over time, bone and cartilage are damaged by the chronic inflammation process, resulting in joint deformity and loss of function. Progression of the disease and ensuing disability is unpredictable.

RA affects approximately 1 million adults in the United States. It is present in nearly all geographic areas and affects all ethnic groups. The disease typically presents between 30 and 50 years of age and affects twice as many women as men (American College of Rheumatology, 2019). The course of RA during pregnancy is usually benign. In about three fourths of pregnancies, the symptoms of the disease lessen. In these cases, most women experience relief in the first trimester that continues throughout the pregnancy. For many women with RA, pregnancy can provide a reprieve from long-term joint pain and inflammation, but others will not experience remission and will continue to need medication. RA does not adversely affect pregnancy outcomes. With occasional exceptions, RA returns after the third to fourth month postpartum (Arthritis Foundation, 2019).

Individuals with RA typically present with pain, swelling, and tenderness in joints; decreased mobility; and stiffness after periods of inactivity. Treatment of RA focuses on reducing joint inflammation, managing pain, and preventing joint destruction. The categories of medications used to accomplish this are NSAIDs, glucocorticoids,

hydroxychloroquine, methotrexate, immunomodulators/biologic agents, and complementary and alternative therapies such as physical therapy, exercise, acupuncture, and joint splinting for pain relief. During pregnancy, medications are limited to hydroxychloroquine, glucocorticoids, and NSAIDs. Methotrexate is contraindicated during pregnancy (King et al., 2019). Careful preconception counseling and risk assessment is important in women with RA. Antibody status and all medications need to be reviewed before pregnancy. Maintaining low disease activity before and during pregnancy is essential for optimal outcomes.

Nursing care should address the teratogenicity (the ability to cause birth defects) and adverse effects of some of the medications used to treat RA. Methotrexate and leflunomide should be avoided completely due to the toxic effect on the fetus. Women with RA must be monitored closely following childbirth because most are likely to have arthritis flare-ups during the postpartum period. The general nursing care is similar to that outlined for the low-risk pregnant woman. Nurses caring for women with any disability (physical or cognitive) in general need to provide level-appropriate education on all reproductive health issues and improved access to health care. The woman's specific disability, her resources, and her approach to pregnancy and childbirth all help shape her experience. The nurse can play a role in making the experience a positive, memorable time in the woman's life. Care for the woman with a disability should be well planned and coordinated by ensuring all documentation of the woman's needs and concerns is readily available to all personnel involved in her care. All members of the health care team should be involved in the plan of care and kept up to date of any changes. It is essential that the nurse facilitate care to ensure continuity of care throughout the woman's pregnancy and childbirth experience (Jordan et al., 2019).

INFECTIONS

A wide variety of infections can affect the progression of pregnancy, possibly negatively impacting the outcome. The effect of the infection depends on the timing and severity of the infection and the body systems involved. Common viral infections include cytomegalovirus, rubella, herpes simplex, hepatitis B, varicella, parvovirus B19, and several sexually transmitted infections (STIs; Table 20.4). Toxoplasmosis and group B streptococcus are common nonviral infections. Only the most common infections will be discussed here.

TABLE 20.4 Sexually Transmitted Infections Affecting Pregnancy

Infection/Organism	Effect on Pregnancy and Fetus/Newborn	Implications
Syphilis (*Treponema pallidum*)	Maternal infection increases risk of premature labor and birth. Newborn may be born with congenital syphilis, causing jaundice, rhinitis, anemia, IUGR, and central nervous system involvement.	All pregnant women should be screened for this STI and treated with benzathine penicillin G 2.4 million units IM to prevent placental transmission.
Gonorrhea (*Neisseria gonorrhea*)	Majority of women are asymptomatic. It causes ophthalmia neonatorum in the newborn from birth through infected birth canal.	All pregnant women should be screened at first prenatal visit with repeat screening in the third trimester. All newborns receive mandatory eye prophylaxis with tetracycline or erythromycin within the first hour of life. Mother is treated with ceftriaxone (Rocephin) 125 mg IM in a single dose before going home.
Chlamydia (*Chlamydia trachomatis*)	Majority of women are asymptomatic. Infection is associated with infertility and ectopic pregnancy, spontaneous abortions, preterm labor, premature rupture of membranes, low birth weight, stillbirth, and neonatal mortality. Infection is transmitted to the newborn through vaginal birth.	All pregnant women should be screened at the first prenatal visit and treated with erythromycin.

	Neonate may develop conjunctivitis or pneumonia.	
Human papillomavirus (HPV)	Infection causes warts in the anogenital area, known as condylomata acuminata. These warts may grow large enough to block a vaginal birth. Fetal exposure to HPV during birth is associated with laryngeal papillomas.	Warts are treated with trichloroacetic acid, liquid nitrogen, or laser therapy under colposcopy. Two HPV vaccines have been FDA-approved (9-valent Gardasil and Cervarix) against the viral types most likely to cause cervical cancer (types 16 and 18) and genital warts (types 6 and 11) and have been licensed in the United States for girls and women 9–26 years old. The vaccines are 95–100% effective. The vaccines are now recommended for young girls and boys.
Trichomonas (*Trichomonas vaginalis*)	Infection produces itching and burning, dysuria, strawberry patches on cervix, and vaginal discharge. Infection is associated with premature rupture of membranes and preterm birth.	Treatment is with a single 2-g dose of metronidazole (Flagyl).

Cytomegalovirus

Cytomegalovirus is a member of the herpesvirus family, which includes herpes simplex virus (HSV) types 1 and 2, varicella zoster virus, and Epstein–Barr virus. Cytomegalovirus (CMV) infects more than 60% of the human population. Humans are the only known hosts of CMV, which is transmitted via body fluids. Worldwide, the birth prevalence is estimated at seven per 1,000 births with the highest rates seen in developing countries (Leruez-Ville et al., 2020). It is typically asymptomatic in most individuals. CMV is the most common congenital and perinatal viral infection in the world (Leruez-Ville et al., 2020) (Fig. 20.4). CMV is the leading cause of congenital infection, with morbidity and mortality at birth and sequelae. Each year, approximately 1% to 7% of pregnant women acquire a primary CMV infection (Akhter, 2019). Of these, about 30% to 40% transmit the infection to their fetuses (Akhter, 2019; CDC, 2019d). The risk of serious fetal injury is greatest when maternal infection develops in the first trimester or early in the second trimester. There is no proven in utero treatment for infected fetuses (Norwitz et al., 2019). Between 10% and 15% of congenitally infected infants are acutely symptomatic at birth, and most of the survivors have serious long-term complications (March of Dimes, 2019d). It is a leading cause of hearing loss and intellectual disability in the United States. Pregnant women acquire active disease primarily from sexual contact, blood transfusions, kissing, and contact with children in daycare centers. It can also be spread through vertical transmission from mother to child in utero (causing congenital CMV), during birth, or through breastfeeding. The virus can be found in virtually all body fluids. Prevalence rates in women in the United States range from 50% to 85% (CDC, 2019d). In the United States, approximately one in 60 people undergo seroconversion each year. Although prevalent in U.S. population, CMV is not easily transmitted from host to recipient. CMV is transmitted by direct contact with infectious body fluids, such as urine, saliva, blood, tears, semen, and breast milk. The incidence of primary CMV infection in pregnant women in the United States ranges from 1% to 4% (CDC, 2019d). CMV infection during pregnancy may result in abortion, stillbirth, low birth weight, IUGR, microcephaly, deafness, blindness, intellectual disability, jaundice, or

congenital or neonatal infection. If it occurs during pregnancy, the first or primary infection is the most dangerous to the fetus; the fetus has a 30% to 40% chance of being infected (CDC, 2019d).

FIGURE 20.4. Clinical appearance of infant with congenital cytomegalovirus with stigmata of disease, including petechial rash, microcephaly, jaundice, and abnormal posture of upper extremities secondary to central nervous system damage.

There are three time periods during which mother-to-child transmission can occur: in utero, during birth, and after birth. However, permanent disability only occurs in association with in utero infection. Such disability can result from maternal infection during any point in the pregnancy, but more severe disabilities are usually associated with maternal infection during the first trimester.

Most women are asymptomatic and do not know that they have been exposed to CMV. Symptoms of CMV in the fetus and newborn, known as CMV inclusion disease, include hepatomegaly, thrombocytopenia, IUGR, jaundice, microcephaly, hearing loss, chorioretinitis, and intellectual disability. Newborns that are asymptomatic at birth may go on to develop late

neurodevelopmental sequelae, with sensorineural hearing loss the most common condition (Rogan & Beigi, 2019). Prenatal screening for CMV infection is not routinely performed. Unfortunately, a preventive vaccine remains elusive at this time. Since there is no therapy to prevent or treat CMV infections, nurses are responsible for educating and supporting childbearing-age women at risk for CMV infection. Stressing the importance of good hand hygiene and the use of sound hygiene practices can help to reduce transmission of the virus. A few specific hygiene guidelines for pregnant women include:

- Wash hands frequently with soap and water and wear gloves, especially after diaper changes, feeding, wiping nose or drool, and handling children's toys.
- Do not share cups, plates, utensils, food, or toothbrushes.
- Do not share towels or washcloths.
- Do not put a child's pacifier in your mouth.
- Clean toys, countertops, and other surfaces that come in contact with children's urine or saliva.
- Practice safe sex, including limiting sexual partners and using condoms consistently.

Rubella

Rubella is a global public health problem with more than 100,000 cases reported annually (Singh, 2020). Rubella, commonly called German measles, is spread by droplets or through direct contact with a contaminated object. The risk of a pregnant woman transmitting this virus through the placenta to her fetus increases with earlier exposure to the virus. When infection occurs within the first month after conception, 50% of fetuses show signs of infection; in the second month following conception, 25% of fetuses will be infected; and in the third month, 10% of fetuses will be affected (Shukla, 2019). Congenital rubella can manifest with a diverse range of symptoms in the newborn, including congenital cataracts, glaucoma, cardiac defects, microcephaly, and hearing and intellectual

disabilities. Hearing impairment is the most common manifestation (Shukla, 2019).

Preconception care has been defined as a set of interventions designed to identify and modify risks to a woman's health or pregnancy outcome through prevention and management. This care should be provided any time a health care provider sees a reproductive age woman. Personal and family history, physical exam, laboratory screening, reproductive plan, nutrition, supplements, weight, exercise, vaccinations, and injury prevention should be reviewed in all women. Folic acid 400 mcg per day, as well as proper diet and exercise, should be encouraged. Women should receive the influenza vaccine if planning pregnancy during flu season; the rubella and varicella vaccines if there is no evidence of immunity to these viruses; and tetanus/diphtheria/pertussis if lacking adult vaccination (Domachowske, 2019).

Education for primary prevention is the key. Ideally, all women have been vaccinated and have adequate immunity against rubella. However, all women are still screened at their first prenatal visits to determine their statuses. A rubella antibody titer of 1:8 or greater proves evidence of immunity. Women who are not immune should be vaccinated during the immediate postpartum period so that they will be immune before becoming pregnant again (Stevens, 2019). Nurses need to check the rubella immune status of all new mothers and should make sure all mothers with a titer of less than 1:8 are immunized prior to discharge after birth of the newborn. Adherence to the recommended CDC immunization schedule will go a long way toward primary prevention of rubella.

Herpes Simplex Virus

HSV is a highly contagious, incurable, recurrent infection with high prevalence and rapid acquisition. Genital herpes is an STI caused by the HSV type 1 or type 2. Both types can cause genital infections, though in recent years, HSV-1 has become the predominant cause of genital herpes. Approximately 110 million people are infected with genital herpes in the United States, and 20 million new cases are

diagnosed annually, costing $16 billion in medical costs each year. Most infected persons are unaware of their infection (CDC, 2019e). Neonatal infection with herpes virus occurs in one out of every 3,200 to 10,000 live births, causing serious morbidity and mortality. The global incidence of neonatal herpes is estimated to be approximately 10 cases per 100,000 live births (Demmler-Harrison, 2019). Because herpes is not a reportable disease in all states, reliable data on its true incidence and prevalence are lacking. Despite strategies designed to prevent perinatal transmission, the number of cases of newborn HSV infection continues to rise, mirroring the rising prevalence of genital herpes infection in women of childbearing age (Fig. 20.5) (Rogan & Beigi, 2019).

HSV is a DNA virus with two subtypes: HSV-1 and HSV-2. HSV-1 infections were traditionally associated with oral lesions (fever blisters), while HSV-2 infections occurred in the genital region. Currently, either type can be found in either location, but HSV-1 is predominantly causing genital herpes now (Ayoub et al., 2019).

FIGURE 20.5. Newborn with disseminated herpes simplex virus infection. Note the healing ulcerations on the abdomen of the infant. (From Sweet, R. L., Gibbs, R. S. [2009]. *Infectious diseases of the female genital tract* [5th ed.]. Lippincott Williams & Wilkins.)

Infection occurs by direct contact of the skin or mucous membranes with an active lesion through such activities as kissing, sexual (vaginal, oral, anal) contact, or routine skin-to-skin contact. A primary infection lasts approximately 3 weeks and manifests with multiple genital lesions that begin as vesicles and develop into ulcerative lesions. Recurrent episodes are less severe than those associated with the primary infection. HSV is associated with infections of the genital tract that when acquired during pregnancy, can result in severe systemic symptoms in the mother and significant morbidity and mortality in the newborn. In addition, it may cause spontaneous abortion, birth anomalies, IUGR, or preterm labor. Once the virus enters the body, it never leaves.

Infants born to mothers with primary HSV infections have a 30% to 50% risk of acquiring the infection via perinatal transmission near or during birth. Recurrent genital HSV infections carry a 1% to 3% risk of neonatal infection if the recurrence occurs around the time of

vaginal birth (March of Dimes, 2019e). About one in four pregnant women is infected with genital herpes, though most do not know it. However, only a small number pass the infection on to their newborns (March of Dimes, 2019e).

The greatest risk of transmission occurs when the mother develops a primary infection near term and it is not recognized. Most neonatal infections are acquired at or around the time of birth through either ascending infection after ruptured membranes or contact with the virus at the time of birth. The method and timing of birth in a woman with genital herpes are controversial. The CDC (2019e) recommends that in the absence of active lesions, a vaginal birth is acceptable, but if the woman has active herpetic lesions within 6 weeks of term, a cesarean birth is preferred. All invasive procedures that might cause a break in the infant's skin should be avoided, such as artificial rupture of membranes, fetal scalp electrode, or forceps and vacuum extraction (Jordan et al., 2019).

Management for the woman with genital herpes during pregnancy involves caring for her as well as reducing the risk of newborn herpes. There is no known cure for genital herpes, and the methods of treatment largely treat the symptoms rather than the underlying disease itself. Some health care providers start the mother on prophylactic antiviral medications to prevent an active outbreak at the time of childbirth. No therapy can eradicate HSV, and this chronic infection is noted for its frequent asymptomatic viral shedding. Because the majority of newborn herpes cases result from perinatal transmission of the virus during vaginal birth, and because transmission can result in severe neurologic impairment or death, treatment of the mother with an antiviral agent such as acyclovir (Zovirax) must be started as soon as the culture comes back positive. Since the introduction of acyclovir, newer second-generation antivirals have been introduced (e.g., valacyclovir [Valtrex] and famciclovir [Famvir]) and are available (King et al., 2019). Use of condoms and antiviral mediations assist in preventing transmission. Evidence does not currently support routine HSV serologic screening among asymptomatic pregnant women (Levy et al., 2019), so nurses need to remain knowledgeable about current

practice to provide accurate and sensitive care to all women. Despite the surge in vaccine research, there is unfortunately no readily available or preventative or therapeutic vaccine for HSV to date.

Hepatitis B Virus

Hepatitis B virus (HBV) is one of the most prevalent chronic diseases in the world. It is a serious global public health problem in Asia, Africa, Southern Europe, and Latin America especially. It has infected approximately 2 billion people worldwide, of whom more than 248 million are chronically infected. Life-threatening liver disease (cirrhosis, liver failure, and hepatocellular carcinoma) occurs in as many as 40% of people with hepatitis B. HBV infection causes about 5,000 deaths annually in the United States (Mahale et al., 2019). HBV can be transmitted through contaminated blood, illicit drug use, and sexual contact. The virus is 100 times more infectious than HIV and, unlike HIV, it can live outside the body in dried blood for more than a week (Locarnini & Raimondo, 2019).

Sexual transmission accounts for most adult HBV infections in the United States. Acutely infected women develop hepatitis with anorexia, nausea, vomiting, fever, abdominal pain, and jaundice. In women with acute hepatitis B, vertical transmission occurs in approximately 10% of newborns when infection occurs in the first trimester and in 80% to 90% of newborns when acute infection occurs in the third trimester. Without intervention, 40% of infants born to women who are positive for hepatitis B will have chronic hepatitis B by 6 months of age (CDC, 2019f). In addition, hepatitis B infection during pregnancy is associated with an increased risk of preterm birth, fetal distress during labor, meconium peritonitis, low birth weight, and neonatal death. Newborns infected with HBV are likely to become chronic carriers of the virus, becoming reservoirs for continued infection in the population (CDC, 2019g). The fetus is at particular risk during birth because of the possible contact with contaminated blood at this time.

The CDC (2019h) recommends that all pregnant women should be tested for hepatitis B surface antigen (HBsAg) regardless of previous

HBV vaccine or screening. Infants born to HBsAg-positive mothers should receive single-antigen HBV vaccine and hepatitis B immunoglobulin (HBIG) within 12 hours after birth. Completion of the vaccine schedule is recommended by HBV vaccination at 1 and 6 months (CDC, 2020a). There is a growing body of literature supporting the safety and efficacy of antiviral therapies administered in the third trimester of pregnancy to the reduce the vertical transmission of the HBV from the mother to the fetus, but to date there has not been any formal recommendations (Song et al., 2019).

Nursing Assessment

Review the woman's history for factors placing her at high risk:

- History of STIs
- Household contacts with HBV-infected persons
- Employment as a health care provider
- Abuse of IV drugs
- Prostitution
- Foreign born
- Multiple sexual partners
- Chinese, Southeast Asian, or African heritage
- Sexual partners who are HBV-infected (CDC, 2019g)

At the first prenatal visit, all pregnant women should be screened for HbsAg via blood studies, even if they were previously vaccinated or tested. Expect to repeat this screening later in pregnancy for women in high-risk groups (Norwitz et al., 2019).

Nursing Management

If a woman tests positive for HBV, expect to administer HBV immune globulin (HBIG, Hep-B-Gammagee). The newborn will also receive HBV vaccine (Recombivax-HB, Engerix-B) within 12 hours of birth. The second and third doses of the vaccine are given at 1 and 6 months of age (CDC, 2019f). The CDC recommends routine vaccination of all newborns.

Women who are HbsAg-negative may be vaccinated safely during pregnancy. No current research supports the use of surgical births to

reduce vertical transmission of HBV. Breastfeeding by mothers with chronic HBV infection does not increase the risk of viral transmission to their newborns, nor is it a contraindication to breastfeeding unless the woman is taking antiviral medication and has bleeding nipples. Since hepatitis B is spread by infected blood, women with bleeding nipples should abstain from breastfeeding until they are healed (CDC, 2019i).

Client education related to prevention of HBV is essential. Teach the woman about safer sex practices, good hand hygiene techniques, and the use of standard precautions (Teaching Guidelines 20.4). Protection can be afforded with the highly effective hepatitis B vaccine.

TEACHING GUIDELINES 20.4
Teaching to Prevent Hepatitis B Virus Progression

- Abstain from alcohol and potentially hepatotoxic medications.
- Avoid IV drug exposure or sharing of needles.
- Encourage all household contacts and sexual partners to be vaccinated.
- Receive immediate treatment for any STI.
- Know that your newborn will receive the hepatitis B vaccine soon after birth.
- Use good hand hygiene techniques at all times.
- Avoid contact with blood or body fluids.
- Use barrier methods such as condoms during sexual intercourse.
- Avoid sharing any personal items, such as razors, toothbrushes, or eating utensils.
- Inform all health care providers of your HBV status.

Permanent remission of the disease even with treatment rarely occurs. Therefore, therapy is directed at long-term suppression of viral replication and prevention of end-stage liver disease. Urge the woman to consume a high-protein diet and avoid fatigue. A healthy lifestyle can help delay disease progression. Initiate an open

discussion about the modes of transmission and use of condoms to prevent spread.

Varicella Zoster Virus

Varicella zoster virus (VZV) is one of the eight herpes family viruses. It is the virus that causes both varicella (chickenpox) and herpes zoster (shingles). Primary VZV leads to varicella and establishes latency in dorsal root ganglia. Reactivation of VZV causes herpes zoster. Herpes zoster can occur once immune response against the virus wanes, usually with advancing age.

Pregnant women are at risk for developing varicella when they come in close contact with children who have active infections. Varicella is highly contagious and occurs year-round, but there is a higher incidence during winter and spring months. Maternal varicella can be transmitted to the fetus through the placenta, leading to congenital varicella syndrome if the mother is infected during the first half of pregnancy via an ascending infection during birth or by direct contact with infectious lesions, leading to infection after birth. The varicella vaccine is contraindicated for pregnant women because the effects of the vaccine on the fetus are unknown (CDC, 2019j). Varicella occurs in up to 5% cases per 10,000 pregnancies (Resnik et al., 2019).

Congenital varicella syndrome can occur in newborns of mothers infected during early pregnancy. The vertical transmission rate is estimated to be up to 2% (Speer, 2020). It is characterized by low birth weight, skin lesions in a dermatomal distribution, spontaneous abortion, chorioretinitis, cataracts, pneumonia, fetal growth restriction, delayed milestones, cutaneous scarring, limb hypoplasia, microcephaly, ocular abnormalities, intellectual disability, and early death (Schafer et al., 2019).

Preconception counseling is important for preventing this condition. A major component of counseling involves determining the woman's varicella immunity. Vaccination is the cornerstone of prevention. The vaccine is administered if needed. Varicella vaccine is a live attenuated viral vaccine. It should be administered to all

adolescents and adults 13 years of age and older who do not have evidence of varicella immunity (King et al., 2019). Provide education to women who work in occupations that increase the risk of exposure to the virus, such as daycare workers, teachers of young children, and staff caring for children in institutional settings.

Varicella during pregnancy can be associated with severe illnesses for both the mother and her newborn. If contracted in the first half of pregnancy, some pregnant women are at risk for developing varicella pneumonia, which may put them at risk of life-threatening ventilatory compromise and death. Risk of varicella pneumonia appears to increase during pregnancy (CDC, 2019j). If the mother develops varicella rashes close to her due date, generalized neonatal varicella leading to death in about 30% of cases can be expected (Jordan et al., 2019).

Parvovirus B19

Parvovirus B19 infection, often referred to as fifth disease, occurs worldwide and is extremely common. It is transmitted by respiratory secretions of hand-to-mouth contact. Most infected persons are asymptomatic. The incidence of acute B19 infection in pregnancy is about 3.5%, and the risk of vertical transmission is 25% to 50%. Approximately 35% to 65% of pregnant women are not immune, and vertical transmission is common following maternal infection in pregnancy (Cennimo, 2019). Fetal infection may be associated with a normal outcome, but fetal death may also occur without ultrasound evidence of infectious sequelae (Norwitz et al., 2019). Parvovirus B19 is a common, self-limiting, benign childhood virus that causes erythema infectiosum. It is commonly called fifth disease, referring to its fifth place in a list of common childhood infections. Infection with parvovirus B19 affects one in 400 pregnant women, but the majority have no adverse pregnancy outcomes. Those who do may experience spontaneous abortion and severe fetal anemia.

Pathophysiology

The infection is spread transplacentally, by the oropharyngeal route in casual contact, and through infected blood. Infection of the fetus occurs through transplacental passage of the virus. Acute infection in pregnancy can cause B19 infection in the fetus, leading to nonimmune fetal hydrops (a serious abnormal accumulation of fluid in two or more fetal compartments, including ascites, pleural effusion, pericardial effusion, and skin edema) secondary to severe anemia or fetal loss, depending on the gestational age at the time of infection. The risk to the fetus is greatest when the woman is exposed and infected within the first 20 weeks' gestation. In addition to hydrops, other fetal effects of parvovirus include spontaneous abortion, congenital anomalies (central nervous system, craniofacial, and eye), and long-term effects such as hepatic insufficiency, myocarditis, and learning disabilities (Riley & Fernandes, 2019). Fetal infection with B19 is also associated with intrauterine fetal death, nonimmune hydrops fetalis, thrombocytopenia, myocarditis, and neurologic manifestations. Fetal infection can also remain clinically unrecognized (Domachowske, 2019).

Therapeutic Management

Generally, a diagnosis of parvovirus is based on clinical symptoms and serologic antibody testing for parvovirus immunoglobulin G (IgG) and parvovirus immunoglobulin M (IgM). Parvovirus B19 infection is followed by lifelong immunity, which is shown by positive serum B19 IgG. Pregnant women who have been exposed to or who develop symptoms of parvovirus B19 require assessment to determine whether they are susceptible to infection. If the woman is immune, she can be reassured that she will not develop infection and that the virus will not adversely affect her pregnancy. If she is nonimmune, then referral to a perinatologist is recommended, and counseling regarding the risks of fetal transmission, fetal loss, and hydrops is necessary. Knowledge of how best to manage this infection during pregnancy lags behind our understanding of the potential adverse consequences.

Intrauterine B19 infection is a cause of fetal anemia, hydrops, and demise and perhaps also of congenital anomalies. The best strategy for surveillance of the infected pregnant woman is serial ultrasounds for detection of hydropic changes and fetal anemia, and treatment for severe fetal anemia. Serial ultrasounds are advocated because the rates of fetal death and complications peak 4 to 6 weeks after exposure, but they can occur as late as 3 months following onset of symptoms. The infected newborn is assessed for any anomaly and followed for up to 6 years to identify any sequelae (Martin & Rosenfeld, 2019).

Nursing Assessment

Review the mother's history for any risk factors. Teachers, daycare workers, and women living with school-age children are at highest risk for being seropositive for parvovirus B19, especially if a recent outbreak has occurred in those settings. Also assess the woman for specific signs and symptoms. The characteristic rash starts on the face with a "slapped-cheeks" appearance and is followed by a generalized maculopapular rash. Fever, arthralgia, and generalized malaise are usually present in the mother. Prepare the mother for antibody testing.

Nursing Management

Prevention is the best strategy because there is no treatment for the pregnant woman with a parvovirus B19 infection. Stress the need for hand hygiene after handling children; cleaning toys and surfaces that children have been in contact with; and avoiding the sharing of food and drinks. Screening for parvovirus B19 during early pregnancy may help in early diagnosis, but the cost effectiveness of a national screening program has not been accepted to date. The nurse can provide information regarding risk factors and potential complications if exposed and support the parents' decision.

Group B Streptococcus

Group B streptococcus (GBS) is a naturally occurring bacterium found in approximately 50% of healthy adults. It is a Gram-positive bacteria which colonizes in the gastrointestinal and genitourinary tracts. Women who test positive for GBS bacteria are considered carriers. Carrier status is transient and does not indicate illness. Approximately 50% of pregnant women carry GBS in the rectum or vagina, thus introducing the risk of colonization of the fetus during birth. GBS affects about one in every 1,000 newborns in the United States (March of Dimes, 2019f). Approximately one out of every 100 to 200 newborns born to mothers who carry GBS will develop signs and symptoms of GBS disease. Although GBS is rarely serious in adults, it can be life threatening to newborns. GBS is the most common cause of sepsis and meningitis in newborns and is a frequent cause of newborn pneumonia (Morgan & Cooper, 2019). Newborns with early-onset (within a week after birth) GBS infections may have pneumonia or sepsis, while late-onset (after the first week) infections often manifest in meningitis (CDC, 2019k).

Genital tract colonization poses the most serious threat to the newborn because of exposure during birth and to the mother due to ascending infection after the membranes rupture. GBS colonization in the mother is thought to cause chorioamnionitis, endometritis, and postpartum wound infection.

Therapeutic Management

The principal defense against early-onset GBS infection is administration of antibiotic prophylaxis to mothers during childbirth. Antibiotic therapy is usually effective in treating women with GBS infections of the urinary tract or uterus or chorioamnionitis without any sequelae. According to the CDC guidelines, all pregnant women should be screened for GBS at 35 to 37 weeks' gestation and treated (2019k). Vaginal and rectal specimens are cultured for the presence of the bacterium. Both pregnant women and women during labor who have positive cultures are treated with a penicillin-based antiinfective agent.

Penicillin G is the treatment of choice for GBS infection because of its narrow spectrum. Alternative antibiotics can be prescribed for clients with a penicillin allergy. The drug is usually administered IV at least 4 hours before birth so that it can reach adequate levels in the serum and amniotic fluid to reduce the risk of newborn colonization. Close monitoring is required during the administration of IV antibiotics because severe allergic reactions can occur rapidly.

Nursing Assessment

Review the woman's prenatal history, and ask about any previous infection. Determine if the woman's membranes have ruptured and the time of rupture. Rupture of amniotic membranes more than 18 hours before birth increases the risk for infection (ACOG, 2020b). Monitor the mother's vital signs, reporting any maternal fever greater than 100.4°F (38°C). Assess the woman for other risk factors for perinatal transmission of GBS, including previous colonization with GBS, low socioeconomic status, African American race, age younger than 20 years, positive colonization at 35 to 37 weeks' gestation, GBS in urine sample, previous birth of GBS-positive newborn, preterm birth, and use of invasive obstetric procedures (March of Dimes, 2019f). Document this information to help prevent vertical transmission to the newborn.

Many women with GBS infection are asymptomatic, but they may have urinary tract infections, uterine infections, and chorioamnionitis.

Nursing Management

Nurses play major roles as educators and advocates for all women and newborns to reduce the incidence of GBS infections. Ensure that pregnant women between 36 and 37 weeks' gestation are universally screened for GBS infection during a prenatal visit and if positive, receive appropriate intrapartum antibiotic prophylaxis. Record the results and notify the birth attendant if the woman has tested positive for GBS. During labor, be prepared to administer IV antibiotics to all women who are GBS-positive.

Toxoplasmosis

Toxoplasmosis is a relatively widespread parasitic infection caused by a one-celled organism, *Toxoplasma gondii.* It is found all over the world, and approximately one third of the global population has been infected. It can affect any warm-blooded animal, including humans, but the primary host is the cat. More than 60 million people in the United States may be infected with toxoplasmosis. Estimates suggest that more than 1 million people in the United States become newly infected annually (Gilbert & Peterson, 2020). When a pregnant woman is exposed to this protozoan, the infection can pose serious risks to her fetus through transplacental transfer from the mother to the fetus. Approximately 400 to 4,000 cases of toxoplasmosis occur in newborns annually in the United States (CDC, 2019l). Cats are the definitive hosts of this parasite and shed it in their feces. It is transferred by hand to mouth after touching cat feces while changing the cat litter box or through gardening in contaminated soil. Consuming undercooked infected meat, such as pork, lamb, or venison drinking contaminated water, and eating unwashed fruits and vegetables can also transmit this organism.

A pregnant woman who contracts toxoplasmosis for the first time has an approximately 30% chance of passing the infection to her fetus. Toxoplasmosis acquired during pregnancy means high risk of damage for the fetus in addition to preterm labor and stillbirth (March of Dimes, 2019g). Although the woman typically remains asymptomatic, transmission to her fetus can occur throughout pregnancy. A fetus who contracts congenital toxoplasmosis typically has a low birth weight, enlarged liver and spleen, visual problems, cerebral palsy, hearing loss, seizures, chorioretinitis, jaundice, IUGR, hydrocephalus, microcephaly, neurologic damage, and anemia. Severity varies with gestational age; usually, the earlier the infection, the more severe the effects (Borges et al., 2019).

Treatment of the woman during pregnancy to reduce the risk of congenital infection is a combination of pyrimethamine and sulfadiazine. Treatment with sulfonamides during pregnancy has been shown to reduce the risk of congenital infection.

Although there is much to learn about the best approach to the identification and treatment of toxoplasmosis, it is known that early treatment leads to the best neurodevelopmental outcomes in infants. Prevention is the key to managing this infection. Nurses play a key role in educating the woman about measures to prevent toxoplasmosis (Teaching Guidelines 20.5).

TEACHING GUIDELINES 20.5
Teaching to Prevent Toxoplasmosis

- Avoid eating raw or undercooked meat, especially lamb or pork. Cook all meat to an internal temperature of 160°F (71°C) throughout.
- Clean cutting boards, work surfaces, and utensils with hot, soapy water after contact with raw meat or unwashed fruits and vegetables.
- Peel or thoroughly wash all raw fruits and vegetables before eating them.
- Wash hands thoroughly with warm water and soap after handling raw meat.
- Avoid feeding the cat raw or undercooked meats.
- Wash hands with soap and water after handling fruits and vegetables.
- Avoid emptying or cleaning the cat's litter box. Have someone else do it daily.
- Keep outdoor sandboxes covered to prevent cat feces contamination.
- Keep the cat indoors to prevent it from hunting and eating birds or rodents.
- Avoid uncooked eggs and unpasteurized milk.
- Wear gardening gloves when in contact with outdoor soil.
- Avoid contact with children's sandboxes, because cats can use them as litter boxes.

Women Who Are HIV-Positive

The **human immunodeficiency virus (HIV)** infection is a chronic infection causes by the retrovirus HIV infection of T-cells that express CD4 receptors causing immunodeficiency. Once the CD4-positive cell count falls below a certain level, HIV infection causes increased susceptibility to infections, cancers, and neurologic damage (Peterson, 2019). HIV is transmitted by blood and body fluids. The number of people in the United States who contract HIV infection annually is estimated at nearly 38,000 (UNAIDS, 2020). Worldwide, 1.8 million people are newly infected with HIV, and more than 50% of these infections occur in women (Pitzen et al., 2019). According to the most recent incidence estimates, more than 1.1 million people in the United States are living with HIV infection, and almost one in nine women are unaware of their status (CDC, 2019m).

Despite the revolutionary strides that have been made in treatment and detection and recent clinical advances and cautious optimism associated with combination therapies and vaccines, the number of individuals who are HIV-positive continues to climb worldwide. To achieve a durable end to the HIV pandemic, a vaccine remains essential in the fight against this virus. Progress continues with new vaccine concepts and insights moving forward, making an effective vaccine against HIV a possibility for the near future (Burton, 2019). Also, despite dramatic reductions in perinatal transmission of HIV in the United States, barriers to prevention still exist, and perinatal HIV infections continue.

Initially, HIV/AIDS was associated with the male homosexual community and IV drug users, but currently the prevalence of HIV/AIDS is now increasing more rapidly among women than men. Women account for one in four people living with HIV in the United States, and are the fastest growing segment of persons becoming infected with HIV; transmission in women occurs most frequently from sexual contact (87%) and from IV drug use (12%) (CDC, 2019n). Most women, a large number of whom are mothers, have acquired the disease through heterosexual contact. The risk of acquiring HIV through heterosexual contact is greater for women due to exposure to the higher viral concentration in semen. In addition,

sexual intercourse may cause breaks in the vaginal lining, increasing the chances that the virus will enter the woman's body. AIDS is the third leading cause of death among all U.S. women aged 25 to 44 years and the leading cause of death among African American women in this age group. At some point in their lifetimes, an estimated one in 32 African American women will be diagnosed with an HIV infection (CDC, 2019n).

Pathophysiology

HIV is an RNA retrovirus that is transmitted through infected blood and bodily secretions. The three recognized modes of HIV transmission are unprotected sexual intercourse with an infected partner, contact with infected blood or blood products, and perinatal transmission.

TAKE NOTE!

HIV is not transmitted by doorknobs, faucets, toilets, dirty dishes, mosquitoes, wet towels, coughing or sneezing, shaking hands, or being hugged or by any other indirect method.

HIV proceeds through several stages after infecting the immune system's CD4 cells (a type of T-cell). The virus attacks the T4 cells, decreases the CD4 cell count, and disables the immune system. HIV can progress to a severe immunosuppressed state termed **acquired immunodeficiency syndrome (AIDS)**. AIDS is a progressive, debilitating disease that suppresses cellular immunity, predisposing the infected person to opportunistic infections and malignancies. The CDC defines AIDS as an HIV infection with a specific opportunistic infection or a CD4 count of less than 200. Eventually, death occurs. The time from infection with HIV to development of AIDS is a median of 11 years but varies depending on whether the client is taking current antiretroviral therapy (ART) (McCance & Huether, 2019). Research indicates that pregnancy does not accelerate the progression of HIV to AIDS or death (King et al., 2019).

Once infected with HIV, the woman develops antibodies that can be detected with an enzyme-linked immunosorbent assay (ELISA) and confirmed with the Western blot test. Antibodies develop within 6 to 12 weeks after exposure, though this latent period is much longer in some people. Table 20.5 highlights the four stages of HIV infection according to the CDC (2019o).

TABLE 20.5 Stages of HIV Infection Outlined by the CDC

Stages	Description	Clinical Picture
I	Acute infection	Early stage with pervasive viral production Flu-like symptoms 2–4 weeks after exposure Signs and symptoms: weight loss, low-grade fever, fatigue, sore throat, night sweats, and myalgia Ability to spread HIV is highest during this stage because large amounts of HIV are being produced in the body, and the CD4 count drops.
II	Asymptomatic infection or clinical latency	Viral replication continues within lymphatics, but slows down Usually free of symptoms; lymphadenopathy
III	Persistent generalized lymphadenopathy	Possibly remaining in this stage for years; AIDS develops in most within 7–10 years Opportunistic infections occur
IV	End-stage disease (AIDS)	Severe immune deficiency; very vulnerable to infections High viral load and low CD4 counts Signs and symptoms: bacterial, viral, or fungal opportunistic infections, fever, wasting syndrome, fatigue, neoplasms, and cognitive changes

Control and Prevention (CDC). (2019o). *HIV and pregnant women, infants, and children.* Retrieved June 16, 2020, from https://www.cdc.gov/hiv/group/gender/pregnantwomen/index.html.

Impact of HIV on Pregnancy

When a woman who is infected with HIV becomes pregnant, the risks to herself, her fetus, and the newborn are great. The risks are compounded by problems such as drug abuse, lack of access to prenatal care, poverty, poor nutrition, and high-risk behaviors such as unsafe sex practices and multiple sex partners, which can predispose the woman to additional STIs such as herpes, syphilis, or human papillomavirus (HPV). Additional risk factors to assess for include women who exchange sex for money or drugs or have sex partners who do; a woman whose past or present sex partners were HIV-infected; high maternal viral load; chorioamnionitis; prolonged rupture of membranes; vaginal birth; breastfeeding; and having had a blood transfusion between 1978 and 1985. Early identification of maternal HIV seropositivity allows early antiretroviral treatment to prevent mother-to-child transmission, allows a provider to avoid obstetric practices that may increase the risk for transmission, and allows an opportunity to counsel the mother against breastfeeding (also known to increase the risk for transmission) (USPSTF, 2019). Subsequently, pregnant women who are HIV-positive are at risk for preterm delivery, fetal growth restriction, premature rupture of membranes, intrapartal or postpartum hemorrhage, postpartum infection, poor wound healing, and genitourinary tract infections (CDC, 2019n).

Perinatal transmission of HIV (from the mother to the fetus or child) can also occur. However, such cases have decreased in recent years in the United States, primarily due to the use of antiretroviral therapy in pregnant women infected with HIV. This has not been the case in poor countries without similar resources. Perinatal transmission rates are as high as 35% when there is no intervention and below 1% when antiretroviral treatment and appropriate care are available. African American and Hispanic women make up 82% of HIV/AIDS cases among women in the

United States, and according to CDC data (CDC, 2019n), the majority of prenatally infected children were African American or Hispanic. Lack of timely HIV testing during pregnancy is a major contributor to this outcome. Interventions are needed that will address knowledge barriers to HIV. Research has found that women who have information about methods to prevent perinatal HIV transmission and the importance of testing for the baby's or mother's health are more likely to be tested. Media campaigns addressing the benefits of HIV testing may be a significant intervention. Media campaigns are not only successful in promoting HIV testing, but in populations with high HIV prevalence, they also are cost-effective (International AIDS Society, 2020).

With perinatal transmission, approximately half of children manifest AIDS within the first year of life, and about 80% have clinical symptoms of the disease within 3 to 5 years (CDC, 2019p). Breastfeeding is a major contributing factor for mother-to-child transmission, and the infected mother must be informed about this (March of Dimes, 2019h). The U.S. Department of Health and Human Services (USDHHS) recommends that women who are HIV-positive should avoid breastfeeding to prevent HIV transmission to the newborn. Given the devastating effects of HIV infection on children, preventing its transmission is critical (2019a).

In addition to perinatal transmission, the fetus and newborn also are at risk for prematurity, IUGR, low birth weight, and infection. Prompt treatment with antiretroviral medications for the infant with an HIV infection may slow the progression of the disease.

Therapeutic Management

Women who are seropositive for HIV require counseling about the risk of perinatal transmission and the potential for obstetric complications. The risk of perinatal transmission directly correlates with the viral load (Resnik et al., 2019). A discussion of the options on continuing the pregnancy, medication therapy, risks, perinatal outcomes, and treatment is warranted. Women who elect to continue with the pregnancy should be treated with ART regardless of their

CD4 count or viral load. Interventions to reduce HIV transmission include antiretroviral therapy for the mother and the newborn, consideration of elective cesarean section in women with elevated plasma viral load, and the avoidance of breastfeeding. With these interventions, the risk of HIV transmission in the United States is now less than 1% (CDC, 2019p).

Drug therapy is the mainstay of treatment for pregnant women infected with HIV. The standard treatment is oral antiretroviral drugs given daily until giving birth, IV administration during labor, and oral zidovudine (AZT) for the newborn within 6 to 12 hours of birth (Jordan et al., 2019). The goal of therapy is to reduce the viral load as much as possible, which reduces the risk of transmission to the fetus.

Decisions about the birthing method to be used are made on an individual basis based on several factors involving the woman's health. Some reports suggest that cesarean birth may reduce the risk of HIV infection (King et al., 2019). Efforts to reduce instrumentation, such as avoiding the use of an episiotomy, fetal scalp electrodes, and fetal scalp sampling, will reduce the newborn's exposure to body fluids.

With appropriate therapies, the prognosis for pregnant women with HIV infection has improved significantly. In addition, the newborns of women with HIV who have received treatment usually do not become infected. However, therapy is complicated and medications are expensive. Moreover, the medications are associated with numerous adverse effects and possible toxic reactions. These therapies offer a dual purpose: reduce the likelihood of mother-to-infant transmission and provide optimal suppression of the viral load in the mother. The core goal of all medical therapy is to bring the client's viral load to an undetectable level, thus minimizing the risk of transmission to the fetus and newborn.

Nursing Assessment

Nursing assessment begins with a thorough history and physical examination. HIV testing is recommended for all pregnant women

upon entry to prenatal care. In addition, the woman is offered screening for HIV antibodies. Early screening allows for prompt confirmation of the HIV diagnosis and initiation of therapies to safeguard the woman's health. Screening and effective intervention for women who are HIV-positive are essential components of prenatal services, which also include education, counseling, testing, treatment, and continued care.

HEALTH HISTORY AND PHYSICAL EXAMINATION

Review the woman's history for risk factors, such as unsafe sex practices, multiple sex partners, and injectable drug use. Also have the woman complete a risk assessment survey. In addition, question the woman about any flu-like symptoms such as a low-grade fever, fatigue, sore throat, night sweats, diarrhea, cough, skin lesions, or muscle pain. Numerous factors influence perinatal transmission. Factors that increase risk of perinatal transmission include high maternal viral load; maternal immune depletion (low CD4 T-cell counts); maternal genital tract infections; nutritional deficiencies; drug abuse; cigarette smoking; unprotected sexual intercourse; other opportunistic and coexisting infections (TB, malaria); prolonged ruptured membranes; and breastfeeding. Nurses need to take a thorough history to identify risk factors present.

Perform a complete physical examination. Obtain the woman's weight and determine if she has lost weight recently. Assess for signs and symptoms of STIs, such as vulvovaginal candidiasis, bacterial vaginosis, HSV, chancroid, CMV, or chlamydia.

TAKE NOTE!

Women who request HIV tests despite reporting no individual risk factors should be considered at risk, since many are not likely to disclose their high-risk behaviors.

LABORATORY AND DIAGNOSTIC TESTING

The USPSTF (2019) recommends that all pregnant women be offered HIV antibody testing, regardless of their risk of infection, and that testing be done during the initial prenatal evaluation. Testing is essential because treatments are available that can reduce the likelihood of perinatal transmission and maintain the health of the woman.

TAKE NOTE!

Screening only women who are identified as high risk based on their histories is inadequate due to the prolonged latency period that can exist after exposure. Additionally, research indicating that treatment with antiretroviral agents could reduce vertical transmission from the infected mother to the newborn has dramatically increased the importance of HIV antibody screening in pregnancy.

Offer all women who are pregnant or planning a pregnancy HIV testing using ELISA. Prepare the woman with a reactive screening test for an additional test, such as the Western blot or an immunofluorescence assay. The Western blot is the confirmatory diagnostic test. A positive antibody test confirmed by a supplemental test indicates that the woman has been infected with HIV and can pass it on to others. HIV antibodies are detectable in at least 95% of women within 3 months after infection (ACOG, 2019c).

In addition to the usual screening tests done in normal pregnancy, additional testing for STIs may be necessary. Women infected with HIV have high rates of STIs, especially HPV, vulvovaginal candidiasis, bacterial vaginosis, syphilis, HSV, chancroid, CMV, gonorrhea, chlamydia, and hepatitis B (Peterson, 2019).

Nursing Management

Women infected with HIV should have comprehensive prenatal care, which starts with pretest and post-test counseling. In pretest counseling, the client completes a risk assessment survey, and the nurse explains the meaning of positive versus negative test results,

obtains informed consent for HIV testing, and educates the woman about how to prevent HIV infection by changing lifestyle behaviors if needed. Post-test counseling includes informing the client of the test results, reviewing the meaning of the results again, and reinforcing safer sex guidelines. All pretest and post-test counseling should be documented in the client's chart.

EDUCATING THE CLIENT

Pregnant clients are dealing with many issues at their first prenatal visit. The confirmation of pregnancy may be accompanied by feelings of joy, anxiety, depression, or other emotions. Simultaneously, the client is given written information and receives advice and counseling about many important health issues (e.g., nutrition, prenatal development, appointment schedules). This health teaching may be done while the woman feels excited, tired, and anxious. To expect women to understand detailed explanations of a complex disease entity like HIV/AIDS as well may be unrealistic. Determine the client's readiness for this discussion. Identify the client's individual needs for teaching, emotional support, and physical care. Nurses need to approach education and counseling of HIV-positive pregnant women in a caring, sensitive manner. Address the following information:

- Infection control issues at home
- Safer sex precautions
- Stages of the HIV disease process and treatment for each stage
- Symptoms of opportunistic infections
- Preventive drug therapies for the unborn infant
- Avoidance of breastfeeding
- Referrals to community support, counseling, and financial aid
- Client's support system and potential caregiver
- Importance of continual prenatal care
- Need for a well-balanced diet
- Measures to reduce exposure to infections

Be knowledgeable about HIV infection and how HIV is transmitted, and share this knowledge with all women. Nurses also can work to

influence legislators, public health officials, and the entire health establishment toward policies to address the HIV epidemic. Research toward treatment and cure is tremendously important, but the major key to prevention of the spread of the virus is education. Nurses play a major role in this education.

SUPPORTING THE CLIENT

Be aware of the psychosocial sequelae of HIV/AIDS. A diagnosis of HIV can put a woman into an emotional tailspin, during which she is worried about her own health and that of her unborn infant. She may experience grief, fear, or anxiety about the future of herself and her child. Along with the medications that are so important to her health maintenance, address the woman's mental health needs, family dynamics, capacity to work, and social concerns, and provide appropriate support and guidance.

A stigma against both mothers and newborns who are HIV-exposed or infected persists as a challenge on many maternity care units. As nurses work to address this preventable disease, they should do so in a respectful conscientious manner. Beyond basic nursing care, nurses should strive to provide respectful care for all mothers and their newborns together. To accomplish this, be aware of your personal beliefs and attitudes toward women who are HIV-positive or who have AIDS. Incorporate this awareness in your actions as you help the woman face the reality of the diagnosis and treatment options. Empathy, understanding, caring, and assistance are key to helping the client and her family.

PREPARING FOR LABOR, BIRTH, AND POSTPARTUM

Current evidence suggests that cesarean birth performed before the onset of labor and before the rupture of membranes significantly reduces the rate of perinatal transmission. ACOG recommends HIV-positive women be offered elective cesarean birth to reduce the rate of transmission beyond that which may be achieved through ART.

ACOG further suggests operative births be performed at 38 weeks' gestation and amniocentesis be avoided to prevent contamination of the amniotic fluid with maternal blood. Decisions concerning the method of delivery should be based on the woman's viral load, the duration of ruptured membranes, the progress of labor, and other pertinent clinical factors (USPSTF, 2019).

Prepare the woman physically and emotionally for the possibility of cesarean birth, and assist as necessary. Ensure that she understands the rationale for the surgical birth.

After the birth of the newborn, the motivation for taking antiretroviral medications may be lower, thus affecting the woman's adherence to therapy. Encourage the woman to continue therapy for her own sake as well as that of the newborn. Nurses can make a difference in helping women adhere to their complex drug regimens.

Reinforce family planning methods during this time, incorporating a realistic view of the mother's disease status. It is clear that hormonal contraceptives are not protective against HIV infection and that dual protection with condoms should be the goal for women using hormonal contraception (Family Planning 2020, 2019). Advise the woman that breastfeeding is not recommended. Instruct the woman who is HIV-positive in self-care measures, including the proper method for disposing of perineal pads to reduce the risk of exposing others to infected body fluids. Finally, teach her the signs and symptoms of infection in newborns and infants, encouraging her to report any to the health care provider.

The evolution of HIV infection into a chronic disease has implications across all clinical care settings. Every nurse should be knowledgeable about the prevention, testing, treatment, and chronicity of the disease in order to provide high-quality care to people with or at risk for HIV. Breakthroughs in the prevention of HIV important to public health include male circumcision, antiretrovirals to prevent mother-to-child transmission, ART in HIV-positive people to prevent transmission, and antiretrovirals for preexposure prophylaxis. Nurses, therefore, need to have an understanding of the changing epidemiology of the disease, the most recent testing recommendations, developments in screening technology, the

implications of aging with HIV infection, and the nursing implications of this ongoing epidemic.

TAKE NOTE!

When providing direct care, *always* follow standard precautions.

VULNERABLE POPULATIONS

There are approximately 132 million births per year, 360,000 infants born each day, and 15,000 births per hour worldwide (Guttmacher Institute, 2019a). Each pregnancy runs the risk of an adverse outcome for the mother and the baby, but risks are dramatically increased for certain vulnerable populations: adolescents, women over the age of 35, women who are obese, and women who abuse substances. Although risks cannot be totally eliminated once pregnancy has begun, they can be reduced through appropriate and timely interventions.

Every woman's experience with pregnancy is unique and personal. The circumstances each one faces and what pregnancy means involve emotions and experiences that belong solely to her. Many women in these special population groups go through this experience with confusion and isolation, feeling desperately in need of help but not knowing where to go. Although all pregnant women may experience these emotions to a certain extent, they are heightened in women who have potentially complicating factors. Pregnancy is a stressful time. Pregnant women face wide-ranging changes in their lives, relationships, and bodies as they move toward parenthood. These changes can be challenging for a woman without any additional stresses but are even more so in the face of age extremes, illness, or substance abuse.

Skilled nursing interventions are essential in promoting the best outcome for the client and her baby. Timely support and appropriate interventions during the perinatal period can have long-standing

implications for the mother and her newborn, ultimately with the goal of stability and integration of the family as a unit.

Pregnant Adolescents

Adolescence lasts from the onset of puberty to the cessation of physical growth, roughly from 11 to 19 years of age. Adolescents are in between being children and being adults. They need to adjust to the physiologic changes their bodies are undergoing and establish a sexual identity during this time. They search for personal identity and desire freedom and independence of thought and action. However, in American society, they continue to have a strong dependence on their parents (Stevens, 2019).

Adolescent pregnancy has emerged as one of the most significant social problems facing our society. Early pregnancies among adolescents have major health consequences for mothers and their infants. The latest estimates show that approximately 1 million teenagers become pregnant each year in the United States, accounting for 13% of all U.S. births, but the rates have been declining in the last several years (Guttmacher Institute, 2019b). Among these, approximately half will give birth, slightly over one third will opt for abortions, and the remaining 14% will have miscarriages or stillbirths. Despite the fact that the United States is an advanced and relatively affluent nation, American teens have higher rates of pregnancy and childbearing than any other industrialized country, including Canada and the United Kingdom (USDHHS, 2019b). It is estimated that 11% of births worldwide are to adolescents 15 to 19 years old (WHO, 2020b). In addition, about half of all teen pregnancies occur within 6 months of first having sexual intercourse. About one in four teen mothers under age 18 have a second baby within 2 years after the birth of the first baby. Most of these girls are unmarried, and many are not well prepared for the emotional, psychological, and financial responsibilities of parenthood. Adolescents are the least likely of all maternal age groups to get early and regular prenatal care (USDHHS, 2019c). Adolescent pregnancy is further complicated by the adolescent's

lack of financial resources: the income of teen mothers is half that of women who have given birth in their 20s (USDHHS, 2019c).

Although teen birth rates in the United States have declined, they remain high, especially among African American and Hispanic teenagers and adolescents in southern states. Currently, fewer high school students are having sexual intercourse, and more sexually active students are using some method of contraception. However, many teens who have had sexual intercourse have not spoken with their parents about sex, and use of contraceptives remains rare (CDC, 2019q). Subsequently, adolescent pregnancy is considered a major health problem and is addressed in *Healthy People 2030* (see *Healthy People 2030* 20.2).

HEALTHY PEOPLE 2030 • 20.2

Objective	Nursing Significance
FP-2030-03 Reduce pregnancies among adolescent females aged 15 to 19 years.	Will help foster a continued decline in adolescent pregnancy rates by focusing on interventions related to pregnancy prevention, including safe sex practices and teaching about the complications associated with adolescent pregnancy.
FP-2030-04 Increase the proportion of adolescents aged 15 to 17 who have never had sexual intercourse.	Discuss the various family planning methods available to prevent unintended pregnancies in adolescents.
FP-2030-11 Increase the proportion of adolescent females aged 15 to 19 at risk of unintended pregnancy who use most effective or moderately effective methods of contraception.	
NWS-2030-16 Reduce iron deficiency among females aged 12 to 49 years.	Providing nutritional instruction on iron-rich foods will help reduce the incidence of iron-deficiency anemia during pregnancy.

Impact of Pregnancy in Adolescence

Adolescence is a time of enormous transition in the move toward adulthood. Teenagers grow physically, cognitively, emotionally, socially, and with regard to morals and values. Nurses caring for pregnant adolescents need to not only be knowledgeable of the higher physical risk factors but also have an increased awareness and screening for social risks such as tobacco use, intimate partner violence, food insecurity, and financial instability (King et al., 2019). The impact of adolescent pregnancy is evident in maternal and

perinatal morbidity and mortality. Adolescent pregnancy also reflects previous conditions such as malnutrition, communicable diseases, and deficiencies in health care. The most important impact lies in the psychosocial area; adolescent pregnancy contributes to a loss of self-esteem, societal discrimination, a destruction of life projects, and the prolonging of poverty (WHO, 2019d).

Adolescents are a unique group with special needs related to their stage of development. Adolescent pregnancy can be an emotionally charged situation, laden with ethical dilemmas and decisions. Topics such as abstinence, safer sex, abortion, and the decision to have a child are sensitive issues to be discussed.

Adolescent pregnancy is an area in which a nurse's moral convictions may influence the care that they provide to clients. Nurses need to examine their own beliefs about teen sexuality to identify personal assumptions. Putting aside one's moral convictions may be difficult, but it is necessary when working with pregnant adolescents. To be effective, health care providers must be able to communicate with adolescents in a manner they can understand and respect them as individuals.

"It takes a village to raise a child" is an African proverb that means an entire community of people must interact with children for them to grow up in a safe environment. This concept is perhaps even more valid than previously thought regarding teen pregnancy. The evidence suggests that it's not enough to teach teens to "just say no," nor is it enough to give them information about contraceptive methods; teens need to be connected to their parents, their peers, and their community (WHO, 2020b). Nurses should feel that there is always hope and the chance of positive outcomes. Nurses have to believe in that and work toward connecting with their teen clients. Nurses are on the front line of health care and are often the first to interact and build rapport with teenagers. Adolescents who engage in risky sexual behavior may seek out nurses first. Nurses' scope of practice includes providing education and a source of comfort and support to all ages. It is therefore imperative for all nurses to be able to provide age-appropriate information about sexual health. In

providing this care, the quality of life and outcome of both the mother and her infant can be improved.

Developmental Issues

An adolescent must accomplish certain developmental tasks to advance to the next stage of maturity. These developmental tasks include:

- Seeking economic and social stability
- Adjusting to sexually maturing bodies and feelings

FIGURE 20.6. Adolescent girls sharing time together.

- Developing a personal value system
- Building meaningful relationships with others (Fig. 20.6)
- Becoming comfortable with their changing bodies
- Working to become independent from their parents
- Understanding abstract ideas
- Learning to verbalize conceptually (CDC, 2019r)

Adolescents have special needs when working to accomplish their developmental tasks and making a smooth transition to young

adulthood. One of the biggest areas of need is sexual health. Adolescents commonly lack the information, skills, and services necessary to make informed choices related to their sexual and reproductive health. Developmentally, adolescents are trying to figure out who they are and how they fit into society. As adolescents mature, their parents become less influential, and peers become more influential. Peer pressure can lead adolescents to participate in sexual activity, as can the typical adolescent's belief that "it won't happen to me" (Box 20.3). As a result, unplanned pregnancies occur. Work on the developmental tasks of adolescence, especially identity, can be interrupted as the adolescent attempts to integrate the tasks of pregnancy, bonding, and preparing to care for another with the tasks of developing self-identity and independence. A pregnant adolescent must try to meet her own needs along with those of her fetus. The process of learning how to separate from the parents while learning how to bond and attach to a newborn brings conflict and stress. A pregnancy can exacerbate an adolescent's feeling of loss of control and helplessness (AAP, 2019b).

Health and Social Issues

Adolescent pregnancy has a negative impact in terms of both health and social consequences. For example, seven out of 10 adolescents will drop out of school. More than 75% will receive public assistance within 5 years of having their first child. In addition, children of adolescent mothers are at greater risk of preterm birth, low birth weight, child abuse, neglect, poverty, and death. The younger the adolescent is at the time of the first pregnancy, the more likely it is that she will have another pregnancy during her teens (Chacko, 2019). Adolescent pregnancy also places the client at high risk for obstetric complications such as preterm labor and births; low-birth-weight infants; STIs; poor maternal weight gain; preeclampsia; iron-deficiency anemia; poor eating habits and inadequate nutrition; and postpartum depression (King et al., 2019).

BOX 20.3 Possible Factors Contributing to Adolescent Pregnancy

- Early menarche
- Peer pressure to become sexually active
- Sexual or other abuse as a child
- Lack of accurate contraceptive information
- Fear of telling parents about sexual activity
- Feelings of invulnerability
- Poverty
- Culture or ethnicity
- Unprotected sex
- Low self-esteem and inability to negotiate with potential sexual partners
- Lack of appropriate role models
- Strong need for someone to love
- Drug use, truancy from school, or other behavioral problems
- Wish to escape a bad home situation
- Early dating without supervision

Centers for Disease Control and Prevention (CDC). (2019q). *About teen pregnancy*. Retrieved June 16, 2020, from https://www.cdc.gov/teenpregnancy/about/index.htm; Chacko, M. R. (2019). *Pregnancy in adolescents*. Retrieved February 18, 2020, from https://www.uptodate.com/contents/pregnancy-in-adolescents; and Guttmacher Institute. (2019b). *Teen pregnancy*. Retrieved June 16, 2020, from https://www.guttmacher.org/united-states/teens/teen-pregnancy.

The psychosocial risks associated with early childbearing often have an even greater impact on mothers, families, and society than the obstetric or medical risks (Akella, 2019). Pregnant adolescents experience higher rates of domestic violence and substance abuse. Those experiencing abuse are more likely to abuse substances, receive inadequate prenatal care, and have lower pregnancy weight compared with those who are not (WHO, 2019d). Moreover, substance abuse (cigarettes, alcohol, or illicit drugs) can contribute to low birth weight, fetal growth restriction, preterm births, newborn addiction, and sepsis (March of Dimes, 2019i).

Although early childbearing (12 to 19 years of age) occurs in all socioeconomic groups, it is more prevalent among poor women and those from minority backgrounds who face more obstetric and newborn risks than their more affluent counterparts. Over 2 million

teens are living in households with incomes below the poverty level and will remain in that status after the pregnancy (Pew Research Center, 2019). Poverty often contributes to delayed prenatal care and medical complications related to poor nutrition, such as anemia.

The financial burden of adolescent pregnancy is high and costs taxpayers an estimated $12 billion annually in the United States (Guttmacher Institute, 2019c). Much of the expense stems from Medicaid, food stamps, state health department maternity clinics, the federal Aid to Families with Dependent Children program, and direct payments to health care providers. However, this amount does not address the costs to society in terms of the loss of human resources and the far-reaching intergenerational effects of adolescent parenting. For some adolescents, pregnancy may be seen as a hopeless situation—a grim story of poverty and lost dreams, of being trapped in a life that was never wanted. Health-related behaviors, such as smoking, diet, substance misuse, sexual behavior, and help-seeking behaviors, which are developed during adolescence, often endure into later life (Kapetanovic et al., 2019). The consequences associated with an adolescent's less-than-optimal health status at this age due to pregnancy can ultimately affect her long-term health and that of her children. However, some adolescents can create happy, stable lives for themselves and their children by facing their challenges and working hard to beat the odds.

Recall Rose, the pregnant teenager with asthma. What issues would be important for the nurse to discuss with her related to her pregnancy, her asthma, and her age?

Nursing Assessment

Assessment of the pregnant adolescent is the same as that for any pregnant woman. However, when dealing with pregnant teens, the nurse also needs to ask:

- How does the client see herself in the future?
- Are realistic role models available to her?
- How much does she know about child development?

- What financial resources are available to her?
- Does she work? Does she go to school?
- What emotional support is available to her?
- Can she resolve conflicts and manage anger?
- What does she know about health and nutrition for herself and her child?
- Will she need help dealing with the challenges of the new parenting role?
- Does she need information about community resources?

Having an honest regard for adolescent clients requires getting to know them and being able to appreciate the important aspects of their lives. Doing so forms a basis for the nurse's clinical judgment and promotes care that takes into account the concerns and practical circumstances of the teen and her family. Skillful practice includes knowing how and when to advise a teen and when to listen and refrain from giving advice. Giving advice insensitively and without context can be interpreted as "preaching," and the adolescent may be inclined to ignore the information. The nurse must be perceptive, flexible, and sensitive to establish a therapeutic relationship.

Nursing Management

For adolescents, as for all women, pregnancy can be a physically, emotionally, and socially stressful time. The pregnancy is often both the result of and cause of social problems and stressors that can be overwhelming. Teen mothers often present with depression, social complexity, and inadequate parenting skills. Nurses must support adolescents during the transition from childhood into adulthood, which is complicated by the emergence into motherhood. Assist the adolescent in identifying family and friends who want to be involved and provide support throughout the pregnancy.

Help the adolescent identify the options for this pregnancy, such as abortion, self-parenting of the child, temporary foster care for the baby or herself, or placement of the child for adoption. Explore with the adolescent if the pregnancy was planned or unintended.

Becoming aware of why she decided to have a child is necessary to help with the development of the adolescent and her ability to parent. Identify barriers to seeking prenatal care, such as lack of transportation, too many problems at home, financial concerns, the long wait for an appointment, and lack of sensitivity on the part of the health care system. Encourage the client to set goals and work toward them. Assist her in returning to school and furthering her education. As appropriate, initiate a referral for career or job counseling.

Stress that the client's physical well-being is important for both her and her developing fetus, which depends on her for its own health-related needs. Assist with arrangements for care, including stress management and self-care. Having a healthy newborn eases the transition to motherhood somewhat, rather than having to deal with the added stress of caring for an unhealthy baby (Cox et al., 2019). Monitor weight gain, sleep and rest patterns, and nutritional status to promote positive outcomes for both mother and child. Stress the importance of attending prenatal education classes. Provide appropriate teaching based on the adolescent's developmental level and emphasize the importance of continued prenatal and follow-up care. Monitor maternal and fetal well-being throughout pregnancy and labor (Fig. 20.7).

Nurses can play a major role in preventing adolescent pregnancies, perhaps by volunteering to talk to teen groups. Teaching Guidelines 20.6 highlights the key areas for teaching adolescents about pregnancy prevention.

FIGURE 20.7. A pregnant adolescent receiving care during labor.

TEACHING GUIDELINES 20.6

Topics for Teaching Adolescents to Prevent Pregnancy

- High-risk behaviors that lead to pregnancy
- Absolute effectiveness of sexual abstinence
- Involvement in programs such as Free Teens, Teen Advisors, or Postponing Sexual Involvement
- Planning and goal setting to visualize futures in terms of career, college, travel, and education
- Choice of abstinence even after first becoming sexually active
- Discussions about sexuality with a wise adult, someone they respect who can help put things in perspective
- Protection against STIs and pregnancy if they choose to remain sexually active
- Critical observation and review of peers and friends to make sure they are creating the right atmosphere for friendship
- Empowerment to make choices that will shape their lives for years to come, including getting control of their own lives now
- Appropriate use of recreational time, such as sports, drama, volunteer work, music, jobs, religious activities, and school clubs

C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning.

Tackling many issues surrounding adolescent pregnancy is difficult. Making connections with clients is crucial regardless of how complex the situation is. The future challenges nurses to find solutions to teenage pregnancies. Nurses must take proactive positions while working with adolescents, parents, schools, and

communities to reduce the problems associated with early childbearing.

Nurses who provide care to adolescents have an opportunity to discuss future pregnancies and to use health care visits to teach about preconception health. Teaching adolescents who both express a desire for pregnancy and those who do not express such a desire is an important part of comprehensive nursing care. Teens require thorough teaching about health care risks such as smoking cessation, body weight control, interpersonal violence, and the need for folic acid. Adolescents should be the prime recipients of preconception education at every health care visit.

Teen childbearing is associated with adverse consequences for mothers and their children and imposes high public sector costs. Prevention of teen pregnancy requires evidence-based sex education, support for parents in talking with their children about pregnancy prevention and other aspects of sexual and reproductive health, and ready access to effective and affordable contraception for teens who are sexually active (CDC, 2019q).

The Woman of Advanced Maternal Age

It is estimated that by the year 2025, about 25% of mothers will begin their childbearing period at an “advanced age.” Advanced age is a risk factor for female infertility, pregnancy loss, fetal anomalies, stillbirth, and obstetric complications such as gestational diabetes, gestational hypertension, preeclampsia, small-for-gestational-age infants, spontaneous late preterm births, and cesarean sections (Kahveci et al., 2018). A few decades ago, a woman having a baby after the age of 35 was probably giving birth to the last of multiple children, but today, she may be having her first. With advances in technology and the tendency of women to seek career advancement to meet career goals prior to childbearing, the dramatic increase in women having first pregnancies after the age of 35 will likely continue, particularly among those 40 years and older.

Impact of Pregnancy on the Woman of Advanced Maternal Age

Although maternal complications increase as a woman ages, her pregnancy remains a physiologic, not a pathologic, process. ACOG defines advanced maternal age as pregnant women aged 35 and older. Approximately one in six pregnant women in the United States is older than 35 years (2020c). Whether childbearing is delayed by choice or by chance, women starting a family at age 35 or older are not doing so without risk. Women in this age group may already have chronic health conditions that can put the pregnancy at risk. In addition, numerous studies have shown that increasing maternal age is a risk factor for infertility and spontaneous abortions, gestational diabetes, chronic hypertension, postpartum hemorrhage, preeclampsia, preterm labor and birth, multiple pregnancy, genetic disorders and chromosomal abnormalities, placenta previa, fetal growth restriction, low Apgar scores, and surgical births (Dillion et al., 2019). However, even though increased age implies increased complications, most women today who become pregnant after age 34 have healthy pregnancies and healthy newborns.

Nursing Assessment

Nursing assessment of the pregnant woman over age 34 is the same as that for any pregnant woman. For a woman of this age, a preconception visit is important to identify chronic health problems that might affect the pregnancy and also to address lifestyle issues that may take time to modify. Encourage the advanced maternal aged woman to plan for the pregnancy by seeing her health care provider before getting pregnant to discuss preexisting medical conditions, medications, and lifestyle choices. Assess the woman for risk factors such as cigarette smoking, poor nutrition, overweight or underweight, alcohol use, or illicit drug use.

A preconception visit also provides the opportunity to educate the woman about risk factors and provide information on how to modify lifestyle habits to improve the pregnancy outcome. Assist the woman with lifestyle changes so that she can begin pregnancy in an optimal

state of health. For example, if the woman is overweight, educate her about weight loss so that she can start the pregnancy at a healthy weight. If the woman smokes, encourage smoking cessation to reduce the effects of nicotine on herself and her fetus.

Prepare the woman for laboratory and diagnostic testing to establish a baseline for future comparisons. The risk of having a baby with Down syndrome increases with age, especially over age 34. Amniocentesis is routinely offered to all older women to allow the early detection of numerous chromosomal abnormalities, including Down syndrome. Additionally, a quadruple blood test screen (AFP, human chorionic gonadotropin [hCG], unconjugated estriol [UE], and inhibin A [placental hormone]) drawn between 15 and 20 weeks of pregnancy can be helpful in screening for Down syndrome and neural tube defects.

Nursing Management

During routine prenatal visits, the nurse can play a key role in promoting a healthy pregnancy. Consider social, genetic, and environmental factors that are unique to advanced maternal aged pregnant women, and prepare to address these factors when providing care.

Assess the woman's knowledge about risk factors and measures to reduce them. Educate her about measures to promote a positive outcome. Encourage her to get early and regular prenatal care. Advise her to eat a variety of nutritious foods, especially fortified cereals, enriched grain products, and fresh fruits and vegetables, and drink at least six to eight glasses of water daily and to take the prescribed vitamin containing 400 mcg of folic acid daily. Meta-analyses confirm that daily intake of low-dose aspirin (81 mg/day) provides modest benefits in preventing preeclampsia in at-risk women, specifically women with chronic hypertension, diabetes, and renal and autoimmune diseases (Dillion et al., 2019). Also stress the need for the client to avoid alcohol intake during pregnancy, avoid exposure to second-hand smoke, and take no drugs unless they are

prescribed. Provide continued surveillance of the mother and fetus throughout the pregnancy.

The Obese Pregnant Woman

The global epidemic of obesity is widely acknowledged as a serious challenge to improvement of global health and sustainable developmental goals. The prevalence of obesity in the United States has reached epidemic proportions. One in 50 Americans were obese 40 years ago, but currently estimates are one in 10. More striking, however, is the increase in severe obesity (BMI over 40 kg/m^2). Obesity has emerged as a leading cause of morbidity in reproductive-age women (National Academy of Medicine, 2020). Obese pregnant women are a particularly vulnerable group because obesity is highly visible. In the United States, nearly 40% of adults are obese, including two out of every five women. Obesity during pregnancy affects approximately one in two pregnant women (CDC, 2019s). Excess weight and obesity have gained attention as serious global health care threats. Obesity during pregnancy is defined as a BMI of 30 kg/m^2 or more, calculated using the height and weight measured at the first prenatal visit. Compared to women of healthy weight, overweight and obese women tend to gain excessive weight in pregnancy and are at high risk for negative maternal and birth outcomes. Excessive gestational weight gain is strongly associated with postpartum weight retention, which increases the risk of additional weight gain in subsequent pregnancies and an increased risk of childhood obesity in the offspring (Ramsey, 2019). Poor diet, low levels of physical activity, and high levels of sedentary activities all contribute to weight gain. Obesity contributes to social, psychological, and economic problems throughout a woman's life. Negative attitudes and discrimination by society can have negative consequences for the woman's quality of life. The number of women who are overweight or obese during pregnancy has also increased. During pregnancy, excess weight increases both obstetric and neonatal risks, including:

- Gestational diabetes

- Hypertension
- Thromboembolism
- Preeclampsia
- Preterm labor and birth
- Congenital anomalies
- Childhood and adolescent obesity
- Fetal macrosomia (birth weight over 4,000 g)
- Difficulty fighting postpartum infections
- Depression
- Tendency to remain overweight/obese between pregnancies
- Prolongation of pregnancy/increased likelihood of post-term infant
- Increased risk of stillbirth
- Low birth weight
- Higher rate of cesarean births
- Early pregnancy loss
- Increased risk of maternal mortality
- High risk for postpartum hemorrhage (ACOG, 2019d)

Negative or judgmental attitudes toward overweight or obese individuals can be encountered within the health care community and from its providers, including nurses. Nurses and physicians can both find it difficult to discuss weight issues during prenatal visits with obese women. However, obesity is a medical condition and should be treated as such (ACOG, 2019e). Preconception assessment and counseling are needed for obese women and should include specific information about maternal and fetal risks of obesity in pregnancy, as well as encouragement to undertake a weight reduction program that includes diet, exercise, and behavior modification, to enable achievement of a healthy weight prior to conception.

Obese pregnant women require individualized nursing care. Extra time may be needed to promote healthful practices, which should include dealing with issues of weight, diet, and exercise. Specialist dietary interventions and evidence-based guidelines for working with childbearing women must be seen as a public health priority by all nurses. This care must be done with honesty and respect for all of the woman’s needs. There is an opportunity for health promotion

aimed at disseminating information about the risks of obesity in pregnancy to overweight and obese women of childbearing age.

The Pregnant Woman and Substance Abuse

Substance abuse in pregnancy is a significant public health problem causing increased morbidity in both the mother and the fetus. The epidemic of substance abuse continues to pose a significant challenge. Although there is a tendency to simply associate drug abuse with poverty, the problem affects every social stratum, gender, and race, and pregnant women are no exception. **Perinatal drug abuse** includes the use of alcohol and other drugs by pregnant women. The incidence of substance abuse during pregnancy is highly variable because most pregnant women are reluctant to reveal the extent of their use. The National Institute on Drug Abuse (NIDA, 2020a) estimates that up to 10% of women in the United States have used illicit drugs while pregnant. These include cocaine, marijuana, opioids, heroin, and psychotherapeutic drugs that were not prescribed by a health care provider. More than 20% used alcohol and 19% smoked cigarettes during their pregnancy (NIDA, 2020a).

Impact of Substance Abuse on Pregnancy

Research shows that the use of tobacco, alcohol, illicit drugs or misuse of prescription drugs by pregnant women can have serious health consequences for infants (NIDA, 2020a). Substance use can be viewed along a continuum between social recreational drug use and addiction. Substance abuse is prevalent and continues to remain undetected and underdiagnosed in many pregnant women. Substance abuse rarely starts during pregnancy. More often, women enter pregnancy already abusing or dependent on drugs.

Prenatal education and counseling are essential to successfully impacting this high-risk population. The positive overall impact of adequate prenatal care on birth outcomes is well documented. For pregnant substance users, the receipt of adequate prenatal care is especially critical. Several studies have reported that increasing the adequacy of prenatal care utilization in pregnant substance users reduces risks for prematurity, low birth weight, and perinatal mortality. However, many pregnant women who are substance users do not seek prenatal care for fear of being reported to Child Protective Services (Substance Abuse and Mental Health Services Administration [SAMHSA], 2018).

The use of drugs, legal or not, increases the risk of medical complications in the mother and poor birth outcomes in the newborn. The placenta acts as an active transport mechanism, not as a barrier, and substances pass from a mother to her fetus through the placenta. Thus, along with the mother, the fetus experiences substance use, abuse, and addiction. Additionally, fetal vulnerability to drugs is much greater because the fetus has not developed the enzymatic system needed to metabolize drugs (Shukla & Pomar, 2019).

EFFECTS OF ADDICTION

Addiction is a multifaceted process that is affected by environmental, psychological, family, and physical factors. Women who use drugs, alcohol, or tobacco come from all socioeconomic backgrounds,

cultures, and lifestyles. Factors associated with substance abuse during a pregnancy may include low self-esteem, inadequate support systems, low self-expectations, high levels of anxiety, socioeconomic barriers, involvement in abusive relationships, chaotic familial and social systems, and a history of psychiatric illness or depression. Women often become substance abusers to relieve anxiety; previous physical, sexual, and emotional traumas in their lives; depression; and feelings of worthlessness (Chang, 2019).

Societal attitudes regarding women and substance abuse may prohibit them from admitting the problem and seeking treatment. Society sanctions women for failing to live up to expectations of how a pregnant woman “should” behave, thereby possibly driving them further away from the treatment they need. For many reasons, pregnant women who abuse substances feel unwelcome in prenatal clinics or medical settings. Often they seek prenatal care late or not at all. They may fear being shamed or reported to legal or child protection authorities. A nonjudgmental atmosphere and unbiased teaching to all pregnant women regardless of their lifestyle is crucial. A caring, concerned manner is critical to helping these women feel safe and respond honestly to assessment questions.

Pregnancy can be a motivator for some who want to try treatment. The goal of therapy is to help the client deal with pregnancy by developing a trusting relationship. Providing a full spectrum of medical, social, and emotional care is necessary.

EFFECTS OF COMMONLY ABUSED SUBSTANCES

Substance abuse in pregnancy has increased during the past three decades in the United States, resulting in approximately one infant born addicted every 15 minutes in the United States (CDC, 2019t). Routine screening and education of women of childbearing age remain the most important ways to reduce addiction in pregnancy.

Substance abuse during pregnancy, particularly in the first trimester, has a negative effect on the health of the mother and the growth and development of the fetus. The fetus experiences the

same systemic effects as the mother, but often more severely. The fetus cannot metabolize drugs as efficiently as the expectant mother and will experience the effects long after the drugs have left the women's system. Substance abuse during pregnancy is associated with preterm labor, abortion, IUGR, placental abruption, depressed Apgar scores, third-trimester bleeding, meconium staining at birth, fetal demise, low birth weight, neurobehavioral abnormalities, and long-term childhood developmental consequences (Stevens, 2019). Table 20.6 summarizes the effects of select drugs during pregnancy. *Healthy People 2030* also addresses goals for perinatal substance abuse.

Alcohol.

Alcohol abuse is a major public health issue in the United States. Alcohol is a **teratogen**, a substance known to be toxic to human development. The true rate of prenatal alcohol consumption is unknown. It is recognized that fetal alcohol spectrum disorder (FASD) is entirely preventable through alcohol abstinence. Theoretically, no mother would give a glass of wine, beer, or hard liquor to her newborn, but when she drinks, her embryo or fetus is exposed to the same blood alcohol concentration as she is.

TABLE 20.6 Effects of Select Drugs on Pregnancy

Substance	Effect on Pregnancy
Alcohol	Spontaneous abortion, inadequate weight gain, IUGR, FASD (the leading cause of intellectual disability)
Caffeine	Vasoconstriction and mild diuresis in mother; fetal stimulation, but teratogenic effects not documented via research
Nicotine	Vasoconstriction, reduced uteroplacental blood flow, decreased birth weight, abortion, prematurity, placental abruption, fetal demise
Cocaine	Vasoconstriction, gestational hypertension, placental abruption, abortion, central nervous system defects, IUGR
Marijuana	Anemia, inadequate weight gain, "amotivational syndrome," hyperactive startle reflex, newborn tremors, prematurity, IUGR
Opiates and Narcotics	Maternal and fetal withdrawal, placental abruption, preterm labor, premature rupture of membranes, perinatal asphyxia, newborn sepsis and death, intellectual impairment, malnutrition
Sedatives	Central nervous system depression, newborn withdrawal, maternal seizures in labor, neonatal abstinence syndrome, delayed lung maturity

American College of Obstetricians and Gynecologists (ACOG). (2019g). *Tobacco, alcohol, drugs, and pregnancy.* Retrieved June 16, 2020, from https://www.acog.org/Patients/FAQs/Tobacco-Alcohol-Drugs-and-Pregnancy?IsMobileSet=false; Chang, G. (2019). Substance use by pregnant women. *UpToDate*. Retrieved October 9, 2019, from https://www.uptodate.com/contents/substance-use-by-pregnant-women; and Jones, H. E., & Kraft, W. K. (2019). Analgesia, opioids, and other drug use during pregnancy and neonatal abstinence syndrome, *Clinics in Perinatology*, *46*(2), 349–366.

The teratogenic effects of heavy maternal drinking have been recognized since 1973, when fetal alcohol syndrome was first described. Fetal alcohol syndrome is now a classification under the broader term of **fetal alcohol spectrum disorder (FASD)**; this disorder includes the full range of birth defects, such as structural anomalies and behavioral and neurocognitive disabilities caused by prenatal exposure to alcohol (Mattson et al., 2019). FASD affects one in 100 infants each year, more than autism, Down syndrome, cerebral palsy, cystic fibrosis, spina bifida, and sudden infant death syndrome (SIDS) combined (National Organization on Fetal Alcohol Syndrome [NOFAS], 2020). Each year in the United States, up to 40,000 infants are born with FASD. It is the leading cause of nongenetic intellectual disability in the United States, possibly exceeding even Down syndrome, which is currently approaching one in 500 live births. Alcohol consumption during pregnancy results in brain, craniofacial, and heart defects, neurotoxicity, and immune systems dysfunction.

Characteristics of FASD include craniofacial dysmorphia (thin upper lip, small head circumference, and small eyes), IUGR, microcephaly, and congenital anomalies such as limb abnormalities, and cardiac defects. Long-term sequelae include postnatal growth restriction, attention deficits, delayed reaction time, and poor scholastic performance (NOFAS, 2020). The complex neurobehavioral problems typically manifest themselves insidiously. Children with prenatal alcohol exposure struggle with cognitive, academic, social, emotional, and behavioral challenges. These challenges reduce the child's ability to learn and function successfully in many structured environments (Mattson et al., 2019). Common cognitive and behavioral problems are listed in Box 20.4, and Figure 20.8 illustrates the characteristic facial features of a child born with FASD. See Chapter 24 for a more detailed discussion of the newborn with FASD.

The preferred action taken to prevent alcohol consumption during pregnancy is abstinence. However, the detection, diagnosis, and treatment of FASD remain major public health needs in this country and throughout the world. Not every woman who drinks during

pregnancy will give birth to an affected child. Based on the best research available, the following is known about alcohol consumption during pregnancy:

- Intake increases the risk of alcohol-related birth defects, including growth deficiencies, facial abnormalities, central nervous system impairment, behavioral disorders, and intellectual development.

BOX 20.4 Common Cognitive and Behavioral Problems Associated with FASD and Attention-Deficit/Hyperactivity Disorder

- Inability to foresee consequences
- Inability to learn from previous experience
- Lack of organization
- Intellectual disability
- Difficulty in school, especially with math
- Learning difficulties
- Poor abstract thinking
- Poor reasoning and judgment skills
- Poor memory
- Poor impulse control
- Speech and language delays

Retrieved June 16, 2020, from https://www.acog.org/topics/fetal-alcohol-spectrum-disorders.

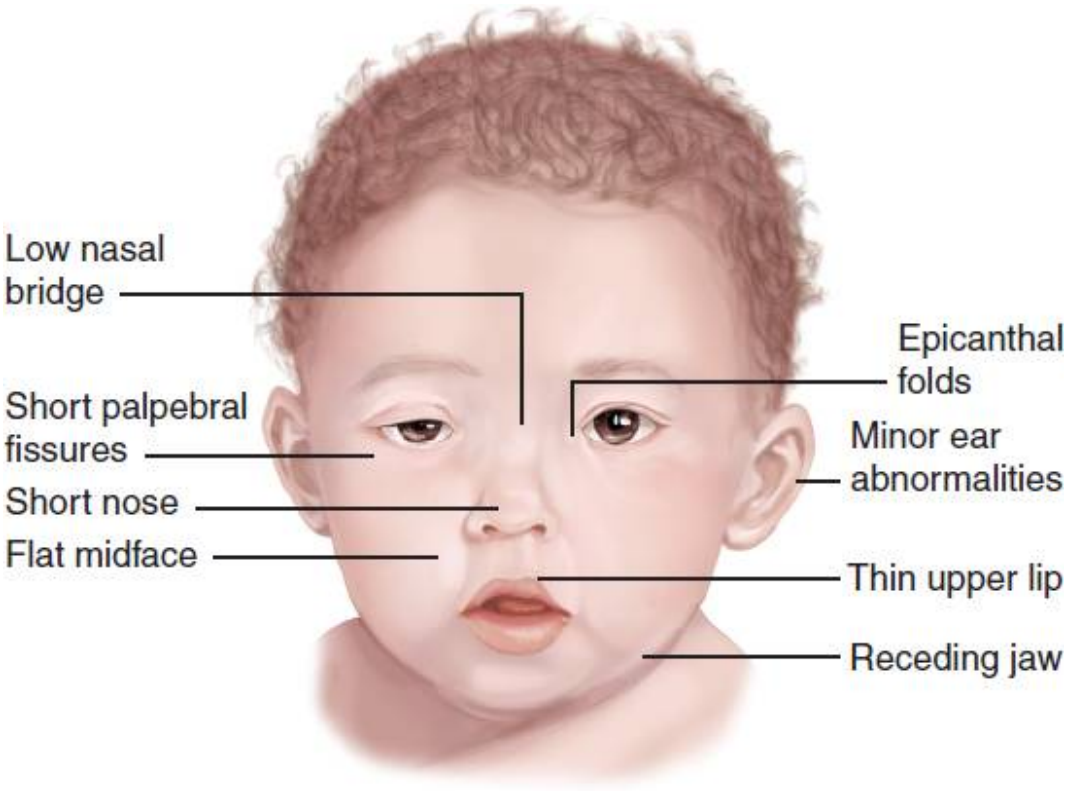

FIGURE 20.8. Typical facial characteristics of a newborn with fetal alcohol spectrum disorder.

- No amount of alcohol consumption is considered safe during pregnancy.
- Damage to the fetus can occur at any stage of pregnancy, even before a woman knows she is pregnant.
- Cognitive defects and behavioral problems resulting from prenatal exposure are lifelong.
- Alcohol-related birth defects are completely preventable (ACOG, 2019f).

Risk factors for giving birth to an alcohol-affected newborn include maternal age, socioeconomic status, ethnicity, genetic factors, poor nutrition, depression, family disorganization, unplanned pregnancy, and late prenatal care (ACOG, 2019f). Identification of risk factors strongly associated with alcohol-related birth outcomes could help identify high-risk pregnancies requiring intervention.

One of the biggest challenges in determining the true prevalence of FASD is how to recognize the syndrome, which depends in part

on the age and physical features of the person being assessed. Difficulty identifying alcohol abuse results from the client's denial of alcohol use, unwillingness to report alcohol consumption, underreporting, and limited ability to recollect the frequency, quantity, and type of alcohol consumed. This makes it difficult to identify women who are drinking during pregnancy, institute preventive measures, or refer them for treatment.

Women who drink excessively while pregnant are at high risk for giving birth to children with birth defects. To prevent these defects, women should stop drinking during all phases of a pregnancy. Unfortunately, many women continue to drink during pregnancy despite warnings from professionals.

Currently, it is not known whether there is a minimal amount of alcohol safe to drink during pregnancy; an occasional glass of wine might be harmless or it might not be. Therefore, eliminating alcohol consumption during pregnancy is the best way to prevent FASD. Most women know they should not drink during pregnancy, but the window of vulnerability (i.e., the time lag between conception and the discovery of pregnancy) may put substantial numbers of children at risk. Additionally, traditional alcohol-screening questionnaires, such as the Michigan Alcoholism Screening Test (MAST) and the CAGE Questionnaire, are not sensitive enough to detect low levels of alcohol consumption among women.

Several challenges remain in preventing birth defects due to alcohol consumption:

- Ways to improve clinical recognition of high-risk women who drink alcohol
- Ways to intervene more effectively to modify drinking behaviors
- In utero approaches to prevent or minimize fetal injury
- Strategies to address the neurodevelopmental problems of children affected by maternal alcohol ingestion

Sedatives.

Sedatives relax the central nervous system and are used medically for inducing relaxation and sleep, relieving tension, and treating seizures. Sedatives easily cross the placenta and can cause birth

defects and behavioral problems. Infants born to mothers who abuse sedatives during pregnancy may be physically dependent on the drugs themselves and are more prone to respiratory problems, feeding difficulties, seizures, hyperactivity, disturbed sleep patterns, sweating, irritability, and fever (Jansson, 2019).

Nicotine.

Cigarette smoking during pregnancy is the biggest preventable cause of death and illness in women and infants and is associated with numerous obstetric, fetal, and developmental complications, as well as an increased risk of adverse health consequences in the adult offspring. Nicotine replacement therapy has been developed as a pharmacotherapy for smoking cessation and is considered to be a safer alternative for women to smoking during pregnancy. The safety of nicotine replacement therapy (transdermal patches and bupropion) use during pregnancy has been evaluated in a limited number of short-term human trials, but there is currently no information on the long-term effects of developmental nicotine exposure in humans. However, nicotine replacement therapies do help smokers quit, so their use is considered safer than continued smoking (Diamanti et al., 2019).

Nicotine is found in cigarettes and is another substance that is harmful to the pregnant women and her fetus. Nicotine, which causes vasoconstriction, transfers across the placenta and reduces blood flow to the fetus, contributing to fetal hypoxia. When compared with alcohol, marijuana, and other illicit drug use, tobacco use is less likely to decline as the pregnancy progresses (American Lung Association, 2019). Smoking is associated with adverse pregnancy outcomes. However, these adverse outcomes can be avoided if the woman stops smoking before becoming pregnant.

Smoking increases the risk of spontaneous abortion, tubal ectopic pregnancy, preterm labor and birth, fetal growth restriction, stillbirth, premature rupture of membranes, low fetal iron stores, maternal hypertension, SIDS, cardiac arrhythmias, placenta previa, and placental abruption. The perinatal death rate among infants of smoking mothers is higher than that of nonsmoking mothers (Dalli,

2019). Perinatal and childhood risks associated with mothers smoking during their pregnancies include increased risk of cleft lip and palate, clubfoot, asthma, middle ear infections, SIDS, reduced head circumference, altered brain stem development, and cerebral palsy (Cunningham et al., 2018).

Smoking is considered an important risk factor for low birth weight, SIDS, and cognitive deficits, especially in language, reading, and vocabulary, as well as poorer performances on tests of reasoning and memory. Researchers have also reported behavior problems, such as increased activity, attention-deficit/hyperactivity disorder (ADHD), impulsivity, opposition, and aggression (Carroll, 2019). Women who smoke during the pregnancy often continue to smoke after giving birth, and thus the infant will be exposed to nicotine after birth. This environmental or passive exposure affects the child's development and increases the risk of childhood respiratory disorders.

Caffeine.

Caffeine is a stimulant found in tea, coffee, soft drinks, chocolate, and energy drinks. During pregnancy, caffeine clearance from the blood slows down significantly. Results from some observational studies suggest that excess caffeine intake may be associated with growth restriction, reduced birth weight, preterm birth, and stillbirth (WHO, 2019e). Caffeine is a widely used and accepted substance. About 80% of pregnant women consume caffeine orally on a daily basis. The socially sanctioned nature of caffeinated beverages promotes caffeine's popularity and at the same time obscures the fact that as a drug, it can definitely be abused. The effect of caffeine intake during pregnancy on fetal growth and development is still unclear. A recent study found that caffeine intake of no more than 200 mg/day during pregnancy does not affect pregnancy duration and the condition of the newborn (Wierzejska et al., 2019). Birth defects have not been linked to caffeine consumption, but maternal coffee consumption decreases iron absorption and may increase the risk of anemia during pregnancy.

Energy drinks represent a newer class of caffeinated beverages that are marketed to improve energy, athletic performance, concentration, endurance, and weight loss, though the claims have not been supported by rigorous scientific evidence (Grumezescu & Holban, 2019). All energy drinks surpass the FDA official soft drink concentration of caffeine limit, typically two to four times the amount seen in one serving of soda or tea. Adverse effects of energy drinks can even occur in healthy people, and pregnant women are considered an at-risk group, so they should avoid excessive caffeine intake, which has been linked to adverse reproductive outcomes, such as low birth weight. Consumption of energy drinks is associated with increased demand of the heart causing hypertension, tachycardia, dysrhythmias, coronary artery spasm, and sudden cardiac death (De Giuseppe et al., 2019). Health care providers recommend pregnant women exclude carbonated and energy drinks, as they contain large amounts of sugar, caffeine, colorants, and preservatives. Nurses should advise pregnant clients to drink water instead of soda or energy drinks.

Marijuana.

Marijuana is the most widely used illicit drug during pregnancy in the United states, and it is on the rise among all adult groups. Its estimated prevalence in pregnant women is about 10% to 15%, but this is underreported (SAMHSA, 2020). It is often called pot, reefer, herb, widow, hash, grass, weed, Mary Jane, or MJ (NIDA, 2020b). Marijuana is a preparation of the leaves and flowering tops of *Cannabis sativa,* the hemp plant, which contains a number of pharmacologically active agents. Tetrahydrocannabinol (THC) is the most active ingredient of marijuana. With heavy smoking, THC narrows the bronchi and bronchioles and produces inflammation of the mucous membranes. Smoking marijuana causes tachycardia and a reduction in blood pressure, resulting in orthostatic hypotension. Although the federal government considers marijuana a Schedule I substance (having no medicinal uses and high risk for abuse), several states have legalized it for adult recreational use, and several states have passed laws allowing its use as a treatment

for medical conditions (pain, nausea and vomiting, HIV/AIDS, cancer).

The effects of marijuana smoking on pregnancy are not yet fully understood because there are few studies on its long-term effects on child development. One can speculate that the effects of marijuana on the immature nervous system may be subtle and not detected until more complex functions are required, usually in a formal educational setting. There is some evidence that marijuana increases the risk of spontaneous abortion and preterm delivery (ACOG, 2018b). Although marijuana is not considered teratogenic, many newborns display altered responses to visual stimuli, increased tremulousness, and a high-pitched cry, which might indicate insults against the central nervous system (Stickrath, 2019). A strong correlation exists between the use of marijuana and the use of alcohol and cigarettes. ACOG (2018b) advises cessation of cannabis use in pregnancy and lactation, even if prescribed for medicinal purposes.

Opiates and Narcotics.

Over the past decade, the United States has experienced an epidemic of prescription opioid misuse. Opiates and narcotics include opium, heroin, morphine, codeine, hydromorphone (Dilaudid), oxycodone (Percodan), meperidine (Demerol), and methadone (meth). Opiates can be inhaled, injected, snorted, ingested, or used subcutaneously. These drugs are central nervous system depressants that soothe and lull. They may be used medically for pain, but all have a high potential for abuse. Most are capable of causing intense addiction in both mother and newborn.

Narcotic dependence is particularly problematic in pregnant women. It leads to medical, nutritional, and social neglect by the woman due to the long-term risks of physical dependence, malnutrition, compromised immunity, hepatitis, and fatal overdose (Jordan et al., 2019). Taking opiates or narcotics during pregnancy places the woman at increased risk for preterm labor, fetal growth restriction, placental abruption, perinatal mortality, preterm rupture of membranes, and preeclampsia (Chang, 2019).

Heroin is the most common illicitly used opioid. It is derived from the seeds of the poppy plant and can be sniffed, smoked, or injected. It crosses the placenta via simple diffusion within 1 hour of maternal consumption (ACOG, 2018c). Use of heroin during pregnancy is believed to affect the developing brain of the fetus and may cause behavioral abnormalities in childhood. Risks of perinatal opiate exposure are not limited to the fetus. Maternal opiate overdose deaths have increased dramatically, which translates to 18 women dying per day, and for every woman who dies, 30 are being treated in emergency departments for abuse. Opioid use disorder has gone up tremendously among pregnant women, with an estimated 14% to 22% filling an opioid prescription while pregnant (CDC, 2019u).

The most common harmful effect of heroin and other narcotics on newborns is withdrawal, or **neonatal abstinence syndrome (NAS)** (see Chapter 24). This collection of symptoms may include irritability, hypertonicity, jitteriness, fever, excessive and often high-pitched cry, vomiting, diarrhea, feeding disturbances, respiratory distress, disturbed sleeping, excessive sneezing and yawning, nasal stuffiness, diaphoresis, fever, poor sucking, tremors, and seizures (Jones & Kraft, 2019).

Withdrawal from opiates during pregnancy is extremely dangerous for the fetus, so a prescribed oral methadone maintenance program combined with psychotherapy is recommended for the pregnant woman. This closely supervised treatment program reduces withdrawal symptoms in the newborn, reduces drug cravings, and blocks the euphoric effects of narcotic drugs in order to reduce illicit drug use. Management of opioid addiction in pregnancy includes maintenance therapy with methadone or buprenorphine in addition to traditional prenatal care and psychosocial treatment of substance abuse, such as self-help, 12-step groups, individual and group substance abuse counseling, and psychotherapy. Maintenance therapy drugs provide a steady state of opiate levels, thus reducing the risk of withdrawal to the fetus and exposure to HIV and other STIs because the mother is no longer injecting drugs. However, maintenance therapy drugs have the same withdrawal

consequences for women and newborns as heroin does (Kosten & Baxter, 2019).

Methamphetamines.

Methamphetamine is a highly addictive central nervous stimulant which approximately 1.6 million adults use annually (CDC, 2020b). Use of this stimulant results in increased risk of adverse perinatal, neonatal, and childhood outcomes. This highly addictive stimulant is commonly known as speed, meth, or chalk. In its smoked form, it is often referred to as ice, crystal, crank, and glass. Smoking or injecting the drug quickly delivers it to the brain for an immediate, intense euphoria. Because the pleasure also fades quickly, users often take repeated doses in a “binge-and-crash” pattern. It is a white, odorless, bitter-tasting powder that was developed from its parent drug, amphetamine, and was used originally in nasal decongestants and bronchial inhalers. Maternal effects include increased energy and alertness, an intense rush, decreased appetite, tachycardia, and tachypnea. Chronic use can lead to psychosis, including paranoia, hallucinations, memory loss, and aggressive or violent behavior. Signs of methamphetamine use include track marks from IV injection, malnutrition, severe dental decay (meth mouth), and skin abscesses from skin picking (Smid et al., 2019). Few studies have been done on the effects of methamphetamine abuse during pregnancy, but the few done indicate an increased risk for preterm births, low birth weight, placental abruption, fetal growth restriction, and congenital anomalies (Prasad & Metz, 2019). These findings are hard to interpret, however, due to small sample size and polydrug use of the participants.

Cocaine.

Cocaine use is second only to marijuana use in women who abuse drugs during pregnancy. The incidence of cocaine exposure in utero is approximately one to 10 per 1,000 live births (Rodriguez & Smith, 2019). There is evidence that cocaine affects infant development

both directly, via in utero exposure, and indirectly via alterations in maternal care after birth.

Cocaine is a psychoactive drug derived from the leaves of the coca plant, which grows in the Andes Mountains of Peru, Ecuador, and Bolivia. The freebase form, called “crack” because of the cracking or popping noise made in its preparation, is less expensive, easily made, and smokable. Cocaine is a powerful vasoconstrictor. When sniffed into the mucous membranes of the nose, it produces an intense “rush.” Smoked crack is absorbed rapidly by the pulmonary vasculature and reaches the brain’s circulation in 6 to 8 seconds (NIDA, 2020a).

Cocaine use produces vasoconstriction, dilates pupils, and increases body temperature, tachycardia, and hypertension in both the mother and the fetus (Chang, 2019). Uteroplacental insufficiency may result from reduced blood flow and placental perfusion. Chronic use can result in low birth weight, smaller infant head circumference, and length (NIDA, 2020a).

Studies suggest that perinatal cocaine use increases the risk of preterm labor, abortion, placental abruption, fetal growth restriction, intrauterine fetal distress and demise, seizures, withdrawal, and cerebral infarcts. Cocaine may increase the risk of uterine rupture and congenital anomalies (NIDA, 2020a). Fetal anomalies associated with cocaine use in early pregnancy involve neurologic problems such as neural tube defects and microcephaly; cardiovascular anomalies such as congenital heart defects; growth restriction; sleep alterations; genitourinary conditions such as prune belly syndrome, hydronephrosis, and ambiguous genitalia; and gastrointestinal system problems such as necrotizing enterocolitis (ACOG, 2019g). Some infants exposed to cocaine in utero show increased irritability and are difficult to calm and soothe to sleep.

Prescription Drugs Misuse.

In addition to alcohol and illicit drug use, a new worldwide trend has emerged and may soon exceed illicit drug use—the nonmedical use of prescription drugs found in many home medicine cabinets. A global trend of drug consumption has emerged, showing that over

250 million people abuse drugs worldwide (Cataldo et al., 2019). Prescription drug abuse has reached epidemic levels in the United States. Estimates of prescription drug abuse rates during pregnancy range from 5% to 20%. Common drugs of choice include analgesics, stimulants, sedatives, and tranquilizers. A frequent belief among abusers is that prescribed medications are less dangerous than street drugs, and using a friend's medication is safe. Unfortunately, unintentional poisoning deaths occur frequently.

Early detection through a comprehensive evaluation is essential to improving overall treatment outcomes. New research supports screening all pregnant women for substance abuse. A major role of the nurse is to focus on prevention by educating all women about the dangers associated with misuse of prescription medications. Community education is vital to manage risks to prevent problems from developing.

Nursing Assessment

Complete a thorough history and physical examination to evaluate a client for substance use and abuse. Substance abuse screening in pregnancy is done to detect the use of any substance known or suspected to exert a deleterious effect on the client or her fetus. Routinely ask about substance abuse with all women of childbearing age, inform them of the risks involved, and advise them against continuing. Screening questionnaires are helpful in identifying potential users, may reduce the stigma of asking clients about substance abuse, and may result in a more accurate and consistent evaluation. The questions in Box 20.5 may be helpful in assessing a client who is at risk for substance abuse during pregnancy. Using "accepting" terminology may encourage the woman to give honest answers without fear of reproach.

BOX 20.5 Sample Questions for Assessing Substance Use

- Have you ever used recreational drugs? If so, when and what?
- Have you ever taken a prescription drug other than as intended?
- What are your feelings about drug use during pregnancy?
- How often do you smoke cigarettes? How many per day?
- How often do you drink alcohol?
- Have you ever felt guilty about drinking or drug use?

If the assessment reveals substance use, obtain additional information by using the CRAFFT questionnaire, which is a sensitive screening instrument for identifying substance abuse (CRAFFT Organization, 2018):

- **C:** Have you ever ridden in a **c**ar driven by someone (including yourself) who was high or drunk?
- **R:** Do you drink or take drugs to **r**elax, improve your self-image, or fit in?
- **A:** Do you ever drink or take drugs while **a**lone?
- **F:** Do you have any close **f**riends who drink or take drugs?
- **F:** Does a close **f**amily member have a problem with alcohol or drugs?
- **T:** Have you ever gotten in **t**rouble from drinking or taking drugs?

A woman who claims to have taken no drugs while pregnant may be unaware that substances such as hair dye, diet cola, paint, or over-the-counter medications for colds or headaches are still considered drugs. Thus, it is difficult to get a true picture of the real use of drugs by pregnant women.

Many drugs are considered to have a teratogenic effect on growing fetuses. A teratogen is any environmental substance that can cause physical defects in the developing embryo and fetus. Pregnant women with substance abuse commonly present with polysubstance abuse, which is likely to be more damaging than the use of any single substance. Thus, it is inherently difficult to ascribe a specific perinatal effect to any one substance (Resnik et al., 2019).

A urine toxicology screen may also be helpful in determining drug use, although a urine screen identifies only recent or heavy use of drugs. The length of time a drug is present in urine is as follows:

- Cocaine: 24 to 48 hours in an adult, 72 to 96 hours in an infant
- Heroin: 24 hours in an adult, 24 to 48 hours in an infant
- Opioids: 1 to 4 days after use

- Marijuana: 1 week to 1 month in an adult, up to a month or longer in an infant
- Methadone: up to 10 days in an infant (Mukherji & Sharma, 2019)

Nursing Management

If the woman's drug screen is positive, use this as an opportunity to discuss prenatal exposure to substances that may be harmful. The discussion may lead the nurse to refer the client for a diagnostic assessment or identify an intervention such as counseling that may be helpful. Being nonjudgmental is a key to success; a client is more apt to trust and reveal patterns of abuse if the nurse does not judge her and her lifestyle choices.

A positive drug screen in a newborn warrants an investigation by the state protection agency. In the interim, institute measures to reduce stress and stimuli to promote the newborn's comfort (see Chapter 24 for a more in-depth discussion).

Be proactive, supportive, and accepting when caring for the client. Assure women with substance abuse problems that sharing information of a confidential nature with health care providers will not render them liable to criminal prosecution. Provide counseling and education, emphasizing the following:

- Effects of substance exposure on the fetus
- Interventions to improve mother–child attachment and improve parenting
- Psychosocial support if treatment is needed to reduce substance abuse
- Referral to outreach programs to improve access to treatment facilities
- Hazardous legal substances to avoid during pregnancy
- Follow-up of children born to substance-dependent mothers
- Dietary counseling to improve the pregnancy outcome for both mother and child
- Drug screening to identify all drugs a client is using
- More frequent prenatal visits to monitor fetal well-being
- Maternal and fetal benefits of remaining drug free
- Cultural sensitivity

- Coping skills, support systems, and vocational assistance

There is nothing categorically different about addiction during pregnancy compared to addiction in general. Pregnant women who use drugs are women who use drugs, get pregnant, and cannot stop using drugs. The fact that they are condemned in society leads to their further marginalization, which does nothing to improve their lives or the lives of their children.

Substance abuse is a complex problem that requires sensitivity to each woman's unique situation and contributing factors. Be sure to address individual psychological and sociocultural factors to help the woman regain control. Nurses must be aware of these women's unique needs and the related legal and ethical ramifications surrounding pregnancy. Treatment must combine different approaches and provide ongoing support for women learning to live drug-free. Developing personal strengths, such as communication skills, assertiveness, and self-confidence, will help the woman to resist drug use. Encourage the use of appropriate coping skills. Enhancing self-esteem also helps provide a foundation to avoid drugs. Through therapeutic communication, nursing interventions, clinical assessment, and building trusting relationships, nurses can have a significant impact in managing clients with substance abuse.

KEY CONCEPTS

- Preconception counseling for the woman with diabetes is helpful in promoting blood glucose control to prevent congenital anomalies.
- The classification system for diabetes is based on disease etiology and not pharmacology management; the classification includes type 1 diabetes, type 2 diabetes, and gestational diabetes.
- The WHO classification for heart disease during pregnancy is based on how much risk the woman has for morbidity and mortality.
- Chronic hypertension exists when the woman has a blood pressure of 140/90 mm Hg or higher before pregnancy or before the 20th week of gestation or when hypertension persists for more than 12 weeks postpartum.
- Successful management of asthma in pregnancy involves elimination of environmental triggers, drug therapy, and client education.
- Ideally, women with hematologic conditions are screened before conception and are made aware of the risks to themselves and to a pregnancy.
- A wide variety of infections, such as cytomegalovirus, rubella, herpes simplex, hepatitis B, varicella, parvovirus B19, and many sexually transmitted infections can affect a pregnancy, having negative impacts on its outcome.
- The prevalence of HIV/AIDS is increasing more rapidly among women than men; half of all the HIV/AIDS cases worldwide now occur in women. There are only three recognized modes of HIV transmission: unprotected sexual intercourse with an infected partner, contact with infected blood or blood products, and perinatal transmission. Breastfeeding is a major contributing factor in mother-to-child transmission of HIV.
- Cases of perinatal AIDS have decreased in the past several years in the United States, primarily because of the use of antiretroviral therapy in pregnant women with HIV. The USPSTF recommends all pregnant women should be offered HIV antibody testing regardless of their risk of infection and that testing should be done during the initial prenatal evaluation.

- The younger an adolescent is at the time of her first pregnancy, the more likely it is that she will have another pregnancy during her teens. About 1 million teenagers between the ages of 15 and 19 become pregnant each year; about half give birth and keep their infants.
- The nurse's role in caring for the pregnant adolescent is to assist her in identifying the options for this pregnancy, including abortion, self-parenting of the child, temporary foster care for the baby or herself, or placement for adoption.
- Pregnant women with substance abuse problems commonly abuse several substances, making it difficult to ascribe a specific perinatal effect to any one substance. Societal attitudes regarding pregnant women and substance abuse may prohibit them from admitting the problem and seeking treatment.
- Substance abuse during pregnancy is associated with preterm labor, abortion, low birth weight, central nervous system and fetal anomalies, and long-term childhood developmental consequences.
- Fetal alcohol spectrum disorder is a lifelong yet completely preventable set of physical, mental, and neurobehavioral birth defects; it is the leading cause of intellectual disability in the United States.
- Nursing management for the woman with substance abuse focuses on screening and preventing substance abuse to reduce the high incidence of obstetric and medical complications as well as the morbidity and mortality among passively addicted newborns.

Unfolding Patient Stories: Amelia Sung • Part 2

Think back to Amelia Sung, who, as you learned in Chapter 12, is 36 years old and gravida 2 para 1. She is diagnosed with gestational diabetes mellitus at 26 weeks. Explain the areas of education the nurse should provide regarding diabetes management. How does the nurse evaluate Amelia's understanding of the information provided and her ability to manage diabetes and maintain normal glucose levels?

Care for Amelia and other patients in a realistic virtual environment: (**thepoint.lww.com/vSimMaternity**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. Which information would the nurse include when teaching a pregnant woman about the pathophysiologic mechanisms associated with gestational diabetes?

   a. Pregnancy fosters the development of carbohydrate cravings.
   b. There is progressive resistance to the effects of insulin.
   c. Hypoinsulinemia develops early in the first trimester.
   d. Glucose levels decrease to accommodate fetal growth.

2. When providing prenatal education to a pregnant woman with asthma, which action would be important for the nurse to take?

   a. Explain that the client should avoid steroids during her pregnancy.
   b. Demonstrate how to assess her blood glucose levels.
   c. Teach correct administration of subcutaneous bronchodilators.
   d. Ensure she seeks treatment for any acute exacerbation.

3. Which condition would most likely cause a pregnant woman with type 1 diabetes the greatest difficulty during her pregnancy?

   a. Placenta previa
   b. Hyperemesis gravidarum
   c. Placental abruption
   d. Rh incompatibility

4. Women who drink alcohol during pregnancy

a. often produce more alcohol dehydrogenase.
b. usually become intoxicated more quickly than before.
c. can give birth to an infant with fetal alcohol spectrum disorder.
d. gain fewer pounds throughout the gestation.

5. When explaining to a pregnant woman about HIV infection and transmission, which information would the nurse include?

a. It primarily occurs when there is a large viral load in the blood.
b. HIV is most commonly transmitted via sexual contact.
c. It affects the majority of infants of mothers with HIV infection.
d. Nurses are most frequently affected by needlesticks.

6. Women who are obese have a greater risk of developing which condition during pregnancy?

a. Type 1 diabetes
b. Hypotension
c. Low–birth-weight infant
d. Gestational hypertension

7. Maintenance on methadone or buprenorphine is the most common medical treatment for addiction to which drug?

a. Alcohol
b. Nicotine
c. Opiates
d. Marijuana

CRITICAL THINKING EXERCISES

1. A client at 26 weeks' gestation came to the clinic to follow up on her previous 1-hour glucose screening. Her results had come back outside the accepted screening range, and a 3-hour glucose tolerance test (GTT) had been

ordered. It resulted in three abnormal values, confirming a diagnosis of gestational diabetes. As the nurse in the prenatal clinic, you are seeing her for the first time.

a. What additional information will you need to provide care for her?
b. What education will she need to address this new diagnosis?
c. How will you evaluate the effectiveness of your interventions?

2. A 14-year-old girl comes to the public health clinic with her mother. The mother tells you that her daughter has been “out messing around and has gotten herself pregnant.” The girl is crying quietly in the corner and avoids eye contact with you. The mother reports that her daughter “must be following in my footsteps” because she became pregnant when she was 15 years old. The client’s mother goes back out into the waiting room and leaves the client with you.

a. What is your first approach with the client to gain her trust?
b. List the client’s educational needs during this pregnancy.
c. What prevention strategies are needed to prevent a second pregnancy?

3. A 27-year-old G3P2 is admitted to the labor and birth suite because of preterm rupture of membranes at an estimated 35 weeks’ gestation. She has received no prenatal care and reports this was an unplanned pregnancy. The client appears distracted and very thin. She reports that her two previous children have been in foster care since birth because the child welfare authorities “didn’t think I was an adequate mother.” She denies any recent use of alcohol or drugs, but you smell alcohol on her breath. She has a spontaneous vaginal

birth a few hours later, producing a 4-lb baby boy with Apgar scores of 8 at 1 minute and 9 at 5 minutes.

a. What aspects of this woman's history may lead the nurse to suspect that this infant may be at risk for fetal alcohol spectrum disorder?
b. What additional screening or laboratory tests might validate your suspicion?
c. What physical and neurodevelopmental deficits might present later in life if the infant has fetal alcohol spectrum disorder?

STUDY ACTIVITIES

1. In the maternity clinic or hospital setting, interview a pregnant woman with a preexisting medical condition (e.g., diabetes, asthma, sickle cell anemia) and find out how this condition affects her life and this pregnancy, especially her lifestyle choices.
2. You have a close friend who you believe has a problem with alcohol but denies it. She now admits to you that she thinks she is pregnant because she missed her period. What specific information and advice should you give her concerning alcohol use during pregnancy?
3. Should marijuana be legalized in the United States? What impact might your view have on pregnant women and their offspring?
4. Outline a discussion you might have with an HIV-positive pregnant woman who doesn't see the need to take antiretroviral agents to prevent perinatal transmission.
5. The nurse is preparing a teaching session about breastfeeding for a group of pregnant women who have various infections listed below. The nurse would include women with which conditions? Select all that apply.

a. Hepatitis B
b. Parvovirus B19
c. Herpesvirus type 2

d. HIV-positive status
e. Cytomegalovirus
f. Varicella zoster virus

BRINGING IT ALL TOGETHER: A CASE STUDY

Linda is an 18-year-old client who has been abusing alcohol since the age of 12. She lived in foster care for much of her life and is recently on her own with a part-time job. She reports she had experienced both emotional and sexual abuse during her childhood. At 16, she was introduced to crack cocaine. So many of her friends and relatives were using that it was impossible for her to see any other lifestyle or want to seek help for her addiction. She states she wanted to start a new life and get clean when she found out she was pregnant, but admitted she ended up partying and using drugs for the past 4 months of this pregnancy. She presents today for her first prenatal visit and appears very thin. She claims she is ready to commit to a positive change.

ASSESSMENT

Based on Linda's history, she is vulnerable because of her young age, underweight body composition, history of abuse, substance abuse, and lack of a supportive network to assist her in making a "positive change" in her life. Although she states she is ready to get off drugs, she has been unable to move toward that goal on her own previously. At this stage of her pregnancy, her vital signs and fetal heart rates were within normal limits, her weight is below standard limits for her height, and lab tests are normal except for low hemoglobin indicating iron-deficiency anemia.

Go to thePoint to find questions to consider about this case.

Nursing Management of Labor and Birth at Risk

WOW

WORDS OF WISDOM

In the face of a crisis or a potentially bad outcome, add a mixture of warmth and serenity to your technical abilities.

KEY TERMS

arrest disorders
cesarean birth
dystocia (dis-tō´sē-ă)
forceps
hypertonic uterine dysfunction
hypotonic uterine dysfunction
labor induction
macrosomia (mak´rō-sō´mē-ă)
multiple gestation
post-term pregnancy
precipitate labor (prē-sip´i-tāt lā´bŏr)
preterm labor
protracted disorders
shoulder dystocia
tocolytic (tō´kō-lit´ik)
umbilical cord prolapse
vacuum extractor
vaginal birth after cesarean (VBAC)

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Identify risk factors associated with dystocia.
2. Differentiate the major abnormalities or problems associated with dysfunctional labor patterns, giving examples of each problem.
3. Examine the nursing management for the woman with dysfunctional labor experiencing a problem with the powers, passenger, passageway, or psyche.
4. Devise a plan of care for the woman experiencing preterm labor.
5. Outline the nontraditional family health care needs and best practices of nursing care to address them.

6. Outline the nursing assessment and management of the woman experiencing a prolonged pregnancy.
7. Discuss the nursing management for the woman undergoing labor induction or augmentation.
8. Evaluate the key areas to be addressed when caring for a woman that undergoes a vaginal birth after cesarean (VBAC).
9. Identify risk factors associated with fetal demise and the management of the family experiencing a stillbirth.
10. Assess obstetric emergencies that can complicate labor and birth, including appropriate management for each.
11. Discuss forceps-assisted and vacuum-assisted birth.
12. Summarize the plan of care for a woman who is to undergo a cesarean birth.

Jennifer, a 29-year-old G1P0, is at 41 weeks' gestation. Her health care provider has recommended that she come in for induction. She is anxious about doing this since she has heard "horror stories" about the "hard, painful contractions" that can result. What can the nurse do to calm her fears?

INTRODUCTION

Pregnancy can be an exciting time, but the development of an unexpected problem can suddenly change circumstances dramatically. Consider the woman who has had a problem-free pregnancy and then suddenly develops a condition during labor, turning a routine situation into a possible crisis. Many complications occur with little or no warning and present challenges for the perinatal health care team as well as the family. Sadly, about 700 women die annually in the United States as a result of childbirth complications (CDC, 2019b). The nurse plays a major role in identifying potential problems quickly and coordinating immediate intervention with the goal of achieving positive outcomes.

National health goals address maternal and newborn outcomes involving complications of labor and birth and cesarean birth (U.S. Department of Health and Human Services, 2020). These goals are highlighted in *Healthy People 2030* 21.1.

HEALTHY PEOPLE 2030 • 21.1

Objective	Nursing Significance
MICH-2030-01 Reduce preterm births.	Will help to focus attention on the need for close antepartum surveillance and identification of risks factors for preterm labor/births and provide appropriate interventions to reduce it.
MICH-2030-06 Reduce cesarean births among low-risk women with no prior births.	Will help to reduce the number of surgical births with accompanying risk factors and costs by appropriate labor management, continual labor support, and practice patterns, while helping to ensure positive maternal and newborn outcomes.

Adapted from USDHHS. (2020). *Proposed objectives for inclusion in Healthy People 2030*. https://www.healthypeople.gov/sites/default/files/ObjectivesPublicComment508.pdf

This chapter will address several conditions that can occur during labor and birth that may increase the risk of an adverse outcome for the mother and/or fetus. It also describes birth-related procedures that may be necessary for the woman who develops a condition that increases her risk or that may be needed to reduce the woman's risk for developing a condition, thus promoting optimal maternal and fetal outcomes. Nursing management of the woman and her family focuses on professional support and compassionate care.

DYSTOCIA

Dystocia is the abnormal progression of labor. It can be influenced by a number of maternal and fetal factors. Dystocia is characterized by a slow and abnormal progression of labor. It occurs in approximately 10% of all labors and is the leading indicator for

primary cesarean birth in the United States (Ehsanipoor & Satin, 2020). It is a fatiguing factor for both the mother and fetus and is associated with an increase in postpartum hemorrhage, infections, and perineal lacerations; it frequently requires medical or surgical interventions, which increases risk (Zipori et al., 2019).

To characterize a labor as abnormal, a basic understanding of normal labor is essential. Normal labor starts with regular uterine contractions that are strong enough to result in cervical effacement and dilation. Early in labor, uterine contractions are irregular, and cervical effacement and dilation occurs gradually. When cervical dilation reaches 5 to 6 cm and uterine contractions become more powerful, the active phase of labor begins. It is usually during the active phase that dystocia becomes apparent. Because dystocia cannot be predicted or diagnosed with certainty, the term “failure to progress” is often used. This term includes lack of progressive cervical dilation, lack of descent of the fetal head, or both. An adequate trial of labor is needed to declare with confidence that dystocia or failure to progress exists.

Early identification of and prompt interventions for dystocia are essential to minimize risk to the woman and fetus. According to the American College of Obstetricians and Gynecologists (ACOG) factors associated with an increased risk for dystocia include epidural analgesia, excessive analgesia, multiple pregnancy, hydramnios, maternal exhaustion, ineffective maternal pushing technique, occiput posterior position, longer first stage of labor, nulliparity, short maternal stature (less than 5 ft tall), fetal birth weight (more than 8.8 lb), shoulder dystocia, abnormal fetal presentation or position (breech), fetal anomalies (hydrocephalus), maternal age older than 34 years, high caffeine intake, overweight, gestational age more than 41 weeks, chorioamnionitis, ineffective uterine contractions, and high fetal station at complete cervical dilation (2016).

One in three women who gives birth in the United States today does so by cesarean birth (Statista, 2019). The most common indications for primary cesarean births include, in order of frequency, labor dystocia, abnormal fetal heart rate (FHR) tracing, fetal

malpresentation, multiple gestations, and suspected macrosomia. It is time to revisit the definition of labor dystocia because recent studies show that contemporary labor progresses at a rate substantially slower than what was historically taught. Labors today are often longer, which may in part be due to higher body mass index (BMI), higher rates of labor induction, and the significant increase in the use of epidural anesthesia (ACOG, 2016). The World Health Organization (WHO) maintains that a surgical birth rate higher than 10% is not associated with better outcomes, and higher rates contribute to excess morbidity and mortality (2019).

Admitting women too early to the hospital while still in the early latent phase of labor may increase the diagnosis of dystocia and increase the risk of augmentation of labor and epidural analgesia. These two interventions may result in surgical birth. Adequate hydration, rest, emotional and physical support, and if needed, pharmacologic sedation can be encouraged as alternatives to early hospital admission. Patience is a critical factor.

Dystocia can result from problems or abnormalities involving the expulsive forces (known as the “powers”); presentation, position, and fetal development (the “passenger”); the maternal bony pelvis or birth canal (the “passageway”); and maternal stress (the “psyche”). Table 21.1 summarizes the diagnosis, therapeutic management, and nursing management of the common problems associated with dystocia.

Problems with the Powers

When the expulsive forces of the uterus become dysfunctional, the uterus may either never fully relax (hypertonic contractions), placing the fetus in jeopardy, or relax too much (hypotonic contractions), causing ineffective contractions. Additionally, the uterus may contract so frequently and with such intensity that a very rapid birth will take place (precipitate labor).

Hypertonic uterine dysfunction occurs when the uterus never fully relaxes between contractions. Subsequently, contractions are ineffectual, erratic, and poorly coordinated because they involve only

a portion of the uterus and because more than one uterine pacemaker is sending signals for contraction. Women in this situation experience a prolonged latent phase, stay at 2 to 3 cm, and do not dilate as they should. Placental perfusion becomes compromised, thereby reducing oxygen to the fetus. These hypertonic contractions exhaust the mother, who is experiencing frequent, intense, and painful contractions with little progression. This dysfunctional pattern occurs in early labor and affects nulliparous women more often than multiparous women (Ehsanipoor & Satin, 2020).

Hypotonic uterine dysfunction occurs during active labor (dilation more than 5 to 6 cm) when contractions become poor in quality and lack sufficient intensity to dilate and efface the cervix. Factors associated with this abnormal labor pattern include overstretching of the uterus, a large fetus, multiple fetuses, hydramnios, multiple parity, bowel or bladder distention preventing descent, and excessive use of analgesia. Clinical manifestations of hypotonic uterine dysfunction include weak contractions that become milder, a uterine fundus that can be easily indented with fingertip pressure at the peak of each contraction, and contractions that become more infrequent and briefer (King et al., 2019). The major risk with this complication is hemorrhage after giving birth because the uterus cannot contract effectively to compress blood vessels.

"Labor" refers to uterine contractions resulting in progressive dilation and effacement of the cervix, and accompanied by descent and expulsion of the fetus. "Abnormal labor," "dystocia," and "failure to progress" are imprecise terms that have been used to describe a difficult labor pattern that deviates from that observed in the majority of women who have spontaneous vaginal deliveries. A better classification is to characterize labor abnormalities as protracted disorders (i.e., slower-than-normal progress) or arrest disorders (i.e., complete cessation of progress).

The term **protracted disorders** refers to a series of events including protracted active phase dilation (slower-than-normal rate of cervical dilation) and protracted descent (delayed descent of the fetal head in the active phase). A laboring woman with a slower-than-

normal rate of cervical dilation is said to have a protracted labor pattern disorder. Slow progress may be the result of cephalopelvic disproportion. Most women, however, benefit greatly from adequate hydration and some nutrition, emotional reassurance, and position changes; these women may go on and give birth vaginally.

Arrest disorders include secondary arrest of dilation (no progress in cervical dilation in over 2 hours), arrest of descent (fetal head does not descend for more than 1 hour in primiparas and more than 30 minutes in multiparas), and failure of descent (no descent). About 20% of labors involve either protracted or arrest disorders (Ehsanipoor & Satin, 2020).

Precipitate labor is labor that is completed in less than 3 hours from the start of contractions to birth. Not only can labor be too slow, but it can be abnormally rapid. The prevailing opinion has been that too rapid a labor can result in maternal injury and place the fetus at risk for traumatic or asphyxia insults (Borhart & Voss, 2019). Women experiencing precipitate labor typically have soft perineal tissues that stretch readily, permitting the fetus to pass through the pelvis quickly, or abnormally strong uterine contractions. Maternal complications are rare if the maternal pelvis is adequate and the soft tissues yield to a fast fetal descent. However, if the fetus delivers too fast, it does not allow the cervix to dilate and efface, which leads to cervical lacerations and the potential for uterine rupture. Potential fetal complications may include head trauma, such as intracranial hemorrhage or nerve damage, and hypoxia due to the rapid progression of labor (Cunningham et al., 2018).

Precipitate labor is an anxiety-producing situation and frequently very painful with little rest between contractions. Continuous monitoring, frequent updates on labor progress, pain management, and reassurance about the mother’s condition can assist her anxiety. Management includes readiness of the health care team for this rapid birth.

TABLE 21.1 Diagnosis and Management of Common Problems Associated with Dystocia

	Description	Diagnosis	Therapeutic Management	Nursing Management
Problems with the Powers				
Hypertonic uterine dysfunction	Occurring in the latent phase of the first stage of labor (cervical dilation of <4 cm); uncoordinated Force of contraction typically in the midsection of uterus at the junction of the active upper and passive lower segments of the uterus rather than in the fundus Loss of downward pressure to push the presenting part against the cervix Woman commonly becomes discouraged due to lack of progress; also has increased pain secondary to uterine anoxia	Characteristic hypertonicity of the contractions and the lack of labor progress	Therapeutic rest with the use of sedatives to promote relaxation and stop the abnormal activity of the uterus Identification and intervention of any contributing factors Ruling out placental abruption (also associated with high resting tone and persistent pain) Onset of a normal labor pattern occurs in many women after a 4- to 6-hour rest period	Institute bed rest and sedation to promote relaxation and reduce pain. Assist with measures to rule out fetopelvic disproportion and fetal malpresentation. Evaluate fetal tolerance to labor pattern, such as monitoring of FHR patterns. Assess for signs of maternal infection. Promote adequate hydration through IV therapy. Provide pain management via epidural or IV analgesics. Assist with amniotomy to augment labor. Explain to woman and family about dysfunctional pattern. Plan for operative birth if normal labor pattern is not achieved.
Hypotonic uterine dysfunction	Often termed "secondary uterine inertia" because the labor begins normally and then the frequency and intensity of contractions decrease Possible contributing factors: overdistended uterus with multifetal pregnancy or large single fetus, too much pain medicine given too early in labor, fetal malposition, and regional anesthesia	Evaluation of the woman's labor to confirm that she is having hypotonic active labor rather than a long latent phase Evaluation of maternal pelvis and fetal presentation and position to ensure that they are not contributing to the prolonged labor without noticeable progress	Identification of possible cause of inefficient uterine action (a malpositioned fetus, a too-small maternal pelvis, overdistention of the uterus with fluid or a macrosomic fetus) Rupture of amniotic sac (amniotomy) if all causes ruled out Possible augmentation with oxytocin (Pitocin) to stimulate effective uterine contractions Cesarean birth if amniotomy and augmentation ineffective	Administer oxytocin as ordered once fetopelvic disproportion is ruled out. Assist with amniotomy if membranes are intact. Provide continuous electronic fetal monitoring. Monitor vital signs, contractions, and cervix continually. Assess for signs of maternal and fetal infection. Explain to the woman and family about dysfunctional pattern. Plan for surgical birth if normal labor pattern is not achieved or fetal distress occurs.
Precipitate labor	Abrupt onset of higher-intensity contractions occurring in a shorter period of time instead of the more gradual increase in frequency, duration, and intensity that typifies most spontaneous labors	Identification based on the rapidity of progress through the stages of labor	Vaginal delivery if maternal pelvis is adequate	Closely monitor a woman with previous history. Anticipate use of scheduled induction to control labor rate. Administer pharmacologic agents, such as tocolytics, to slow labor. Stay in constant attendance to monitor progress.

Problems with the Passenger				
Persistent occiput posterior position	Engagement of fetal head in the left or right occipito-transverse position with the occiput rotating posteriorly rather than into the more favorable occiput anterior position (fetus born facing upward instead of the normal downward position) Labor usually much longer and more uncomfortable (causing increased back pain during labor) if fetus remains in this position Possible extensive caput succedaneum and molding from the sustained occiput posterior position	Leopold maneuvers and vaginal examination to determine position of fetal head in conjunction with the mother's complaints of severe back pain (back of fetal head pressing on mother's sacrum and coccyx)	Labor to proceed, preparing the woman for a long labor (spontaneous resolution possible) Comfort measures and maternal positioning to help promote fetal head rotation	Assess for complaints of intense back pain in first stage of labor. Anticipate possible use of forceps to rotate to anterior position at birth or manual rotation to anterior position at end of second stage. Assess for prolonged second stage of labor with arrest of descent (common with this malposition). Encourage maternal position changes to promote fetal head rotation: hands and knees and rocking pelvis back and forth; side-lying position; side lunges during contractions; sitting, kneeling, or standing while leaning forward; squatting position to give birth and enlarge pelvic outlet. Prepare for possible cesarean birth if rotation is not achieved. Administer agents as ordered for pain relief (effective pain relief crucial to help the woman tolerate the back discomfort). Apply low back counterpressure during contractions to ease the discomfort. Use other helpful measures to attempt to rotate the fetal head, including lateral abdominal stroking in the direction that the fetal head should rotate; assisting the client into a hands-and-knees position (all fours); and squatting, pelvic rocking, stair climbing, assuming a side-lying position toward the side that the fetus should rotate, and side lunges. Provide measures to reduce anxiety. Continuously reinforce the woman's progress. Teach the woman about measures to facilitate fetal head rotation.
Face and brow presentation	Face presentation with complete extension of the fetal head Brow presentation: fetal head between full extension and full flexion so that the largest fetal skull diameter presents to the pelvis	Diagnosis only once labor is well established via vaginal examination; palpation of facial features as the presenting part rather than the fetal head	Vaginal birth possible with face presentation with an adequate maternal pelvis and fetal head rotation; cesarean birth if head rotates backward Cesarean birth for brow presentation unless head flexes	Assist with evaluating for fetopelvic disproportion. Anticipate cesarean birth if vertex position is not achieved. Explain fetal malposition to the woman and her partner. Provide close observation for any signs of fetal hypoxia as evidenced by late decelerations on the fetal monitor.

Breech presentation	Fetal buttocks or breech, presenting first rather than the head 1. Frank breech: buttock as the presenting part, with hips flexed and legs and knees extended upward 2. Complete breech (or full breech): buttock as presenting part, with hips flexed and knees flexed in a "cannonball" position 3. Footling or incomplete breech: One or two feet as the presenting part, with one or both hips extended	Vaginal examination to determine breech presentation Ideally, ultrasound to confirm a clinically suspected presentation and to identify any fetal anomalies	The optimal method of birth is controversial: cesarean birth by some providers unless the fetus is small and the mother has a large pelvis; vaginal birth by others with each occurrence treated individually and labor monitored closely Regardless of the birth method selected, the risk for trauma is high. Breech vaginal births are not recommended by ACOG and come with a higher risk to the mother and infant than a planned surgical birth. Vaginal delivery: fetus allowed to spontaneously deliver up to the umbilicus; then maneuvers to assist in the delivery of the remainder of the body, arms, and head; fetal membranes left intact as long as possible to act as a dilating wedge and to prevent cord prolapse; anesthesiologist and pediatrician present Cesarean birth: Use of external cephalic version to reduce the chance of breech presentation at birth; attempted after the 35th week of gestation but before the start of labor (some fetuses spontaneously turn to a cephalic presentation on their own toward term, and some will return to the breech presentation if external cephalic version is attempted too early); variable success rates, with risk for fractured bones, ruptured viscera, placental abruption, fetomaternal hemorrhage, and umbilical cord entanglement Tocolytic drugs to relax the uterus as well as other methods to facilitate external cephalic version at term Individual evaluation of each woman for all factors before any intervention is initiated	Assess for associated conditions such as placenta previa, hydramnios, fetal anomalies, and multifetal pregnancy. Arrange for ultrasound to confirm fetal presentation. Assist with external cephalic version possible after 36 weeks, and administer tocolytics to assist with external cephalic version. Anticipate trial labor for 4–6 hours to evaluate progress if version is unsuccessful. Plan for cesarean birth if no progress is seen or fetal distress occurs. After external cephalic version, administer RhoGAM to the Rh-negative woman to prevent a sensitization reaction if trauma has occurred and the potential for mixing of blood exists.

Shoulder dystocia	Delivery of fetal head with neck not appearing; retraction of chin against the perineum; shoulders remaining wedged behind the mother's pubic bone, causing a difficult birth with potential for injury to both mother and baby If shoulders still above the brim at this stage, no advancement Newborn's chest trapped within the vaginal vault; chest unable to expand with respiration (although nose and mouth are outside) Risk of umbilical cord compression between the fetal body and the maternal pelvis	Emergency, often unexpected complication Diagnosis made when newborn's head delivers without delivery of neck and remaining body structures Primary risk factors, including suspected infant macrosomia (weight >4,500 g), maternal diabetes mellitus, excessive maternal weight gain, abnormal maternal pelvic anatomy, maternal obesity, postdated pregnancy, short stature, a history of previous shoulder dystocia, and use of epidural analgesia	If anticipated, preparatory tasks instituted: alerting of key personnel; education of woman and family regarding steps to be taken in the event of a difficult birth; emptying of woman's bladder to allow additional room for possible maneuvers needed for the birth McRobert maneuver Suprapubic pressure (not fundal) (see Fig. 21.1) Combination of maneuvers effective in more than 50% of cases of shoulder dystocia Newborn resuscitation team readily available	Intervene immediately due to cord compression. Perform McRobert maneuver and application of suprapubic pressure. Assist with positioning the woman in squatting position, hands-and-knees position, or lateral recumbent position for birth to free shoulder. Anticipate cesarean birth if no success in dislodging shoulders. Clear room of unnecessary clutter to make room for additional personnel and equipment. After the birth, assess newborn for crepitus, deformity, Erb palsy, or bruising, which might suggest neurologic damage or a fracture.
Multiple pregnancy	More than one fetus, leading to uterine overdistention and possibly resulting in hypotonic contractions and abnormal presentations of the fetuses Fetal hypoxia during labor a significant threat due to placenta providing oxygen and nutrients to more than one fetus	Nearly all multiples are now diagnosed early by ultrasound. Most women go into labor before 37 weeks.	Admission to facility with specialized care unit if a woman goes into labor Spontaneous progression of labor if woman has no complicating factors and first fetus is in longitudinal lie Separate monitoring of each FHR during labor and birth After birth of first fetus, clamping of cord and lie of the second twin assessed; possible external cephalic version necessary to assist in providing a longitudinal lie Second and subsequent fetuses at greater risk for birth-related complications, such as umbilical cord prolapse, malpresentation, and placental abruption Cesarean birth if risk factors high.	Assess for hypotonic labor pattern due to overdistention. Evaluate for fetal presentation, maternal pelvic size, and gestational age to determine mode of delivery. Ensure presence of neonatal team for birth of multiples. Anticipate need for cesarean birth, which is common in multifetal pregnancy.
Excessive fetal size and abnormalities	Macrosomia leading to fetopelvic disproportion (fetus unable to fit through the maternal pelvis to be born vaginally) Reduced contraction strength due to overdistention by large fetus leading to a prolonged labor and the potential for birth injury and trauma Fetal abnormalities possibly interfering with fetal descent, leading to prolonged labor and difficult birth	A diagnosis of fetal macrosomia can be confirmed by measuring the birth weight after birth. Suspicion of macrosomia based on the findings of an ultrasound examination before onset of labor (if suspected due to conditions such as maternal diabetes or obesity, estimation of fetal weight via ultrasound) Leopold maneuvers to estimate fetal weight and position on admission to labor and birth unit	Scheduled cesarean birth if diagnosis is made before the onset of labor to reduce the risk of injury to both the newborn and the mother If identified by Leopold maneuvers, possible trial of labor to evaluate progress; however, providers usually opt to proceed with a cesarean birth in a primigravida with a macrosomic fetus	Assess for inability of fetus to descend. Anticipate need for vacuum- and forceps-assisted births (common). Plan for cesarean birth if maternal parameters are inadequate to give birth to large fetus.

Problems with the Passageway				
	Contraction of one or more of the three planes of the pelvis Poorer prognosis for vaginal birth in women with android and platypelloid types of pelvis Contracted pelvis involving reduction in one or more of the pelvic diameters interfering with progress of labor: inlet, midpelvis, and outlet contracture Obstruction in the birth canal, such as placenta previa that partially or completely obstructs the internal os of the cervix, fibroids in the lower uterine segment, a full bladder or rectum, an edematous cervix caused by premature bearing-down efforts, and human papillomavirus (HPV) warts	Shortest A-P diameter <10 cm or greatest transverse diameter <12 cm (approximation of A-P diameter via measurement of diagonal conjugate, which in the contracted pelvis is <11.5 cm) X-ray pelvimetry to determine the smallest A-P diameter through which the fetal head must pass Interischial tuberous diameter of <8 cm possibly compromising outlet contracture (outlet and midpelvic contractures frequently occur together)	Focus on allowing natural forces of labor contractions to push the largest diameter (biparietal) of the fetal head beyond the obstruction or narrow passage Possible forceps and vacuum extraction to assist navigation through this passageway	Assess for poor contractions, slow dilation, and prolonged labor. Evaluate bowel and bladder status to reduce soft tissue obstruction and allow increased pelvic space. Anticipate trial of labor; if no labor progression after an adequate trial, plan for cesarean birth.
Problems with the Psyche				
	Release of stress-related hormones (catecholamines, cortisol, epinephrine, beta-endorphin), which act on smooth muscle (uterus) and reduce uterine contractility Excessive release of catecholamines and other stress-related hormones not therapeutic Release also results in decreased uteroplacental perfusion and increased risk for poor newborn adjustment.	Ruling out of other possible causes of dystocia	Treatment dependent on woman's responses such as anxiety, fear, anger, frustration, or denial (highly variable due to woman's understanding of the condition itself, past experiences, previous coping mechanisms, and the amount of family and nursing support received) Appropriate medical or surgical interventions depending on the underlying condition	Provide comfortable environment, such as with dim lighting or music. Encourage partner to participate. Provide pain management to reduce anxiety and stress. Ensure continuous presence of staff to allay anxiety. Provide frequent updates concerning fetal status and progress. Provide ongoing encouragement to minimize the woman's stress and help her to cope with labor and promote a positive, timely outcome. Assist in relaxation and comfort measures to help her body work more effectively with the forces of labor. Engage the woman in conversation about her emotional well-being; offer anticipatory guidance and reassurance to increase her self-esteem and ability to cope, decrease frustration, and encourage cooperation.

Problems with the Passenger

Any presentation other than occiput anterior (head down and anterior facing) or a slight variation of the fetal position or size increases the probability of dystocia. These variations can affect the contractions or fetal descent through the maternal pelvis. Common problems involving the fetus include occiput posterior position, breech presentation, multifetal pregnancy, excessive size (macrosomia) as it relates to cephalopelvic disproportion, and structural anomalies.

Persistent occiput posterior is the most common malposition, occurring in up to 5% of laboring women (Havelkova et al., 2019). The reasons for this malposition are often unclear. This position presents slightly larger diameters to the maternal pelvis, thus slowing fetal descent. A fetal head that is poorly flexed may be responsible. In addition, poor uterine contractions may not push the fetal head

down into the pelvic floor to the extent that the fetal occiput sinks into it rather than being pushed to rotate in an anterior direction.

Face and brow presentations are rare and are associated with fetal abnormalities (anencephaly), pelvic contractures, high parity, placenta previa, hydramnios, low birth weight, or a large fetus (Resnik et al., 2019).

By 35 to 36 weeks' gestation, the majority of fetuses will spontaneously settle into the vertex presentation (head down toward the birth canal). In about 3% of cases, however, the fetus will remain in a breech presentation with the buttocks or feet presenting (Hofmeyr, 2020). There is less risk to the fetus and mother when the head is down at the time of birth. This presentation is frequently associated with multifetal or multiple pregnancies, grand multiparity (more than five births), pregnancy over age 35, placenta previa, hydramnios, preterm births, uterine malformations or fibroids, a scarred uterus, a female infant, and fetal anomalies such as hydrocephaly (Norwitz et al., 2019). In a persistent breech presentation, an increased frequency of prolapsed cord, placenta previa, low birth weight from preterm birth, fetal or uterine anomalies, and perinatal morbidity and mortality from a difficult birth may occur (Cunningham et al., 2018). A breech presentation may be an indicator for subtle fetal abnormalities, as healthy breech infants have, on average, poorer long-term neurodevelopmental scores than cephalic infants (Hofmeyr, 2019). Perinatal mortality is increased two- to fourfold with a breech presentation, regardless of the mode of delivery.

External cephalic version refers to a procedure in which the fetus is rotated from the breech to the cephalic presentation by manipulation through the mother's abdominal wall at or near term. Several national organizations (ACOG, WHO, American Academy of Family Physicians [AAFP]), recommend that this maneuver be offered to women between 36 and 38 weeks' gestation. It is performed only in hospital settings under direct ultrasound guidance and continuous fetal monitoring. External cephalic version is successful in approximately 50% of cases. Women with breech

presentations are now often advised to have surgical births with no attempt to rotate the fetal position (ACOG, 2018).

Shoulder dystocia is defined as the obstruction of fetal descent and birth by the axis of the fetal shoulders after the fetal head has been delivered. Shoulder dystocia is a fundamentally mechanical problem. The incidence of shoulder dystocia is increasing due to increasing birth weight, with reports of it occurring in about one in every 200 (3%) vaginal births. It can result in approximately 5,000 new permanent brachial plexus palsy cases annually in the United States (Easley & Beste, 2019). It is an obstetric emergency that requires a coordinated team response, as there is no reliable way to predict it, and thus decrease the rate at which adverse outcomes occur (Davis et al., 2020). It can be one of the most anxiety-provoking emergencies encountered during labor. Failure of the shoulders to deliver spontaneously places both the woman and the fetus at risk for injury. Postpartum hemorrhage secondary to uterine atony, vaginal lacerations, anal tears, and uterine rupture are major complications to the mother. Transient Erb or Duchenne brachial plexus palsies and clavicular or humeral fractures are the most common fetal injuries encountered with shoulder dystocia. The occurrence of neonatal brachial plexus palsy in the United States is up to two per 1,000 live births, with about one third experiencing permanent upper extremity functional insufficiencies (McLaren et al., 2019). Newborns experiencing shoulder dystocia typically have greater shoulder-to-head and chest-to-head disproportions compared with those delivered without dystocia (Cunningham et al., 2018). Prompt recognition and appropriate management, such as with McRobert maneuver or suprapubic pressure, can reduce the severity of injuries to the mother and newborn (Fig. 21.1).

TAKE NOTE!

Prompt recognition and appropriate management of shoulder dystocia can reduce the severity of injuries to the mother and infant. Immediately assess the infant for signs of trauma such as a fractured clavicle, Erb palsy, or neonatal asphyxia. Assess the mother for excessive vaginal bleeding and blood in the urine from bladder trauma.

Multifetal or **multiple gestation** refers to twins, triplets, or more infants within a single pregnancy (Box 21.1). The incidence is increasing, primarily as a result of infertility treatment (both ovarian stimulation and in vitro fertilization) and an increased number of women giving birth at older ages. The incidence of twins, triples, and higher-order multiple gestations have now reached approximately 4% of all pregnancies (March of Dimes, 2019a). The incidence of twins is approximately one in 80 conceptions, with about two thirds of them due to the fertilization of two ova (dizygotic or fraternal) and about one third occurring from the splitting of one fertilized ovum (monozygotic or identical twins). One in approximately 8,100 pregnancies results in triplets (March of Dimes, 2019a). The most common maternal complication is postpartum hemorrhage resulting from uterine atony. Compared with singletons (one fetus), the risk of perinatal morbidity and mortality is markedly increased in multiple gestations. Based on recent evidence from a randomized controlled study, there was no difference in newborn outcomes between a planned surgical birth versus a planned vaginal birth for twins between 32 and 39 weeks' gestation. As long as the presenting twin is vertex, a vaginal birth should be considered (Mandy, 2019).

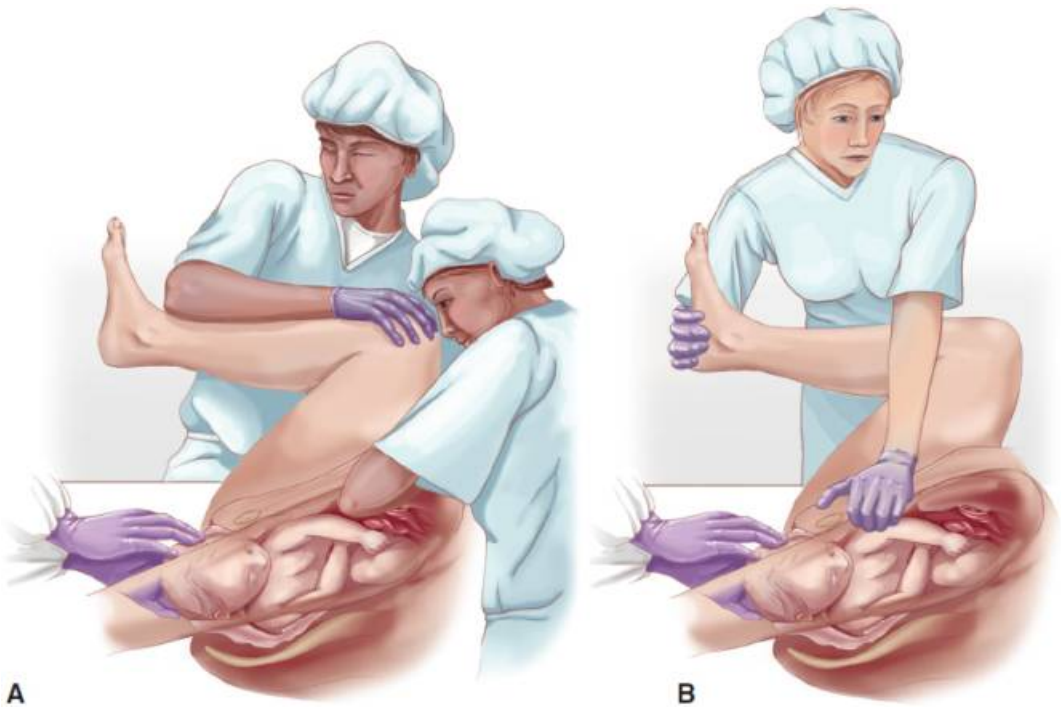

FIGURE 21.1. Maneuvers to relieve shoulder dystocia. **A.** McRobert maneuver. The mother's thighs are flexed and abducted as much as possible to straighten the pelvic curve. **B.** Suprapubic pressure. Light pressure is applied just above the pubic bone, pushing the fetal anterior shoulder downward to displace it from above the mother's symphysis pubis. The newborn's head is depressed toward the mother's anus while light suprapubic pressure is applied.

BOX 21.1 Multiple Gestation

As the name implies, a multiple gestation or a multifetal pregnancy involves more than one fetus. These fetuses can result from fertilization of a single ovum or multiple ova. Monozygotic (identical) twins develop from one single ovum that divides into equal halves during early cleavage phase. Monozygotic twins are genetically identical, always the same gender, and look very similar in appearance. The number of amnions and chorions depends on the timing of division (cleavage). One fertilized ovum splitting into two separate individuals is termed *natural clones*. This type of twinning occurs in approximately one in 250 live births (March of Dimes, 2019a).

Twin pregnancies that are multiple-ova conceptions (dizygotic twins) result from two ova fertilized by two sperms. They are referred to as fraternal twins. Genetically, dizygotic twins are as alike (or unlike) as any other pair or siblings. There are separate amnions and chorions although the chorions and placentas may be fused. The incidence of dizygotic twinning varies by race 10 to 40 per 1,000 births among black pregnancies; seven to 10 per 1,000 births among White pregnancies; and three per 1,000 births among Asian pregnancies (Fletcher, 2019). Fraternal twins account for two thirds of all twins and there is a tendency to repeat within families. The incidence of fraternal twins is increasing secondary to advancing maternal age when pregnancy occurs and an increase in use of fertility drugs and procedures being done.

Multiple births other than twins can be of the identical type, the fraternal type, or combinations of the two. Triplets can occur from the division of one zygote into two, with one dividing again, producing identical triplets, or they can come from two zygotes, one dividing into a set of identical twins, and the second zygote developing as a single fraternal sibling, or from three separate zygotes. Triplets are said to occur once in 7,000 births and quadruplets once in 660,000 births (March of Dimes, 2019a). In recent years, fertility drugs used to induce ovulation have resulted in a greater frequency of quadruplets, quintuplets, sextuplets, and even octuplets.

Excessive fetal size and abnormalities can also contribute to labor and birth dysfunctions. **Macrosomia**, in which a newborn weighs 4,000 to 4,500 g (8.13 to 9.15 lb) or more at birth, complicates approximately 10% of all pregnancies (ACOG, 2020). It is the result of a change in body composition in the neonate with an increase in both percentage of fat and fat mass. Macrosomia is associated with later-in-life obesity, diabetes, and cardiovascular disease (Wang et al., 2018). Fetal abnormalities may include hydrocephalus, ascites, or a large mass on the neck or head. Complications associated with

dystocia related to excessive fetal size and anomalies include an increased risk for postpartum hemorrhage, shoulder dystocia, low Apgar scores, dysfunctional labor, fetopelvic disproportion, soft tissue laceration during vaginal birth, fetal injuries or fractures, and perinatal asphyxia. Accurate prenatal identification of a macrosomic fetus is difficult; ACOG recommends elective cesarean birth be considered after consultation with the family (Jordan et al., 2019).

Problems with the Passageway

Problems with the passageway (pelvis and birth canal) are related to a contraction of one or more of the three planes of the maternal pelvis: inlet, midpelvis, and outlet. The female pelvis can be classified into four types based on the shape of the pelvic inlet, which is bounded anteriorly by the posterior border of the symphysis pubis, posteriorly by the sacral promontory, and laterally by the linea terminalis. The four basic types are gynecoid, anthropoid, android, and platypelloid (see Chapter 12 for additional information). Contraction of the midpelvis is more common than inlet contraction and typically causes an arrest of fetal descent. Obstructions in the maternal birth canal, such as swelling of the soft maternal tissue and cervix, termed soft tissue dystocia, can also hamper fetal descent and impede labor progression outside the maternal bony pelvis.

Problems with the Psyche

Many women experience an array of emotions during labor which may include fear, anxiety, helplessness, isolation, and weariness. These emotions can lead to psychological stress, which indirectly can cause dystocia. Hormones released in response to anxiety can cause dystocia. Intense anxiety stimulates the sympathetic nervous system, which releases catecholamines that can lead to myometrial dysfunction. Norepinephrine and epinephrine then lead to uncoordinated or increased uterine activity. Anxiety can also increase fear and tension, and reduce pain tolerance, decreasing uterine contractility (Blackburn, 2018).

Nursing Assessment

Begin the assessment by reviewing the client's history to look for risk factors for dystocia which may include maternal short stature, obesity, hydramnios, uterine abnormalities, fetal malpresentation, cephalopelvic disproportion, overstimulation with oxytocin, maternal exhaustion, ineffective pushing, excessive size fetus, poor maternal positioning in labor, and maternal anxiety and fear (Stevens, 2019). Assess the mother's frame of mind to identify fear, anxiety, stress, lack of support, and pain, which can interfere with uterine contractions and impede labor progress. Helping the woman relax will promote normal labor progress.

Assess the woman's vital signs. Note any elevation in temperature (suggesting a potential infection) or changes in heart rate or blood pressure (potential hypovolemia). Evaluate the uterine contractions for frequency and intensity. Ask the woman about any changes in her contraction pattern, such as a decrease or increase in frequency or intensity, and report these. Assess FHR and pattern, reporting any abnormal patterns immediately.

FIGURE 21.2. The nurse applies a cool, moist washcloth to the client's forehead and offers her ice chips to combat thirst and provide comfort while she experiences dystocia.

Assess fetal position via Leopold maneuvers (see Chapter 14 for more information) to identify any deviations in presentation or position, and report any deviations. Assist with or perform a vaginal examination to determine cervical dilation, effacement, and engagement of the fetal presenting part. Evaluate for evidence of membrane rupture. Report any malodorous fluid.

Nursing Management

Nursing management of the woman with dystocia, regardless of the etiology, requires patience. The nurse should provide physical and emotional support to the client and her family. The final outcome of any labor depends on the size and shape of the maternal pelvis; the quality of the uterine contractions; and the size, presentation, and position of the fetus. Thus, dystocia is diagnosed after labor has progressed for a time, not at the beginning of labor.

Promoting the Progress of Labor

The nurse plays a major role in determining the progress of labor. Continue to assess the woman, frequently monitoring cervical dilation and effacement, uterine contractions, and fetal descent, and document that all assessed parameters are progressing. Evaluate progress in active labor by using the simple rule of 1 cm per hour for cervical dilation. When the woman's membranes rupture, if they have not already ruptured, observe for visible cord prolapse.

TAKE NOTE!

If dysfunctional labor occurs, contractions will slow or fail to advance in frequency, duration, or intensity; the cervix will fail to respond to uterine contractions by dilating and effacing; and the fetus will fail to descend.

Throughout labor, assess the woman's fluid balance status. Check skin turgor and mucous membranes. Monitor intake and output. Also monitor the client's bladder for distention at least every 2 hours and encourage her to empty her bladder often. In addition, monitor her bowel status. A full bladder or rectum can impede descent.

Continue to monitor fetal well-being. If the fetus is in the breech position, be especially observant for visible cord prolapse and note any variable decelerations in heart rate. If either occurs, report it immediately.

Be prepared to administer a labor stimulant such as oxytocin (Pitocin) if ordered to treat hypotonic labor contractions. Anticipate the need to assist with manipulations if shoulder dystocia is

diagnosed. Prepare the woman and her family for the possibility of a cesarean birth if labor does not progress.

Providing Physical and Emotional Comfort

Employ physical comfort measures to promote relaxation and reduce stress. Offer blankets for warmth and a backrub if the client wishes to reduce muscle tension. Provide an environment conducive to rest so the woman can conserve her energy. Lower the lights and reduce external noise by closing the hallway door. Offer a warm shower to promote relaxation (if not contraindicated). Use pillows to support the woman in a comfortable position, changing her position every 30 minutes to reduce tension and to enhance uterine activity and efficiency. Offer her fluids and/or food as appropriate to moisten her mouth and replenish her energy (Fig. 21.2).

Assist with providing counterpressure along with backrubs if the fetus is in the occiput posterior position. Encourage the woman to assume different positions to promote fetal rotation. Upright positions are helpful in facilitating fetal rotation and descent. Also encourage the woman to visualize the descent and birth of the fetus.

Assess the woman's level of pain and degree of distress. Administer analgesics as ordered or according to the facility's protocol. Evaluate the mother's level of fatigue throughout labor, such as verbal expressions of feeling exhausted, inability to cope in early labor, or inability to rest or calm down between contractions. Praise the woman and her partner for their efforts. Provide empathetic listening to increase the client's coping ability, and remain with the client to demonstrate caring.

Promoting Empowerment

Educate the client and family about dysfunctional labor and its causes and therapies. Explain therapeutic interventions that may be needed to assist with the labor process. Encourage the client and her partner to participate in decision-making about interventions.

Assist the woman and partner in expressing their fears and anxieties. Provide encouragement to help them to maintain control.

Support the client and her partner in their coping efforts. Keep the woman and her partner informed of progress and advocate for them.

NONTRADITIONAL FAMILIES

There are a growing number of nontraditional families in the world. If one considers family forms cross-nationally, a variety of configurations exist. Awareness requires nurses to shift away from heterosexist thinking when caring for the childbearing family. Nurses must be adequately educated about lesbian, gay, bisexual, transgender, queer, and intersex (LGBTI) health issues to be empathetic and conscious of the needs of this population. With increasing numbers of LGBTI couples getting married or cohabitating and the availability of alternative methods of conception, nurses are helping these families navigate the birthing process. LGBTI families may face making complex childbearing decisions, navigating a health care system designed for heterosexual couples, and confronting barriers such as insurance issues, negative attitudes from health care workers, and uncertain legal rights. It is essential for nurses to create a culture of inclusion through appropriate communication and respect as well as a nonjudgmental approach (Landry & Kensler, 2019).

Like any other populations, the LGBTI population is not a homogeneous group, and individuals are shaped by a range of factors including race, sexual orientation, ethnicity, socioeconomic status, and age. This community has traditionally been marginalized in American society. Nurses caring for LGBTI clients need to facilitate them expressing their own identities, values, and beliefs. Every client should be treated with kindness and an individualized approach, and the nurse must be an advocate for every client's needs. Nurses need to consider using appropriate language, identification, and cultural representation by asking clients how they wish to be identified and by personalizing care that includes all intersecting aspects of identity. Cultivating an environment of

inclusion and acceptance makes clients more comfortable and more likely to seek health care (Kuzma et al., 2019).

PRETERM LABOR

Preterm labor is defined as the occurrence of regular uterine contractions accompanied by cervical effacement and dilation before the end of the 37th week of gestation. If not halted, it leads to preterm birth. Preterm births remain one of the biggest contributors to perinatal morbidity and mortality in the world. According to the March of Dimes (2019e) about one in 10 infants in the United States are born premature.

Preterm birth is one of the most common obstetric complications, and its sequelae have a profound effect on the survival and health of the newborn. The rate of preterm births in the United States has increased dramatically in the past 20 years. Rates vary across different states, and African American clients experience almost twice the rate of preterm labor compared to other demographic groups (Suman & Luther, 2019). Preterm births account for 75% of neurodevelopmental disorders and other serious morbidities, as well as behavioral and social problems. They account for 85% of all perinatal morbidity and mortality (Stewart & Barfield, 2019). In addition, up to $820 million is spent on maternal and infant care related to prematurity annually (March of Dimes, 2019e). Infants born prematurely also are at risk for serious sequelae such as respiratory distress syndrome, infections, congenital heart defects, thermoregulation problems that can lead to acidosis and weight loss, intraventricular hemorrhage, jaundice, hypoglycemia, feeding difficulties resulting from diminished stomach capacity and an underdeveloped suck reflex, and neurologic disorders related to hypoxia and trauma at birth. Many will face the prospect of numerous lifelong disabilities, such as cerebral palsy, intellectual impairment, vision defects, and hearing loss. A recent study's findings indicated that a single course of corticosteroids prenatally improved most neonate's neurodevelopmental outcomes if given

before 34 weeks' gestation; this treatment is relatively noncontroversial (Briceno-Perez et al., 2019). Although great strides have been made in neonatal intensive care, prematurity remains the leading cause of death within the first month of life and is the second leading cause of all infant deaths (March of Dimes, 2019e). The exact cause of preterm labor is not known. Currently, prevention is the goal (see Evidence-Based Practice 21.1).

Therapeutic Management

Predicting the risk of preterm labor is valuable only if there is an available intervention that is likely to improve the situation. According to ACOG, many factors must be considered before selecting an intervention. Many factors influence the decision to intervene when women present with symptoms of preterm labor, including the probability of progressive labor, gestational age, and the risks of treatment. ACOG (2019a) recommends the following guidelines:

- There are no clear first-line **tocolytic** drugs (drugs that promote uterine relaxation by interfering with uterine contractions) to manage preterm labor, and the results of research on their efficacy are mixed. Clinical circumstances and the health care provider's preference should dictate treatment.
- Deferring birth to the 39th week is not recommended if there is a medical or obstetric indication for an earlier delivery.

EVIDENCE-BASED PRACTICE 21.1

Interventions during Pregnancy to Prevent Preterm Birth: An Overview of Cochrane Systematic Reviews

STUDY

Preterm birth is devastating and costly for women, families, and the health care system. Preterm births are a major contributing factor to global rates of neonatal mortality and to long-term health problems in surviving infants. Both the WHO and the United Nations consider prevention of preterm births central to improving the health status for pregnant women and newborns. The objective of this review was to summarize all evidence for promising interventions to prevent preterm births. Eighty-three studies were found to address this issue, showing clear evidence of benefit.

Findings

Four systematic reviews reported clear evidence of benefit to prevent specific populations of pregnant women from giving birth early, including midwife-led continuity models of care for all women; screening for lower genital tract infections for women less than 37 weeks' gestation and without signs of labor; checking for bleeding; and zinc supplementation for women without systemic illness. The overview found no evidence to support interventions of cervical pessary, cervical length assessment, and vaginal progesterone.

Nursing Implications

The findings can serve as a map and guide in discussions with women who have risk factors for preterm labor prevention. The

four interventions found to be beneficial in preterm labor prevention can be discussed with pregnant women prenatally to make them aware of possible interventions available to assist them. Nurses can integrate information from this study in their teaching about the risks associated with preterm labor and births. They can also use this information to help answer couples' questions about interventions currently used and their effectiveness as well as provide anticipatory guidance about the procedure. Doing so fosters empowerment of the woman and her family, promoting optimal informed decision-making.

Adapted from Medley, N., Vogel, J. P., Care, A., & Alfirevic, Z. (2018). Interventions during pregnancy to prevent preterm birth: a overview of Cochrane systematic reviews. Cochrane Database of Systematic Reviews, 11:CD012505.

FIGURE 21.3. The mother with preterm labor resting in bed at home.

- Antibiotics do not appear to prolong gestation and should be reserved for group B streptococcal prophylaxis in women in whom birth is imminent.

- Tocolytic drugs may prolong pregnancy for 2 to 7 days; during this time, steroids can be given to improve fetal lung maturity and the woman can be transported to a tertiary care center.
- A single course of corticosteroids is recommended for all pregnant women between 24 and 34 weeks' gestation who are at risk of preterm birth within 7 days. Prenatal corticosteroids significantly reduce the incidence and severity of neonatal respiratory distress syndrome.

With these recommendations, health care providers continue to prescribe pharmacologic treatment for preterm labor at home and in the hospital setting. This treatment often includes oral or intravenous tocolytics and varying degrees of activity restriction (Fig. 21.3). Antibiotics may also be prescribed to treat presumed or confirmed infections. Steroids may be given to enhance fetal lung maturity between 24 and 34 weeks' gestation.

Tocolytic Therapy

The decision to stop preterm labor is individualized based on risk factors, extent of cervical dilation, membrane status, fetal gestational age, and presence or absence of infection. Tocolytic therapy is most likely ordered if preterm labor occurs before the 34th week of gestation in an attempt to delay birth and thereby reduce the severity of respiratory distress syndrome and other complications associated with prematurity. Tocolytic therapy does not typically prevent preterm birth, but it may delay it. It is contraindicated for placental abruption, acute fetal distress or death, oliohydramnios, eclampsia or severe preeclampsia, active vaginal bleeding, dilation of more than 6 cm, chorioamnionitis, and maternal hemodynamic instability (Ross, 2019).

Medications commonly used for tocolysis include magnesium sulfate (which reduces the muscle's ability to contract), indomethacin (Indocin, a prostaglandin synthetase inhibitor), atosiban (Tractocile, Antocin, an oxytocin receptor antagonist), and nifedipine (Procardia, a calcium channel blocker). These drugs are used "off label," which means that they are effective for this purpose but have not been

officially tested and developed for this purpose by the U.S. Food and Drug Administration (FDA) (Troiano et al., 2019). In a recent review of the literature, calcium channel blockers were found to be better in preventing preterm labor when compared to beta-mimetics (Hanley et al., 2019). All of these medications have serious side effects, and the woman needs close supervision when they are being administered (Drug Guide 21.1).

Corticosteroids

Corticosteroids given to the mother in preterm labor can help prevent or reduce the frequency and severity of respiratory distress syndrome in premature infants delivered between 24 and 34 weeks' gestation. The beneficial effects of corticosteroids on fetal lung maturation have been reported within 48 hours of initial administration. The current available evidence reassuringly shows no significant harm in early childhood, though no benefit beyond the initial lung maturation. Further research is needed on the long-term benefits and risks for the woman and baby. Individual client data meta-analysis may clarify how to maximize benefit and minimize harm (Stevens, 2019). These drugs require at least 24 hours to become effective, so timely administration is crucial.

Nursing Assessment

The preterm birth rate cannot be reduced until there are ways to predict the risk for preterm birth. Because the etiology is often multifactorial, an individualized approach is needed.

Health History and Physical Examination

The signs of preterm labor are subtle and may be overlooked by the client as well as the health care provider. Obtain a thorough health history and be alert for risk factors associated with preterm labor and birth (Box 21.2).

Frequently, women are unaware that uterine contractions, effacement, and dilation are occurring, thus making early

intervention ineffective in arresting preterm labor and preventing the birth of a premature newborn. Ask the woman about any complaints, being alert for subtle symptoms of preterm labor, which may include:

- Change or increase in vaginal discharge with mucous, water, or blood in it
- Pelvic pressure (pushing-down sensation)

DRUG GUIDE 21.1 Medications Used with Preterm Labor

Medication	Action/Indications	Nursing Implications
Magnesium sulfate	Relaxes uterine muscles to stop irritability and contractions, to arrest uterine contractions for preterm labor (off-label use). Has been used in seizure prophylaxis and treatment of seizures in preeclamptic and eclamptic clients for almost 100 years.	Administer IV with a loading dose of 4–6 g over 15–30 minutes initially, and then maintain infusion at 1–4 g/hr. Assess vital signs and deep tendon reflexes (DTRs) hourly; report any hypotension or depressed or absent DTRs. Monitor level of consciousness; report any headache, blurred vision, dizziness, or altered level of consciousness. Perform continuous electronic fetal monitoring; report any decreased FHR variability, hypotonia, or respiratory depression. Monitor intake and output hourly; report any decrease in output (<30 mL/hr). Assess respiratory rate; report respiratory rate <12 breaths/min; auscultate lung

		sounds for evidence of pulmonary edema. Monitor for common maternal side effects, including flushing, nausea and vomiting, dry mouth, lethargy, blurred vision, and headache. Assess for nausea, vomiting, transient hypotension, and lethargy. Assess for signs and symptoms of magnesium toxicity, such as decreased level of consciousness, depressed respirations and DTRs, slurred speech, weakness, and respiratory and/or cardiac arrest. Have calcium gluconate readily available at the bedside to reverse magnesium toxicity.
Indomethacin (Indocin)	Inhibits prostaglandins, which stimulate contractions; inhibits	Continuously assess vital signs, uterine activity, and FHR. Administer oral form with food to reduce

	uterine activity to arrest preterm labor.	gastrointestinal irritation. Do not give to women with peptic ulcer disease. Schedule ultrasound to assess amniotic fluid volume and function of ductus arteriosus before initiating therapy; monitor for signs of maternal hemorrhage. Be alert for maternal adverse effects such as nausea and vomiting, heartburn, rash, prolonged bleeding time, oligohydramnios, and hypertension. Monitor for neonatal adverse effects, including constriction of ductus arteriosus, premature ductus closure, necrotizing enterocolitis, oligohydramnios, and pulmonary hypertension. Contraindicated in >32 weeks' gestations, fetal growth restriction, history of asthma,

		urticaria, or allergic-type reactions to aspirin or nonsteroidal antiinflammatory drugs.
Nifedipine (Procardia)	Blocks calcium movement into muscle cells, inhibits uterine activity to arrest preterm labor.	Use caution if giving this drug with magnesium sulfate because of increased risk for hypotension. Monitor blood pressure hourly if giving with magnesium sulfate; report a pulse rate >110 bpm. Monitor for fetal effects such as decreased uteroplacental blood flow manifested by fetal bradycardia, which can lead to fetal hypoxia. Monitor for adverse effects, such as flushing of the skin, headache, transient tachycardia, palpitations, postural hypertension, peripheral edema,

		and transient fetal tachycardia. Contraindicated in women with cardiovascular disease or hemodynamic instability.
Betamethasone (Celestone)	Promotes fetal lung maturity by stimulating surfactant production; prevents or reduces risk of respiratory distress syndrome and intraventricular hemorrhage in the preterm neonate less than 34 weeks' gestation.	Administer two doses intramuscularly 24 hours apart. Monitor for maternal infection or pulmonary edema. Educate parents about potential benefits of drug to preterm infant. Assess maternal lung sounds and monitor for signs of infection.

C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning; and Resnik, R., Lockwood, C. J., Moore, T. R., Greene, M. F., Copel, J. A., & Silver, R. M. (2019). *Creasy & Resnik's Maternal-fetal Medicine: Principles and practice* (8th ed.). Elsevier.

BOX 21.2 Risk Factors Associated with Preterm Labor and Birth

- African American race (doubles the risk)
- Maternal age extremes (<16 years and >40 years old)
- Low socioeconomic status
- Alcohol or other drug use, especially cocaine
- Poor maternal nutrition
- Maternal periodontal disease
- Cigarette smoking
- Low level of education
- History of prior preterm birth (triples the risk)
- Uterine abnormalities, such as fibroids
- Low pregnancy weight for height
- Preexisting diabetes or hypertension
- Multiple pregnancy
- Premature rupture of membranes
- Late or no prenatal care
- Short cervical length
- Sexually transmitted infections: gonorrhea, *chlamydia,* trichomoniasis
- Bacterial vaginosis (50% increased risk)
- Chorioamnionitis
- Hydramnios
- Gestational hypertension
- Cervical insufficiency
- Short interpregnancy interval (<1 year between births)
- Placental problems, such as placenta previa and abruption placenta
- Maternal anemia
- Urinary tract infection
- Domestic violence
- Stress, acute and chronic

American College of Obstetricians and Gynecologists (ACOG). (2019d). *Preterm labor and birth*. Retrieved June 16, 2020, from https://www.acog.org/Patients/FAQs/Preterm-Labor-and-Birth?IsMobileSet=false#risk; March of Dimes. (2020). *Preterm labor and premature birth: Are you at risk?* Retrieved June 16, 2020, from https://www.marchofdimes.org/complications/preterm-labor-and-premature-birth-are-you-at-risk.aspx

- Low, dull backache
- Menstrual-like cramps
- Urinary tract infection symptoms
- Feeling of pelvic pressure or fullness
- Gastrointestinal upset like nausea, vomiting, and diarrhea

- General sense of discomfort or unease
- Heaviness or aching in the thighs
- Uterine contractions with or without pain
- More than six contractions per hour
- Intestinal cramping with or without diarrhea (Jordan et al., 2019)

Assess the pattern of the contractions; the contractions must be persistent, such that four contractions occur every 20 minutes or eight contractions occur in 1 hour. Evaluate cervical dilation and effacement; cervical effacement is 80% or greater and cervical dilation is greater than 1 cm (ACOG, 2019d). Upon examination, engagement of the fetal presenting part will be noted.

Laboratory and Diagnostic Testing

Commonly used diagnostic testing for preterm labor risk assessment includes a complete blood count to detect infection, which may be a contributing factor to preterm labor; urinalysis to detect bacteria and nitrites, which are indicative of a urinary tract infection; and an amniotic fluid analysis to determine fetal lung maturity and the presence of subclinical chorioamnionitis.

Other tests that may be used for preterm labor prediction include fetal fibronectin testing and cervical length evaluation by transvaginal ultrasound. Fetal fibronectin and cervical length examinations have a high negative predictive value and are thus better at predicting which pregnant women are unlikely to have a preterm birth as opposed to predicting those who will. A short cervical length was found to be a risk factor for preterm birth and higher fetal fibronectin results were related to short gestational latency (Kyozuka et al., 2019).

FETAL FIBRONECTIN

Fetal fibronectin, a glycoprotein produced by the chorion, is found at the junction of the chorion and decidua (fetal membranes and uterus). It acts as biologic glue, attaching the fetal sac to the uterine lining. It is normally present in cervicovaginal secretions up to 22 weeks of pregnancy and again at the end of the last trimester (1 to 3

weeks before labor). It cannot usually be detected between 24 and 34 weeks of pregnancy (5 1/2 to 8 1/2 months) unless there has been a disruption between the chorion and deciduas. It is present in cervicovaginal fluid prior to delivery, regardless of gestational age.

The test is a useful marker for impending membrane rupture within 7 to 14 days if the level increases to more than 0.05 mcg/mL. The accuracy of fetal fibronectin is decreased in the presence of lubricants, blood, recent intercourse, or cervical manipulation within the previous 24 hours. Conversely, a negative fetal fibronectin test is a strong predictor that preterm labor in the next 2 weeks is unlikely (Jordan et al., 2019).

A sterile applicator is used to collect a cervicovaginal sample during an examination by speculum. The result is either positive (fetal fibronectin is present) or negative (fetal fibronectin is not present). Interpretation of fetal fibronectin results must always be viewed in conjunction with the clinical findings; it is not used as a lone indicator for predicting preterm labor. The primary importance of cervicovaginal fetal fibronectin lies in the high negative predictive values of the test for reducing preterm birth risk. Fibronectin testing can be a useful tool in the triaging of women symptomatic for preterm labor, but it isn't a conclusive test on its own.

CERVICAL LENGTH MEASUREMENT

Transvaginal ultrasound of the cervix has been used as a tool to predict preterm labor in high-risk pregnancies and to differentiate between true and false preterm labor. Three parameters are evaluated during the transvaginal ultrasound: cervical length and width, funnel width and length, and percentage of funneling. Measurement of the closed portion of the cervix visualized during the transvaginal ultrasound is the single most reliable parameter for prediction of preterm delivery in high-risk women. A cervical length measurement is best obtained between 16 and 24 weeks' gestation (Norwitz et al., 2019).

Cervical length varies during pregnancy and can be measured fairly reliably after 16 weeks' gestation using an ultrasound probe

inserted in the vagina. A cervical length of 3 cm or more indicates that delivery within 14 days is unlikely. Women with a short cervical length of 2.5 cm during the mid-trimester have a substantially greater risk of preterm birth prior to 35 weeks' gestation. As with fetal fibronectin testing, negative results can be reassuring and prevent unnecessary interventions. The information obtained from both of these predictor tests is helpful in deciding who to treat with corticosteroids and possibly tocolytics (Cunningham et al., 2018).

Nursing Management

Nurses play a key role in reducing preterm labor and births to improve pregnancy outcomes for both mothers and their infants. Early detection of preterm labor is currently the best strategy to improve outcomes. Because of the numerous factors associated with preterm labor, it is challenging to identify and address all of them, especially when women experiencing contractions are frequently falsely reassured and not assessed thoroughly to determine the cause. This delay impedes initiation of interventions to reduce infant death and morbidity.

Preterm birth prevention programs for women at high risk have used self-monitoring of symptoms and patterns, weekly cervical examinations, clinical markers, telephone monitoring, and home visiting alone or in combination with disappointing results. Preterm labor is currently thought to be a chronic, long-term multifactorial process with a genetic component. A recent study found a multiple pregnancy, prior preterm birth, short time between pregnancies, maternal smoking, low socioeconomic status, maternal medical disorders, abnormal placental and fetal blood flow pattern, and maternal infections were statistically significant risk factors for predicting spontaneous preterm labor (Ylijoki et al., 2019). Despite technologic and pharmacologic advances in the identification and treatment of preterm labor, the incidence remains high and is growing in the United States.

Supportive nursing care is needed for the woman in preterm labor whether the contractions are stopped with tocolytic therapy or not.

Nursing tasks include monitoring vital signs, measuring intake and output, encouraging bed rest on the woman's left side to enhance placental perfusion, monitoring the FHR via an external monitor continuously, limiting vaginal examinations to prevent an ascending infection, and monitoring the mother and fetus closely for any adverse effects from the tocolytic agents. Offering the woman ongoing explanations will help prepare her for the birth.

Administering Tocolytic Therapy

Tocolysis is the use of drugs to inhibit uterine contractions. The primary goals of tocolytic therapy are to arrest labor and delay birth for up to 48 hours, to initiate prophylactic corticosteroid therapy when indicated for stimulation of fetal lung maturity, and to arrange for maternal–fetal transport to a perinatal tertiary care hospital. A firm diagnosis of preterm labor is necessary before treatment is considered. Diagnosis requires the presence of both uterine contractions and cervical change (or an initial cervical examination of more than 2 cm and/or more than 80% effacement in a nulliparous client). A cause for preterm labor should always be sought.

Absolute contraindications to administering tocolytic agents to stop labor include intrauterine infection, active hemorrhage, fetal distress, fetus before viability, fetal abnormality incompatible with life, fetal growth restriction severe preeclampsia, heart disease, prolonged premature rupture of the membranes (PPROM), and intrauterine demise (Hanley et al., 2019). Bed rest and hydration are commonly recommended but without proven efficacy.

Primary prevention of preterm labor remains an elusive goal. Effective, evidence-based strategies for preventing preterm births include: smoking and substance use cessation; adequate nutrition and weight gain, pregnancy spacing intervals of 18 months; progesterone therapy for select women at risk; cervical cerclage for women with shortened cervixes; treating infections; and reducing perinatal stress (Daskalakis et al., 2019).

Magnesium sulfate may be ordered. This agent acts as a physiologic calcium antagonist and a general inhibitor of

neurotransmission. Expect to administer it intravenously. Monitor the woman for nausea, vomiting, headache, weakness, hypotension, and cardiopulmonary arrest. Frequent monitoring of maternal respiratory effort and deep tendon reflexes is essential for early recognition of overdose. Because magnesium is exclusively excreted by the kidneys, adequate renal function is essential for safe administration. Assess the fetus for decreased FHR variability, drowsiness, and hypotonia. Magnesium has a wide margin of safety but is not more effective in delaying preterm birth as any other tocolytic agent. However, if administered prenatally, it is effective in helping women who develop preeclampsia and helps in fetal neuroprotection (Brookfield & Vinson, 2019).

Calcium channel blockers usually treat hypertension, angina, and arrhythmias but also promote uterine relaxation by decreasing the influx of calcium ions into myometrium cells to inhibit contractions. Although calcium channel blockers may be prescribed to manage preterm labor, available literature provides little evidence that they have better efficacy in treating preterm labor than any other tocolytic agent (Resnik et al., 2019). Administer calcium channel blockers (nifedipine) orally or sublingually every 4 to 8 hours as ordered. Monitor the woman for hypotension, reflex tachycardia, headache, nausea, and facial flushing.

A *cyclooxygenase inhibitor* (indomethacin [Indocin]) reduces prostaglandin synthesis from decidual macrophages. It readily crosses the placenta and can cause oligohydramnios due to a decrease in fetal renal blood flow if used for more than 48 hours. Maternal side effects include nausea, vomiting, and gastritis. During treatment, urine output, maternal temperature, and amniotic fluid index (AFI) should be evaluated periodically. The initial loading dose is 50 to 100 mg orally or rectally followed by 25 to 50 mg every 6 hours for eight doses. Indomethacin therapy is not recommended for gestations of 32 weeks or longer (King et al., 2019).

Educating the Client

Ensure every pregnant woman receives basic education about preterm labor, including information about harmful lifestyles, signs of genitourinary infections and preterm labor, and appropriate responses to these symptoms. Teach the client how to palpate for and time uterine contractions. Provide written materials to support this education at a level and in a language appropriate for the client. Also educate clients about the importance of prenatal care, risk reduction, and recognizing the signs and symptoms of preterm labor. Teaching Guidelines 21.1 highlights important instructions related to preventing preterm labor.

TEACHING GUIDELINES 21.1

Teaching to Prevent Preterm Labor

- Avoid traveling for long distances in cars, trains, planes, or buses.
- Avoid lifting heavy objects, such as laundry, groceries, or a young child.
- Avoid performing hard, physical work, such as yard work, moving furniture, or construction.
- Mild to moderate levels of exercise are permitted such as walking daily.
- Achieve an appropriate prepregnancy weight.
- Achieve adequate iron stores through balanced nutrition.
- Wait at least 18 months between pregnancies.
- Visit a dentist in early pregnancy to evaluate and treat any periodontal disease.
- Enroll in a smoking cessation program if you are unable to quit on your own.
- Curtail sexual activity until after 37 weeks if experiencing preterm labor symptoms.
- Consume a well-balanced nutritional diet to gain appropriate weight.
- Avoid the use of substances such as marijuana, cocaine, and heroin.
- Identify factors and areas of stress in your life, and use stress management techniques to reduce them.
- If you are experiencing intimate partner violence, seek resources to modify the situation.

Recognize the signs and symptoms of preterm labor and notify your birth attendant if any occur:

- Uterine contractions, cramping, or low back pain
- Feeling of pelvic pressure or fullness
- Increase in vaginal discharge
- Nausea, vomiting, and diarrhea
- Leaking of fluid from vagina

If you are experiencing any of these signs or symptoms, do the following:

- Stop what you are doing and rest for 1 hour.
- Empty your bladder.
- Lie down on your side.
- Drink two to three glasses of water.
- Feel your abdomen and make note of the hardness of the contraction. Call your health care provider and describe the contraction as:
  - Mild if it feels like the tip of the nose
  - Moderate if it feels like the tip of the chin
  - Strong if it feels like your forehead

Jordan, R. G., Farley, C. L., & Grace, K. T. (2019). *Prenatal and postnatal care: A woman-centered approach* (2nd ed.) John Wiley & Sons, Inc.; King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning.

Explaining to the mother or couple what is happening in terms of labor progress, the treatment regimen, and the status of the fetus is important to reduce the anxiety associated with the risk of giving birth to a preterm infant. Educate clients about the importance of promotion of fetal lung maturity with corticosteroids. Include supportive family members in all education. Allow time for the woman and her family to express their concerns about possible outcomes for the infant and the possible side effects of tocolytic therapy. Encourage them to vent any feelings, fears, and anger they may experience. Provide the woman and her family with an honest appraisal of the situation and plan of treatment throughout her care.

Providing Psychological Support

Preterm labor and birth present multifactorial challenges for everyone involved. If the woman's activities are restricted, additional stress may be placed on the family, contributing to the crisis. Assess the stress levels of the client and family, and make appropriate referrals. Emphasize the need for more frequent supervision and

office visits, and encourage clients to talk to the health care provider for reassurance.

Every case of spontaneous preterm labor is unique. Care must account for the clinical circumstances, and the full and informed consent of the woman and her partner is needed. Half of all women who ultimately give birth prematurely have no identifiable risk factors, so with few exceptions, risk factors do not reliably predict preterm labor (King et al., 2019). Nurses should be sensitive to any complaint and should provide appropriate assessment, information, and follow-up. Sensitivity to the subtle differences between normal pregnancy sensations and the prodromal symptoms of preterm labor is a key factor in ensuring timely care. Offer validation and clarification of the woman's symptoms.

If tocolytic therapy is not successful in stopping uterine contractions, support the mother or couple through this stressful period to prepare for the birth. Keep them informed of all progress and changes; for example, continuously monitor maternal and fetal vital signs, especially the maternal temperature to detect signs of early infection. Offer one-on-one contact and be available throughout this difficult and anxiety-producing period.

POST-TERM PREGNANCY

A full-term pregnancy is designated as 39 weeks through 40 weeks and 6 days. A prolonged or **post-term pregnancy** is one that continues past the end of the 42nd week of gestation, or 294 days from the first day of the last menstrual period. Within the United States, up to 10% of singleton pregnancies extend beyond 42 weeks (Norwitz et al., 2019). Incorrect dates account for the majority of these cases: many women have irregular menses and thus cannot identify the date of the last menstrual period accurately.

Recall Jennifer described at the beginning of the chapter, who was at 41 weeks' gestation. What information would be most important to assess upon admission to the facility? What interventions might the nurse anticipate when she arrives?

The exact etiology of a post-term pregnancy is unknown because the mechanism for the initiation of labor is not completely understood. Theories suggest there may be a deficiency of estrogen and continued secretion of progesterone that prohibits the uterus from contracting, but no evidence has validated this. A woman who has one prolonged pregnancy is at greater risk for another in subsequent pregnancies.

Post-term pregnancies may adversely affect both the mother and fetus or newborn. Maternal risk is related to the large size of the fetus at birth, which increases the chances that a cesarean birth will be needed. Other issues might include dystocia, birth trauma, postpartum hemorrhage, and infection. Mechanical or artificial interventions such as forceps- or vacuum-assisted birth and labor induction with oxytocin may be necessary. In addition, maternal exhaustion and feelings of despair over prolonged gestation can add to the woman's anxiety level and reduce her coping ability. Women often blame themselves for prolonging the pregnancy, and a woman's negative feelings about herself can bring about strained relationships with the people closest to her.

Fetal risks associated with a post-term pregnancy include macrosomia, shoulder dystocia, brachial plexus injuries, low Apgar scores, postmaturity syndrome (loss of subcutaneous fat and muscle and meconium staining), and cephalopelvic disproportion. As the placenta ages, its perfusion decreases and it becomes less efficient at delivering oxygen and nutrients to the fetus. Amniotic fluid volume also begins to decline after 38 weeks' gestation, possibly leading to oligohydramnios, subsequently resulting in fetal hypoxia and an increased risk of cord compression because the cushioning effect offered by adequate fluid is no longer present. Hypoxia and oligohydramnios predispose the fetus to aspiration of meconium, which is released by the fetus in response to a hypoxic insult (Norwitz, 2019). All of these issues can compromise fetal well-being and lead to fetal distress.

Nursing Assessment

Obtain a thorough history to determine the estimated date of birth. Many women are unsure of the date of the last menstrual period, so the date given may be unreliable. Despite numerous methods used to date pregnancies, many are still misdated. Accurate gestational dating via ultrasound is essential.

When expectant management is chosen versus labor induction for the post-term pregnancy, the nurse should anticipate that assessments for a post-term pregnancy will typically include daily fetal movement counts done by the woman, nonstress tests with amniotic fluid assessments as part of the biophysical profile done twice weekly, and weekly cervical examinations to evaluate for ripening. Induction can be deferred until 42 weeks if the fetal surveillance is reassuring. In addition, assess

- the client's understanding of the various fetal well-being tests.
- the client's stress and anxiety concerning the prolonged pregnancy.
- the client's coping ability and support network.

Nursing Management

Once the dates have been established and post-term status is confirmed, monitoring fetal well-being becomes critical. When determining the plan of care for a woman with a prolonged pregnancy, the first decision is whether to deliver the baby or wait. If the decision is to wait, fetal surveillance becomes key. If the decision is to have the woman give birth, labor induction is initiated. Both decisions remain controversial, and there is no clear answer about which option is more appropriate. Therefore, the plan must be individualized.

> Think back to Jennifer, who is scheduled for labor induction. What ongoing nursing assessments would be important when providing care for her?

Providing Support

The intense surveillance is time-consuming and intrusive, adding to the anxiety and worry already being experienced by the woman

about the pregnancy's status. Be alert to the woman's anxiety and allow her to discuss her feelings. Provide reassurance about the expected time range for birth and the well-being of the fetus based on the assessment tests. Validating the woman's stress state due to the post-term pregnancy provides an opportunity for her to openly verbalize her feelings.

Educating the Woman and Her Partner

Teach the woman and her partner about the testing required and the reasons for each test. Also describe the methods that may be used for cervical ripening if indicated. Explain about the possibility of induction if the woman's labor is not spontaneous or if a dysfunctional labor pattern occurs. Also prepare the woman for the possibility of a surgical delivery if fetal distress occurs.

Providing Care during the Intrapartum Period

During the intrapartum period, continuously assess and monitor FHR to identify potential fetal distress early (e.g., late or variable decelerations) so that interventions can be initiated. Also monitor the woman's hydration status to ensure maximal placental perfusion. When the membranes rupture, assess amniotic fluid characteristics (color, amount, and odor) to identify previous fetal hypoxia and prepare for prevention of meconium aspiration. Report meconium-stained amniotic fluid immediately when the woman's membranes rupture. Amnioinfusion used to dilute the concentration of meconium has been tried and studied, but recent randomized research studies found no reduction in the incidence or severity of meconium aspiration in neonates, so its use is waning (Resnik et al., 2019). In addition, monitor the woman's labor pattern closely because dysfunctional patterns are common (Goldfarb, 2019). Encourage the woman to verbalize her feelings and concerns, and answer all her questions. Provide support, presence, information, and encouragement throughout this time.

WOMEN REQUIRING LABOR INDUCTION AND AUGMENTATION

Ideally, all pregnancies go to term with labor beginning spontaneously. However, many pregnancies require help with initiating or sustaining the labor process. Labor induction involves the stimulation of uterine contractions by medical or surgical means before the onset of spontaneous labor. The labor induction rate is at an all-time high in the United States. Evidence is compelling that elective induction of labor significantly increases the risk of cesarean birth, increased time spent in labor and birth, instrumented delivery, use of epidural analgesia, and neonatal intensive care unit (NICU) admission, especially for nulliparous women (Souter et al., 2019).

Labor induction is not an isolated event; it brings about a cascade of other interventions that may or may not produce favorable outcomes. It also involves intravenous therapy, bed rest, continuous electronic fetal monitoring, significant discomfort from stimulating uterine contractions, epidural analgesia and/or anesthesia, and a prolonged stay on the labor and birth unit (King et al., 2019). Labor augmentation (stimulating the uterus, typically with oxytocin) enhances ineffective contractions after labor has begun. Continuous electronic FHR monitoring is necessary.

WHO (2018) has put forth recommendations regarding labor induction, including:

- Labor induction should be performed only for a clear medical indication.
- Women being induced should not be left unattended.
- Oxytocin use for delay in labor in women with an epidural is not recommended.
- Labor induction should only be performed after cephalopelvic disproportion has been ruled out.
- Labor induction should not be applied to women with abnormal fetal presentations.
- Close monitoring is needed of the FHR and uterine contraction patterns.

There are multiple medical and obstetric reasons for inducing labor, the most common being prolonged gestation. Other indications for inductions include PPROM, gestational hypertension, cardiac disease, renal disease, chorioamnionitis, dystocia, intrauterine fetal demise, isoimmunization, and diabetes (Jordan et al., 2019). Contraindications to labor induction include complete placenta previa, placental abruption, transverse fetal lie, a prolapsed umbilical cord, a prior classic uterine incision that entered the uterine cavity, pelvic structure abnormality, previous myomectomy, vaginal bleeding with unknown cause, invasive cervical cancer, active genital herpes infection, and abnormal FHR patterns (Cunningham et al., 2018). In general, labor induction is indicated when the benefits of birth outweigh the risks to the mother or fetus for continuing the pregnancy. However, the balance between risk and benefit remains controversial.

TAKE NOTE!

Before labor induction is started, fetal maturity (dating, ultrasound, amniotic fluid studies) and cervical readiness (vaginal examination, Bishop scoring) must be assessed. Both need to be favorable for a successful induction.

Therapeutic Management

The decision to induce labor is based on a thorough evaluation of maternal and fetal status. Typically, this includes an ultrasound to evaluate fetal size, position, and gestational age and to locate the placenta; engaged presenting fetal part; pelvimetry to rule out fetopelvic disproportion; a nonstress test to evaluate fetal well-being; a phosphatidylglycerol (PG) level to assess fetal lung maturity; confirmation of category I FHR pattern; complete blood count and urinalysis to rule out infection; and a vaginal examination to evaluate the cervix for inducibility (SMFM, 2018). Accurate dating of the pregnancy is also essential before cervical ripening and induction are initiated to prevent a preterm birth.

Cervical Ripening

In the United States, more than 20% of women who give birth undergo induction of labor, which frequently involves cervical ripening with a variety of methods. Cervical ripening is a process by which the cervix softens via the breakdown of collagen leading to its elasticity and distensibility preceding cervical dilation. It is the first step in the process of cervical effacement and dilation so that on average, the cervix is approximately 50% effaced and 2 cm dilated at the onset of labor, though wide differences do exist. There has been increasing awareness that if the cervix is unfavorable or unripe, a successful vaginal birth is unlikely. Cervical ripeness is an important variable when labor induction is being considered. A ripe cervix is shortened, centered (anterior), softened, and partially dilated. An unripe cervix is long, closed, posterior, and firm. Cervical ripening usually begins prior to the onset of labor contractions and is necessary for cervical dilation and the passage of the fetus.

Various scoring systems to assess cervical ripeness have been introduced, but the Bishop score is most commonly used today. The Bishop score helps identify women who would be most likely to achieve a successful induction (Table 21.2). The duration of labor is inversely correlated with the Bishop score; a score over 8 indicates a successful vaginal birth. Bishop scores of less than 6 usually indicate that a cervical ripening method should be used prior to induction (Resnik et al., 2019). Medical induction of labor has two components: cervical ripening and induction of contractions. When induction of labor is indicated, cervical readiness for labor is evaluated by pelvic exam and determination of a Bishop score is documented. Cervical ripening can be achieved by either mechanical or pharmacologic methods.

COMPLEMENTARY AND ALTERNATIVE MEDICINE METHODS

Nonpharmacologic methods for cervical ripening are less frequently used today, but nurses need to be aware of them and question clients about their use. Methods may include herbal agents such as

evening primrose oil, black haw, black and blue cohosh, and red raspberry leaves. In addition, castor oil, hot baths, and enemas may be used for cervical ripening and labor induction. The risks and benefits of these agents are unknown. None have been evaluated scientifically, and thus, none can be recommended regarding efficacy or safety.

Another nonpharmacologic method suggested for labor induction is sexual intercourse along with breast stimulation. This promotes the release of oxytocin, which stimulates uterine contractions. In addition, human semen is a biologic source of prostaglandins used for cervical ripening. According to a Cochrane review, sexual intercourse with breast stimulation would appear beneficial, but safety issues have not been fully evaluated, nor can this activity be standardized. It appears to shorten the latent phase of labor (King et al., 2019). Therefore, its use as a method for labor induction is not validated by research.

TABLE 21.2 Bishop Scoring System

Score	Dilation (cm)	Effacement (%)	Station	Cervical Consistency	Position of Cervix
0	Closed	0–30	–3	Firm	Posterior
1	1–2	40–50	–2	Medium	Midposition
2	3–4	60–70	–1 or 0	Soft	Anterior
3	5–6	80	+1 or +2	Very soft	Anterior

Modified from Wormer, K. C., & Williford, A. E. (2019). *Bishop score*. StatPearls. Retrieved February 6, 2020, from https://www.ncbi.nlm.nih.gov/books/NBK470368/

MECHANICAL METHODS

Mechanical methods are used to open the cervix and stimulate the progression of labor. All share a similar mechanism of action; application of local pressure stimulates the release of prostaglandins to ripen the cervix. Potential advantages of mechanical methods compared with pharmacologic methods may include simplicity or preservation of the cervical tissue or structure, lower cost, and fewer side effects. The risks associated with these methods include infection, bleeding, membrane rupture, and placental disruption (Gallagher et al., 2019). For example, an indwelling (Foley) catheter

(e.g., 26 French) can be inserted into the endocervical canal to ripen and dilate the cervix. The catheter is placed in the uterus, and the balloon is filled. Direct pressure is then applied to the lower segment of the uterus and the cervix. This direct pressure causes stress in the lower uterine segment and probably the local production of prostaglandins. The risks, benefits, and expected side effects should be explained to the woman prior to the insertion of the balloon catheter (Zhang et al., 2019).

Hygroscopic dilators absorb endocervical and local tissue fluids; as they enlarge, they expand the endocervix and provide controlled mechanical pressure. The products available include natural osmotic dilators (laminaria, a type of dried seaweed) and synthetic dilators containing magnesium sulfate (Lamicel, Dilapan). Hygroscopic dilators are advantageous because they can be inserted on an outpatient basis and no fetal monitoring is needed. As many dilators are inserted in the cervix as will fit, and they expand over 12 to 24 hours as they absorb water. Absorption of water leads to expansion of the dilators and opening of the cervix. They are a reliable alternative when prostaglandins are contraindicated or unavailable (Norwitz et al., 2019).

Recently, there has been a reduction in the use of hygroscopic and osmotic dilators for the induction of labor in favor of pharmacologic agents. The increased risk of maternal and fetal infections with hygroscopic and osmotic dilators when compared with that associated with the use of other pharmacologic agents and the ease of pharmacologic administration may be reasons for the decline. Placement of dilators also requires additional training and may be associated with rupture of membranes, vaginal bleeding, and client discomfort or pain (Resnik et al., 2019).

Recent systematic review of randomized trials that compared cervical ripening with mechanical methods versus alternative pharmacologic agents or placebo demonstrated that maternal infection was increased in clients who underwent cervical ripening with mechanical methods. Thus, mechanical methods for cervical ripening have fallen into disfavor and are used infrequently today

when compared with pharmacologic or surgical methods for induction (Gallagher et al., 2019).

SURGICAL METHODS

Surgical methods used to ripen the cervix and induce labor include stripping of the membranes and performing an amniotomy. Stripping of the membranes is accomplished by inserting a finger through the internal cervical os and moving it in a circular direction. This motion causes the membranes to detach. Manual separation of the amniotic membranes from the cervix is thought to induce cervical ripening and the onset of labor (Haj Yahya et al., 2019). However, there is no strong evidence at this time that membrane stripping significantly shortens the duration of pregnancy.

An amniotomy involves inserting a cervical hook (Amniohook) through the cervical os to deliberately rupture the membranes. This promotes pressure of the presenting part on the cervix and stimulates an increase in the activity of prostaglandins locally. Risks associated with these procedures include umbilical cord prolapse or compression, maternal or neonatal infection, FHR deceleration, bleeding, and client discomfort (King et al., 2019).

When either of these techniques is used, amniotic fluid characteristics (such as whether it is clear or bloody, or meconium is present) and the FHR pattern must be monitored closely.

PHARMACOLOGIC METHODS

The use of pharmacologic agents has revolutionized cervical ripening. The use of prostaglandins to attain cervical ripening has been found to be highly effective in producing cervical changes independent of uterine contractions (Grobman, 2019). In some cases, women will go into labor and require no additional stimulants for induction. Induction of labor with prostaglandins offers the advantage of promoting both cervical ripening and uterine contractility. A drawback of prostaglandins is their ability to induce excessive uterine contractions, which can increase maternal and

perinatal morbidity (Cunningham et al., 2018). Prostaglandin analogs commonly used for cervical ripening include dinoprostone gel (Prepidil), dinoprostone inserts (Cervidil), and misoprostol (Cytotec). Misoprostol (Cytotec), a synthetic PGE1 analog, is a gastric cytoprotective agent used in the treatment and prevention of peptic ulcers. It can be administered intravaginally or orally to ripen the cervix or induce labor. It is available in 100- or 200-mcg tablets, but doses of 25 to 50 mcg are typically used. It is important to note that only dinoprostone is approved by the FDA for use as a cervical ripening agent, though ACOG acknowledges the apparent safety and effectiveness of misoprostol for this purpose (King et al., 2019). A major adverse effect of the obstetric use of misoprostol is hyperstimulation of the uterus, which may progress to uterine tetany with marked impairment of uteroplacental blood flow, uterine rupture (requiring surgical repair, hysterectomy, and/or salpingo-oophorectomy), or anaphylactoid syndrome of pregnancy (Drug Guide 21.2) (Krugh & Maani, 2020). Furthermore, it is contraindicated for women with prior uterine scars and therefore should not be used for cervical ripening in women attempting a vaginal birth after cesarean.

DRUG GUIDE 21.2 Drugs Used for Cervical Ripening and Labor Induction

Medication	Action/Indications	Nursing Implications
Dinoprostone (Cervidil insert; Prepidil gel)	Directly softens and dilates the cervix to ripen cervix and induce labor FDA-approved for cervical ripening	Provide emotional support. Administer pain medications as needed. Frequently assess degree of effacement and dilation. Monitor uterine contractions for frequency, duration, and strength. Assess maternal vital signs and FHR pattern frequently. Monitor woman for possible adverse effects such as headache, nausea and vomiting, and diarrhea.
Misoprostol (Cytotec)	Ripens cervix to induce labor	Instruct client about purpose and possible adverse effects of medication. Ensure informed consent is signed per hospital policy. Assess vital signs and FHR patterns frequently.

		Monitor client's reaction to drug. Initiate oxytocin for labor induction at least 4 hours after last dose was administered. Monitor for possible adverse effects such as nausea and vomiting, diarrhea, uterine hyperstimulation, and category II FHR patterns.
Oxytocin (Pitocin)	Acts on uterine myofibrils to contract to initiate or reinforce labor	Administer as an IV infusion via pump, increasing dose based on protocol until adequate labor progress is achieved. Assess baseline vital signs and FHR and then frequently after initiating oxytocin infusion. Determine frequency, duration, and strength of contractions frequently. Notify health care provider of any uterine hypertonicity or

	abnormal FHR patterns. Maintain careful intake and output, being alert for water intoxication. Keep client informed of labor progress. Monitor for possible adverse effects such as hyperstimulation of the uterus, impaired uterine blood flow leading to fetal hypoxia, rapid labor leading to cervical lacerations or uterine rupture, water intoxication (if oxytocin is given in electrolyte-free solution or at a rate exceeding 20 mU/min), and hypotension.

Retrieved April 27, 2020, from https://www.uptodate.com/contents/techniques-for-ripening-the-unfavorable-cervix-prior-to-induction; Pierce, S., Bakker, R., Myers, D. A., & Edwards, R. K. (2018). Clinical insights for cervical ripening and labor induction using prostaglandins. *American Journal of Perinatology Reports*, *8*(4), 307–314.

Oxytocin

Oxytocin is a potent endogenous uterotonic agent used for both artificial induction and augmentation of labor. It is naturally produced by the posterior pituitary gland and stimulates contractions of the uterus. For women with low Bishop scores, cervical ripening is typically initiated before oxytocin is used. Once the cervix is ripe, oxytocin is the most popular pharmacologic agent used for inducing or augmenting labor.

Frequently, a woman with an unfavorable cervix is admitted the evening before induction to ripen her cervix with one of the prostaglandin agents. Then induction begins with oxytocin the next morning if she has not already gone into labor. Doing so markedly enhances the success of induction.

Response to oxytocin varies widely; some women are sensitive to even small amounts. The most common adverse effect of oxytocin is uterine hyperstimulation, leading to fetal compromise and impaired oxygenation (King et al., 2019). The response of the uterus to the drug is closely monitored throughout labor so that the oxytocin infusion can be titrated appropriately. In addition, oxytocin has an antidiuretic effect, resulting in decreased urine flow that may lead to water intoxication. Symptoms to watch for include headache and vomiting.

Oxytocin is administered via an intravenous infusion pump piggybacked into the main intravenous line at the port most proximal to the insertion site. Typically, 10 units of oxytocin are added to 1 L of isotonic solution. The dose is titrated according to protocol to achieve stable contractions every 2 to 3 minutes lasting 40 to 60 seconds. Recent studies suggest that a more conservative oxytocin protocol with lower doses reduces the number of NICU admissions and lower cesarean sections, but either regimen is acceptable for use in labor induction (Healy et al., 2019; Prichard et al., 2019).

FIGURE 21.4. The nurse monitors an intravenous infusion of oxytocin being administered to a woman in labor who is being induced.

The uterus should relax between contractions. If the resting uterine tone remains above 20 mm Hg, uteroplacental insufficiency and fetal hypoxia can result. This underscores the importance of continuous FHR monitoring. Unfortunately, neither the optimal oxytocin administration regimen nor the maximum oxytocin dose has been established or agreed upon through research or expert opinion. Nurses assisting with labor inductions need to become familiar with their hospital protocols concerning dosage, infusion rates, and frequency of change (Fig. 21.4).

Oxytocin has many advantages: it is potent and easy to titrate, it has a short half-life (1 to 5 minutes), and it is generally well tolerated. Induction using oxytocin has side effects (water intoxication, hypotension, and uterine hypertonicity), but because the drug does not cross the placental barrier, no direct fetal problems have been

observed. Current evidence is insufficient to modify use of oxytocin (Lonfeldt et al., 2019).

Remember Jennifer, the young woman described at the beginning of the chapter? After her cervix is ripened, an oxytocin infusion is started and her progress is slow. What encouragement can the nurse offer? After a few hours, her contractions begin to increase in intensity and frequency. What typical pain management measures can the nurse implement, and how would the nurse evaluate the effectiveness of these measures?

Nursing Assessment

Nursing assessment of the woman who is undergoing labor induction or augmentation involves a thorough history and physical examination. Review the woman's history for relative indications for induction or augmentation, such as diabetes, hypertension, post-term status, dysfunctional labor pattern, prolonged ruptured membranes, and maternal or fetal infection, and for contraindications such as placenta previa, overdistended uterus, active genital herpes, fetopelvic disproportion, fetal malposition, or severe fetal distress.

Assist with determining the gestational age of the fetus to prevent a preterm birth. Assess fetal well-being to validate the client's and fetus's ability to withstand labor contractions. Evaluate the woman's cervical status, including cervical dilation and effacement, and station via vaginal examination as appropriate before cervical ripening or induction is started. Determine the Bishop score to determine the probable success of induction.

TAKE NOTE!

Nurses working with women in labor play an important role acting as the eyes and ears for the birth attendant because they remain at the client's bedside throughout the entire experience. Close, frequent assessment and follow-up interventions are essential to ensure the safety of the mother and her unborn child during cervical ripening and labor induction or augmentation.

Nursing Management

Explain the induction or augmentation procedure clearly, using simple terms (Teaching Guidelines 21.2). Ensure an informed consent has been signed after the client and her partner have received complete information about the procedure, including its advantages, disadvantages, and potential risks. Ensure that the Bishop score has been determined before proceeding. Nursing Care Plan 21.1 presents an overview of the nursing care for a woman undergoing labor induction.

TEACHING GUIDELINES 21.2

Teaching in Preparation for Labor Induction

- Your health care provider may recommend you have your labor induced. This may be necessary for a variety of reasons, such as elevated blood pressure, a medical condition, prolonged pregnancy over 41 weeks, or problems with FHR patterns or fetal growth.
- Your health care provider may use one or more methods to induce labor, such as stripping the membranes, breaking the amniotic sac to release the fluid, administering medication close to or in the cervix to soften it, or administering a medication called oxytocin (Pitocin) to stimulate contractions.
- Labor induction is associated with some risks and disadvantages, such as overactivity of the uterus; nausea, vomiting, or diarrhea; and changes in FHR.
- Prior to inducing your labor, your health care provider may perform a procedure to ripen your cervix to help ensure a successful induction.
- Medication may be placed around your cervix the day before you are scheduled to be induced.
- During the induction, your contractions may feel stronger than normal. However, the length of your labor may be reduced with induction.
- Medications for pain relief and comfort measures will be readily available.
- Health care staff will be present throughout labor.

NURSING CARE PLAN 21.1 Overview of the Women Undergoing Labor Induction

Rose, a 29-year-old primipara, is admitted to the labor and birth suite at 40 weeks' gestation for induction of labor. Assessment reveals that her cervix is ripe, 80% effaced, and dilated to 2 cm. Rose says, "I'm a bit nervous about being induced. I've never been through labor before and I'm afraid that I'll have a lot of pain from the medicine used to start the contractions." She consents to being induced but wants reassurance that this procedure won't harm the baby. Upon examination, the fetus is engaged and in a cephalic presentation, with the vertex as the presenting part. Her partner is at her side. Induction is initiated with oxytocin. Rose reports that contractions have started and are beginning to get stronger.

NURSING ANALYSIS: Anxiety related to induction of labor and associated medical interventions needed as evidenced by statements about being nervous, not having gone through labor before, fear of pain, and potential harm to fetus

OUTCOME IDENTIFICATION AND EVALUATION

The client will experience decrease in anxiety as evidenced by ability to verbalize understanding of procedures involved and use of positive coping skills to reduce anxious state.

INTERVENTIONS: *Minimizing Anxiety*

- Provide a clear explanation of the labor induction process *to provide client and partner with a knowledge base.*
- Maintain continuous physical presence *to provide physical and emotional support and demonstrate concern for maternal and fetal well-being.*
- Explain each procedure before carrying it out and answer questions *to promote understanding of procedure and rationale for use and decrease fear of the unknown.*
- Review with client measures used in the past to deal with stressful situations *to determine effectiveness;* encourage use of past effective coping strategies *to aid in controlling anxiety.*
- Instruct client's partner in helpful measures to assist client in coping and encourage their use *to foster joint participation in the process and feelings of being in control and to provide support to the client.*
- Offer frequent reassurance of fetal status and labor progress *to help alleviate client's concerns and foster continued participation in the labor process.*

NURSING ANALYSIS: Injury risk (maternal or fetal) related to induction procedure risk factors: hypertonic uterine contractions, potential preterm birth as evidenced by client's concerns about fetal well-being and possible adverse effects of oxytocin administration

OUTCOME IDENTIFICATION AND EVALUATION

The client will remain free of complications associated with induction as evidenced by progression of labor as expected, delivery of healthy newborn, and absence of signs and symptoms of maternal and fetal adverse effects.

INTERVENTIONS: *Promoting Maternal and Fetal Safety*

- Follow agency's protocol for medication use and infusion rate *to ensure accurate, safe drug administration.*
- Set up oxytocin IV infusion to piggyback into the primary IV infusion line *to allow for prompt discontinuation should adverse effects occur.*
- Use an infusion pump *to deliver accurate dose as ordered.*
- Gradually increase oxytocin dose in increments based on assessment findings and protocol *to promote effective uterine contractions.*
- Maintain oxytocin rate once desired frequency of contractions has been reached *to ensure continued progress in labor.*
- Accurately monitor contractions for frequency, duration, and intensity and resting tone *to prevent development of hypertonic contractions.*
- Maintain a nurse-to-client ratio of 1:2 *to ensure maternal and fetal safety.*
- Monitor FHR via electronic fetal monitoring during induction and continuously observe the FHR response to titrated medication rate *to ensure fetal well-being and identify adverse effects immediately.*
- Obtain maternal vital signs every 1 to 2 hours or as indicated by agency's protocol, reporting any deviations *to promote maternal well-being and allow for prompt detection of problems.*
- Communicate with birth attendant frequently concerning progress *to ensure continuity of care.*
- Discontinue oxytocin infusion if tetanic contractions (>90 seconds), uterine hyperstimulation (<2 minutes apart), elevated uterine resting tone, or a distressed FHR pattern occurs *to minimize risk of drug's adverse effects.*
- Provide client with frequent reassurance of maternal and fetal status *to minimize anxiety.*

NURSING ANALYSIS: Acute pain related to uterine contractions as evidenced by client's statements about contractions increasing in intensity and expected effect of oxytocin administration

OUTCOME IDENTIFICATION AND EVALUATION

The client will report a decrease in pain as evidenced by statements of increased comfort and pain rating of 3 or less on numeric pain rating scale.

INTERVENTIONS: *Promoting Maternal and Fetal Safety*

- Explain to the client that she will experience discomfort sooner than with naturally occurring labor *to promote client's awareness of events and prepare client for the experience.*
- Frequently assess client's pain using a pain rating scale *to quantify client's level of pain and evaluate effectiveness of pain relief measures.*
- Provide comfort measures, such as hygiene, backrubs, music, and distraction, and encourage the use of breathing and relaxation techniques *to help promote relaxation.*
- Provide support for her partner *to aid in alleviating stress and concerns.*
- Employ nonpharmacologic methods, such as position changes, birthing ball, hydrotherapy, visual imagery, and effleurage, *to help in managing pain and foster feelings of control over situation.*
- Administer pharmacologic agents such as analgesia or anesthesia as appropriate and as ordered *to control pain.*
- Continuously reassess client's pain level *to evaluate effectiveness of pain management techniques used.*

Administering Oxytocin

If not already done, prepare the oxytocin infusion by diluting 10 units of oxytocin in 1,000 mL of lactated Ringer's solution or ordered isotonic solution. Use an infusion pump on a secondary line connected to the primary infusion. Start the oxytocin infusion in mU/min or mL/hr as ordered. Each hospital has its own standards and protocols for oxytocin infusion and dilution. The nurse must follow that procedure when administering this medication. Maintain the rate once the desired contraction frequency has been reached. To ensure adequate maternal and fetal surveillance during induction or augmentation, the nurse-to-client ratio should not exceed 1:2 (Jackson et al., 2019).

During induction or augmentation, monitoring of the maternal and fetal status is essential. Apply an external electronic fetal monitor or assist with placement of an internal device. Obtain the mother's vital

signs and the FHR every 15 minutes during the first stage. Evaluate the contractions (frequency, duration, and intensity) and resting tone, and adjust the oxytocin infusion rate accordingly. Monitor the FHR, including baseline rate, baseline variability, and decelerations to determine whether the oxytocin rate needs adjustment. Discontinue the oxytocin and notify the health care provider if uterine hyperstimulation or a category II or III FHR pattern occurs. Perform or assist with periodic vaginal examinations to determine cervical dilation and fetal descent; cervical dilation of 1 cm per hour typically indicates satisfactory progress. Continue to monitor the FHR continuously and document it every 15 minutes during the active phase of labor and every 5 minutes during the second stage. Assist with pushing efforts during the second stage. Measure and record the intake and output to prevent excess fluid volume. Encourage the client to empty her bladder every 2 hours to prevent soft tissue obstruction.

Providing Pain Relief and Support

A woman in labor experiences two types of pain—visceral and somatic. The woman's perception of pain is influenced by physiologic, psychological, and cultural factors (Blackburn, 2018). Assess the woman's level of pain. Ask her frequently to rate her pain and provide pain management as needed. Offer position changes and other nonpharmacologic measures. Note her reaction to any medication given, and document its effect. Monitor her need for comfort measures as contractions increase.

Throughout induction and augmentation, frequently reassure the woman and her partner about the fetal status and labor progress. Provide them with frequent updates on the condition of the woman and the fetus. Assess the woman's ability to cope with stronger contractions, and follow protocols of the hospital about how frequent pain assessments are performed for each phase and stage of labor (King et al., 2019). Provide support and encouragement as indicated.

After a long day, Jennifer gives birth to a healthy baby boy with Apgar scores of 9 at 1 minute and 10 at 5 minutes. When transferring her to the postpartum unit, what information is essential to include for the accepting nurse? What specific nursing information should be given to the nursery nurse regarding the laboring experience? With such a lengthy labor, what assessments might the postpartum nurse need to focus on for the first few hours after birth?

VAGINAL BIRTH AFTER CESAREAN

Vaginal birth after cesarean (VBAC) describes giving birth vaginally after having at least one previous cesarean birth. Despite evidence that some women who have had a cesarean birth are candidates for vaginal birth, some women who have had a cesarean birth once undergo cesareans for subsequent pregnancies. Trial of labor after cesarean birth (TOLAC) refers to a planned attempt to give birth vaginally by a woman who has had a previous surgical birth, regardless of the outcome. However, although TOLAC is appropriate for some women, several risk factors increase the incidence of a failed TOLAC, which may increase maternal and fetal morbidity and mortality (ACOG, 2019b).

A multidisciplinary guideline group representing family medicine, epidemiology, obstetrics, and midwifery developed recommendations based on high-quality systematic evidence-based, peer-reviewed research, that individual assessment of risks and benefits be discussed with the pregnant woman with a history of one or more prior cesarean births who are deciding between a planned VBAC or a repeat cesarean birth. A planned VBAC is an appropriate option for many women with histories of prior cesarean birth (King et al., 2019).

Contraindications to VBAC include a prior classic uterine incision, prior transfundal uterine surgery (myomectomy), uterine scar other than low-transverse cesarean scar, obesity, short maternal stature, macrosomia, maternal age (over 40 years), gestational diabetes, contracted pelvis, and inadequate staff or facility if an emergency cesarean birth in the event of uterine rupture is required (Caughey, 2019). Most women go through a trial of labor to see how they progress, but this must be performed in an environment capable of

handling the emergency of uterine rupture. The use of cervical ripening agents increases the risk of uterine rupture and thus is contraindicated in VBAC clients. The woman considering induction of labor after a previous cesarean birth needs to be informed of the risks versus benefits with an induction than with spontaneous labor (Metz, 2019).

Women are the primary decision-makers about the choice of birth method, but they need education about VBAC to make the best decisions for themselves. Management is similar for any women experiencing labor, but certain areas require special focus:

- *Consent:* Fully informed consent is essential for the woman who wants to have a TOLAC. The client must be advised about the risks as well as the benefits. She must understand the ramifications of uterine rupture, even though the risk is small.
- *Documentation:* Record keeping is an important component of safe client care. If and when an emergency occurs, it is imperative to take care of the client but also to keep track of the plan of care, interventions and their timing, and the client's response. Events and activities can be written on the fetal monitoring tracing to correlate with the change in fetal status.
- *Surveillance:* A distressed fetal monitor tracing in a woman undergoing a TOLAC should alert the nurse to the possibility of uterine rupture. Terminal bradycardia must be considered an emergency situation, and the nurse should prepare the team for an emergency delivery.
- *Readiness for emergency:* According to ACOG (2019b), criteria for a safe trial of labor for a woman who has had a previous cesarean birth, the physician, anesthesia provider, and operating room team must be immediately available. Anything less would place the women and fetus at risk.

Women and their health care providers are advised to consider VBAC in the context of potential risk, available resources, and the health care system. The ACOG (2019b) guidelines state that VBACs are safe and appropriate for many women, but they emphasize the need for thorough counseling, shared decision-making, and client autonomy. Nurses must act as advocates, giving input on the

appropriate selection of women who wish to undergo VBAC. Nurses also need to become experts at reading fetal monitoring tracings to identify fetal distress and set in motion an emergency birth. Including all of these nursing strategies will make VBAC safer for all.

INTRAUTERINE FETAL DEMISE

Pregnancy and childbirth are often associated with hope, expectations, joy, and happiness for the future. When an unborn life suddenly ends with fetal loss, the family members are profoundly affected. Intrauterine fetal demise (IUFD) is fetal death that occurs after 20 weeks' gestation but before birth. The cause of IUFD is often unknown. The sudden loss of an expected child is tragic and the family's grief can be intense; it can last for years and can cause extreme psychological stress and emotional problems (Grunebaum & Chervenak, 2019). The family's anticipation of a joyous birth is supplanted by despair, confusion, and loss. To women and their families who have gone through this harrowing experience, culturally appropriate and sensitive care is crucial. Particularly for the mother, fetal death in the last trimester of pregnancy, when she feels very close to the fetus due to its frequent movement in the uterus, can feel similar to losing a part of her body.

IUFD can be due to an extensive range of risk factors and possible causes, such as post-term pregnancy, renal disease, substance abuse, infection, hypertension, advanced maternal age, multiple gestation, Rh disease, uterine rupture, diabetes, congenital anomalies, obesity, smoking, cord accident, abruption, blunt trauma, premature rupture of membranes, or hemorrhage—or it may go unexplained (Stevens, 2019). Trauma in pregnancy remains one of the major contributors to maternal and fetal morbidity and mortality. Potential complications include maternal injury or death, shock, internal hemorrhage, intrauterine fetal demise, direct fetal injury, placental abruption, and uterine rupture. The leading causes of obstetric trauma are motor vehicle accidents, intimate partner violence, falls, assault, and gunshots, and ensuing injuries are

classified as blunt abdominal trauma, pelvic fractures, or penetrating trauma. Approximately 7% of all pregnancies in the United States are affected by trauma (Wilson & Dickson, 2020). In view of the significant impact of trauma on the pregnant woman and her fetus, preventive strategies are paramount (Troiano et al., 2019).

Early pregnancy loss may be through a spontaneous abortion (miscarriage), an induced abortion (therapeutic abortion), or a ruptured ectopic pregnancy. A wide spectrum of feelings may be expressed, from relief to sadness and despair. Fetal death can occur at any gestational age, and typically there is little or no warning other than reduced fetal movement. The loss may affect women and their families for a lifetime. The need to reflect, share, and regain strength is universal for families dealing with this loss. Grief, the typical response to the loss of a valued person or object, is not an intellectual response. Rather, it is personally experienced as a deep emotion of sadness and sorrow. Feelings such as helplessness, disbelief, unreality, and powerlessness are common. Emotional recovery from the pain of perinatal loss occurs with time, but it varies for each family.

The moment fetal death is diagnosed can frequently be described clearly and in detail by most women. In many cases, the death was sudden, and women have no chance to prepare for the impending grief. Once IUFD is confirmed, most women choose to immediately undergo induction of labor. Approximately 90% of women will go into spontaneous labor within 2 weeks of fetal death (Jordan et al., 2019). With the death of a fetus or neonate, a couple’s dreams and hopes for the expected child suddenly dissolve. To women who have experienced a sudden fetal death, the following processes may take place: experiencing a quiet birth without the infant, eclipsed by emptiness, anger, anxiety, loneliness, and sorrow; living without the infant, making it difficult to see others with young infants; and experiencing differences with the partner over the loss (Heazell et al., 2019). The process of grieving a death is not completed within a specific time frame, and for some, it is never complete. In general, the grief accompanying the loss of a fetus proceeds in the following order:

1. Accepting the reality of the loss
2. Getting over suffering from the loss
3. Adapting to the new environment without the deceased
4. Emotionally relocating the deceased and proceeding with life (Grunebaum & Chervenak, 2019)

The period following a fetal death is extremely difficult for the family. For many women, emotional healing takes much longer than physical healing. The feelings of loss can be intense. The grief response in some women may be so great that their relationships become strained, and healing can become hampered unless appropriate interventions and support are provided.

Fetal death also affects the health care staff. Despite the trauma that the loss of a fetus causes, some staff members avoid dealing with the bereaved family, never talking about or acknowledging their grief. This seems to imply that not discussing the problem will allow the grief to dissolve and vanish. As a result, the family's needs go unrecognized. Failing to keep the lines of communication open with a bereaved client and her family closes off some of the channels to recovery and healing that may be desperately needed. Subsequently, the bereaved family members may feel isolated.

Nursing Assessment

A woman experiencing an IUFD is likely to seek care when she notices that the fetus is not moving or when she experiences contractions, loss of fluid, or vaginal bleeding. History and physical examination frequently are of limited value in the diagnosis of fetal death, since many times the only history tends to be recent absence of fetal movement and no fetal heart beat heard. An inability to obtain fetal heart sounds on examination suggests fetal demise, but an ultrasound is necessary to confirm the absence of fetal cardiac activity. Once fetal demise is confirmed, induction of labor or expectant management is offered to the woman.

Nursing Management

IUFD is associated with posttraumatic stress disorder (PTSD) and anxiety in a subsequent pregnancy (Cunningham et al., 2018). The nurse can play a major role in assisting the grieving family. Nurses who can deal honestly with their own feelings regarding loss will be better able to help others cope with theirs. By working with couples who have suffered significant loss, the nurse can grow personally and professionally and gain a deeper perspective about life. With skillful intervention, the bereaved family may be better prepared to resolve their grief and move forward. The nurse's continued presence and availability can provide emotional support and comfort for the woman and her family. The woman and her family can be encouraged to view, touch, and hold the deceased newborn and allow as much time as needed for this.

To assist families in the grieving process, include the following measures:

- Provide accurate, understandable information to the family.
- Acknowledge that the woman's feeling of loss is legitimate.
- Reassure the mother that there was likely nothing she could have done to prevent the loss; this can dispel guilt.
- Be knowledgeable about the grief process and comfortable in sharing another's grief.
- Utilize active listening to provide necessary encouragement to the family members to open up to their feelings.
- Create a warm, receptive, accepting, and caring environment conducive to dialogue.
- Acknowledge the grief by saying that their feeling sad is appropriate.
- Recognize that each family member may express their grief differently.
- Provide reassurance about successful future pregnancies.
- Encourage discussion of the loss and venting of feelings of grief and guilt.
- Provide the family with baby mementos and pictures to validate the reality of the death.

- Allow unlimited time with the stillborn infant after birth to validate the death; provide time for the family members to be together and grieve; and offer the family the opportunity to see, touch, and hold the infant.
- Use appropriate touch, such as holding a hand or touching a shoulder.
- Inform the chaplain or the religious leader of the family's denomination about the death and request their presence.
- Assist the parents with the funeral arrangements or disposition of the body.
- Provide the parents with brochures offering advice about how to talk to any siblings about the loss.
- Refer the family to the support group SHARE Pregnancy and Infant Loss Support, Inc., which is designed for those who have lost an infant through abortion, miscarriage, fetal death, stillbirth, or any tragic circumstances.
- Make community referrals to promote a continuum of care after discharge.

Openness to talking with families about their loss and grief is the basis for support provided by nurses, which can have a positive influence on the long-term adjustment of couples and families coping with perinatal loss. A sensitive nurse who is comfortable talking about loss and is able to assist couples in navigating the process of grief provides a starting point for preparation for future pregnancy. Families need to talk about their loss, its meaning, and the emotions that accompany it while the nurse listens. Nurses play a significant role in linking families to appropriate professional support. As families move through their grief and begin to consider another pregnancy, sensitive nursing care may mediate the understandable anxiety and concern that accompany this process. Nurses are a vital part of the interdisciplinary health care team caring for families who have experienced IUFD and continue to require timely and sensitive care throughout the grieving process.

WOMEN EXPERIENCING AN OBSTETRIC EMERGENCY

Obstetric emergencies are challenging to all labor and birth personnel because of the increased risk of adverse outcomes for the mother and fetus. Quick clinical judgment and good critical decision-making will increase the odds of a positive outcome for both mother and fetus. This section discusses a few of these emergencies: umbilical cord prolapse, placenta previa, placental abruption, uterine rupture, and anaphylactoid syndrome of pregnancy.

Umbilical Cord Prolapse

Umbilical cord prolapse is a rare obstetric emergency that occurs when the cord precedes the fetus out (Fig. 21.5). Its incidence has decreased over time because significant management advances have led to improved perinatal outcomes (Boushra et al., 2019). This condition occurs in one out of every 500 births and requires prompt recognition and intervention for a positive outcome (March of Dimes, 2019f). The risk is increased further when the presenting part does not fill the lower uterine segment, as is the case with incomplete breech presentations (5% to 10%), premature infants, hydramnios, and multiparous women (Dutton et al., 2020). With a 50% perinatal mortality rate, it is one of the most catastrophic events in the intrapartum period (Beall, 2019).

Pathophysiology

The pathogenesis of umbilical cord prolapse is not always clear. If the presenting part doesn't adequately fill the pelvis or obstetric interventions performed that dislodge the presenting part, the risk of prolapse is increased. Prolapse usually leads to total or partial occlusion of the cord. Since this is the fetus's only lifeline, fetal perfusion deteriorates rapidly. Complete occlusion renders the fetus helpless and oxygen-deprived. The fetus will die if the cord compression is not relieved. It is diagnosed by seeing or palpating

the prolapsed cord outside or within the vagina in addition to abnormal FHR patterns. Once diagnosed, birth should be expedited.

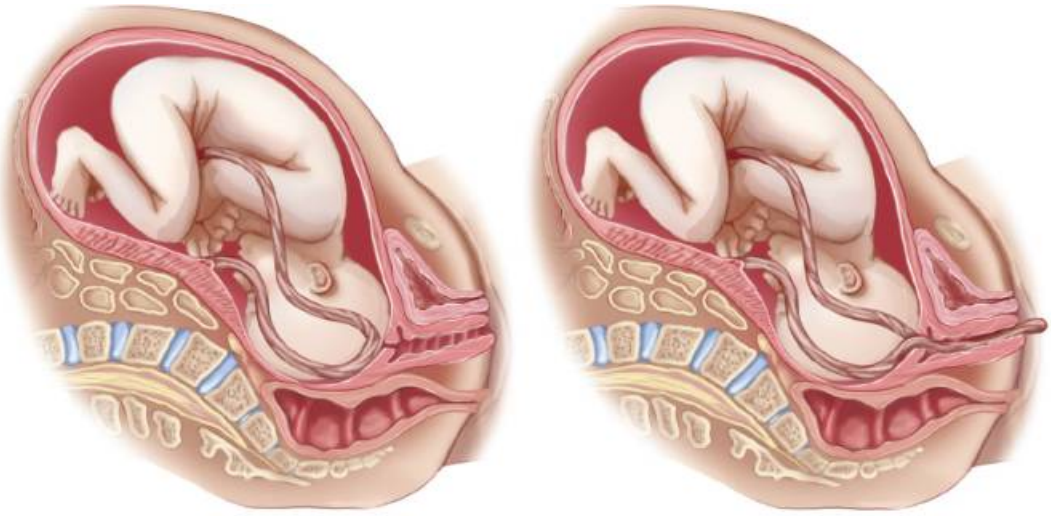

FIGURE 21.5. Prolapsed cord. **A.** Prolapse within the uterus. **B.** Prolapse with the cord visible at the vulva.

Nursing Assessment

Prevention is the key to managing cord prolapse by identifying clients at risk for this condition. Risk factors include multiparity, noncephalic presentations, long length of cord, preterm labor, low birth weight, multifetal pregnancy, and placement of cervical ripening balloon. Carefully assess each client to help predict risk status. Be aware that cord prolapse is more common in pregnancies involving malpresentation, growth restriction, prematurity, ruptured membranes with a fetus at a high station, hydramnios, grand multiparity, and multiple gestation (Cunningham et al., 2018). Continuously assess the client and fetus to detect changes and to evaluate the effectiveness of any interventions performed.

TAKE NOTE!

When the presenting part does not fully occupy the pelvic inlet, prolapse is more likely to occur.

Nursing Management

Prompt recognition of a prolapsed cord is essential to reduce the risk of fetal hypoxia resulting from prolonged cord compression. Often the first sign of cord prolapse is a sudden fetal bradycardia or recurrent variable decelerations that become progressively more severe. Call for help immediately and do not leave the woman. Inform the woman of what is happening and what options she may discuss with her health care provider. When membranes are artificially ruptured, assist with verifying that the presenting part is well applied to the cervix and engaged into the pelvis. If pressure or compression of the cord occurs, assist with measures to relieve the compression. Typically, the examiner places a sterile gloved hand into the vagina and holds the presenting part off the umbilical cord until delivery. Changing the woman's position to a modified Sims, Trendelenburg, or knee–chest position also helps relieve cord pressure. Do not attempt to replace the cord in the uterus. Monitor FHR, maintain bed rest, and administer oxygen if ordered. Provide emotional support and explanations as to what is going on to allay the woman's fears and anxiety. If the mother's cervix is not fully dilated, prepare the woman for an emergency cesarean birth to save the fetus's life if that is the intervention planned for by her health care provider.

Placenta Previa

Placenta previa is the complete or partial covering of the uterine internal os of the cervix with the placenta, typically identified during the second or third trimester of pregnancy. With uterine segment formation and cervical dilation, placental implantation over or near the cervical os instead of along the uterine wall inevitably results in spontaneous placental separation and subsequent hemorrhage. This position can create a barrier for the fetus from the uterus during the birthing process. As the cervix begins to thin and dilate (open up) in preparation for labor, blood vessels that connect the placenta to the uterus may tear and cause bleeding. It is the most common cause of

bleeding in the second half of pregnancy and should be suspected in any woman beyond 24 weeks' gestation presenting with vaginal bleeding; transvaginal ultrasonography is used to diagnose it. During labor and birth, bleeding can be severe, which can place the mother and fetus at risk. Reported incidence is approximately one in 200 births (March of Dimes, 2019c).

There is a direct relationship between the number of previous cesarean births and the risk of placenta previa, probably due to uterine scarring. The degree of occlusion of the internal cervical os may depend on the degree of cervical dilation, so what may appear to be a low-lying or marginal placenta previa prior to the onset of labor can progress to become more serious as the cervix effaces and opens up (King et al., 2019).

The incidence of maternal mortality is less than 1%, but common morbidities include septicemia, renal failure, hemorrhage and hypovolemic shock, invasive placenta (accrete, increta, and percreta), and postpartum anemia. Risk factors for placenta previa include previous cesarean section, infertility treatment, short interval between pregnancies, advanced maternal age older than 34, prior placenta previa, multiparity, multiple gestation, uterine leiomyomas, prior placenta previa, cocaine use, and cigarette smoking. The risk for perinatal mortality is less than 10%, but common neonatal morbidities include stillbirth, prematurity, malpresentation, fetal growth restriction, and fetal anemia (Bakker, 2019).

Maternal signs and symptoms of placenta previa include sudden, painless bleeding (that may be heavy enough to be considered hemorrhaging), anemia, pallor, hypoxia, low blood pressure, tachycardia, soft and nontender uterus, and rapid, weak pulse. Bleeding may be episodic with spontaneous initiation and cessation. In some cases, placenta previa is asymptomatic because there is intrauterine bleeding only without external signs.

Management of placenta previa varies by type and gestational age, and frequent medical surveillance may be sufficient in marginal cases; prompt treatment with bed rest, close monitoring, and control and/or replacement of blood loss greatly reduces risk for maternal and fetal complications and death. Vaginal delivery is possible when

bleeding is minimal, placenta previa is marginal, or labor is rapid. Pregnancy termination, early birth by cesarean section, or a hysterectomy may be necessary in order to control severe bleeding, especially for clients with complete placenta previa. The overall maternal prognosis is good if hemorrhage is controlled and sepsis or other complications are prevented. Fetal prognosis is directly related to the amount of blood loss. The U.S. perinatal mortality rate associated with placental previa is 2% to 3%, and the maternal mortality rate is 0.03%. Risk for placenta previa recurrence in subsequent pregnancies is 4% to 8% (Resnik et al., 2019). A precise diagnosis, availability of sufficient blood transfusion resources, and immediate intervention can reduce morbidity and mortality rates for both the mother and fetus.

Nursing management within the acute care setting includes: monitoring maternal vital signs, intake and output, vaginal bleeding, and physiologic status for signs of hemorrhage, shock, or infection; closely monitoring fetal heart tones for distress (e.g., bradycardia, tachycardia, baseline changes); and treating fetal distress as ordered. Administer prescribed intravenous fluids, packed red blood cells, platelets, and frozen plasma for transfusion if ordered; Rho(D) immune globulin if the client is Rh-negative; intravenous augmented oxytocin (Pitocin) to induce labor if needed; and in cases of preterm labor, tocolytics to inhibit uterine contractions and corticosteroids to enhance fetal lung maturity. Follow facility presurgical and postsurgical protocols if the woman becomes a surgical candidate (e.g., for cesarean section); reinforce presurgical and postsurgical education and ensure completion of facility's informed consent documents; closely monitor the woman postsurgically for bleeding, infection, and other complications; assess her anxiety level and coping ability; and provide emotional support and reassurance.

In the past, placenta previa was categorized by the distance from the placental edge to the internal os and classified as complete, partial, marginal, or low-lying. The availability of transvaginal ultrasound now allows for a high degree of accuracy in measuring the distance between the placental edge and the cervix and has resulted in a change in terminology. All placentas covering the os to

any degree are termed placenta previa; placentas close to but not covering the os are referred to as low-lying (King et al., 2019).

Frequently, there is expectant management for the woman after her first placenta previa bleed if it isn't severe and fetus well-being is validated. After she is assessed, she is released to go home. It is common for women to experience an initial bleeding episode, which then subsides. These women are monitored at home and instructed to report any additional bleeding episodes and come in to be evaluated (King et al., 2019).

Placental Abruption

Placental abruption refers to premature separation of a normally implanted placenta from the maternal myometrium. Placental abruption occurs in about 1% of all pregnancies throughout the world and is associated with significant perinatal mortality and morbidity (March of Dimes, 2019d). Risk factors include preeclampsia, gestational hypertension, seizure activity, maternal age over 34, uterine rupture, trauma, smoking, cocaine use, coagulation defects, chorioamnionitis, premature rupture of membranes, fetal growth restriction, trauma, hydramnios, uterine trauma, external cephalic version for breech presentation, previous history of abruption, intimate partner violence, and placental pathology. These conditions may force blood into the underlayer of the placenta and cause it to detach (Deering, 2019).

Management of placental abruption depends on the gestational age, the extent of the hemorrhage, and maternal–fetal oxygenation perfusion or reserve status (see Chapter 19 for additional information on placental abruption). Treatment is based on the circumstances. Typically, once the diagnosis is established, the focus is on maintaining the cardiovascular status of the mother and developing a plan to deliver the fetus quickly. A cesarean birth may take place quickly if the fetus is still alive with only a partial abruption. A vaginal birth may take place if there is fetal demise secondary to a complete abruption.

Uterine Rupture

Uterine rupture in pregnancy is a rare and often catastrophic complication with a high incidence of fetal and maternal morbidity. Uterine rupture is a catastrophic tearing of the uterus at the site of a previous scar into the abdominal cavity. Its onset is often marked only by sudden fetal bradycardia, and treatment requires rapid surgery for good outcomes. From the time of diagnosis to delivery, only a short amount of time is available before clinically significant fetal morbidity occurs. Fetal morbidity occurs secondary to catastrophic hemorrhage, fetal anoxia, or both.

Nursing Assessment

Review the mother's history for risk conditions such as uterine scars, prior cesarean births, prior rupture, trauma, prior invasive molar pregnancy, history of placenta percreta or increta, congenital uterine anomalies, multiparity, previous uterine myomectomy, malpresentation, labor induction with excessive uterine stimulation, and crack cocaine use (Smith & Wax, 2019). Reviewing a client's history for risk factors might prove lifesaving for both mother and fetus.

Generally, the first and most reliable symptom of uterine rupture is sudden fetal distress. Other signs may include acute and continuous abdominal pain with or without an epidural, vaginal bleeding, hematuria, irregular abdominal wall contour, loss of station in the fetal presenting part, and hypovolemic shock in the woman, fetus, or both (Smith & Wax, 2019).

Timely management of uterine rupture depends on prompt detection. Because many women desire a TOLAC, the nurse must be familiar with the signs and symptoms of uterine rupture. It is difficult to prevent uterine rupture or to predict which women will experience rupture, so constant preparedness is necessary. Screening all women with previous uterine surgical scars is important, and continuous electronic fetal monitoring should be used

during labor because this may provide the only indication of an impending rupture.

Nursing Management

Because the presenting signs may be nonspecific, initial management will be the same as that for any other cause of acute fetal distress. Urgent delivery by cesarean birth is usually indicated. Monitor maternal vital signs and observe for hypotension and tachycardia, which might indicate hypovolemic shock. Assist in preparing for an emergency cesarean birth by alerting the operating room staff, anesthesia provider, and neonatal team. Insert an indwelling urinary catheter if one is not in place already. Inform the woman of the seriousness of this event and remind her that the health care staff will be working quickly to ensure her health and that of her fetus. Remain calm and provide reassurance that everything is being done to ensure a safe outcome for both.

The life-threatening nature of uterine rupture is underscored by the fact that the maternal circulatory system delivers approximately 500 mL of blood to the term uterus every minute (Cunningham et al., 2018). Maternal death is a real possibility without rapid intervention. Newborn outcome after rupture depends largely on the speed of surgical rescue. As in any case of acute obstetric emergency, preparation and timely mobilization of all necessary personnel is essential to optimizing outcome.

TAKE NOTE!

When excessive bleeding occurs during the childbirth process and it persists or signs such as bruising or petechiae appear, disseminated intravascular coagulation (DIC) should be suspected.

Anaphylactoid Syndrome of Pregnancy

Anaphylactoid syndrome of pregnancy (ASP) is an unforeseeable, life-threatening complication of childbirth. The etiology of ASP

remains an enigmatic, devastating obstetric condition associated with significant maternal and newborn morbidity and mortality. It is a rare and often fatal event characterized by the sudden onset of hypotension, cardiopulmonary collapse, hypoxia, and coagulopathy. Amniotic fluid containing particles of debris (e.g., hair, skin, vernix, or meconium) enters maternal circulation and obstructs the pulmonary vessels, causing respiratory distress and circulatory collapse (McBride, 2018). Prediction and diagnosis of the event are nearly impossible. However, timely recognition and response is critical in saving a woman's life. Although estimates vary, ASP, also called amniotic fluid embolism, occurs in one in 40,000 births with a reported mortality rate reaching 20% despite technologic advances in critical care life support (Moore, 2019).

Pathophysiology

The pathophysiology of ASP continues to be researched and debated; it involves the introduction of amniotic fluid into the woman's circulation and an abnormal maternal response to fetal tissue exposure associated with breaches of the maternal–fetal physiologic barrier during the postpartum period. Normally, amniotic fluid does not enter the maternal circulation because it is contained within the uterus, sealed off by the amniotic sac. An embolus occurs when the barrier between the maternal circulation and the amniotic fluid is broken and amniotic fluid enters the maternal venous system via the endocervical veins, the placental site (if the placenta is separated), or a site of uterine trauma. Within minutes after the amniotic fluid and maternal blood mix, the woman experiences dyspnea and cyanosis followed by respiratory distress and respiratory arrest. This condition has a high mortality rate: as many as 50% of women die within the first hour after the onset of symptoms, and about 85% of survivors have permanent hypoxia-induced neurologic damage; 50% of neonates that survive sustain permanent neurologic injury (Barnhart & Rosenbaum, 2019).

Although medical science has supplied many answers to questions about this condition, health care providers remain largely

unable to predict or prevent ASP or to decrease its mortality rate.

Nursing Assessment

Predisposing factors associated with amniotic fluid embolism include placental abruption, uterine overdistention, fetal demise, eclampsia, amniocentesis, uterine trauma, oxytocin-stimulated labor, multiparity, advanced maternal age, and ruptured membranes. However, many women who experience ASP have none of the risk factors.

Early recognition and the use of immediate resuscitative measures improve the chances of survival. Currently, there are no laboratory tests that can confirm the diagnosis. Nurses must stay a step ahead and be prepared at all times in this obstetric emergency. A team response is essential because every person will be needed. No test can diagnose ASP. Therefore, the nurse's assessment skills are critical. Immediate recognition and diagnosis of this condition are essential to improving maternal and fetal outcomes. The four cardinal signs of ASP include respiratory failure, altered mental status, hypotension, and DIC.

TAKE NOTE!

ASP should be suspected in any pregnant women with an acute onset of dyspnea, hypotension, and DIC. By knowing how to intervene, the nurse can promote a better chance of survival for both the mother and her newborn. Most women are transferred to the intensive care unit.

Nursing Management

Upon recognizing the signs and symptoms of this life-threatening diagnosis, institute supportive measures: oxygenation (resuscitation and 100% oxygen), circulation (intravenous fluids, inotropic agents to maintain cardiac output and blood pressure), control of hemorrhage and coagulopathy (oxytocic agents to control uterine atony and bleeding), seizure precautions, and administration of steroids to control the inflammatory response. Monitor vital signs, pulse oximetry, skin color, and temperature, and observe for clinical signs

of coagulopathy (vaginal bleeding, bleeding from intravenous site, bleeding from gums) (Troiano et al., 2019).

Care is largely supportive and aimed at maintaining oxygenation and hemodynamic function and correcting coagulopathy. There is no specific therapy that is lifesaving once this condition starts. Adequate oxygenation is necessary with endotracheal intubation and mechanical ventilation for most women. Vasopressors are used to maintain hemodynamic stability. Management of DIC may involve replacement with packed red blood cells or fresh-frozen plasma as necessary. Oxytocin infusions and prostaglandin analogs can be used to address uterine atony.

Explain to the client and family what is happening and what therapies are being instituted. The woman is usually transferred to a critical care unit for intensive observation and care. Assist the family with expressing their feelings and provide support as needed. Inform and reassure the woman and family as much as possible during this crisis.

WOMEN REQUIRING BIRTH-RELATED PROCEDURES

Many women can give birth without the need for any operative obstetric interventions. Most do not anticipate the need for any medical intervention. However, in some situations, interventions are necessary to safeguard the health of the mother and fetus. The most common birth-related procedures are forceps-assisted or vacuum-assisted birth, cesarean birth, episiotomy, and VBAC (see “Vaginal Birth after Cesarean” section earlier in this chapter). Nurses play a major role in helping mothers and families cope with any unanticipated procedures by offering thorough explanations of the procedure, its anticipated benefits and risks, and any other options available.

Forceps- or Vacuum-Assisted Birth

Forceps or a vacuum extractor may be used to apply traction to the fetal head or to provide a method of rotating the fetal head during birth. **Forceps** are stainless steel instruments, similar to tongs, with rounded edges that fit around the fetus's head. Some forceps have open blades and some have solid blades. Outlet forceps are used when the fetal head is crowning and low forceps are used when the fetal head is at a +2 station or lower but not yet crowning. The forceps are applied to the sides of the fetal head. The type of forceps used is determined by the birth attendant. All forceps have a locking mechanism that prevents the blades from compressing the fetal skull. Use of forceps has declined in popularity over recent years because many obstetricians are not trained to use them in residency since they are rarely used in obstetric practice today. Overall, the rates of operative births are decreasing both nationally and regionally in the United States (Fig. 21.6) (Wegner & Bernstein, 2019).

A **vacuum extractor** is a cup-shaped instrument attached to a suction pump used for extraction of the fetal head (Fig. 21.7). The suction cup is placed against the occiput of the fetal head. The pump is used to create negative pressure (suction) of approximately 50 to 60 mm Hg. The birth attendant then applies traction until the fetal head emerges from the vagina.

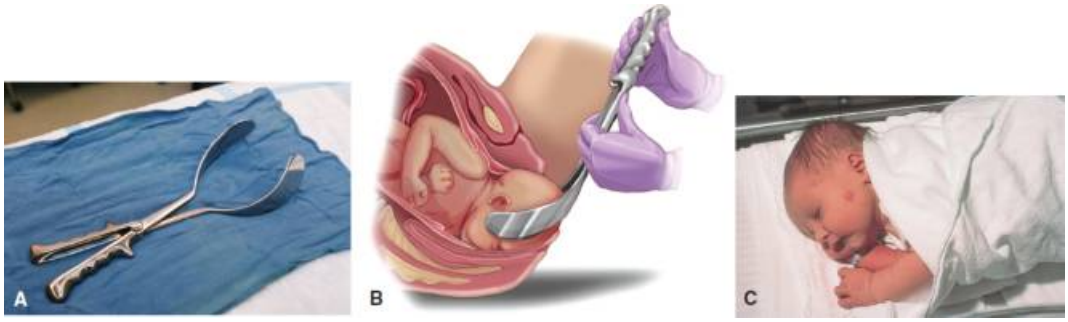

FIGURE 21.6. Forceps delivery (uncommon). **A.** Example of forceps. **B.** Forceps being applied to the fetus. **C.** Forceps marks are commonly found in newborns delivered by forceps. Such marks are transient and disappear in a day or two.

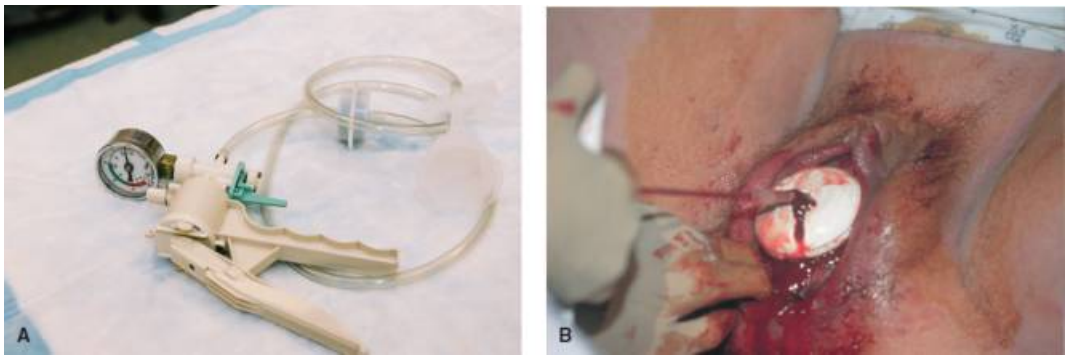

FIGURE 21.7. Vacuum extractor for delivery. **A.** Example of a vacuum extractor. **B.** Vacuum extractor applied to the fetal head to assist in delivery.

The indications for the use of either method are similar and include a prolonged second stage of labor, a distressed FHR pattern, failure of the presenting part to fully rotate and descend in the pelvis, limited sensation and inability to push effectively due to the effects of regional anesthesia, presumed fetal jeopardy or fetal distress, maternal heart disease, acute pulmonary edema, intrapartum infection, maternal fatigue, or infection. There is a clear trend to choose vacuum extraction over forceps to assist delivery, but the evidence supporting that trend is unconvincing. Recent literature confirms some advantages for forceps (e.g., a lower failure rate but higher maternal pelvic floor injuries) and some disadvantages for vacuum extraction (e.g., increased neonatal injury) depending on the clinical circumstances. Collective evidence between the two operative instruments has led some authorities to recommend the vacuum extractor as the instrument of first choice for operative vaginal births (Muraca et al., 2019).

The use of forceps or a vacuum extractor poses the risk of tissue trauma to the mother and the newborn. Maternal trauma may include lacerations of the cervix, vagina, or perineum; hematoma; extension of the episiotomy incision into the anus; hemorrhage; and infection. Potential newborn trauma includes ecchymoses, facial and scalp lacerations, facial nerve injury, cephalohematoma, and caput succedaneum (Cunningham et al., 2018). For forceps or a vacuum extractor to be applied, the following criteria need to be met:

membranes ruptured, cervix completely dilated, fetus vertex and engaged, and an adequate maternal pelvis size.

Prevention is the key to reducing the use of these techniques. Preventive measures include frequently changing the client's position, encouraging ambulation if permitted, frequently reminding the client to empty her bladder to allow maximum space for birth, and providing adequate hydration throughout labor. Additional measures include assessing maternal vital signs, the contraction pattern, the fetal status, and the maternal response to the procedure. Provide a thorough explanation of the procedure and the rationale for its use. Reassure the mother that any marks or swelling on the newborn's head or face will disappear without treatment within 2 to 3 days. Alert the postpartum nursing staff about the use of the technique so that they can observe for any bleeding or infection related to genital lacerations.

Cesarean Birth

A **cesarean birth** is the surgical birth of the fetus through an incision in the abdomen and uterine wall (Fig. 21.8). It is the most commonly performed surgery in the United States (ACOG, 2019c).

High cesarean birth rates are an international concern. The cesarean birth rate in the United States is on the rise at a rapid rate. Today, approximately 33% or one in three births occurs this way (CDC, 2019a). The cesarean birth rate continues to rise despite a number of medical organizations, including the WHO and ACOG, urging medical care providers to work on lowering the cesarean birth rate (CDC, 2019a). Cesarean births may result from maternal, fetal, or placental factors that interfere with a vaginal birth. Several factors may explain the increased incidence of cesarean deliveries: the use of electronic fetal monitoring, which identifies fetal distress early; the reduced number of forceps-assisted births; older maternal age and reduced parity; increasing maternal obesity; convenience to the client and doctor; and an increase in malpractice suits. The leading indications for cesarean births are previous cesarean birth, breech presentation, dystocia, and fetal distress. Once a woman has

experienced a primary cesarean birth, she has a 90% chance of having another one in a subsequent pregnancy (March of Dimes, 2019b).

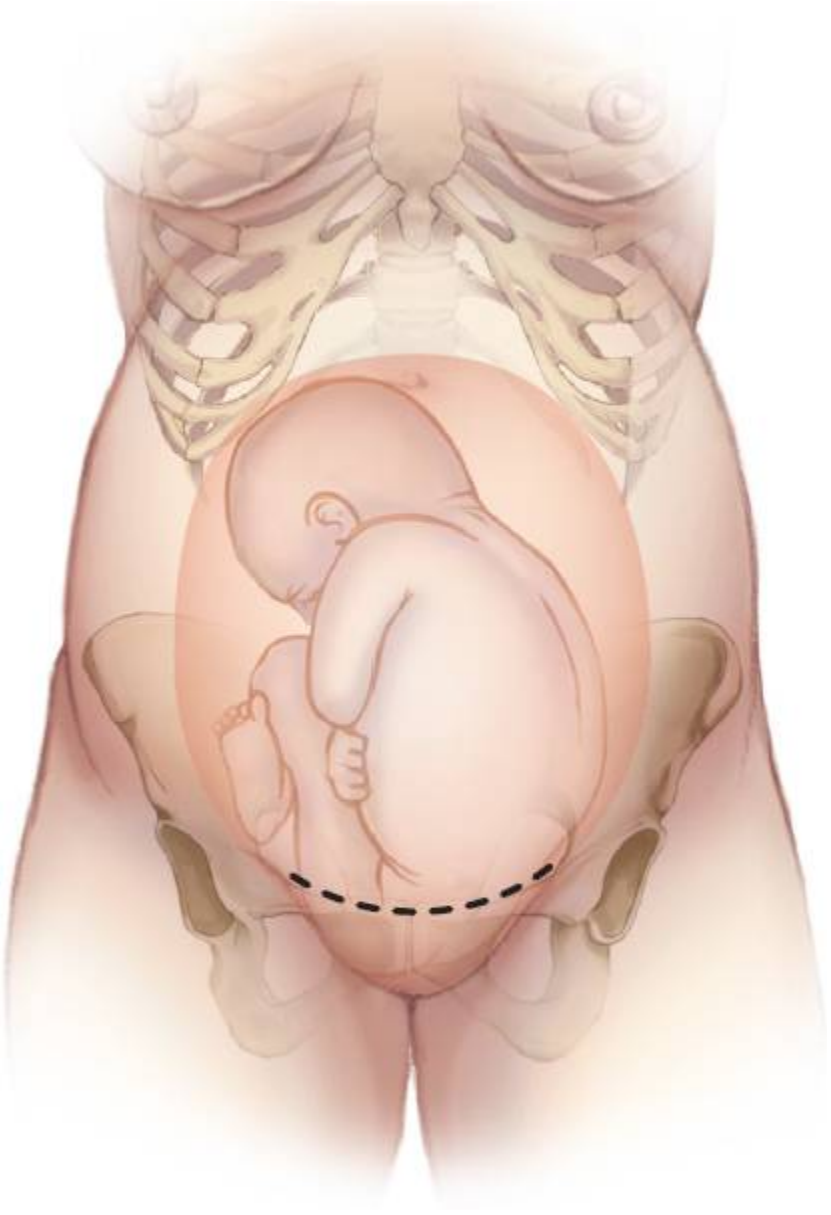

FIGURE 21.8. Low transverse incision for cesarean birth.

Cesarean birth is a major surgical procedure with increased risks in comparison to a vaginal birth. The client is at risk for complications such as infection, hemorrhage, aspiration, pulmonary embolism, urinary tract trauma, thrombophlebitis, paralytic ileus, and

atelectasis. Fetal injury and transient tachypnea of the newborn may also occur (Cunningham et al., 2018).

Spinal, epidural, or general anesthesia is used for cesarean births. Epidural anesthesia is most commonly used because it is associated with less risk and most women wish to be awake and aware of the birth experience.

Nursing Assessment

Review the woman's history for indications associated with cesarean birth and complete a physical examination. Any condition that prevents the safe passage of the fetus through the birth canal or that seriously compromises maternal or fetal well-being may be an indication for a cesarean birth. Controversy exists for the option of elective cesarean birth on maternal request. The Agency for Healthcare Research and Quality (AHRQ) has published a report on personal maternal request for a surgical birth, and although there is no high-quality medical evidence to support this, it is recognized that women have the right to be actively involved in choosing the route of her childbirth (Norwitz et al., 2019). The pregnant woman who requests a surgical birth must be made aware of the associated risks and benefits for the current and any subsequent pregnancies. The clinician's role should be to provide the best evidence-based counseling possible to the woman and to respect her autonomy and decision-making capabilities when considering route of birth.

Examples of specific indications include active genital herpes, fetal macrosomia, fetopelvic disproportion, prolapsed umbilical cord, placental abnormality (placenta previa or placental abruption), previous classic uterine incision or scar, gestational hypertension, diabetes, positive human immunodeficiency virus (HIV) status, and dystocia. Fetal indications include malpresentation (nonvertex presentation), congenital anomalies (fetal neural tube defects, hydrocephalus, abdominal wall defects), and fetal distress (Saint Louis, 2019).

Nursing Management

Once the decision has been made to proceed with a cesarean birth, assess the woman's knowledge of the procedure and necessary preparation. Assist with obtaining diagnostic tests as ordered. These tests are usually ordered to ensure the well-being of both parties and may include a complete blood count; urinalysis to rule out infection; blood type and cross-match so that blood is available for transfusion if needed; an ultrasound to determine fetal position and placental location; and an amniocentesis to determine fetal lung maturity if needed.

Although the nurse's role in a cesarean birth can be technical and skill-oriented at times, the focus must remain on the woman, not the equipment surrounding the bed. Care should be centered on the family, not the surgery. Provide education and minimize separation of the mother, partner, and newborn. Remember that the client is anxious and concerned about her welfare as well as that of her child. Use touch, eye contact, therapeutic communication, and genuine caring to provide couples with a positive birth experience, regardless of the type of delivery.

PROVIDING PREOPERATIVE CARE

Client preparation varies depending on whether the cesarean birth is planned or unplanned. The major difference is the time allotted for preparation and teaching. In an unplanned cesarean birth, institute measures quickly to ensure the best outcomes for the mother and fetus. Ensure that the woman has signed an informed consent, and allow for discussion of fears and expectations. Provide essential teaching and explanations to reduce the woman's fears and anxieties.

Ascertain the client's and family's understandings of the surgical procedure. Reinforce the reasons for surgery provided by the surgeon. Outline the procedure and expectations of the surgical experience. Ensure that all diagnostic tests ordered have been completed, and evaluate the results. Explain to the woman and her family about what to expect postoperatively. Reassure the woman that pain management will be provided throughout the procedure

and afterward. Encourage the woman to report any pain. Ask the woman about the time she last had anything to eat or drink. Document the time and what was consumed. Throughout the preparations, assess maternal and fetal status frequently.

Provide preoperative teaching to reduce the risk of postoperative complications. Demonstrate the use of the incentive spirometer and deep breathing and leg exercises. Instruct the woman on how to splint her incision.

Complete preoperative procedures which may include:

- Preparing the surgical site as ordered
- Starting an intravenous infusion for fluid replacement therapy as ordered
- Inserting an indwelling catheter and informing the client about how long it will remain in place (usually 24 hours)
- Administering any preoperative medications as ordered; documenting the time administered and the client's reaction

Maintain a calm, confident manner in all interactions with the client and family. Help transport the client and her partner to the operative area.

PROVIDING POSTOPERATIVE CARE

Postoperative care for the mother who has had a cesarean delivery is similar to that for one who has had a vaginal birth with a few additional measures. Assess vital signs and lochia flow every 15 minutes for the first hour, then every 30 minutes for the next hour, and then every 4 hours if stable. Assist with perineal care and instruct the client in the same. Inspect the abdominal dressing and document description, including any evidence of drainage. Assess uterine tone to determine fundal firmness. Check the patency of the intravenous line, making sure the infusion is flowing at the correct rate. Inspect the infusion site frequently for redness.

Assess the woman's level of consciousness if sedative drugs were administered. Institute safety precautions until the woman is fully alert and responsive. If a regional anesthetic was used, monitor for the return of sensation to the legs.

Assess for evidence of abdominal distention and auscultate bowel sounds. Assist with early ambulation to prevent respiratory and cardiovascular problems and to promote peristalsis. Monitor intake and output at least every 4 hours initially and then every 8 hours as indicated.

Encourage the woman to cough, perform deep breathing exercises, and use the incentive spirometer every 2 hours. Enhance comfort and general well-being. Administer analgesics as ordered and provide comfort measures, such as splinting the incision and pillows for positioning. Assist the client with moving in bed and turning side to side to improve circulation. Also encourage the woman to ambulate to promote venous return from the extremities.

Assessment of maternal and family adjustment is crucial. The general areas to address during the early postpartum period should include homeostasis, involution, vital signs, bladder function, maternal comfort, initiation of lactation if breastfeeding, review of the birth experience to help the mother process it, and infant care (Jordan et al., 2019). Encourage early touching and holding of the newborn to promote bonding. Promote family unity and bonding. Assist with breastfeeding initiation and offer continued support. Suggest alternate positioning techniques to reduce incisional discomfort while breastfeeding. (See Chapter 18 for breastfeeding positions.)

Review with the family their perception of the surgical birth experience. Allow them to verbalize their feelings and assist them in positive coping measures. Promote a positive emotional response to the birth experience and parenting role. Prior to discharge, teach the woman about the need for adequate rest, activity restrictions such as lifting, and signs and symptoms of infection. Provide information about postpartum care at home upon discharge.

KEY CONCEPTS

- Risk factors for dystocia include epidural analgesia, occiput posterior position, longer first stage of labor, nulliparity, short maternal stature (shorter than 5 ft tall), high birth weight, maternal age older than 35 years, gestational age more than 41 weeks, chorioamnionitis, pelvic contractions, macrosomia, and high station at complete cervical dilation.
- Dystocia may result from problems in the powers, passenger, passageway, or psyche.
- Problems involving the powers that lead to dystocia include hypertonic uterine dysfunction, hypotonic uterine dysfunction, and precipitate labor.
- Management of hypertonic labor pattern involves therapeutic rest with the use of sedatives to promote relaxation and stop the abnormal activity of the uterus.
- Any presentation other than occiput or a slight variation of the fetal position or size increases the probability of dystocia.
- A multifetal pregnancy may result in dysfunctional labor due to uterine overdistention, which may lead to hypotonic dystocia and abnormal presentations of the fetuses.
- During labor, evaluation of fetal descent, cervical effacement and dilation, and characteristics of uterine contractions are paramount to determine progress or lack thereof.
- Antepartum assessment for a post-term pregnancy typically includes daily fetal movement counts done by the woman, nonstress tests done twice weekly, amniotic fluid assessments as part of the biophysical profile, and weekly cervical examinations to check for ripening for induction.
- Once the cervix is ripe, oxytocin is the most popular pharmacologic agent used for inducing or augmenting labor.
- Generally, the first and most reliable symptom of uterine rupture is fetal distress.
- Anaphylactoid syndrome of pregnancy (ASP) is a rare but often fatal event characterized by the sudden onset of hypotension, hypoxia, and coagulopathy.
- Cesarean births have steadily risen in the United States; today, approximately one in three births occurs this way. It is a major

surgical procedure and has increased risks when compared to vaginal birth.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. When reviewing the medical record of a client, the nurse notes that the woman has a condition in which the fetus cannot physically pass through the maternal pelvis. The nurse interprets this as

   a. cervical insufficiency.
   b. contracted pelvis.
   c. maternal disproportion.
   d. fetopelvic disproportion.

2. The nurse would anticipate a cesarean birth for a client who has which active infection present at the onset of labor?

   a. Hepatitis
   b. Herpes simplex virus
   c. Toxoplasmosis
   d. Human papillomavirus

3. After a vaginal examination, the nurse determines that the client's fetus is in an occiput posterior position. The nurse would anticipate that the client will have

   a. intense back pain.
   b. frequent leg cramps.
   c. nausea and vomiting.
   d. a precipitous birth.

4. When assessing the following women, who would the nurse identify as being at the greatest risk for preterm labor?

   a. Woman who had twins in a previous pregnancy

b. Client living in a large city close to the subway
c. Woman working full-time as a computer programmer
d. Client with a history of a previous preterm birth

5. The rationale for using a prostaglandin gel for a client prior to the induction of labor is to

a. stimulate uterine contractions.
b. numb cervical pain receptors.
c. prevent cervical lacerations.
d. soften and efface the cervix.

6. A client who is in active labor and whose cervix had dilated to 6 cm experiences a weakening in the intensity and frequency of her contractions and exhibits no further progress in labor. The nurse interprets this as a sign of

a. hypertonic labor.
b. precipitate labor.
c. hypotonic labor.
d. dysfunctional labor.

7. The nurse is developing a plan of care for a woman experiencing dystocia. Which nursing intervention would be the nurse's highest priority?

a. Changing the woman's position frequently
b. Providing comfort measures to the woman
c. Monitoring the fetal heart rate patterns
d. Keeping the couple informed of the labor progress

8. The nurse is caring for a woman experiencing hypertonic uterine dystocia. The woman's contractions are erratic in their frequency, duration, and of high intensity. The priority nursing intervention would be to

a. encourage ambulation every 30 minutes.
b. provide pain relief measures.
c. monitor the ocytocin infusion rate closely.

d. prepare the woman for an amniotomy.

9. What is the Bishop score used to assess?

a. Presence of bacterial vaginosis
b. Amount of amniotic fluid present
c. Overall fetal well-being in labor
d. Cervical readiness for induction

CRITICAL THINKING EXERCISES

1. A 26-year-old multipara is admitted to the labor and birth suite in active labor. After a few hours, the nurse notices a change in her contraction pattern—poor contraction intensity and no progression of cervical dilatation beyond 7 cm. The client keeps asking about her labor progress and appears anxious about "how long this labor is taking."

   a. Based on the nurse's findings, what might be happening?
   b. How can the nurse address the client's anxiety?
   c. What are the appropriate interventions to change this labor pattern?

2. The woman activates her call light and states, "I feel increased wetness down below."

   a. What might be occurring?
   b. How will the nurse confirm the suspicions?
   c. What interventions are appropriate for this finding?

STUDY ACTIVITIES

1. Visit the SHARE Pregnancy and Infant Loss Support, Inc., website and assess its helpfulness to parents.
2. Outline the fetal and maternal risks associated with a prolonged pregnancy.
3. An abnormal or difficult labor describes _____.

BRINGING IT ALL TOGETHER: A CASE STUDY

Tegan is a nulliparous woman who is now at 41 3/7 weeks' gestation with a male fetus. She presents for a routine prenatal visit. Fetal well-being is reassuring at this point with FHR 144, active fetal movement, and no complaints voiced except for fatigue and a mild backache when she stands for long periods of time. She expresses concern that she has not yet gone into labor.

ASSESSMENT

The mean duration of pregnancy is 40 weeks (280 days) dated from the first day of the last normal menstrual period. Post-term pregnancy is defined as a gestational age of more than 42 weeks (more than 292 days) dated from the last menstrual period. Approximately 10% of low-risk pregnancies continue beyond the 42nd week of gestation. Her fetal well-being assessment is within normal limits.

Go to thePoint to find questions to consider about this case.

22

Nursing Management of the Postpartum Woman at Risk

WOW

WORDS OF WISDOM

Nurses should remain vigilant and observant throughout the childbirth experience all the way through discharge of the childbearing family.

KEY TERMS

endometritis (en´dō-mē-trī´tis)

mastitis (mas-tī´tis)

postpartum depression (PPD)

postpartum hemorrhage (PPH)

subinvolution (sŭb´in´vŏ-lū´shŭn)

uterine atony (yū´tĕr-in at´ŏ-nē)

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Examine the major conditions that place the postpartum woman at risk.
2. Analyze the risk factors, assessment, preventive measures, and nursing management of common postpartum complications.
3. Differentiate the causes of postpartum hemorrhage based on the underlying pathophysiologic mechanisms.
4. Outline the nurse's role in assessing and managing the care of a woman with a thromboembolic condition.
5. Characterize the nursing management of a woman who develops a postpartum infection.
6. Compare and contrast affective disorders that can occur in women after birth, describing specific therapeutic management for each.

Joan gave birth about an hour ago to her fifth baby boy, who weighed 10 lb, and she is resting in bed when the nurse comes in to assess her. She tells the nurse that she feels like there is "something really wet" between her legs. She also feels a bit light-headed. What would the nurse suspect is happening? What findings would support the nurse's suspicion? What should the nurse do first?

INTRODUCTION

The postpartum period is the culmination of the childbearing experience. The weeks following birth are a critical period for the woman and her newborn, setting the stage for long-term health and well-being. Numerous adaptations and adjustments must be made to assimilate the newborn into the established family unit. It is a time designed for maternal recovery, family attachment, and new role development. The American College of Obstetricians and Gynecologists (ACOG) has recently revised their postpartum guidelines to recommend health care providers have contact with new mothers within the first 3 weeks postpartum, previously 6 weeks, and provide ongoing care with a comprehensive visit no later than 12 weeks after birth (ACOG, 2018a). Typically, recovery from childbirth progresses without complications both physiologically and psychologically. The woman's body faces significant changes in the weeks and months following childbirth. It is a time filled with many transformations and wide-ranging emotions, and the new mother commonly experiences a great sense of accomplishment. However, the woman can experience deviations from health, developing postpartum conditions that can place her at risk. These high-risk conditions or complications can become life threatening. *Healthy People 2030* addresses these risks in national health goals (*Healthy People 2030* 22.1).

This chapter addresses the nursing management of the most common conditions that place the postpartum woman at risk:

hemorrhage, thromboembolic disease, infections, and postpartum affective disorders.

HEALTHY PEOPLE 2030 • 22.1

Objective	Nursing Significance
MHMD-2030-05 Increase the proportion of adults with major depressive episodes who receive treatment.	Will help foster the need for early identification of risk factors and prompt intervention to reduce the potential negative outcomes of pregnancy and birth. Will help to minimize the devastating effects of complications during the postpartum period and the woman's ability to care for her newborn.
MICH-2030-04 Reduce maternal deaths.	Will help to contribute to lower rates of maternal mortality by focusing on thorough risk assessments in the postpartum period of potential infections and postpartum hemorrhage.

Adapted from USDHHS. (2020). *Proposed objectives for inclusion in Healthy People 2030*. https://www.healthypeople.gov/sites/default/files/ObjectivesPublicComment508.pdf

POSTPARTUM HEMORRHAGE

Postpartum hemorrhage (PPH) is a potentially life-threatening complication that can occur after both vaginal and cesarean births. It is the leading cause of maternal death in both developed and developing countries, accounting for about 25% of all maternal deaths worldwide. Every year, about 14 million women globally suffer from PPH or approximately one in 20 births (Agency for Healthcare Research and Quality [AHRQ], 2019). A hemorrhage occurs in 5% of all births and is responsible for a major portion of maternal mortality. The majority of these deaths occur within 4 hours of childbirth. It is estimated that 90% of maternal deaths secondary to obstetric hemorrhage are preventable (Troiano et al., 2019).

PPH is defined as a cumulative blood loss greater than 1,000 mL with signs and symptoms of hypovolemia within 24 hours of the birth

process, regardless of the route of delivery (Wormer & Bryant, 2019). Morbidity from PPH can be severe, with sequelae including organ failure, shock, edema, thrombosis, acute respiratory distress, sepsis, anemia, intensive care admissions, and prolonged hospitalization (AHRQ, 2019). Hemorrhage is the most common reason postpartum women are admitted to intensive care units and it is the most preventable cause of maternal death. Timely, accurate identification of risk factors and initiation of appropriate interventions would improve outcomes (Norwitz et al., 2019). Blood loss that occurs within 24 hours of birth is termed *primary (immediate or early) postpartum hemorrhage*; blood loss that occurs 24 hours to 12 weeks after birth is termed *delayed (late) postpartum hemorrhage.* A more objective definition of PPH would be any amount of bleeding that places the mother in hemodynamic jeopardy.

Pathophysiology

Excessive bleeding can occur at any time between the separation of the placenta and its expulsion or removal. The most common cause of PPH is **uterine atony**, failure of the uterus to contract and retract after birth. The uterus must remain contracted after birth to control bleeding from the placental site. Uterine atony is responsible for the majority of primary or immediate PPH, while obstetric lacerations, uterine inversion, subinvolution, and rupture are generally causes of late or delayed hemorrhage (Blackburn, 2018). Any factor that causes the uterus to relax after birth will cause bleeding, even a full bladder that displaces the uterus.

During the third stage of labor, the muscles of the uterus contract downward, causing constriction of the blood vessels that pass through the uterine wall to the placental surface and stop the flow of blood. This action also causes the placenta to separate from the uterine wall. The absence of uterine contractions may result in excessive blood loss. Uterotonic medications promote uterine contractions to prevent atony and speed delivery of the placenta.

TABLE 22.1 Clinical Manifestations of Shock Due to Blood Loss

Degree of Shock	Blood Loss	Signs and Symptoms
Mild	20%	Diaphoresis, increased capillary refilling, cool extremities, maternal anxiety
Moderate	20–40%	Tachycardia, postural hypotension, oliguria
Severe	>40%	Hypotension, agitation/confusion, hemodynamic instability

Cunningham, F. G., Leveno, K. J., Bloom, S. L., Dashe, J. S., Hoffman, B. L., Casey, B. M., & Spong, C. Y. (2018). *William's obstetrics* (25th ed.). McGraw-Hill Education; Udeani, J. (2019). Hemorrhagic shock treatment & management. *eMedicine*. Retrieved September 12, 2018, from https://emedicine.medscape.com/article/432650-treatment.

Over the course of pregnancy, maternal blood volume increases as much as 50% (from 4 to 6 L). The plasma volume increases twice as much in comparison to the total red blood cell volume. As a result, hemoglobin and hematocrit fall. The increase in blood volume meets the perfusion demands of the low-resistance uteroplacental unit and provides a reserve for the blood loss that occurs at delivery (Cunningham et al., 2018). Given this increase, the typical signs of hemorrhage (e.g., falling blood pressure, increasing pulse rate, and decreasing urinary output) do not appear until as much as 1,800 to 2,100 mL of blood has been lost. Current evidence on postpartum volume replacement suggests packed red blood cells, fresh frozen plasma, platelets, and recombinant factor VIIa be used for volume replacement (Resnik et al., 2019). Clinical manifestations of shock resulting from blood loss are outlined in Table 22.1.

In addition, accurate determination of actual blood loss is difficult because of blood pooling inside the uterus, on peripads, mattresses, and the floor. Because no universal clinical standard exists, nurses

must remain vigilant, assessing for risk factors and checking clients carefully before the health care provider leaves the birthing area.

Other causes of PPH include lacerations of the genital tract, episiotomy, retained placental fragments, uterine inversion, coagulation disorders, large-for-gestational-age newborn, failure to progress during the second stage of labor, placenta accreta, induction or augmentation of labor with oxytocin, surgical birth, and hematomas of the vulva, vagina, or subperitoneal areas (Sanders, 2019). A helpful way to remember the causes of postpartum hemorrhage is by using the five Ts:

1. *Tone*: uterine atony, distended bladder
2. *Tissue*: retained placenta and clots; uterine subinvolution
3. *Trauma*: lacerations, hematoma, inversion, rupture
4. *Thrombin*: coagulopathy (preexisting or acquired)
5. *Traction*: too much pulling on umbilical cord

Tone

Tone is the T that refers to uterine atony. A uterus with sufficient tone can clamp down on itself to constrict the uterine blood vessels to clot abnormal bleeding. Altered uterine muscle tone most commonly results from overdistention of the uterus. Overdistention can be caused by multiple gestation, fetal macrosomia, hydramnios, fetal abnormality, placenta previa, precipitous birth, or retained placental fragments. Other causes might include prolonged or rapid, forceful labor, especially if stimulated by oxytocin; bacterial toxins (e.g., chorioamnionitis, endomyometritis, septicemia); use of anesthesia, especially halothane; and magnesium sulfate used in the treatment of preeclampsia (Jordan et al., 2019). Overdistention of the uterus is a major risk factor for uterine atony, the most common cause of early postpartum hemorrhage, which can lead to hypovolemic shock. A distended bladder can also displace the uterus from the midline to either side, which impedes its ability to contract to reduce bleeding.

Tissue

Tissue is the T that refers to having retained placental fragments, membranes or clots left inside the uterus. Uterine contraction and retraction lead to detachment and expulsion of the placenta after birth. Classic signs of placental separation include a small gush of blood with lengthening of the umbilical cord and a slight rise of the uterus in the pelvis. Complete detachment and expulsion of the placenta permit continued contraction and optimal occlusion of blood vessels. Failure of complete placental separation and expulsion leads to retained fragments (tissue), which occupy space and prevent the uterus from contracting fully to clamp down on blood vessels; this can lead to hemorrhage. Clots can also occupy space, inhibiting uterine contractions.

After the placenta has been expelled, a thorough inspection is necessary to confirm its intactness; tears or fragments left inside may indicate an accessory lobe or placenta accreta (an uncommon condition in which the chorionic villi adhere to the myometrium, causing the placenta to adhere abnormally to the uterus and not separate and deliver spontaneously). Profuse hemorrhage results because the uterus cannot contract fully.

SUBINVOLUTION OF THE UTERUS

Subinvolution refers to incomplete involution of the uterus or failure to return to its normal size and condition after birth. Typically, subinvolution occurs when the myometrial fibers of the uterus do not contract effectively, causing relaxation. Complications of subinvolution include hemorrhage, pelvic peritonitis, salpingitis, and abscess formation (King et al., 2019). Causes of subinvolution include retained placental fragments, distended bladder, excessive maternal activity prohibiting proper recovery, uterine myoma, and infection. All of these conditions contribute to delayed postpartum bleeding. The clinical picture includes a postpartum fundal height that is higher than expected with a boggy uterus; the lochia fails to change colors from red to serosa to alba within a few weeks. This condition is usually identified at the woman’s postpartum examination 4 to 6 weeks after birth with a bimanual vaginal

examination or ultrasound. Treatment is directed toward stimulating the uterus to expel fragments with a uterine stimulant, and antibiotics are given to prevent infection.

Trauma

Damage to the genital tract may occur spontaneously or through the manipulations used during birth. Lacerations and hematomas resulting from birth trauma can cause significant blood loss. Hematomas can present as pain or as a change in vital signs disproportionate to the amount of blood loss. Most often, hematoma formation is associated with episiotomy, instrumental birth, or nulliparity. Many hematomas can be prevented with gentle, controlled birth and appropriate inspection and repair of lacerations or episiotomy (Jordan et al., 2019). Uterine inversion happens when the top of the uterus collapses into the inner cavity due to excessive fundal pressure or pulling on the umbilical cord when the placenta is still firmly attached to the fundus after the infant has been born. Treatment for uterine inversion includes giving uterine relaxants and immediate manual replacement by the health care provider. Additionally, uterine rupture can occur and cause damage to the genital tract and is more common in women with previous cesarean incisions or those who have undergone any procedure resulting in disruption of the uterine wall, including myomectomy, perforation of the uterus during a dilation and curettage, biopsy, or intrauterine system insertion. Classically, its signs and symptoms combine pain, fetal heart rate abnormalities, and vaginal bleeding. Uterine rupture is a catastrophic complication that requires a rapid diagnosis and intervention, but initial clinical manifestations may be nonspecific (Stevens, 2019).

Trauma can also occur after prolonged or vigorous labor, especially if the uterus has been stimulated with oxytocin or prostaglandins. Trauma can also occur after extrauterine or intrauterine manipulation of the fetus.

Cervical lacerations commonly occur during a forceps delivery or in mothers who have not been able to resist bearing down before the

cervix is fully dilated. Vaginal side wall lacerations are associated with operative vaginal births but may occur spontaneously, especially if the fetal hand presents with the head. Lacerations can arise during manipulations to resolve shoulder dystocia. Lacerations should always be suspected in the face of a contracted uterus with bright red blood continuing to trickle out of the vagina.

Thrombin

Thrombin is the T that refers to inherited and acquired bleeding disorders and lack of coagulating factors. Thrombosis (formation of a blood clot) helps prevent PPH immediately after birth by providing hemostasis. Fibrin deposits and clots in supplying vessels play a significant role in the hours and days after birth. Disorders that interfere with the clot formation can lead to postpartum hemorrhage. Medication used to prevent hemorrhage by stimulating uterine contractions may delay the appearance of coagulation disorders. Coagulopathies should be suspected when postpartum bleeding persists without any identifiable cause (Dutton et al., 2020).

Disorders of coagulation are relatively uncommon as a sole cause of PPH. Coagulation disturbances should be suspected in women with a family history of such abnormalities and women with a history of menorrhagia. Clinical circumstances may also suggest coagulation defect as a cause of PPH. Diagnosis of a coagulation disorder often requires a high index of suspicion and should not be overlooked in the evaluation of obstetric hemorrhage (Matsunaga et al., 2019).

Ideally, the client's coagulation status is determined during pregnancy. However, if she received no prenatal care, coagulation studies should be ordered immediately to determine her status. Abnormal results typically include decreased platelet and fibrinogen levels, increased prothrombin time, partial thromboplastin time, fibrin degradation products, and a prolonged bleeding time (Cunningham et al., 2018). Selected conditions associated with coagulopathies in the postpartum client include thrombotic thrombocytopenic purpura

(TTP), von Willebrand disease, and disseminated intravascular coagulation (DIC).

THROMBOTIC THROMBOCYTOPENIC PURPURA

TTP is an autoimmune disorder of increased platelet destruction caused by autoantibodies, which can increase a woman's risk of hemorrhaging. There is a decrease in the number of circulating platelets in the absence of toxic exposure or a disease associated with a low platelet count. It is most common in young women during childbearing age and may be associated with maternal and fetal complications. Glucocorticoids and caplacizumab are two mainstays of medical therapy (Scully et al., 2019).

VON WILLEBRAND DISEASE

von Willebrand disease is a congenital bleeding disorder that is inherited as an autosomal dominant trait. It is characterized by a prolonged bleeding time, a deficiency of von Willebrand factor, and impairment of platelet adhesion (Centers for Disease Control and Prevention [CDC], 2019d). It is the most common hereditary bleeding disorder, affecting approximately 1% of the general population (Kadir et al., 2019). Although von Willebrand disease is thought to affect men and women equally, it is diagnosed more frequently in women because of menorrhagia, and it is more common among White women than African American women (Rick, 2019). Most cases remain undiagnosed due to lack of awareness, difficulty in diagnosis, a tendency to attribute bleeding to other causes, and variable symptoms.

The most common symptoms of von Willebrand disease include bleeding gums, easy bruising, menorrhagia, blood in urine and stools, nosebleeds, and hematomas. Prolonged bleeding from trivial wounds, oral cavity bleeding, and excessive menstrual bleeding are common. Gastrointestinal bleeding is rare. During pregnancy, von Willebrand factor level increases in most women; thus, labor and birth usually proceed normally. However, all women should be

monitored for excessive bleeding, particularly during the first week postpartum (Jordan et al., 2019).

DISSEMINATED INTRAVASCULAR COAGULATION

DIC is a life threatening, acquired coagulopathy in which the clotting system is abnormally activated, resulting in widespread clot formation in the small vessels throughout the body, which leads to the depletion of platelets and coagulation factors. This is why DIC is also known as consumption coagulopathy.

DIC is not itself a specific illness; rather it is always a secondary diagnosis that occurs as a complication of placental abruption, anaphylactoid syndrome of pregnancy, intrauterine fetal death with prolonged retention of the fetus, acute fatty liver of pregnancy, severe preeclampsia, HELLP syndrome (hemolysis, i.e., the breakdown of red blood cells, elevated liver enzymes, and low platelet count), septicemia, and postpartum hemorrhage. Clinical features include petechiae, ecchymoses, bleeding gums, fever, hypotension, acidosis, hematomas, tachycardia, proteinuria, uncontrolled bleeding during birth, and acute renal failure (Resnik et al., 2019). Treatment goals are to maintain tissue perfusion through aggressive administration of fluid therapy, oxygen, heparin, and blood products. The most important treatment concept in DIC is that it is a secondary manifestation of an underlying disorder. The most important therapeutic maneuver is treating the initiating disorder; DIC will disappear, and the coagulation status will normalize. Without this, supportive measures ultimately fail (Cunningham et al., 2018).

Prompt diagnosis and understanding of the underlying triggers of this complication is essential for a favorable outcome. Teamwork and prompt treatment are essential for the successful management of women with DIC. Therapeutic management focuses on the underlying cause of the hemorrhage. For example, uterine massage is used to treat uterine atony. If retained placental fragments are the cause, the fragments are usually manually separated and removed and a uterine stimulant is given to promote the uterus to expel fragments. Antibiotics are administered to prevent infection.

Lacerations are sutured or repaired. Glucocorticoids and intravenous immunoglobulin, intravenous anti-RhoD, and platelet transfusions may be given for immune thrombocytopenia (ITP) which is an acquired autoimmune disease resulting in destruction of platelets. Perinatal management of TTP should also include maintenance of maternal platelet count and regular monitoring of fetal growth along with prediction and prevention of fetal passive ITP (Belfort, 2019).

The mainstays of therapy for DIC are administration of blood components and coagulation factors. Delayed postpartum hemorrhage may occur, despite adequate prophylaxis. Frequent monitoring and continued prophylaxis and/or treatment are recommended for at least 2 weeks after childbirth (Troiano et al., 2019).

Traction

Traction is the T that refers to the pulling of the umbilical cord after the birth of the fetus to extract the placenta before it is completely separated from the uterine wall. Strong traction placed on the umbilical cord to expel the placenta can result in cord detachment from the placenta or uterine inversion resulting in a massive hemorrhage. If detachment of the cord from the placenta occurs, manual removal of the placenta will be needed, exposing the woman to unnecessary pain and an increased risk of infection. Uterine inversion is associated with maternal shock and DIC.

Nursing Assessment

Most women will not have identifiable risk factors. Nonetheless, primary prevention of a PPH begins with an assessment of identifiable risk factors. Pregnancy and childbirth involve significant health risks, even for women with no preexisting health problems. In the United States, where most births occur in hospitals and where resources are likely to be available more so than in developing countries, PPH still continues to be among the top causes of maternal deaths. Retrospective studies of these events suggest that

the majority of cases are preventable. As with many other sources of perinatal harm, delays in recognition, diagnosis, and treatment, problems with hierarchy and communication, and lack of knowledge, policies, and protocols were often cited as contributing factors (Jordan et al., 2019).

The period after the birth and the first hours postpartum are crucial times for the prevention, assessment, and management of bleeding. Compared with other maternal risks such as infection, bleeding can rapidly become life threatening, and nurses, along with other health care providers, need to identify this condition quickly and intervene appropriately.

Begin by reviewing the mother's history, including labor and birth history, for risk factors associated with PPH (Table 22.2). The incidence of PPH has been rising, though the mortality has come down, suggesting improvement in the management of this condition. Although specific risk factors have been identified, PPH is often unanticipated and still occurs in approximately 5% of all births and increasing (King et al., 2019).

Since the most common cause of immediate severe PPH is uterine atony, assess uterine tone after birth by palpating the fundus for firmness and location. A soft, boggy fundus indicates uterine atony.

TAKE NOTE!

A soft, boggy uterus that deviates from the midline suggests that a full bladder is interfering with uterine involution. If the uterus is not in correct position (midline), it will not be able to contract to control bleeding.

TABLE 22.2 Factors Placing a Woman at Risk for Postpartum Hemorrhage

Clinical Risk Factors	Associated Clinical Conditions
Tone (abnormalities of uterine contractions)	
Overdistention of uterus	Polyhydramnios
	Multifetal gestation
	Macrosomia
Uterine muscle exhaustion	Rapid labor
	Prolonged labor
	Oxytocin use
Uterine infection	Maternal fever
	Prolonged rupture of membranes
Tissue (retained in uterus)	
Products of conception	Incomplete placenta at birth
Retained blood clots	Atonic uterus
Trauma (of the genital tract)	
Lacerations anywhere	Precipitate birth or operative birth
Laceration extensions	Malposition of fetus
	Previous uterine surgery
Uterine inversion	Forceful pulling when placenta isn't separated yet; traction on the cord when uterus isn't contracted
Thrombin (coagulation abnormalities)	
Preexisting conditions	Hereditary inheritance Hemophilia von Willebrand disease History of previous PPH Acquired in pregnancy Idiopathic thrombocytopenia purpura Bruising, elevated blood pressure Disseminated intravascular coagulation

Traction on umbilical cord	Strong traction placed on umbilical cord prior to its separation from the uterine wall may lead to hemorrhage

Centers for Disease Control and Prevention (CDC). (2019d). *Von Willebrand disease*. Retrieved June 16, 2020, from https://www.cdc.gov/ncbddd/vwd/facts.html; Kadir, R. A., James, P. D. & Lee, C. A. (2019). *Inherited bleeding disorders in women* (2nd ed.). John Wiley & Sons; and Smith, J. R. (2019). Postpartum hemorrhage treatment and management. *eMedicine*. Retrieved June 27, 2018, from https://emedicine.medscape.com/article/275038-treatment#d10.

Assess the amount of bleeding. Visual estimation is the most frequently practiced method of determining blood loss during childbirth in the United States, and the results are usually included in the documentation of events pertaining to the birth. This method is used despite repeated studies showing its inaccuracy and underestimation. In any method used, nurses should consult hospital protocols and follow them. If bleeding continues even though there are no lacerations, suspect retained placental fragments. The uterus remains large with painless, dark red bleeding mixed with clots. This cause of hemorrhage can be prevented by carefully inspecting the placenta for intactness.

If trauma is suspected, attempt to identify the source and document it. Typically, the uterus will be firm with a steady stream or trickle of unclotted, bright red blood noted in the perineum. Most deaths from PPH are not due to gross bleeding but rather to inadequate management of slow, steady blood loss. Astute assessment to identify this slow hemorrhage is needed to optimize outcomes (Belfort, 2020).

Assess for hematomas, which may require surgical treatment. Most hematomas arise from bleeding lacerations related to operative deliveries. The uterus would be firm, with bright red bleeding. Observe for a localized bluish bulging area just under the skin surface in the perineal area (Fig. 22.1). Often the woman will report severe perineal or pelvic pain and will have difficulty voiding. In addition, she may exhibit hypotension, tachycardia, and anemia. Frequently, the health care provider will incise the skin bulge to

evacuate the hematoma of trapped blood. A pressure dressing is applied to this area to prevent further bleeding (Roman, 2019).

FIGURE 22.1. Perineal hematoma. Note the bulging swollen mass.

Inspect the skin and mucous membranes for gingival bleeding or petechiae and ecchymoses. Check venipuncture sites for oozing or prolonged bleeding. These findings might suggest a coagulopathy as a cause of PPH. Also assess the amount of lochia, which would be much greater than usual. Urinary output would be diminished, with signs of acute renal failure. Vital signs would show an increased pulse rate and a decreased level of consciousness. However, signs of shock do not appear until hemorrhage is far advanced due to the increased fluid and blood volume of pregnancy.

Nursing Management

When excessive bleeding is encountered, initial management steps are aimed at improving uterine tone with immediate fundal massage, intravenous fluid resuscitation, and administration of uterotonic medications. If these methods fail to control bleeding, additional resources are mobilized and more aggressive interventions such as bimanual compression, internal uterine packing, and/or balloon tamponade techniques are employed by the health care provider. Other potential causes of bleeding should be thoroughly explored, and laboratory tests such as a complete blood count, type and cross-match, and coagulation studies should be obtained immediately. Transfusion of blood products should be instituted without hesitation once estimates of bleeding reach 1,500 to 2,000 mL (Smith, 2019).

Concept Mastery Alert

Priority Intervention for Uterine Atony

Before initiating fundal massage, the nurse must first place a hand over the symphysis pubis to anchor the uterus and prevent possible uterine inversion.

Clearly, in all cases of unexpected hemorrhage, the interventions discussed as follows must be performed without delay. PPH is best managed by using a stepwise progressive approach. Manual massage and pharmacologic therapies are first-line treatments. If the bleeding continues, second-line interventions might include the use of intrauterine balloon (or gauze) tamponade and uterine compression sutures. If these second-line therapies still don't stop the bleeding, women may need to undergo radiologic embolization, pelvic devascularization, or hysterectomy. Peripartum hysterectomy remains the last-resort lifesaving measure and carries with it a higher mortality rate compared with nonobstetric hysterectomy. It is a most demanding obstetric surgery performed under trying circumstances of life-threatening hemorrhage (Cunningham et al., 2018). Moreover, high-volume transfusions are often required, and there are significant postsurgical morbidity risks such as renal failure, hepatic failure, respiratory distress syndrome, coagulopathies, septicemia, tissue

hypoxia, and pituitary necrosis (Sheehan syndrome) (Stevens, 2019). PPH outcomes can be improved by thorough preparation, anticipating risks, and coordinating consultants for interventional procedures if warranted.

PPH is a serious complication of pregnancy that is often unanticipated. Even with prompt aggressive management, postpartum bleeding can quickly evolve into a life-threatening event. Perinatal nurses are often the first to observe significant postpartum bleeding and their prompt initial response and continued assessments are pivotal in the anticipation and coordination of necessary interventions. Multidisciplinary team support is critical because obstetric caregivers need a full array of medical and surgical strategies to manage intractable bleeding. Because all postpartum women are at risk for hemorrhage, nurses need to possess the knowledge and skills to practice active management of the third stage of labor to prevent hemorrhage and to recognize, assess, and respond rapidly to excessive blood loss in their clients.

Massage the Uterus

Massage the uterus if uterine atony is noted. The uterine muscles are sensitive to touch; massage stimulates the muscle fibers to contract. Massage the boggy uterus to stimulate contractions and expression of any accumulated blood clots while supporting the lower uterine segment. As blood pools in the vagina, stasis of blood causes clots to form. These clots need to be expelled as pressure is placed on the fundus. Note, however, that overly forceful massage can tire the uterine muscles, resulting in further uterine atony and increased pain. See Nursing Procedure 22.1 for steps in massaging the fundus.

Administer a Uterotonic Drug

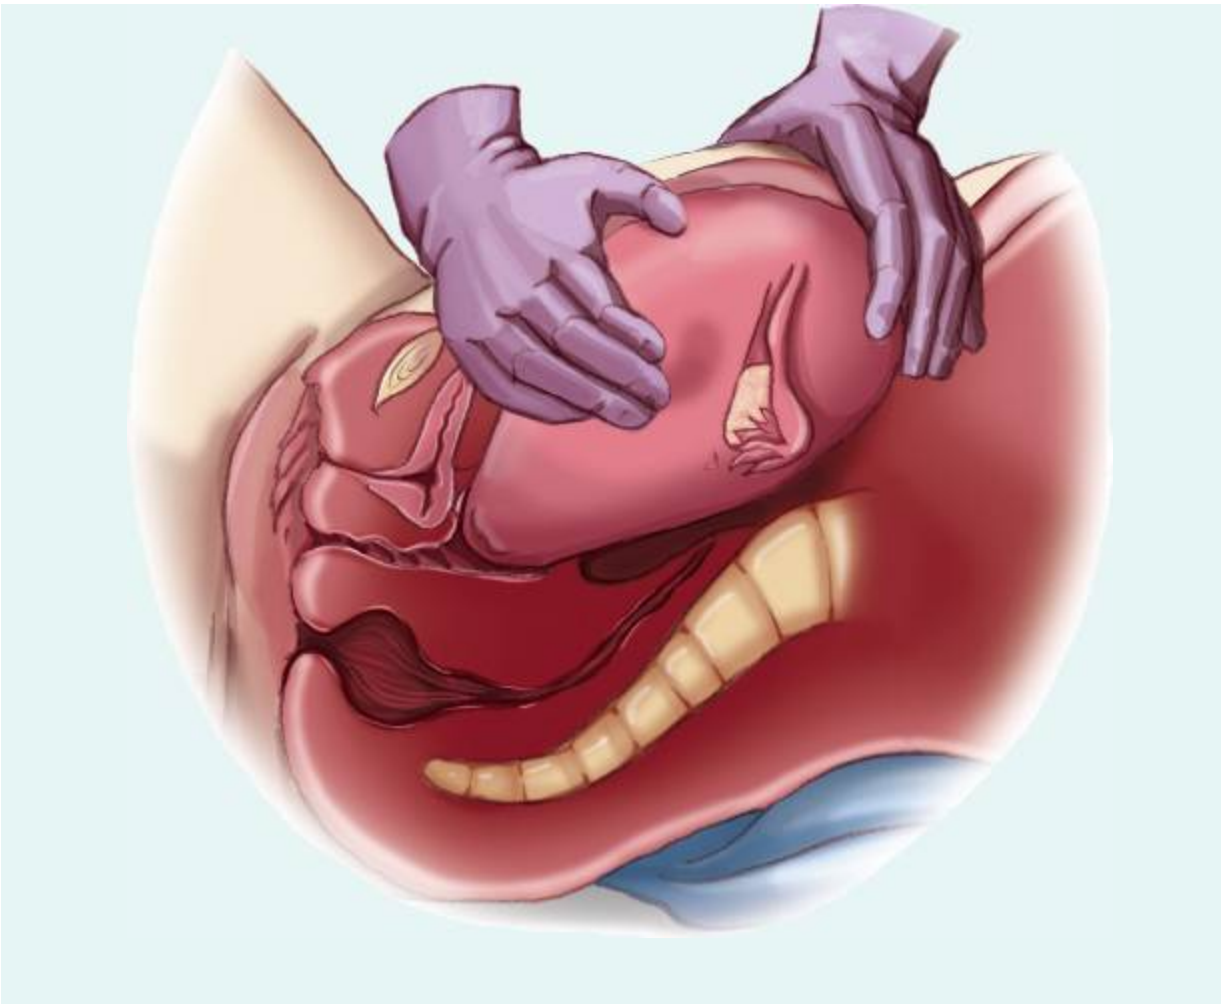
Administer a uterotonic drug if repeated fundal massage and expression of clots fail; medication is probably needed to contract the uterus in order to control bleeding from the placental site. The injection of a uterotonic drug immediately after birth is an important

intervention used to prevent PPH. Oxytocin (Pitocin); misoprostol (Cytotec); dinoprostone (Prostin E2); methylergonovine maleate (Methergine); and a derivative of prostaglandin (PGF2α), carboprost (Hemabate), are drugs used to manage postpartum hemorrhage (Drug Guide 22.1). However, misoprostol is not approved by the U.S. Food and Drug Administration (FDA) for this purpose. The choice of which uterotonic drug to use for management of bleeding depends on the judgment of the health care provider, the availability of drugs, and the risks and benefits of the drug.

NURSING PROCEDURE 22.1 Massaging the Fundus

Purpose: To Promote Uterine Contraction

1. After explaining the procedure to the woman, place one gloved hand on the area above the symphysis pubis (this helps support the lower uterine segment).
2. Place the other gloved hand (usually the dominant hand) on the fundus.
3. With the hand on the fundus, gently massage the fundus in a circular manner. Be careful not to over-massage the fundus, which could lead to muscle fatigue and uterine relaxation.
4. Assess for uterine firmness (uterine tissue responds quickly to touch).
5. If firm, apply gentle yet firm pressure in a downward motion toward the vagina to express any clots that may have accumulated.
6. Do not attempt to express clots until the fundus is firm because the application of firm pressure on an uncontracted uterus could cause uterine inversion, leading to massive hemorrhage.
7. Assist the woman with perineal care and applying a new perineal pad.
8. Remove gloves and wash hands.



DRUG GUIDE 22.1 Drugs Used to Control Postpartum Hemorrhage

Drug	Action/Indications	Nursing Implications
Oxytocin (Pitocin) First-line therapy	Stimulates the uterus to contract/to contract the uterus to control bleeding from the placental site 20–40 units in a liter IV or 10 units IM	Assess fundus for evidence of contraction and compare amount of bleeding every 15 minutes or according to orders. Monitor vital signs every 15 minutes. Monitor uterine tone to prevent hyperstimulation. Reassure client about the need for uterine contraction and administer analgesics for comfort. Offer explanation to client and family about what is happening and the purpose of the medication. Provide nonpharmacologic comfort measures to assist with pain management. Set up the IV infusion to be piggybacked into a primary IV line. This ensures

		that the medication can be discontinued readily if hyperstimulation or adverse effects occur while maintaining the IV site and primary infusion.
Misoprostol (Cytotec)	Stimulates the uterus to contract/to reduce bleeding; a prostaglandin analog 800 mcg per rectum, one dose (range, 400–1,000 mcg)	Contraindications: Never give undiluted as a bolus injection IV. As above. Not FDA-approved for this indication, but an effective drug therapy for acute postpartum hemorrhage Contraindications: allergy, active cardiovascular disease, pulmonary or hepatic disease; use with caution in women with asthma
Dinoprostone (Prostin E2)	20 mg vaginal or rectal suppository May be repeated every 2 hours	Monitor blood pressure frequently since hypotension is a frequent side effect along with vomiting and diarrhea, nausea,

		temperature elevation
Methylergonovine maleate (Methergine)	Stimulates the uterus to prevent and treat postpartum hemorrhage due to atony or subinvolution 0.2 mg IM injection May be repeated in 5 minutes Thereafter every 2–4 hours	Assess baseline bleeding, uterine tone, and vital signs every 15 minutes or according to protocol. Offer explanation to client and family about what is happening and the purpose of the medication. Monitor for possible adverse effects, such as hypertension, seizures, uterine cramping, nausea, vomiting, and palpitations. Report any complaints of chest pain promptly. Contraindications: Hypertension
Prostaglandin (PGF2α), Carboprost, (Hemabate)	Stimulates uterine contractions/to treat postpartum hemorrhage due to uterine atony when not controlled by other methods	Assess vital signs, uterine contractions, client's comfort level, and bleeding status as per protocol.

	0.25 mg IM injection May be repeated every 15–90 minutes up to eight doses Stimulates uterine contractions to reduce bleeding when not controlled by the first-line therapy of oxytocin	Offer explanation to client and family about what is happening and the purpose of the medication. Monitor for possible adverse effects, such as fever, chills, headache, nausea, vomiting, diarrhea, flushing, and bronchospasm. Contraindications: asthma or active cardiovascular disease Same as above Contraindications: active cardiac, pulmonary, renal, or hepatic disease

Resnik, R., Lockwood, C. J., Moore, T. R., Greene, M. F., Copel, J. A., & Silver, R. M. (2019). *Creasy & Resnik's Maternal-fetal Medicine: Principles and practice* (8th ed.). Elsevier; Skidmore-Roth, L. (2021). *Mosby's 2021 nursing drug reference* (34th ed.). Mosby Elsevier; and Wormer, K. C., & Bryant, S. B. (2019). *Pregnancy, acute postpartum hemorrhage*. StatPearls. Retrieved November 19, 2019, from https://www.ncbi.nlm.nih.gov/books/NBK499988/.

All nurses need to be aware of the contraindications of administering each of the medications used to control postpartum hemorrhage as follows:

- *Pitocin*—never give undiluted as a bolus injection intravenously
- *Cytotec*—allergy, active cardiovascular disease, pulmonary or hepatic disease
- *Prostin E2*—active cardiac, pulmonary, renal, or hepatic disease

- *Methergine*—if the woman is hypertensive, do not administer
- *Hemabate*—contraindicated with asthma due to risk of bronchial spasm

Remember Joan, the woman described at the beginning of the chapter? The nurse assesses her and finds that her uterus is boggy. What would the nurse do next? What additional nursing measures might be used if Joan's fundus remains boggy? When should the health care provider be notified?

Maintain the Primary Intravenous Infusion

Maintain the primary intravenous infusion and be prepared to start a second infusion at another site if blood transfusions are necessary. Draw blood for type and cross-match and send it to the laboratory. Administer oxytocics as ordered, correlating and titrating the infusion rate to assessment findings of uterine firmness and lochia. Assess for visible vaginal bleeding, and count or weigh perineal pads.

TAKE NOTE!

Postpartum hemorrhage outcomes can be improved by thorough preparation, anticipating risks factors in every woman admitted, and coordinating consultants for interventional procedures if warranted.

Check Vital Signs

Check vital signs every 15 to 30 minutes, depending on the acuity of the mother's health status. Monitor her complete blood count to identify any deficit or assess the adequacy of replacement. Assess the woman's level of consciousness to determine changes that may result from inadequate cerebral perfusion.

A Foley catheter is typically in place to keep the bladder empty to avoid displacement of the uterus. A fundus above the umbilicus and deviated laterally indicates a full bladder and interferes with uterine contractions to slow the bleeding.

Prepare the Woman for Removal of Retained Placental Fragments

Prepare the woman for removal of retained placental fragments. These fragments are usually manually separated and removed by the health care provider. Be sure that the health care provider remains long enough after birth to assess the bleeding status of the woman and determine the etiology. Assist the health care provider with suturing any lacerations immediately to control hemorrhage and repair the tissue.

Nurses should anticipate and prepare the woman for transfer to the operating room for surgical intervention if tamponade techniques fail to achieve hemostasis. The blood bank should be notified that additional transfusions may be required and the woman's condition closely monitored for signs of hypovolemic shock.

Continually Assess the Woman for Signs and Symptoms of Hemorrhagic Shock

Continually assess the woman for signs and symptoms of hemorrhagic shock, a condition in which inadequate perfusion of organs results in insufficient availability of oxygen to satisfy the metabolic needs of the tissues (Jordan et al., 2019). Hemorrhagic shock is the most common form of shock encountered in obstetric practice. Subsequently, a catabolic state develops, leading to inflammation, endothelial dysfunction, and disruption of normal metabolic processes in vital organs. Once these events become established, the process of shock is often irreversible, even if volume and red blood cell deficits are corrected. The main goals of treatment of hemorrhagic shock include controlling the source of bleeding, fluid resuscitation, correction of the imbalance between oxygen delivery and consumption, and treating DIC (Udeani, 2019).

A postpartum hemorrhage is a traumatic experience because medical complications are unexpected during what is anticipated as a joyful time. Assess the anxiety level of the woman; the woman going into hypovolemic shock is highly anxious and may lose

consciousness. The woman's significant others experience a high level of anxiety as well and need a great deal of support.

Monitor the woman's blood pressure, pulse, capillary refill, mental status, and urinary output. These assessments allow estimation of the severity of blood loss and help direct treatment. If the woman develops hemorrhagic shock, interventions focus on controlling the source of blood loss; restoring adequate oxygen-carrying capacity; and maintaining adequate tissue perfusion. Successful treatment depends on efficient collaboration among all health care team members to meet the woman's specific needs.

For the woman with idiopathic thrombocytopenic purpura, expect to administer glucocorticoids, intravenous immunoglobulin, intravenous anti-RhoD, and platelet transfusions. Prepare the woman for a splenectomy if the bleeding tissues do not respond to medical management. Be alert for women with abnormal bleeding tendencies, ensuring that they receive proper diagnosis and treatment. Teach them how to prevent severe hemorrhage by learning how to feel for and massage their fundus when boggy, assisting the nurse in keeping track of the number of and amount of bleeding on perineal pads, and avoiding any medications with antiplatelet activity such as aspirin, antihistamines, or nonsteroidal antiinflammatory drugs (NSAIDs).

Institute Emergency Measures If DIC Develops

If the woman develops DIC, institute emergency measures to control bleeding and impending shock and prepare to transfer her to the intensive care unit. Identification of the underlying condition and elimination of the causative factor are essential to correct the coagulation problem. Be ready to replace fluid volume, administer blood component therapy, and optimize the mother's oxygenation and perfusion status to ensure adequate cardiac output and end-organ perfusion. Continually reassess the woman's coagulation status via laboratory studies. DIC can quickly lead to multiorgan failure and death, particularly if early recognition and treatment fail to

occur. A high index of suspicion remains paramount to improve outcomes.

Monitor vital signs closely, remaining alert for changes that signal an increase in bleeding or impending shock. Observe for early signs of ecchymosis, including spontaneous bleeding from the gums or nose, petechiae, excessive bleeding from the cesarean incision site or intravenous site, hematuria, and blood in the stool. Late signs include progressive changes in vital signs, skin color, and reduction of urinary output. Collectively, these findings correlate with decreased blood volume, decreased organ and peripheral tissue perfusion, and clots in the microcirculation. The goals of treatment are to optimize hemodynamic function, improve tissue oxygenation, reduce the risk of end-organ dysfunction, and reduce the incidence of morbidity and mortality (Troiano et al., 2019).

TAKE NOTE!

Always remember the five causes of postpartum hemorrhage and the appropriate intervention for each: (1) uterine atony—massage and oxytocics; (2) retained placental tissue—evacuation and oxytocics; (3) lacerations or hematoma—surgical repair; (4) thrombin (bleeding disorders)—blood products; and (5) uterine inversion caused by too much cord traction—gentle replacement of the uterus and oxytocics.

Institute measures to avoid tissue trauma or injury, such as giving injections and drawing blood. Also provide emotional support to the client and her family throughout this critical time by being readily available and providing explanations and reassurance.

Preventing Postpartum Hemorrhage

Avoid an episiotomy unless an emergency birth is necessary and the perineum is a limiting factor. It is important to have the continuous intrapartum presence of an experienced labor and birth nurse. Provide active management of the third stage of labor, including administration of a uterotonic medication after birth of the anterior

shoulder, controlled and gentle cord traction to deliver the placenta, and uterine massage after the placenta is out. Authors of a Cochrane review concluded that active management of the third stage of labor is associated with reduced blood loss, reduced risk of PPH, and a shortened third stage of labor (Begley et al., 2019).

Frequent staff education and PPH drills will help keep skills up to date. Nurses must identify and correct anemia and screen for coagulopathies before labor and birth. After birth, it is important to inspect the placenta (once it is delivered) for completeness. Assess woman for lower genital tract lacerations immediately after birth and reevaluate the woman's vital signs and vaginal flow after childbirth. Finally, it is important to be aware of the mother's beliefs about blood transfusions. Recently, a workgroup representing all major women's health professional organizations developed an obstetric hemorrhage safety bundle for practice to improve PPH outcomes. Some of the selected readiness action domains include:

- Having a hemorrhage cart with supplies and instruction cards on every obstetric unit
- Having immediate access to medications used to treat a massive hemorrhage
- Establishing a response team within the hospital that can be called
- Developing emergency-release transfusion protocols in the blood bank
- Educating all staff on protocols and holding unit-based drills frequently (Mann et al., 2018)

In summary, careful monitoring of the mother's vital signs, laboratory tests (in particular, coagulation testing) and immediate diagnosis of the cause of PPH are important key factors in reducing maternal morbidity and mortality. Nurses must always be prepared to identify signs and symptoms of PPH, recognize maternal compromise, and deal with hemorrhage promptly. By identifying hemorrhage promptly and providing swift interventions, maternal mortality and morbidity can be reduced. The four Rs (readiness, recognition, response, and report) are the tenets in reducing preventable maternal morbidity and mortality based on best

practices. All health care providers and nurses need to embrace this protocol and always be prepared (Mann et al., 2018).

An intravenous oxytocin infusion is started for Joan. What assessments will need to be done frequently to make sure Joan is not losing too much blood? What discharge instructions need to be reinforced with Joan?

VENOUS THROMBOEMBOLIC CONDITIONS

Venous thromboembolism is a potentially serious complication of the postpartum period. It is one of the leading causes of maternal mortality and morbidity with an annual incidence of one per 1,000 pregnancies, a risk 10 times higher than that of the nonpregnant population (ACOG, 2018c). A thrombosis (blood clot within a blood vessel) can cause an inflammation of the blood vessel lining (thrombophlebitis), which in turn can lead to a thromboembolism (obstruction of a blood vessel by a blood clot carried by the circulation from the site of origin). Thrombi can involve the superficial or deep veins in the legs or pelvis. Superficial venous thrombosis usually involves the saphenous venous system and is confined to the lower leg. Superficial thrombophlebitis may be caused by the use of the lithotomy position during birth. Deep venous thrombosis (DVT) can involve deep veins from the foot to the calf, thighs, or pelvis. Thrombi can dislodge and migrate to the lungs, causing a pulmonary embolism (PE).

DVT is a common condition that can have serious complications. Deep venous thrombi have a high probability of propagating and leading to pulmonary emboli, which may cause chest pain, breathlessness, and sudden death. Thus, an accurate and timely diagnosis of DVT is imperative. Although DVT is often clinically silent, it may present with a number of signs, including calf pain, edema, and venous distention.

The three most common venous thromboembolic conditions occurring during the postpartum period are superficial venous thrombosis, DVT, and PE. Although venous thromboembolic disorders occur in less than 1% of all postpartum women, pulmonary

embolus can be fatal if a clot obstructs the lung circulation; thus, early identification and treatment are paramount. Risk for postpartum venous thromboembolism is highest during the first 3 weeks after childbirth. Women with obstetric complications are at highest risk for this, and this risk remains elevated throughout the first 12 weeks postpartum (CDC, 2019c).

Pathophysiology

Thrombus formation typically results from venous stasis, injury to the innermost layer of the blood vessel, and hypercoagulation related to pregnancy. Venous stasis and hypercoagulation are both common in the postpartum period.

If a clot dislodges and travels to the pulmonary circulation, PE can occur. When the clot is large enough to block one or more of the pulmonary vessels that supply the lungs, it can result in sudden death. Approximately 600,000 PEs occur yearly in the United States, resulting in 60,000 to 100,000 deaths (CDC, 2019b). Only 25% of all clients with PE are actually diagnosed, indicating that thousands of PEs go undetected. Many deaths due to PE are unrecognized, and the diagnosis is often made during autopsy. PE is one of the leading causes of pregnancy-related death in the United States. The diagnosis PE should always be considered in any postpartum woman who presents with dyspnea or hypoxia (Malhotra & Weinberger, 2019). A national review of severe obstetric complications found a significant increase in the rate of PE associated with the increasing rate of cesarean births and obesity. Adequate treatment of thrombotic events in pregnancy with heparin (unfractionated or low molecular weight) is important to prevent progression of thrombosis to the development of PE (Norwitz et al., 2019).

Nursing Assessment

Assess the woman closely for risk factors and signs and symptoms of thrombophlebitis. Look for risk factors in the woman's history such

as use of oral contraceptives before the pregnancy; smoking; employment that necessitates prolonged standing; history of thrombosis; thrombophlebitis or endometritis; or evidence of current varicosities. Also look for other factors that can increase a woman's risk, such as prolonged bed rest, diabetes, obesity, cesarean birth, progesterone-induced distensibility of the veins of the lower legs during pregnancy, severe anemia, varicose veins, maternal age older than 34 years, and multiparity. The likelihood of thrombophlebitis is increased through most of pregnancy and for approximately 12 weeks after childbirth. This is partly due to increased platelet stickiness and partly due to reduced fibrinolytic activity. Once a clot forms, it is likely it will extend if predisposing factors persist over time as occurs with pregnancy (Blackburn, 2018).

Ask the woman if she has pain or tenderness in the lower extremities. Suspect superficial venous thrombosis in a woman with varicose veins who reports tenderness and discomfort over the site of the thrombosis, most commonly in the calf area. The area appears reddened along the vein and is warm to the touch. The woman will report increased pain in the affected leg when she ambulates and bears weight.

Manifestations of DVT are often absent and diffuse. If present, they are caused by an inflammatory process and obstruction of venous return. DVT is more common in the left lower extremity, presumably due to compression of the left iliac artery. Calf swelling and tenderness, difference in leg circumference, erythema, warmth, tenderness, pain with calf pressure, and pedal edema may be noted.

Be alert for signs and symptoms of PE, including unexplained sudden onset of shortness of breath and severe chest pain. The woman may be apprehensive and diaphoretic. Additional manifestations may include tachypnea, tachycardia, fever, hypotension, syncope, distention of the jugular vein, decreased oxygen saturation (shown by pulse oximetry), cardiac arrhythmias, hemoptysis, and a sudden change in mental status as a result of hypoxemia (Cunningham et al., 2018). Prepare the woman for a lung scan to confirm the diagnosis.

Nursing Management

Nursing management focuses on preventing thrombotic conditions, promoting adequate circulation if thrombosis occurs, and educating the client about preventive measures, anticoagulant therapy, and danger signs.

Preventing Thrombotic Conditions

Prevention of thrombotic conditions is an essential aspect of nursing management and can be achieved with the routine use of simple measures:

- Developing public awareness about risk factors, symptoms, and preventive measures
- Preventing venous stasis by encouraging activity that causes leg muscles to contract and promotes venous return (leg exercises and walking)
- Dorsi/plantar flexion of feet with prolonged sitting to promote venous return
- Using intermittent sequential compression devices to produce passive leg muscle contractions until the woman is ambulatory
- Elevating the woman's legs above her heart level to promote venous return
- Stopping smoking to reduce or prevent vascular vasoconstriction
- Applying compression stockings and removing them daily for inspection of legs
- Using postoperative deep-breathing exercises to improve venous return by relieving the negative thoracic pressure on leg veins
- Reducing hypercoagulability with the use of aspirin or anticoagulation therapy
- Preventing venous pooling by avoiding pillows under knees, not crossing legs for long periods, and not leaving legs up in stirrups for long periods
- Padding stirrups to reduce pressure against the popliteal angle
- Avoiding sitting or standing in one position for prolonged periods
- Avoiding trauma to the legs to prevent injury to the vein wall
- Increasing fluid intake to prevent dehydration
- Avoiding the use of oral contraceptives

In women at risk, early ambulation is the easiest and most cost-effective method. Use of compression stockings decreases distal calf vein thrombosis by decreasing venous stasis and augmenting venous return (Dutton et al., 2020). Women who are at a high risk for thromboembolic disease based on risk factors or a previous history of DVT or PE may be placed on prophylactic anticoagulation therapy during pregnancy. A low-molecular-weight heparin such as enoxaparin (Lovenox) can be given as can rivaroxaban (Xarelto), apixaban (Eliquis), or dabigatran etexilate (Pradaxa) (King et al., 2019). It is typically discontinued during labor and birth and then restarted during the postpartum period.

Promoting Adequate Circulation

The mainstay of venous thromboembolic conditions is anticoagulation, while interventions such as thrombolysis and inferior vena cava filters are reserved for limited circumstances. For the woman with superficial venous thrombosis, administer NSAIDs for analgesia, facilitate rest and elevation of the affected leg, apply warm compresses to the affected area to promote healing, and use antiembolism stockings to promote circulation to the extremities.

Implement bed rest or limited ambulation if ordered and elevation of the affected extremity for the woman with DVT. These actions help reduce interstitial swelling and promote venous return from that leg. Apply antiembolism stockings to both extremities as ordered. Fit the stockings correctly to avoid excess pressure and constriction and urge the woman to wear them at all times. Sequential compression devices can also be used for women with varicose veins, a history of thrombophlebitis, or a surgical birth.

Anticoagulant therapy using a continuous intravenous infusion of low-molecular-weight heparin along with vitamin K antagonists is usually initiated to prolong the clotting time and prevent extension of the thrombosis. Monitor the woman's coagulation studies closely; these might include activated partial thromboplastin time (aPTT), whole-blood partial thromboplastin time, and platelet levels. A therapeutic aPTT value typically ranges from 35 to 45 seconds,

depending on which standard values are used (Pagana et al., 2019). Also apply warm, moist compresses to the affected leg and administer analgesics as ordered to decrease the discomfort.

After several days of intravenous low-molecular-weight heparin therapy, expect to begin oral anticoagulant therapy as ordered. In most cases, the woman will continue to take this medication for several months after discharge.

For the woman who develops a PE, institute emergency measures immediately. The objectives of treatment are to prevent growth or multiplication of thrombi in the lower extremities, prevent more thrombi from traveling to the pulmonary vascular system, and provide cardiopulmonary support if needed. Administer oxygen via mask or cannula as ordered and initiate intravenous low-molecular-weight heparin therapy titrated according to the results of the coagulation studies. Maintain the client on bed rest, and administer analgesics as ordered for pain relief. Be prepared to assist with administering thrombolytic agents, such as alteplase (tPA), which might be used to dissolve pulmonary emboli and the source of the thrombus in the pelvis or deep leg veins, thus reducing the potential for a recurrence.

Educating the Client

Provide teaching about the use of anticoagulant therapy and danger signs that should be reported (Teaching Guidelines 22.1). Provide anticipatory guidance, support, and education about associated signs of complications and risks.

TEACHING GUIDELINES 22.1

Teaching to Prevent Bleeding Related to Anticoagulant Therapy

- Watch for possible signs of bleeding and notify your health care provider if any occur:
  - Nosebleeds
  - Bleeding from the gums or mouth
  - Black tarry stools
  - Brown “coffee grounds” vomitus
  - Red to brown speckled mucus from a cough
  - Oozing at incision, episiotomy site, cut, or scrape
  - Pink, red, or brown-tinged urine
  - Bruises, “black and blue marks”
  - Increased lochia discharge (from present level)
- Practice measures to reduce your risk of bleeding:
  - Brush your teeth gently using a soft toothbrush.
  - Use an electric razor for shaving.
  - Avoid activities that could lead to injury, scrapes, bruising, or cuts.
  - Do not use any over-the-counter products containing aspirin or aspirin-like derivatives.
  - Avoid consuming alcohol.
  - Inform other health care providers about the use of anticoagulants, especially dentists.
- Be sure to comply with follow-up laboratory testing as scheduled.
- If you accidentally cut or scrape yourself, apply firm direct pressure to the site for 5 to 10 minutes. Do the same after receiving any injections or having blood specimens drawn.
- Wear an identification bracelet or band that indicates that you are taking an anticoagulant.
- Eliminate modifiable risk factors for DVT (smoking, use of oral contraceptives, a sedentary lifestyle, and obesity).
- Understand the importance of using compression stockings.
- Avoid constrictive clothing and prolonged standing or sitting in a motionless, leg-dependent position.

- Know the danger signs and symptoms (sudden onset of chest pain, dyspnea, and tachypnea) to report to the health care provider.

POSTPARTUM INFECTION

Infection during the postpartum period is a common cause of maternal morbidity and mortality. Overall, postpartum infection is estimated to occur in up to 8% of all births and accounts for 15% of global maternal mortality. There is a higher occurrence in cesarean births than in vaginal births (Wong, 2019). Postpartum infection is defined as a fever of 100.4°F (38°C) or higher after the first 24 hours after childbirth, occurring on at least 2 of the first 10 days after birth, exclusive of the first 24 hours (Woodd et al., 2019).

Risk factors include surgical birth, prolonged rupture of membranes, long labor with multiple vaginal examinations, inadequate hand hygiene, internal fetal monitoring, uterine manipulation, chorioamnionitis, instrumental birth, obesity, untreated infection prior to birth, retained placental fragments, obesity, gestational diabetes, extremes of client age, low socioeconomic status, and anemia during pregnancy (Jordan et al., 2019).

Infections can easily enter the female genital tract externally and ascend through the internal genital structures. Postpartum women possess an increased risk for infection due to tissue trauma during birth, vulnerability from placenta separation site, and the incision from cesarean section. In addition, the normal physiologic changes of childbirth increase the risk of infection by decreasing the vaginal acidity due to the presence of amniotic fluid, blood, and lochia, all of which are alkaline. An alkaline environment encourages the growth of bacteria. Signs and symptoms of postpartum infection include elevated temperature, general malaise, pain, chills, increased pulse rate, abdominal pain, and malodorous lochia.

Postpartum infections usually arise from organisms that constitute the normal vaginal flora, typically a mix of aerobic and anaerobic species. Generally, they are polymicrobial and involve the following

microorganisms: *Staphylococcus aureus, Escherichia coli, Klebsiella*, *Gardnerella vaginalis,* gonococci, coliform bacteria, group A or B hemolytic streptococci, *Chlamydia trachomatis,* and the anaerobes that are common to bacterial vaginosis. Prevention can be achieved by screening and treating vaginal colonization during pregnancy (Resnik et al., 2019). Common postpartum infections include endometritis, surgical site infections, urinary tract infections (UTIs), and mastitis.

Endometritis

Endometritis is a uterine infection that typically develops within 2 to 4 days postpartum to as late as 6 weeks. It is an infectious condition that involves the endometrium, decidua, and adjacent myometrium of the uterus. Extension of endometritis can result in parametritis, which involves the broad ligament and possibly the ovaries and fallopian tubes, or septic pelvic thrombophlebitis, which results when the infection spreads along venous routes into the pelvis (King et al., 2019).

The uterine cavity is sterile until rupture of the amniotic sac. As a consequence of labor, birth, and associated manipulations, anaerobic and aerobic bacteria can contaminate the uterus. In most cases, the bacteria responsible for pelvic infections are those that normally reside in the bowel, vagina, perineum, and cervix, such as *E. coli, Klebsiella pneumoniae,* or *G. vaginalis.*

The risk of endometritis increases dramatically after a cesarean birth; puerperal endometritis is 25 times more common in women who underwent cesarean sections versus a vaginal birth (Taylor & Pillarisetty, 2020). This is typically an extension of chorioamnionitis that was present before birth (indeed, that may have been why the cesarean birth was performed). In addition, trauma to the tissues and a break in the skin (incision) provide entrances for bacteria to enter the body and multiply.

ACOG (2018d) recommends use of one dose of prophylactic antibiotic therapy administered 1 hour before any cesarean section and this has become standard practice in the United States today.

Once rupture of the amniotic membranes occurs during labor and birth, the uterus becomes more susceptible to colonization and infection, especially if it is a prolonged labor. Any area traumatized during childbirth is susceptible to infection.

Surgical Site Infections

Any break in the skin or mucous membranes provides a portal for bacteria. In the postpartum woman, sites of wound infection include cesarean surgical incisions, the episiotomy site in the perineum, and genital tract lacerations (Fig. 22.2). Wound infections are usually not identified until the woman has been discharged from the hospital because symptoms may not show up until 24 to 48 hours after birth.

Urinary Tract Infections

UTIs are most commonly caused by bacteria often found in bowel flora, including *E. coli, Klebsiella*, *Proteus*, and *Enterobacter* species. Invasive manipulation of the urethra (e.g., urinary catheterization), frequent vaginal examinations, and genital trauma increase the likelihood of a UTI. UTIs may cause urinary frequency, urgency, dysuria, and lower abdominal pain. It is the most common cause of a fever in the postpartum woman. Definitive diagnosis is made by a clean-catch urine specimen that reveals a significant number of bacteria present. It is treated with antibiotics.

Mastitis

Mastitis is defined as inflammation of the mammary gland, a common problem that may occur within the first 2 days to 2 weeks postpartum. Up to approximately 10% of breastfeeding women develop lactational mastitis (Dixon, 2019). Risk factors associated with mastitis include stasis of milk due to infrequent, inconsistent breastfeeding, previous episodes of mastitis, and nipple trauma. As well as causing significant discomfort, it is a frequent reason for women to stop breastfeeding. It can result from any event that

creates milk stasis including insufficient drainage of the breast, rapid weaning, oversupply of milk, pressure on the breast from a poorly fitting bra, a blocked duct, missed feedings, and breakdown of the nipple via fissures, cracks, or blisters (King et al., 2019). The most common infecting organism is *S. aureus,* which comes from the breastfeeding infant's mouth or throat. *Staphylococcus albus*, *E. coli*, and streptococci are also causative agents but found less frequently. Infection can be transmitted from the lactiferous ducts to a secreting lobule, from a nipple fissure to periductal lymphatics, or by circulation (Fig. 22.3) (Resnik et al., 2019). A breast abscess may develop if mastitis is not treated adequately. Flu-like symptoms are often the first symptoms experienced by the mother. Breasts are red, tender, and hot to the touch. The upper, outer quadrant of the breast is the most common site for mastitis to occur because most of the breast tissue is located there with both the right and left breasts being equally affected. Effective milk removal, pain medication, and antibiotic therapy are the mainstays of treatment.

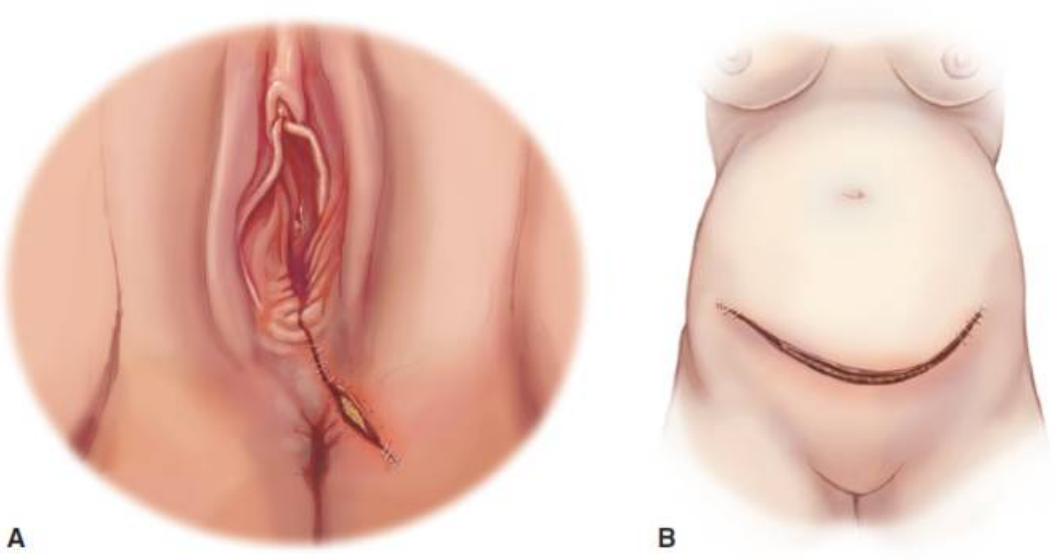


FIGURE 22.2. Postpartum wound infections. **A.** Infected episiotomy site. **B.** Infected cesarean birth incision.

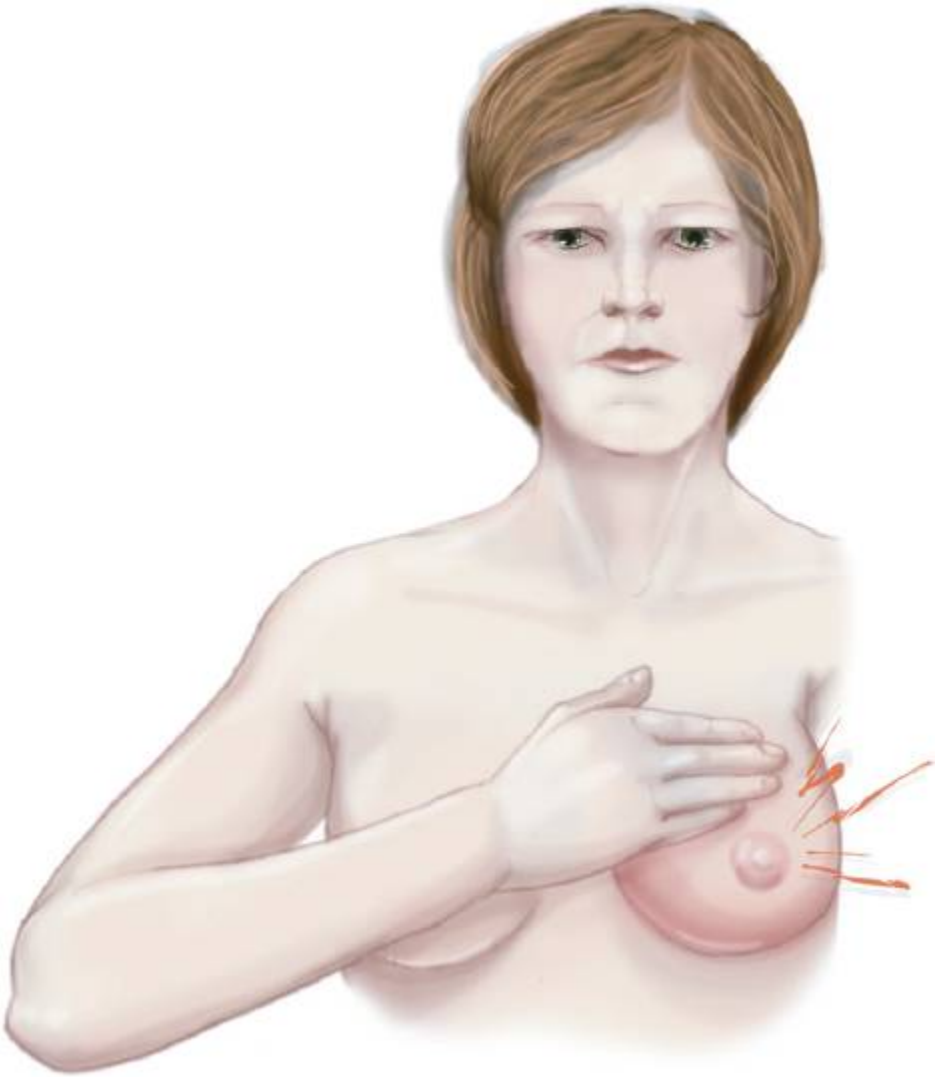

FIGURE 22.3. With mastitis, an area on one breast is tender, hot, red, and painful.

Therapeutic Management

ENDOMETRITIS

When endometritis occurs, broad-spectrum antibiotics are used to treat the infection. Management also includes measures to restore and promote fluid and electrolyte balance, provide analgesia, and provide emotional support. In most treated women, fever drops and symptoms cease within 48 to 72 hours after the start of antibiotic therapy.

SURGICAL SITE INFECTIONS

Management for surgical site infections involves recognition of the infection, followed by opening of the wound to allow drainage. Aseptic wound management with sterile gloves and frequent dressing changes if applicable, good hand hygiene, frequent perineal pad changes, hydration, and ambulation to prevent venous stasis and improve circulation are initiated to prevent development of a more serious infection or spread of the infection to adjacent structures. Parenteral antibiotics are the mainstay of treatment. Analgesics are also important, because women often experience discomfort at the wound site.

URINARY TRACT INFECTIONS

UTIs are common during the postpartum period and could be prevented by timely removal of urinary catheters used during labor or surgical births. Risk factors include catheterization, epidural anesthesia, and vaginal procedures. If the woman develops a UTI, fluids are used to treat dehydration. General nutrition measures include acidifying the urine by taking large doses of vitamin C or a regular intake of cranberry juice. Cranberry juice contains a substance with biologic activity that inhibits the growth of *E. coli* in the urinary tract (Wong, 2019). Antibiotics may also be ordered if appropriate.

MASTITIS

Treatment of mastitis focuses on two areas: emptying the breasts and controlling the infection. Frequent breast emptying helps both infectious and noninfectious mastitis. The breast can be emptied either by the infant sucking or by manual expression. Increasing the frequency of nursing is advised. Lactation need not be suppressed. Control of infection is achieved with antibiotics. Ice or warm packs and analgesics may be needed for pain. In addition to antibiotics, management of lactational breast infections includes symptomatic treatment, assessment of the infant’s attachment to the breast, and

reassurance, emotional support, education, and support for ongoing breastfeeding.

TAKE NOTE!

Regardless of the etiology of mastitis, the focus is on reversing milk stasis, maintaining milk supply, and continuing breastfeeding, along with providing maternal comfort and preventing recurrence.

Nursing Assessment

Perinatal nurses are the primary caregivers for postpartum women and have a unique opportunity to identify subtle changes that place women at risk for infection. Nurses play a key role in identifying signs and symptoms that suggest a postpartum infection. Today women are commonly discharged 24 to 48 hours after giving birth. Therefore, nurses must assess new mothers for risk factors and identify early, subtle signs and symptoms of an infectious process. Factors that place a woman at risk for a postpartum infection are highlighted in Box 22.1.

Review the client's history and physical examination and labor and birth record for factors that might increase her risk for developing an infection. Then complete the assessment (using the "BUBBLE-EE" parameters discussed in Chapter 16), paying particular attention to areas such as the abdomen and fundus, breasts, urinary tract, episiotomy, lacerations, or incisions and being alert for signs and symptoms of infection (Table 22.3).

TAKE NOTE!

A postpartum infection is commonly associated with an elevated temperature. Other generalized signs and symptoms may include chills, foul-smelling vaginal discharge, headache, malaise, restlessness, anxiety, and tachycardia. In addition, the woman may have specific signs and symptoms based on the type and location of the infection.

BOX 22.1 Factors Placing a Woman at Risk for Postpartum Infection

- Prolonged (>18 to 24 hours) premature rupture of membranes (removes the barrier of amniotic fluid so bacteria can ascend)
- Cesarean birth (allows bacterial entry due to break in protective skin barrier)
- Urinary catheterization (could allow entry of bacteria into bladder due to break in aseptic technique)
- Regional anesthesia that decreases perception of need to void (causes urinary stasis and increases risk of urinary tract infection)
- Staff attending to woman are ill (promotes droplet infection from personnel)
- Compromised health status, such as anemia, obesity, smoking, drug abuse (reduces the body's immune system and decreases ability to fight infection)
- Preexisting colonization of lower genital tract with bacterial vaginosis, *Chlamydia trachomatis,* group B streptococci, *S. aureus*, and *E. coli* (allows microbes to ascend)
- Retained placental fragments (provides medium for bacterial growth)
- Manual removal of a retained placenta (causes trauma to the lining of the uterus and thus opens up sites for bacterial invasion)
- Insertion of fetal scalp electrode or intrauterine pressure catheters for internal fetal monitoring during labor (provides entry into uterine cavity)
- Instrument-assisted childbirth, such as forceps or vacuum extraction (increases risk of trauma to genital tract, which provides bacteria access to grow)
- Trauma to the genital tract, such as episiotomy or lacerations (provides a portal of entry for bacteria)
- Prolonged labor with frequent vaginal examinations to check progress (allows time for bacteria to multiply and increases potential exposure to microorganisms or trauma)
- Poor nutritional status (reduces body's ability to repair tissue)
- Gestational diabetes (decreases body's healing ability and provides higher glucose levels on skin and in urine, which encourages bacterial growth)
- Break in aseptic technique during surgery or birthing process (allows entry of bacteria)

Jordan, R. G., Farley, C. L., & Grace, K. T. (2019). *Prenatal and postnatal care: A woman-centered approach* (2nd ed.). John Wiley & Sons, Inc.; King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Burlington, MA: Jones & Bartlett Learning; and Wong, A. W. (2019). Postpartum infections. eMedicine. Retrieved October 11, 2019, from https://emedicine.medscape.com/article/796892-overview#a7

The acronym REEDA is frequently used for assessing a woman's perineum status. It is derived from five components that have been identified to be associated with the healing process of the perineum. These include:

1. Redness—area may also feel warm to touch
2. Edema—may indicate infection or a hematoma
3. Ecchymosis—may indicate vaginal trauma
4. Discharge—should follow the expected lochia pattern
5. Approximation of skin edges—should be well aligned without gaps

Each category is assessed and a number assigned (0 to 3 points) for a total REEDA score ranging from 0 to 15. The higher scores indicate increased tissue trauma. See Figure 22.4 for the REEDA method for assessing perineum healing.

TABLE 22.3 Signs and Symptoms of Postpartum Infections

Postpartum Infection	Signs and Symptoms
Endometritis	Lower abdominal tenderness or pain on one or both sides
	Temperature elevation (>38°C)
	Foul-smelling lochia
	Anorexia
	Nausea
	Fatigue and lethargy
	Leukocytosis and elevated sedimentation rate
Wound infection	Weeping serosanguineous or purulent drainage
	Separation of or unapproximated wound edges
	Edema
	Erythema
	Tenderness
	Discomfort at the site
	Maternal fever
	Elevated white blood cell count
Urinary tract infection	Urgency
	Frequency
	Dysuria
	Flank pain
	Low-grade fever
	Urinary retention
	Hematuria
	Urine positive for nitrates

	Cloudy urine with strong odor
Mastitis	Flu-like symptoms, including malaise, fever, and chills
	Tender, hot, red, painful area on one breast
	Inflammation of breast area
	Breast tenderness
	Cracking of skin around nipple or areola
	Breast distention with milk

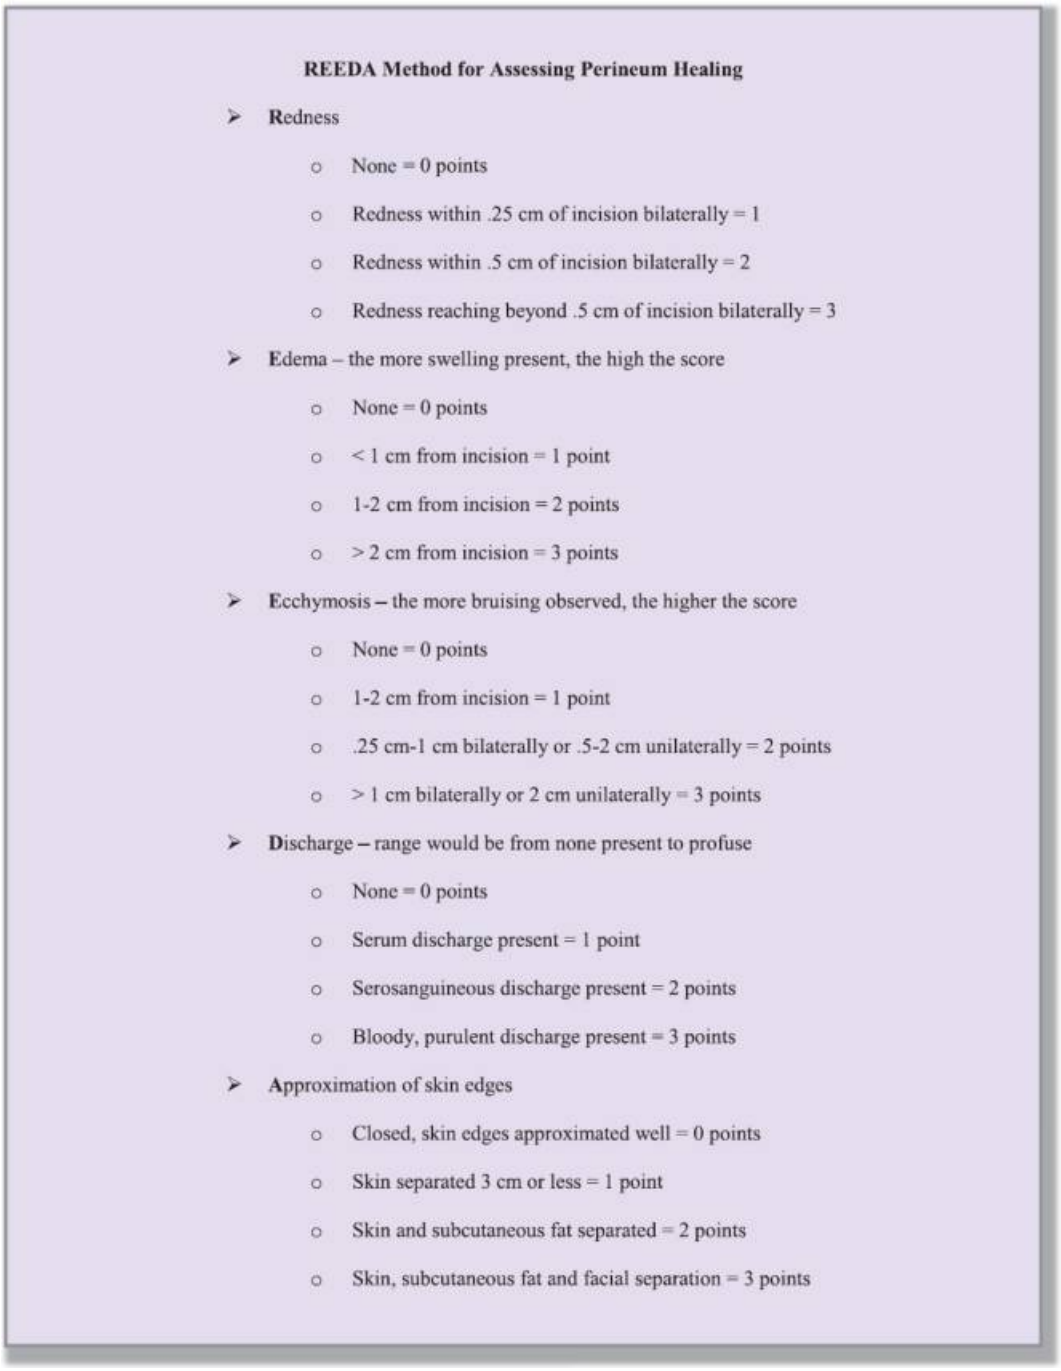
Dixon, J. M. (2020). Lactational mastitis. *UpToDate*. Retrieved January 15, 2020, from https://www.uptodate.com/contents/lactational-mastitis; Norwitz, E., Zelop, C., Miller, D., & Keefe, D. (2019). *Evidence-based obstetrics and gynecology*. Wiley Blackwell; and Wong, A. W. (2019). Postpartum infections. *eMedicine*. Retrieved October 11, 2019, from https://emedicine.medscape.com/article/796892-overview#a7.

Monitor the woman's vital signs, especially her temperature. Changes may also signal an infection.

Nursing Management

Nursing management focuses on preventing postpartum infections. Use the following guidelines to reduce the incidence of postpartum infections:

- Maintain aseptic technique when performing invasive procedures such as urinary catheterization, when changing dressings, and during all surgical procedures.



REEDA Method for Assessing Perineum Healing

- **R**edness
  - None = 0 points
  - Redness within .25 cm of incision bilaterally = 1
  - Redness within .5 cm of incision bilaterally = 2
  - Redness reaching beyond .5 cm of incision bilaterally = 3
- **E**dema – the more swelling present, the high the score
  - None = 0 points
  - < 1 cm from incision = 1 point
  - 1-2 cm from incision = 2 points
  - > 2 cm from incision = 3 points
- **E**cchymosis – the more bruising observed, the higher the score
  - None = 0 points
  - 1-2 cm from incision = 1 point
  - .25 cm-1 cm bilaterally or .5-2 cm unilaterally = 2 points
  - > 1 cm bilaterally or 2 cm unilaterally = 3 points
- **D**ischarge – range would be from none present to profuse
  - None = 0 points
  - Serum discharge present = 1 point
  - Serosanguineous discharge present = 2 points
  - Bloody, purulent discharge present = 3 points
- **A**pproximation of skin edges
  - Closed, skin edges approximated well = 0 points
  - Skin separated 3 cm or less = 1 point
  - Skin and subcutaneous fat separated = 2 points
  - Skin, subcutaneous fat and facial separation = 3 points

FIGURE 22.4. REEDA method for assessing perineum healing. (Adapted from Hrelic, D. A., & Griggs, K. M. [2018]. Critically ill obstetric patients. *American Nurse Today, 13*[11], 20–24.)

- Use good hand hygiene before and after each client care activity.
- Reinforce measures for maintaining good perineal hygiene.

- Practice standard precautions whenever in contact with blood, body fluids, and excretions.
- Use adequate lighting and turn the client to the side to assess the episiotomy site.
- Use extreme caution when handling sharp instruments, specimens, and waste disposal.
- Screen all visitors for any signs of active infections to reduce the client's risk of exposure.
- Review the client's history for preexisting infections or chronic conditions.
- Monitor vital signs and laboratory results for any abnormal values.
- Monitor the frequency of vaginal examinations and length of labor.
- Assess frequently for early signs of infection, especially fever and the appearance of lochia.
- Inspect wounds frequently for inflammation and drainage.
- Encourage rest, adequate hydration, and healthy eating habits.
- Reinforce preventive measures during any interaction with the client.

If the woman develops an infection, review treatment measures, such as antibiotic therapy if ordered, and any special care measures, such as dressing changes, that might be needed (Nursing Care Plan 22.1).

Postpartum women should be offered anticipatory guidance on the signs and symptoms of life-threatening conditions, including sepsis. Information should include the importance of good hand and perineal hygiene and of the need to seek immediate medical care if feeling unwell. Client teaching is a priority due to today's short lengths of stay after childbirth. Some infections may not manifest until after discharge. Review the signs and symptoms of infection, emphasizing the danger signs that need to be reported to the health care provider. Most importantly, stress proper hand hygiene, especially after perineal care and before and after breastfeeding. Also reinforce measures to promote breastfeeding, including proper breast care (see Chapter 16). Teaching Guidelines 22.2 highlights the major teaching points for a woman with a postpartum infection.

TEACHING GUIDELINES 22.2

Teaching for the Woman with a Postpartum Infection

- Continue your antibiotic therapy as prescribed.
- Take the medication exactly as ordered and continue with the medication until it is finished.
- Do not stop taking the medication even when you are feeling better.
- Check your temperature every day and call your health care provider if it is above 100.4°F (38°C).
- Watch for other signs and symptoms of infection, such as chills, increased abdominal pain, change in the color or odor of your lochia, or increased redness, warmth, swelling, or drainage from a wound site such as your cesarean incision or episiotomy. Report any of these to your health care provider immediately.
- Practice good infection prevention:
  - Always wash your hands thoroughly before and after eating, using the bathroom, touching your perineal area, or providing care for your newborn.
  - Wipe from front to back after using the bathroom.
  - Remove your perineal pad using a front-to-back motion. Fold the pad in half so that the inner sides of the pad that were touching your body are against each other. Wrap in toilet tissue or place in a plastic bag and discard.
  - Wash your hands before applying a new pad.
  - Apply a new perineal pad using a front-to-back motion. Handle the pad by the edges (top and bottom or sides) and avoid touching the inner aspect of the pad that will be against your body.
  - When performing perineal care with a peribottle, angle the spray of water so that it flows from front to back.
  - Drink plenty of fluids each day and eat a variety of foods that are high in vitamins, iron, and protein.
  - Be sure to get adequate rest at night and periodically throughout the day.

POSTPARTUM AFFECTIVE DISORDERS

Pregnancy and childbirth is an exciting and celebratory time for many families. However, the postpartum period involves extraordinary physiologic, psychological, and sociocultural changes in the life of a woman and her family. Women have varied reactions to their childbearing experiences, exhibiting a wide range of emotions. Often, the birth of a newborn is associated with positive feelings such as happiness, joy, and gratitude for the birth of a healthy infant. However, women may also feel weepy, overwhelmed, or unsure of what is happening to them. They may experience fear about loss of control. They may also feel scared, alone, or guilty, or as if they have somehow failed. During the postpartum period, up to 85% of women experience some type of mood disorder (Jordan et al., 2019).

Postpartum affective disorders have been documented for years, but only relatively recently have they begun to receive serious medical attention. Plummeting levels of estrogen and progesterone immediately after birth can contribute to postpartum mood disorders. Reproductive hormones influence every biologic system, and many women's moods are sensitive to the effects of perinatal changes in hormone levels after childbirth. It is believed that the greater the change in these hormone levels between pregnancy and postpartum, the greater the chance for developing a mood disorder. Mood and anxiety disorders are influenced by genetics, as well as environment, and they impact the entire family (ACOG, 2018b).

NURSING CARE PLAN 22.1 Overview of the Woman with a Postpartum Complication

Jennifer, a 16-year-old G1P1, gave birth to a boy 3 days ago. It was a cesarean birth due to cephalopelvic disproportion following 25 hours of labor with ruptured membranes. Her temperature is 102.6°F (39.2°C). She is complaining of chills and malaise and says, "My incision really hurts." Jennifer rates her pain as 7 to 8 out of 10. The incision site is red, swollen, and warm to the touch. A 5-cm area of purulent drainage is noted on the dressing; a 3-cm area of the incision is slightly opened, with the wound edges separated. Jennifer's lochia is scant and dark red, with a strong odor. She asks the nurse to take her baby back to the nursery because she doesn't feel well enough to care for him.

NURSING ANALYSIS: Altered thermoregulation related to bacterial invasion as evidenced by fever, complaints of chills and malaise, and statement of not feeling well

OUTCOME IDENTIFICATION AND EVALUATION

The client will exhibit a return to normothermia as evidenced by a body temperature being maintained below 99°F (37.2°C), reports of a decrease in chills and malaise, and statements of feeling better.

INTERVENTIONS: *Promoting Fever Reduction*

- Assess vital signs every 2 to 4 hours and record results *to monitor progress of infection.*
- Administer antipyretics as ordered *to reduce temperature and help combat infection.*
- Encourage fluid intake *to promote fluid balance.*
- Document intake and output *to assess hydration status.*
- Offer cool bed bath or shower *to reduce temperature.*
- Place cool cloth on forehead and/or back of neck *to provide comfort.*
- Change bed linen and gown when damp from diaphoresis *to provide comfort and hygiene.*

NURSING ANALYSIS: Altered tissue integrity related to wound infection as evidenced by purulent drainage, redness, swelling, and separation of wound edges

OUTCOME IDENTIFICATION AND EVALUATION

The client will experience a resolution of wound infection as evidenced by a reduction in redness, swelling, and drainage from wound; absence of purulent drainage; and beginning signs and symptoms of wound healing.

INTERVENTIONS: ***Promoting Wound Healing***

- Administer antibiotic therapy as ordered *to treat infection.*
- Perform frequent dressing changes and wound care as ordered *to promote wound healing*; monitor dressing for drainage, including amount, color, and characteristics, *to evaluate for resolution of infection.*
- Use aseptic technique *to prevent spread of infection.*
- Encourage fluid intake *to maintain fluid balance;* encourage adequate dietary intake, including protein, *to promote healing.*

NURSING ANALYSIS: Acute pain related to infectious process

OUTCOME IDENTIFICATION AND EVALUATION

The client will report a decrease in pain as evidenced by pain rating of 0 or 1 on pain scale, verbalization of relief with pain management, and statements of feeling better and ability to rest comfortably.

INTERVENTIONS: ***Relieving Pain***

- Place client in semi-Fowler position *to facilitate drainage and relieve pressure.*
- Assess pain level on pain scale of 0 to 10 to quantify pain level; reassess pain level after intervening *to determine effectiveness of intervention.*
- Assess fundus gently *to ensure appropriate involution.*
- Administer analgesics as needed and on time as ordered *to maintain pain relief.*
- Provide for rest periods *to allow for healing.*
- Assist with positioning in bed with pillows *to promote comfort.*
- Offer nonpharmacologic pain measures such as a backrub *to ease aches and discomfort if desired and enhance effectiveness of analgesics.*

NURSING ANALYSIS: Altered parent–infant attachment risk related to effects of postpartum infection as evidenced by mother's request to take baby back to the nursery

OUTCOME IDENTIFICATION AND EVALUATION

The client will begin to bond with newborn appropriately with each exposure as evidenced by desire to spend time with newborn, expression of positive feelings toward newborn when holding him, increasing participation in care of newborn

as client's condition improves, and statements about help and support at home to care for self and newborn.

INTERVENTIONS: ***Promoting Mother–Newborn Interaction***

- Promote adequate rest and sleep *to ensure adequate energy for interaction and wound healing.*
- Bring newborn to mother after she is rested and has had an analgesic *to allow mother to focus her energies on the child.*
- Progressively allow the client to care for her infant or comfort him as her energy level and pain level improve *to promote self-confidence in caring for the newborn.*
- Offer praise and positive reinforcement for caregiving tasks; stress positive attributes of newborn to mother while caring for him *to facilitate bonding and attachment.*
- Contact family members to participate in care of the newborn *to allow mother to rest and recover from infection.*
- Encourage mother to care for herself first and then the newborn *to ensure adequate energy for newborn's care.*
- Arrange for assistance and support after discharge from hospital *to provide necessary backup.*
- Refer to community health nurse for follow-up care of mother and newborn at home *to foster continued development of maternal–infant relationship.*

Many types of affective disorders occur in the postpartum period. Although their descriptions and classifications may be controversial, the disorders form a spectrum on the basis of their severity as postpartum or baby blues, postpartum depression, and postpartum psychosis.

Postpartum Blues

Many postpartum women (approximately 80%) experience the "blues" (Viguera, 2019). The woman typically experiences rapid cycling mood symptoms during the first postpartum week. She will exhibit mild depressive symptoms of anxiety, irritability, mood swings, tearfulness, increased sensitivity, despondency, feelings of being overwhelmed, difficulty thinking clearly, insomnia, loss of appetite, and fatigue (King et al., 2019). Emotional lability is the most

prominent symptom of the maternity blues. The “blues” typically peak on postpartum days 4 and 5 and usually resolve by postpartum day 10. Biologic, psychological, and social factors have been hypothesized as relevant to blues causation, but no studies have validated this. Although the woman’s symptoms may be distressing, they do not reflect psychopathology and usually do not affect the mother’s ability to function and care for her infant.

Baby blues are usually self-limiting and require no formal treatment other than reassurance and validation of the woman’s experience, as well as assistance in caring for herself and the newborn. However, follow-up of women with postpartum blues is important because up to 20% go on to develop postpartum depression (Cunningham et al., 2018).

Postpartum Depression

Depression is more prevalent among women than in men, which may be related to biologic, hormonal, and psychosocial factors (WHO, 2020). **Postpartum depression (PPD)** is a form of clinical depression that can affect women, and sometimes men, after childbirth. It affects as many as one in nine women (CDC, 2019a). Unlike the postpartum blues, women with PPD feel worse over time, and changes in mood and behavior do not go away on their own. PPD may persist for a minimum of 6 months if untreated. The symptoms of PPD are more severe than those of the blues and require treatment. Some signs and symptoms of PPD include feelings of:

- Restlessness
- Worthlessness
- Guilt
- Hopelessness
- Moodiness
- Sadness
- Overwhelm
- Loss of enjoyment
- Low-energy levels

- Loss of libido

The new mother may also:

- cry a lot.
- exhibit a lack of energy and motivation.
- be unable to make decisions or focus.
- lose her memory.
- experience a lack of pleasure.
- have changes in sleep or weight.
- show a lack of concern for herself.
- withdraw from friends and family.
- have pains in her body that do not subside.
- feel negatively toward her baby.
- experience appetite disturbances.
- feel isolated from others.
- lack interest in her baby.
- worry about hurting the baby.
- act detached toward others and the infant.
- have recurrent thoughts of suicide and death (Mughal & Siddiqui, 2019).

PPD affects not only the woman but also the entire family. Identifying depression early can substantially improve the client and family outcomes. PPD usually has a gradual onset and becomes evident within the first 6 weeks postpartum.

The cause of PPD is not known, but research suggests it is multifactorial. According to ACOG (2018b), “postpartum depression is likely to result from body, mind, and lifestyle factors combined.” The levels of estrogen, progesterone, serotonin, and thyroid hormone decrease sharply and return to normal during the immediate postpartum period, which can trigger depression and can change a woman’s mood and behavior. Other aspects that can lead to PPD include:

- Unresolved feelings about the pregnancy
- Fatigue after delivery from lack of sleep or broken sleep
- Feelings of being less attractive
- Inadequate assistance from a partner
- Lack of social support network

- History of sexual or physical abuse
- Unemployment or financial insecurity
- Doubts about the ability to be a good mother
- Stressful life events
- Relationship issues
- Stress from changes in work and home routines
- Loss of freedom and old identity (Jordan et al., 2019)

PPD may lend itself to prophylactic intervention because its onset is predictable, the risk period for illness is well defined, and women at high risk potentially could be identified using a screening tool. This is not the case for all women, however. Prophylaxis starts with a prenatal risk assessment and education. Based on the woman's history of prior depression, prophylactic antidepressant therapy may be needed during the third trimester or immediately after giving birth. Management mirrors that of any major depression: a combination of antidepressant medication, antianxiety medication, adequate sleep and rest, and psychotherapy in an outpatient or inpatient setting (March of Dimes, 2019). Marital counseling may be necessary if marital problems are contributing to the woman's depressive symptoms.

The significant other's or partner's emotional health should not be overlooked during the woman's pregnancy and throughout the first postpartum year. PPD, once expected only in new mothers, occurs in partners who are new parents as well. Up to 50% of partners whose partners suffer from PPD also have depressive symptoms, and little is known about the impact of maternal PPD on them. Depressive symptoms are likely to decrease their ability to provide maternal support. A partner's PPD can be difficult to identify. Partners may seem more angry and anxious than sad, yet depression is present. When left untreated, a partner's PPD limits their capacity to provide emotional support to the mother and children. The highest rates of depression among fathers have been reported between 3 and 6 months postpartum. Factors that increase the risk of paternal PPD include a personal history of depression and/or anxiety; a low level of relationship satisfaction; resentment of

the infant; feelings of being lost, forgotten, and neglected by the mother; excessive financial stressors; a lack of parental leave; and the feeling that there is a great discrepancy between one's expectations of parenthood and its realities (Eddy et al., 2019).

Assessing a partner's PPD is not easy. Nevertheless, it is important for all nurses who have contact with new partners to remain open to the notion that new partners are predisposed to PPD, particularly if the mother is afflicted. Delving deeper into understanding behaviors of withdrawing, indecisiveness, cynicism, avoiding, drinking, using drugs, fighting, partner violence, extramarital affairs, and feelings of heightened irritation will reveal important insights. Asking new partners candidly if they are feeling depressed, anxious, or angry can open the door to further exploration of these emotions (Eddy et al., 2019).

Although partner depression is only now beginning to be defined and measured, sufficient evidence exists to warrant nurses' attention and concern. Nurses may be most able to help a new partner devastated by PPD when they plant seeds of awareness that the disorder exists, they are not alone, and help is available.

Despite the negative outcomes associated with PPD, rates of diagnosis and treatment are low mainly because of lack of recognition by the health care provider. In addition, PPD is the most misinterpreted, frequently dismissed, and most underdiagnosed postpartum complication. Early recognition of PPD can eliminate the length of time individuals must suffer with this debilitating condition and can decrease the potentially harmful effects on the infants involved.

Screening for symptoms of PPD in both men and women is an important preliminary step to diagnosis and treatment, but the effectiveness of depression screening is dependent on the reliability and validity of the screening instruments in the population. Both the Edinburgh Postnatal Depression Scale (EPDS) and the Postpartum Depression Predictor Scale (PDSS) have been used to screen mothers for PPD, but it is not clear which instrument best predicts a diagnosis of PPD (ACOG, 2018b).

The EPDS is a self-report, quick, and easy screening tool for PPD that consists of 10 questions with four possible responses. The couple fills out the tool according to their symptoms during the previous 7 days, with each response given a score of 0 to 3 points, creating a maximum score of 30. Using a cutoff score of 9 or 10, the sensitivity is 86%; the specificity, 78%; and positive predictive value, 73% (Cox, 2019).

The PDSS is a self-report, 35-item Likert-type response scale divided into seven conceptual domains:

1. Anxiety/insecurity
2. Sleep/eating disturbance
3. Emotional liability
4. Loss of self-esteem
5. Guilt/shame
6. Cognitive impairment
7. Suicidal thoughts

The scores range from 35 to 175. The scale has five symptoms for each domain, and the woman is asked to identify her degree of disagreement or agreement on the basis of her feelings over the previous 2 weeks. The sensitivity of the PDSS is 91%; the specificity is 72% for detecting PPD. The PDSS takes 5 to 10 minutes to administer and is used during the postpartum period (King et al., 2019).

Early identification, screening, prevention, and treatment of PPD are crucial for improving overall outcomes for the mother and infant, as well as for decreasing mortality and morbidity. This is why it is crucial for nurses to understand and know about the risk factors, signs and symptoms, prevention, and use and interpretation of screening tools and to make appropriate referrals for treatment. Mass screening for PPD using a validated screening tool improves the rates of detection and treatment of PPD and should be implemented in obstetricians' and pediatricians' offices and in primary care settings. The Edinburgh tool is shown in Figure 22.5.

CONSIDER THIS

Even though I was an assertive practicing attorney in my 30s, my first pregnancy was filled with nagging feelings of doubt about this upcoming event in my life. Throughout my pregnancy, I was so busy with trial work that I never had time to really evaluate my feelings. I was always reading about the bodily changes that were taking place, and on one level, I was feeling excited, but on another level, I was emotionally drained. Shortly after the birth of my daughter, those suppressed nagging feelings of doubt surfaced and practically immobilized me. I felt exhausted all the time and was so glad to have someone else care for my daughter. I didn't breastfeed because I thought it would tie me down too much. Although at the time I thought this "low mood" was normal for all new mothers, I have since found out it was postpartum depression. But how could any woman be depressed about a birth of a new child?

Thoughts: Now that postpartum depression has been "taken out of the closet" and recognized as a real emotional disorder, it can be treated. This woman showed tendencies during her pregnancy but was able to suppress the feelings and go forward. Her description of her depression is typical of many women who suffer in silence, hoping to get over these feelings in time. What can nurses do to promote awareness of this disorder? Can it be prevented?

Postpartum Psychosis

At the severe end of the continuum of postpartum emotional disorders is postpartum psychosis, which occurs with one in 1,000 live births and may occur any time in the first year postpartum. Onset can be abrupt and unexpected, though a previous history of mental illness is common (Schofield & Kapoor, 2019). Postpartum psychosis, an emergency psychiatric condition, can result in a

significant increased risk for suicide and infanticide. Symptoms of postpartum psychosis, such as mood lability, delusional beliefs, hallucinations, and disorganized thinking, can be frightening for the women who are affected and for their families. It generally surfaces within 3 months of giving birth and is manifested by sleep disturbances, fatigue, depression, and hypomania. The mother will be tearful, confused, and preoccupied with feelings of guilt and worthlessness. Early symptoms resemble those of depression, but they may escalate to delirium, hallucinations, extreme disorganization of thought, anger toward herself and her infant, bizarre behavior, delusions, disorientation, depersonalization, delirium-like appearance, manifestations of mania, and thoughts of hurting herself and the infant. The mother frequently loses touch with reality and experiences a severe regressive breakdown associated with a high risk of suicide or infanticide (Jordan et al., 2019). Women with postpartum psychosis should not be left alone with their infants. Most women with postpartum psychosis are hospitalized for up to several months. Psychotropic drugs are almost always part of treatment, along with individual psychotherapy and support group therapy.

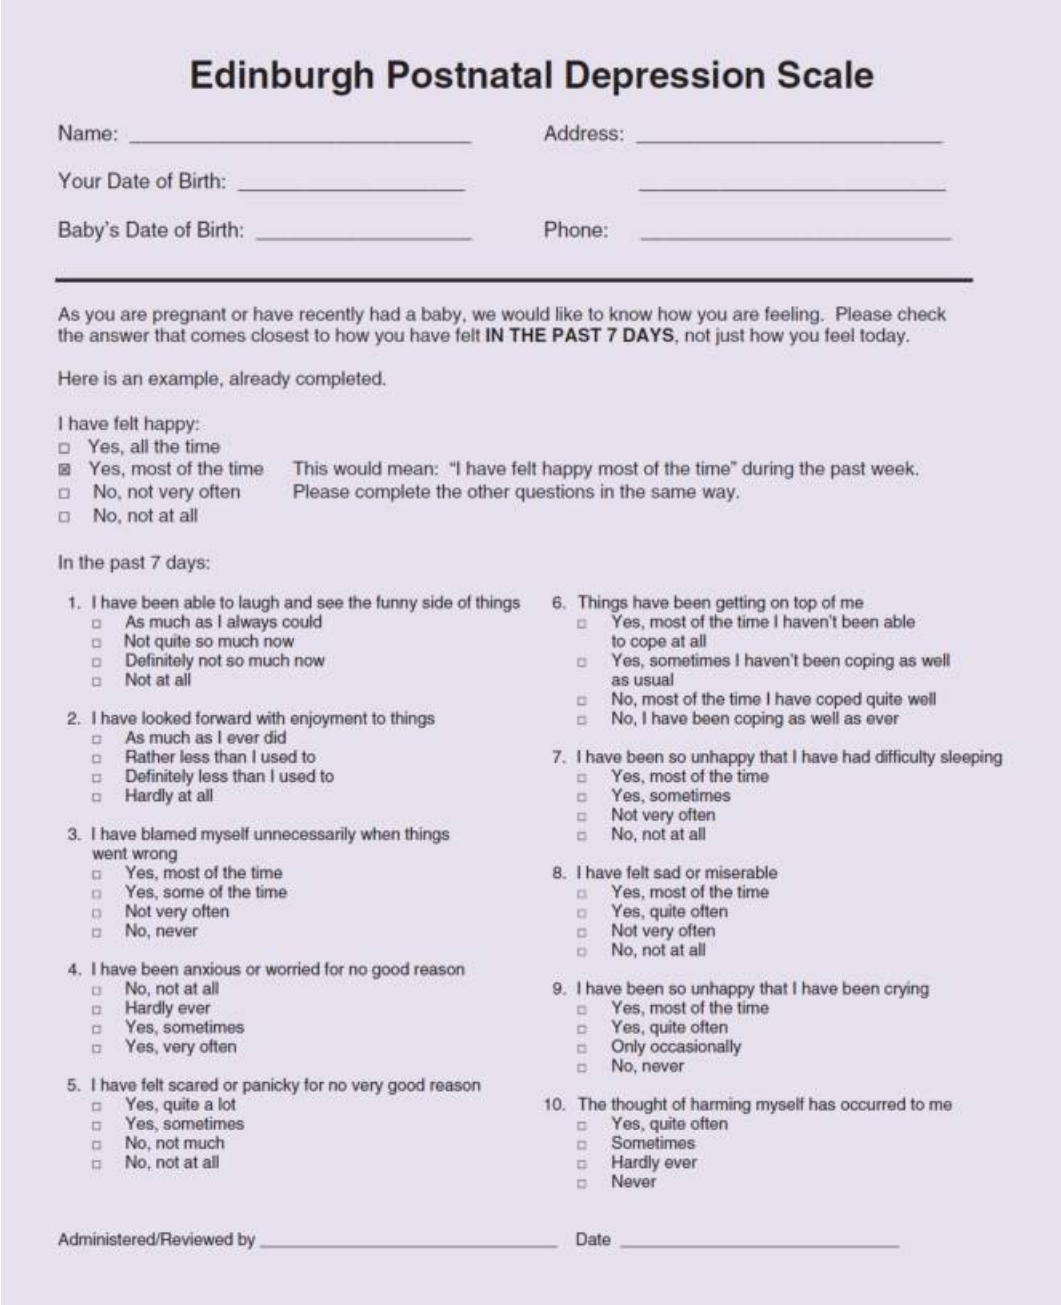
TAKE NOTE!

The greatest hazard of postpartum psychosis is suicide. Infanticide and child abuse are also risks if the woman is left alone with her infant. Early recognition and prompt treatment of this disorder are imperative.

Nursing Assessment

Postpartum affective disorders are often overlooked and go unrecognized despite the large percentage of women who experience them. The postpartum period is a time of increased vulnerability, but few women receive education about the possibility of depression after birth. In addition, many women may feel ashamed of having negative emotions at a time when they “should” be happy; thus, they do not seek professional help. Nurses can play

a major role in providing guidance about postpartum affective disorders, detecting manifestations, and assisting women with obtaining appropriate care.



Edinburgh Postnatal Depression Scale

Name: _____ Address: _____

Your Date of Birth: _____ _____

Baby's Date of Birth: _____ Phone: _____

As you are pregnant or have recently had a baby, we would like to know how you are feeling. Please check the answer that comes closest to how you have felt **IN THE PAST 7 DAYS**, not just how you feel today.

Here is an example, already completed.

I have felt happy:
- ☐ Yes, all the time
- ☒ Yes, most of the time
- ☐ No, not very often
- ☐ No, not at all

This would mean: "I have felt happy most of the time" during the past week. Please complete the other questions in the same way.

In the past 7 days:

1. I have been able to laugh and see the funny side of things
   - ☐ As much as I always could
   - ☐ Not quite so much now
   - ☐ Definitely not so much now
   - ☐ Not at all
2. I have looked forward with enjoyment to things
   - ☐ As much as I ever did
   - ☐ Rather less than I used to
   - ☐ Definitely less than I used to
   - ☐ Hardly at all
3. I have blamed myself unnecessarily when things went wrong
   - ☐ Yes, most of the time
   - ☐ Yes, some of the time
   - ☐ Not very often
   - ☐ No, never
4. I have been anxious or worried for no good reason
   - ☐ No, not at all
   - ☐ Hardly ever
   - ☐ Yes, sometimes
   - ☐ Yes, very often
5. I have felt scared or panicky for no very good reason
   - ☐ Yes, quite a lot
   - ☐ Yes, sometimes
   - ☐ No, not much
   - ☐ No, not at all
6. Things have been getting on top of me
   - ☐ Yes, most of the time I haven't been able to cope at all
   - ☐ Yes, sometimes I haven't been coping as well as usual
   - ☐ No, most of the time I have coped quite well
   - ☐ No, I have been coping as well as ever
7. I have been so unhappy that I have had difficulty sleeping
   - ☐ Yes, most of the time
   - ☐ Yes, sometimes
   - ☐ Not very often
   - ☐ No, not at all
8. I have felt sad or miserable
   - ☐ Yes, most of the time
   - ☐ Yes, quite often
   - ☐ Not very often
   - ☐ No, not at all
9. I have been so unhappy that I have been crying
   - ☐ Yes, most of the time
   - ☐ Yes, quite often
   - ☐ Only occasionally
   - ☐ No, never
10. The thought of harming myself has occurred to me
    - ☐ Yes, quite often
    - ☐ Sometimes
    - ☐ Hardly ever
    - ☐ Never

Administered/Reviewed by _____ Date _____

FIGURE 22.5. The Edinburgh Postnatal Depression Scale aims to detect postpartum depression. A score of 12 or more identifies most women with postpartum depression. (Adapted from Cox, J. [2019]. Thirty years with Edinburgh Postnatal Depression scale: Voices from the past and recommendations of the future. *British Journal of Psychiatry*, *214*[3], 127–129.)

Begin the assessment by reviewing the history to identify general risk factors that could predispose a woman to depression:

- Poor coping skills
- First pregnancy
- Low self-esteem
- Numerous life stressors
- History of abuse
- Mood swings and emotional stress
- Previous psychological problems or a family history of psychiatric disorders
- Substance abuse
- Limited or lack of social support network

Also review the history for specific pregnancy and birth factors that may increase the woman's risk for depression. These may include a history of PPD, evidence of depression during the pregnancy, prenatal anxiety, a difficult or complicated pregnancy, traumatic birth experience, or birth of a high-risk or infant with special needs (ACOG, 2018b).

Be alert for physical findings. Assess the woman's activity level, including her level of fatigue. Ask about her sleeping habits, noting any problems with insomnia. When interacting with the woman, observe for verbal and nonverbal indicators of anxiety as well as her ability to concentrate during the interaction. Difficulty concentrating and anxious behaviors suggest a problem. Also assess her nutritional intake; weight loss due to poor food intake may be present. Assessment can identify women with high-risk profiles for depression, and the nurse can educate them and make referrals for individual or family counseling if needed. Some common assessment findings associated with PPD are listed in Box 22.2.

Nursing Management

Nurses need to educate themselves about this disorder to facilitate early recognition of signs and symptoms of it, which in turn would make early treatment possible, thus supporting recovery. Furthermore, greater knowledge could contribute to providing more effective and compassionate care to these women. Nursing management focuses on assisting any postpartum woman in coping

with the changes of this period. Encourage the client to verbalize what she is going through and emphasize the importance of keeping her expectations realistic. Assist the woman in structuring her day to regain a sense of control over the situation. Encourage her to seek professional help if necessary, using available support systems. Also reinforce the need for good nutrition and adequate exercise and sleep (Mohamied, 2019).

The nurse can play an important role in assisting women and their partners with postpartum adjustment. Providing facts about the enormous changes that occur during the postpartum period is critical. This information includes changes in the woman's body. Review the signs and symptoms of all three affective disorders. This information is typically included as part of prenatal visits and childbirth education classes. Know the risk factors associated with these disorders and review the history of clients and their families. Use specific, nonthreatening questions to aid in early detection, such as "Have you felt down, depressed, or hopeless lately?" and "Have you felt little interest or pleasure in doing things recently?"

BOX 22.2 Common Assessment Findings Associated with Postpartum Depression

- Loss of pleasure or interest in life
- Low mood, especially in the morning, sadness, tearfulness
- Exhaustion that is not relieved by sleep
- Feelings of guilt
- Weight loss
- Low energy
- Irritability
- Poor personal hygiene
- Constipated
- Preoccupied and unfocused
- Indecisiveness
- Diminished concentration
- Anxiety
- Despair
- Compulsive thoughts
- Loss of libido
- Loss of confidence
- Sleep difficulties (insomnia)
- Loss of appetite
- Bleak and pessimistic view of the future
- Not responding to infant's cries or cues for attention
- Social isolation, won't answer the door or the phone
- Feelings of failure as a mother

American College of Obstetrics and Gynecologists (ACOG). (2018b). ACOG Committee Opinion No. 757: Screening for perinatal depression. Obstetrics and Gynecology, 132(5), 208–212; Centers for Disease Control and Prevention (CDC). (2019a). *Depression during and after pregnancy*. Retrieved June 16, 2020, from https://www.cdc.gov/features/maternal-depression/index.html; and Mughal, S., & Siddiqui, W. (2019). *Postpartum depression*. *StatPearls*. Retrieved April 27, 2020, from https://www.ncbi.nlm.nih.gov/books/NBK519070

Discuss factors that may increase a woman's vulnerability to stress during the postpartum period, such as sleep deprivation and unrealistic expectations, so couples can understand and respond to those problems if they occur. Stress that many women need help after childbirth and that help is available from many sources, including people they already know. Assisting women in learning how to ask for help is important so they can gain the support they

need. Also provide educational materials about postpartum emotional disorders. Have available referral sources for psychotherapy and support groups appropriate for women experiencing postpartum adjustment difficulties. See Evidence-Based Practice 22.1.

EVIDENCE-BASED PRACTICE 22.1

Interventions to Prevent Depression: Evidence Report and Systematic Review for the U.S. Preventive Services Task Force (USPSTF)

STUDY

Perinatal depression is common and can have adverse effects on both mother and infant. It is defined as the occurrence of a depressive episode during pregnancy or up to 1 year after childbirth. Risk factors include a history of depression, history of physical or sexual abuse, unplanned or unwanted pregnancy, stressful life events, intimate partner violence, lack of social support, and complications during pregnancy or childbirth. The purpose of the study was to systematically review benefits and harms of relevant interventions to prevent perinatal depression.

Findings

A systematic review was conducted on 50 studies (N = 22,385) that met inclusion criteria. Interventions examined included physical activity, counseling, education, supportive interventions, infant sleep advice, postpartum debriefing, expressive writing, antidepressants, supplements, and yoga. This review found that counseling-based interventions were effective in preventing perinatal depression. The other interventional approaches provided some evidence of effectiveness but lacked a robust evidence base to support it.

Nursing Implications

Based on the findings of this systematic review of a variety of interventions to prevent perinatal depression, nurses can counsel

their clients that cognitive-behavioral therapy (CBT) counseling appears to be the most beneficial intervention in depression prevention. Although other interventions showed some benefit, counseling showed the most promise as a preventive intervention. Primary prevention addressing early detection and intervention are always preferable to dealing with the sequelae of an illness. CBT may help the woman identify and access sources of support, thereby avoiding the development of perinatal depression.

Adapted from O'Connor, E., Senger, C. A., Henninger, M. L., Coppola, E., & Gaynes, B. N. (2019). Interventions to prevent depression: Evidence report and systematic review for the US Preventive Services Task Force (USPSTF). Journal of American Medical Association, 321(6), 588–601.

KEY CONCEPTS

- Postpartum hemorrhage is a potentially life-threatening complication of both vaginal and cesarean births. It is the leading cause of maternal mortality in the United States.
- A good way to remember the causes of postpartum hemorrhage is the “5 Ts:” tone, tissue, trauma, thrombin, and traction.
- Uterine atony is the most common cause of early postpartum hemorrhage, which can lead to hypovolemic shock.
- Oxytocin (Pitocin), misoprostol (Cytotec), dinoprostone (Prostin E2), methylergonovine maleate (Methergine), and prostaglandin PGF2α (carboprost [Hemabate]) are commonly used drugs used to manage postpartum hemorrhage.
- Failure of the placenta to separate completely and be expelled interferes with the ability of the uterus to contract fully, thereby leading to hemorrhage.
- Causes of subinvolution include retained placental fragments, distended bladder, uterine myoma, and infection.
- Lacerations should always be suspected when the uterus is contracted and bright red blood continues to trickle out of the vagina.
- Conditions that cause coagulopathies may include thrombolytic thrombocytopenic purpura, von Willebrand disease, and disseminated intravascular coagulation.
- Pulmonary embolism is a potentially fatal condition that occurs when the pulmonary artery is obstructed by a blood clot that has traveled from another vein into the lungs, causing obstruction and infarction.
- The major causes of a thrombus formation (blood clot) are venous stasis and hypercoagulation, both of which are common in the postpartum period.
- Postpartum infection is defined as a fever of 100.4°F (38°C) or higher after the first 24 hours after childbirth, occurring on at least 2 of the first 10 days exclusive of the first 24 hours.
- Common postpartum infections include endometritis, wound infections, urinary tract infections, and mastitis.
- Postpartum emotional disorders are commonly classified on the basis of their severity: “baby blues,” postpartum depression, and postpartum psychosis.

- Management of postpartum depression mirrors the treatment of any major depression: a combination of antidepressant medication, antianxiety medication, and psychotherapy in an outpatient or inpatient setting.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. A postpartum mother appears very pale and states she is bleeding heavily. The nurse should first
   a. call the client's health care provider immediately.
   b. immediately set up an intravenous infusion of magnesium sulfate.
   c. assess the fundus and ask her about her voiding status.
   d. reassure the mother that this is a normal finding after childbirth.

2. A postpartum woman reports hearing voices and says, "The voices are telling me to do bad things to my baby." The clinic nurse interprets these findings as suggesting postpartum
   a. psychosis.
   b. anxiety disorder.
   c. depression.
   d. blues.

3. When implementing the plan of care for a multigravida postpartum woman who gave birth just a few hours ago, the nurse vigilantly monitors the client for which complication?
   a. Deep venous thrombosis
   b. Postpartum psychosis
   c. Uterine infection
   d. Postpartum hemorrhage

4. Which would the nurse expect to include in the plan of care for a woman with mastitis who is receiving antibiotic therapy?

   a. Stop breastfeeding and apply lanolin.
   b. Administer analgesics and bind both breasts.
   c. Apply warm or cold compresses and administer analgesics.
   d. Remove the nursing bra and expose the breast to fresh air.

5. While assessing a postpartum multiparous woman, the nurse detects a boggy uterus midline 2 cm above the umbilicus. Which intervention would be the priority?

   a. Assessing vital signs immediately
   b. Measuring her next urinary output
   c. Massaging her fundus
   d. Notifying the woman's obstetrician

6. Methergine has been ordered for a postpartum woman because of excessive bleeding. The nurse should question this order if which is present?

   a. Mild abdominal cramping
   b. Tender inflamed breasts
   c. Pulse rate of 68 beats per minute
   d. Blood pressure of 158/96 mm Hg

7. Which finding would lead the nurse to suspect that a woman is developing a postpartum complication?

   a. Moderate lochia rubra for the first 24 hours
   b. Clear lung sounds upon auscultation
   c. Temperature of 100°F
   d. Chest pain experienced when ambulating

8. Which factor in a postpartum woman's history would lead the nurse to monitor the woman closely for an infection?

a. Hemoglobin of 12 mg/dL
b. Manually extracted placenta
c. Labor of 10 hours length
d. Multiparity of five pregnancies

CRITICAL THINKING EXERCISES

1. A client had a 22-hour labor before a cesarean birth. Her membranes ruptured 20 hours before she came to the hospital. Her fetus showed signs of fetal distress, so internal electronic fetal monitoring was used. Her most recent test results indicate she is anemic.
   a. For which postpartum complication is this new mother at highest risk? Why?
   b. What assessments need to be done to detect this complication?
   c. What nursing measures will the nurse use to prevent this complication?

2. A 32-year-old G9P9, had a spontaneous vaginal birth 2 hours ago. She has been having a baby each year for the past 9 years. Her lochia has been heavy with some clots. She hasn't been up to void since she had epidural anesthesia and has decreased sensation to her legs.
   a. What factors place her at risk for postpartum hemorrhage?
   b. What assessments are needed before planning interventions?
   c. What nursing actions are needed to prevent a postpartum hemorrhage?

3. A 25-year-old G2P2, gave birth 2 days ago and is expected to be discharged today. She had severe postpartum depression 2 years ago with her first child. She has not been out of bed for the past 24 hours, is not eating, and provides no care for herself or her newborn.

She states she already has a boy at home and not having a girl this time is disappointing.

a. What factors or behaviors place her at risk for an affective disorder?
b. Which interventions might be appropriate at this time?
c. What education does the family need prior to discharge?

STUDY ACTIVITIES

1. Compare and contrast postpartum blues, postpartum depression, and postpartum psychosis in terms of their characteristics and medical management.
2. Interview a woman who has given birth and ask if she had any complications and what was most helpful to her during the experience.
3. The number one cause of postpartum hemorrhage is _____.
4. When giving report to the nurse who will be caring for a woman and her newborn in the postpartum period, what information should the labor nurse convey?

BRINGING IT ALL TOGETHER: A CASE STUDY

Sheila is an 18-year-old G1P1 client who had her first child 2 days ago via primary cesarean section. Her pregnancy was uneventful, but she didn't attend the prenatal clinic very often. She presented to the hospital in labor at 39 weeks' gestation with ruptured membranes. The client reported that her membranes had been ruptured for a "couple of days," but she wasn't really sure. Upon admission, she was dilated 2 cm with 40% effacement. She labored for about 7 hours when the health care provider came in to check her. She was only 5 cm and completely effaced at that time. She was receiving IV antibiotics for her "prolonged rupture" status as per CDC guidelines. The health care provider inserted an internal fetal monitor with a scalp electrode and also an

intrauterine pressure catheter because she was obese and the nurse was having difficulty in picking up the fetal heart rate tracing. She had no progress for the next 4 hours and the fetus was noted to develop tachycardia with a baseline heart rate increase to 170 bpm. A primary cesarean section was performed, and she was given perioperative antibiotic prophylaxis at the time of surgery. The infant was large for gestational age and Apgar scores were 9/9 at 1 minute and 5 minutes.

ASSESSMENT

On day 1, as the nurse caring for this client, you obtain a set of postpartum vital signs: T—101.6, P—102, BP—110/80, R—18. Sheila appears pale and is diaphoretic. Her lochia rubra is of moderate amount and foul-smelling. She complains of uterine tenderness when you palpate her fundus. Her surgical site is intact without redness or drainage. She states she didn't have the breakfast that was served because she had no appetite. Her breasts are nontender and full upon palpation. She plans to bottle-feed and has a supportive bra on. Sheila ambulates well and does her own perineal care.

Go to thePoint to find questions to consider about this case.

UNIT
VIII

The Newborn at Risk

23

Nursing Care of the Newborn with Special Needs

WOW

WORDS OF WISDOM

Guiding a parent’s hand to touch a frail or ill newborn demonstrates courage and compassion under very difficult circumstances and is a powerful tool in helping parents to deal with the newborn’s special needs.

KEY TERMS

appropriate for gestational age (AGA)
extremely low birth weight
fetal growth restriction (FGR)
full term newborn
large for gestational age (LGA)
late preterm newborn (near term)
low birth weight (LBW)
postterm newborn
preterm newborn
small for gestational age (SGA)
very low birth weight

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Evaluate factors that assist in identifying a newborn at risk due to variations in birth weight and gestational age.
2. Select contributing factors and common complications associated with dysmature infants and their management.
3. Compare and contrast nursing assessment findings and nursing management of a small-for-gestational-age newborn and a large-for-gestational-age newborn; a postterm and a preterm newborn.
4. Analyze nursing assessment and management of newborn conditions associated with variations in birth weight and gestational ages.
5. Outline the nurse's role in helping parents experiencing perinatal grief or loss.
6. Integrate knowledge of the risks associated with late preterm births into nursing interventions, discharge planning, and parent education.

Anna and her husband were stunned when she went into labor at 7 months' gestation. They couldn't understand what would cause her to give birth early, but it happened. When they approached the NICU, Anna took a deep breath and looked down at her tiny baby with tubes coming from everywhere. What feelings might they be experiencing at this moment?

INTRODUCTION

All families look forward to the birth of a healthy newborn, but some pregnancy outcomes don't meet these expectations. Most newborns are born between 38 and 42 weeks' gestation and weigh 6 to 8 lb, but variations in birth weight or gestational age can occur, and newborns with these variations have special needs. Gestational age at birth is inversely correlated with the risk that the infant will experience physical, neurologic, or developmental challenges. Every year, about 15 million infants are born prematurely—more than one in ten of all infants born around the world. Many require special care to stay alive and many face a lifetime of disability (March of Dimes, 2012). Some newborns are born very ill and require special advanced care to survive. Unexpected difficulties may occur during the pregnancy or during childbirth which change the whole course of events for the families. *Healthy People 2030* includes the rate of preterm births and infant deaths as leading health indicators (U.S. Department of Health and Human Services [USDHHS], 2019). While reducing preterm births and low birth weight remain important objectives, the fact remains that 10% of infants are born prematurely and 8.3% are of low birth weight (Martin et al., 2019).

HEALTHY PEOPLE 2030

Objective	Nursing Significance
Reduce preterm births.	• Support and encourage all pregnant women to maintain consistent prenatal care.

Adapted from USDHHS. (2020). *Proposed objectives for inclusion in Healthy People 2030*. https://www.healthypeople.gov/sites/default/files/ObjectivesPublicComment508.pdf

When a woman gives birth to a newborn with problems involving immaturity or birth weight, especially one who is considered high risk, she may go through a grieving process in which she mourns the loss of the healthy full-term newborn she had expected. Through this process she learns to come to terms with the experience she now faces.

The key to identifying a newborn with special needs related to birth weight or gestational age variation is an awareness of the factors that could place a newborn at risk. These factors are similar to those that would suggest a high-risk pregnancy and include:

- Maternal nutritional extremes (malnutrition, overweight, obesity)
- Low socioeconomic status
- Young or advanced maternal age
- Single marital status
- Lack of prenatal care
- Smoking or exposure to passive smoke
- Illicit drug use
- Infection (particularly chorioamnionitis, sexually transmitted infection, bacterial vaginosis, and urinary tract infection)
- Periodontal disease
- Uterine anomaly or history of cervical surgery
- Prior spontaneous preterm birth
- Assisted reproductive technologies
- Multiple gestation
- Idiopathic preterm premature rupture of membranes (PPROM)
- Maternal psychological stress
- Iron deficiency anemia

- Placental complications (placenta previa or placental abruption)
- Maternal disease (e.g., hypertension, diabetes, HIV, autoimmune disease)
- Exposure to occupational hazards, working long hours, or very physical labor (Cunningham et al., 2018; Resnik et al., 2019)

The development of new technologies and regionalized care centers for the care of newborns with special needs has resulted in significant improvements in neonatal morbidity and mortality. The goal of regionalized care centers is for high-risk pregnant women to receive care in facilities that are prepared to provide the required level of specialized care to them and their newborns (American College of Obstetricians and Gynecologists [ACOG], 2019). Being able to anticipate the birth of a newborn at risk allows the birth to take place at a health care facility equipped with the resources to meet the mother's and newborn's needs. Nurses need to have a sound knowledge base to identify the newborn with special needs and to provide coordinated care.

This chapter discusses the nursing management of newborns with special needs related to variations in birth weight and gestational age. It also describes selected associated conditions affecting these newborns. Due to the frailty of these newborns, the care of the family experiencing perinatal loss and the role of the nurse in helping the family cope also are addressed.

BIRTH WEIGHT VARIATIONS

Fetal growth is influenced by maternal nutrition, genetics, placental function, environment, and a multitude of other factors. Assigning size to a newborn is a way to measure and monitor the growth and development of the newborn at birth. Newborns can be classified according to their birth weight and weeks of gestation. Knowing the group into which a newborn fits is important.

Appropriate for gestational age (AGA) describes a newborn with a weight that falls within the 10th to 90th percentile for that

particular gestational age. Infants who are AGA have lower morbidity and mortality than other groups.

FIGURE 23.1. A low–birth-weight newborn in an isolette.

Small for gestational age (SGA) describes newborns that typically weigh less than 2,500 g (5 lb 8 oz) at term due to less growth than expected in utero. A newborn is also classified as SGA if his or her birth weight is at or below the 10th percentile as correlated with the number of weeks of gestation (King et al., 2019).

Large for gestational age (LGA) describes newborns whose birth weight is above the 90th percentile on a growth chart and who weigh more than 4,000 g (8 lb 13 oz) at term due to accelerated overgrowth for length of gestation (Jordan et al., 2019).

The following terms describe other newborns with marginal weights at birth and of any gestational age:

- **Low birth weight (LBW):** less than 2,500 g (5.5 lb) (Fig. 23.1)
- **Very low birth weight:** less than 1,500 g (3 lb 5 oz)
- **Extremely low birth weight:** less than 1,000 g (2 lb 3 oz) (Brady et al. 2020)

Small-for-Gestational-Age Newborns

Being born small lays the foundation for short- and long-term implications for life. Newborns are considered SGA when their weight falls below the 10th percentile for length, weight, or head circumference on a growth chart for gestational age. These infants can be preterm, term, or postterm. Some SGA newborns are constitutionally small; they are statistically small but otherwise healthy.

In some SGA newborns, the rate of growth does not meet the expected growth pattern. These infants are considered to have **fetal growth restriction (FGR)**. FGR is the pathologic counterpart of SGA. Newborns with FGR are considered at risk, having increased morbidity and mortality rates as compared to those of AGA newborns. Placental insufficiency is a principle cause of FGR, which in turn underlies a chronic undersupply of oxygen and nutrients to the fetus. FGR can also result from aneuploidy, maternal malnutrition, hypertension, smoking, preeclampsia, chromosomal abnormalities, congenital malformations, and infections (Resnik et al., 2019). The fetus is thought to have an inherent growth potential that, under normal circumstances, yields a healthy newborn of appropriate size. The maternal–placental–fetal units act in harmony to meet the needs of the fetus during gestation. However, growth potential in the fetus can be limited, and this is analogous to failure to thrive in the infant. The causes of both can be intrinsic or environmental. Factors that can contribute to the birth of an SGA newborn are highlighted in (Box 23.1). FGR is usually categorized as symmetric or asymmetric. Symmetric FGR refers to fetuses with equally poor growth rates of the brain, the abdomen, and the long bones and is thought to result from an early global insult. All parameters of growth are affected. Asymmetric FGR refers to infants whose brain growth is spared compared to their abdomen and internal organs (Cunningham et al., 2018). Fetal growth is dependent on genetic, placental, and maternal factors. Cognitive and motor development during infancy forms the basis for children's subsequent development. Newborns that experience nutritional

deficiencies in utero and are born with FGR are at risk for lifelong developmental deficits, and emotional and behavioral disorders (Blackburn, 2018).

BOX 23.1 Factors Contributing to the Birth of SGA Newborns

- Maternal causes
  - Chronic hypertension
  - Diabetes mellitus with vascular disease
  - Autoimmune diseases
  - Living at a high altitude (hypoxia)
  - Smoking or exposure to passive smoke
  - Periodontal disease of the mouth
  - Maternal age of 20 or 35 years old
  - Failure to seek any prenatal care
  - Substandard living conditions
  - Low socioeconomic status
  - Abuse and violence
  - Substance abuse (heroin, cocaine, methamphetamines)
  - Hemoglobinopathies (sickle cell anemia)
  - Preeclampsia
  - Exposure to occupational hazards
  - Chronic renal disease
  - Maternal nutrition (malnutrition or obesity)
  - Extreme maternal stress
  - Infections
- Placental factors
  - Abnormal cord insertion
  - Chronic abruption
  - Decreased surface area, infarction
  - Decreased placental weight
  - Placenta previa
  - Placental insufficiency
- Fetal factors
  - Trisomies 13, 18, and 21
  - Turner syndrome
  - Chronic fetal infection (cytomegalovirus [CMV], rubella, syphilis, toxoplasmosis)
  - Congenital anomalies (heart, diaphragmatic hernia, tracheoesophageal fistula)
  - Radiation exposure
  - Multiple fetal gestation

Adapted from Cunningham, F. G., Leveno, K. J., Bloom, S. L., Dashe, J. S., Hoffman, B. L., Casey, B. M., & Spong, C. Y. (2018). *William's obstetrics* (25th ed.). McGraw-Hill Education; Fanaroff, A. A., & Fanaroff, J. M. (2019). *Klaus and Fanaroff's care of the high risk neonate* (7th ed.). Elsevier.

Nursing Assessment

Assessment of the SGA infant begins by reviewing the maternal history to identify risk factors such as smoking, drug abuse, alcohol consumption, autoimmune disease, preeclampsia, anemia, intrauterine viral infection, chronic maternal illness, hypertension, multiple gestation, or genetic disorders. This information allows the nurse to anticipate a possible problem and to be prepared to intervene quickly should one occur. At birth, perform a thorough physical examination, closely observing the newborn for typical characteristics, including:

- Head disproportionately large compared with rest of body (asymmetric)
- Wasted appearance of extremities
- Reduced subcutaneous fat stores
- Jittery secondary to hypoglycemia
- Decreased amount of breast tissue
- Scaphoid abdomen (sunken appearance)
- Temperature instability
- Wide skull sutures secondary to inadequate bone growth
- Poor muscle tone over buttocks and cheeks
- Loose and dry skin that appears oversized
- Thin umbilical cord

Also assess the SGA newborn for any congenital malformations, neurologic insults, or indications of infection. SGA newborns commonly face problems after birth because of the decrease in placental function during gestation. Table 23.1 highlights some of the common problems associated with SGA newborns and others experiencing a variation in birth weight or gestational age. Anticipate the need for and provide resuscitation as indicated by the newborn's condition.

Nursing Management

Interventions for the SGA infant may include obtaining weight, length, and head circumference, comparing them with standards, and documenting the findings on a standardized growth chart.

Perform frequent serial blood glucose measurements as ordered and monitor vital signs, being particularly alert for changes in respiratory status that might indicate respiratory distress. Institute measures to maintain a neutral thermal environment to prevent cold stress and acidosis.

Metabolic needs are increased for catch-up growth. Growing research suggests the SGA infant with rapid weight gain in infancy has an increased long-term risk of excessive fat and the accompanying comorbidities across the lifespan (Hong & Chung, 2018). Initiate early and frequent oral feedings unless contraindicated. At birth the newborn's glucose level is about 70% of the mother's serum glucose. Prolonged or sustained neonatal hypoglycemia may lead to brain injury since the brain needs glucose continuously as a primary source of energy (Sperling, 2020). A newborn stressed at birth uses up available glucose stores quickly with resulting hypoglycemia, a plasma glucose concentration at or below 35 to 45 mg/dL (Cunningham et al., 2018). With the loss of the placenta at birth, the newborn now must assume control of glucose homeostasis through intermittent oral feedings. If oral feedings are not accepted, an intravenous infusion with 10% dextrose in water may be needed to maintain the glucose level above 40 mg/dL. Monitor feeding tolerance, sucking, and swallowing ability. Weigh the newborn daily and ensure that he or she has adequate rest periods to decrease metabolic requirements.

Polycythemia is not uncommon and is a potentially serious disorder of newborns. It is defined as a venous hematocrit above 65% and hemoglobin of more than 20 g. The hematocrit in a newborn peaks between 6 and 12 hours of age and decreases gradually after that. The relationship between hematocrit and viscosity is almost linear until 65% and exponential thereafter. Increased viscosity of blood is associated with symptoms of hypoperfusion. Clinical features related to hyperviscosity may affect all organ systems. Hyperviscosity of blood results in increased resistance to blood flow and decreased oxygen delivery. In the newborn, hyperviscosity can cause abnormalities of central nervous system (CNS) function, hypoglycemia, decreased renal function,

cardiorespiratory distress, and coagulation disorders. Hyperviscosity has been reported to be associated with long-term motor and cognitive neurodevelopmental disorders (Martin et al., 2020). Newborns born SGA, infants of diabetic mothers (IDM), and multiple births are at risk for polycythemia. They should therefore undergo screening at 2, 12, and 24 hours of age (Kenner et al., 2020).

Observe for clinical signs of polycythemia (respiratory distress, cyanosis, feeding difficulties, hypoglycemia, jitteriness, jaundice, ruddy skin color, seizures, and lethargy) and monitor blood results. Asymptomatic newborns with a hematocrit between 60% and 70% may simply be supported with fluids, close observation, and a repeat hematocrit level in 12 hours (Niss & Ware, 2020). If the newborn is symptomatic, a partial exchange transfusion with replacement of removed red blood cell volume with normal saline may be used, but this treatment is considered controversial and not validated by current evidence-based practice research.

SGA infants remain a challenge for clinicians. Many cases occur in pregnancies in which no risk factors are present, so nurses must be alert to the possibility of a growth disturbance in all pregnancies. Provide anticipatory guidance to parents about any treatments and procedures that are being done. Emphasize the need for close follow-up and careful monitoring of the infant’s growth in length, weight, and head circumference and feeding patterns throughout the first year of life to confirm any “catch-up” growth taking place.

TABLE 23.1 Common Problems Associated with Newborns Experiencing a Variation in Birth Weight or Gestational Age

Problem	Occurrence	Etiology/Pathophysiology	Assessment Findings	Nursing Implications
Perinatal asphyxia	SGA newborns (common)	Poor tolerance to stress of labor, frequently leading to acidosis and hypoxia Living in hypoxic environment prior to birth due to placental insufficiency, leaving little to no oxygen reserves available to withstand stress of labor: • Uterine contractions increase hypoxic stress • Possible depletion of glycogen stores due to chronic hypoxic state, leading to fetal distress • Impaired uteroplacental circulation due to maternal and uterine conditions predisposing to perinatal depression Compromised newborn at birth experiencing difficulty adjusting to extrauterine environment	Fetal distress (bradycardia, decelerations) during labor Low Apgar scores Potential meconium passage into amniotic fluid	Anticipate possible problem; assess for maternal risk factors. Initiate resuscitation measures immediately at birth.
	Postterm newborns	Placental deprivation or oligohydramnios, leading to cord compression and subsequent reduction in perfusion to fetus		
	Preterm newborns (common)	Surfactant deficiency Unstable chest wall Immaturity of respiratory control centers in the CNS Small respiratory passages, increasing risk for obstruction Inability to clear mucus from airways		
Difficulty with thermoregulation	SGA newborns (common) Postterm newborns	Less muscle mass, less brown fat, less heat-preserving subcutaneous fat, and limited ability to control skin capillaries Associated with depleted glycogen stores, poor subcutaneous fat stores, and disturbances in CNS thermoregulation due to hypoxia Increased risk for acidosis and hypoglycemia secondary to metabolic stress Loss of subcutaneous fat second to placental insufficiency Use of stored nutrients for nutrition due to lost ability of placenta to nourish fetus Subsequent wasting of subcutaneous fat, muscle, or both	Temperature <36.4° C; temperature instability; skin cool to touch; cyanosis of hands and feet Bradypnea (<25 bpm) and tachypnea (>60 breaths/min) Tremors, irritability Wheezing, crackles, retractions Restlessness, lethargy Hypotonia Weak or high-pitched cry Seizures Poor feeding Grunting Acidosis	Maintain a neutral thermal environment to promote stabilization of newborn's temperature. Assess skin temperature and respiration characteristics. Monitor arterial blood gases and blood glucose levels. Eliminate sources of heat loss: • Dry newborn thoroughly. • Wrap in warmed blanket with stockinette cap on head. • Use radiant heat source.
	Preterm newborns (common) Late preterm infant (common)	Loss of natural insulation (subcutaneous fat) important in temperature regulation Immaturity of CNS (temperature-regulating center) interferes with ability to regulate body temperature Inadequate amounts of subcutaneous fat Lack of muscle tone and flexion to conserve heat Inadequate brown fat to generate heat Limited muscle mass activity, reducing ability to produce own heat Inability to shiver to generate heat		
Hypoglycemia	SGA newborns (common) LGA newborns (common) Postterm newborns Preterm newborns Late preterm infants	Increased metabolic rate and lack of adequate glycogen stores to meet newborn's metabolic needs Commonly associated with infants of diabetic mothers Abrupt cessation of high-glucose maternal blood supply with birth and continued insulin production by the newborn Limited ability to release glucagons and catecholamines, which normally stimulate glucagon breakdown and glucose release Hypoxia secondary to depleted glycogen reserves Placental insufficiency secondary to placental aging contributing to chronic fetal nutritional deficiency further depleting glycogen stores Immature sucking and swallowing leading to insufficient intake Perinatal hypoxia Increased energy expenditure Decreased subcutaneous and brown fat with little to no glycogen stores	Often subtle Lethargy, tachycardia Respiratory distress Jitteriness Drowsiness Poor feeding, feeble sucking Hypothermia, temperature instability Diaphoresis Weak cry Seizures Hypotonia Blood glucose levels <40 mg/dL for term newborns, <20 mg/dL for preterm newborns	Monitor blood glucose levels, initially on arrival to nursery and hourly thereafter. Maintain fluid and electrolyte balance. Watch for subtle changes. Initiate early oral feedings if possible; if not, administer IV infusion with 10% dextrose in water.
Polycythemia	SGA newborns LGA newborns Postterm newborns	Chronic mild hypoxia secondary to placental insufficiency Stimulation of erythropoietin release, leading to increased RBC production Secondary to fetal hypoxia, trauma with bleeding, increased erythropoietin production, or delayed cord clamping Intrauterine hypoxia triggers increased RBC production to compensate for lower oxygen levels.	Venous hematocrit >65% Plethora (ruddy appearance) Weak sucking reflex Tachypnea Jaundice Lethargy Jitteriness Hypotonia Irritability Feeding difficulties Difficulty in arousing Seizures	Ensure adequate hydration (orally or IV). Monitor hematocrit levels (goal is ~60%). Administer partial exchange transfusion, albumin, or normal saline IV to reduce RBC volume and increase fluid volume (controversial).

Meconium aspiration	SGA newborns Postterm newborns	Release of meconium into amniotic fluid prior to birth Inhalation of meconium-containing amniotic fluid by the newborn, leading to aspiration Commonly associated with chronic intrauterine hypoxia Struggling by fetus making respiratory efforts and bearing down with abdominal muscles, leading to expulsion of meconium into amniotic fluid Normal sucking and swallowing by fetus leads to meconium filling airways	Green amniotic fluid with rupture of membranes during labor Green staining of the umbilical cord or fingernails Difficulty initiating respirations	Initiate resuscitation measures as necessary. Suction airways and support ventilation (see Chapter 24 for more information).
Hyperbilirubinemia	LGA newborns (common) Preterm newborns Late preterm infants	Associated with polycythemia and RBC breakdown Inability to tolerate feedings in the first few days of life, leading to increased enterohepatic circulation of bilirubin Excessive bruising secondary to birth trauma, leading to higher-than-normal bilirubin levels Increased breakdown of RBCs and immature liver function to handle excess load	Elevated serum bilirubin levels Jaundice Tea-colored urine Clay-colored stools	Ensure adequate hydration. Institute early feedings if possible. Administer phototherapy (see Chapter 24 for more information).
Birth trauma	LGA newborns	Large size requiring use of operative birth procedure	Obvious deformities Bruising Edema Asymmetrical movement	Perform complete physical and neurologic assessment of the newborn. Note symmetry of structure and function. Assist parents in understanding situation (see Chapter 24 for more information).

Large-for-Gestational-Age Newborns

A newborn whose weight is above the 90th percentile on growth charts or two standard deviations above the mean weight for gestational age is defined as LGA. LGA is also termed macrosomia. The infant's weight is over 4,000 g (>9 lb) to 4,500 g (>9 lb 14 oz). LGA infants may be preterm, term, or postterm. Up to 10% of all infants are designated as LGA at birth. This large size can place both the mother and the newborn at risk for adverse outcomes (Fanaroff & Fanaroff, 2019).

Because of the newborn's large size, vaginal birth may be difficult and occasionally results in birth injury. In addition, shoulder dystocia, clavicular fractures, and facial palsies are common. The incidence of cesarean births is very high with LGA newborns to avoid arrested labor and birth trauma.

TAKE NOTE!

Maternal diabetes is commonly associated with LGA newborns. However, due to poor placental perfusion, the newborn may experience fetal growth restriction and be SGA (Potter & Kicklighter, 2016).

Nursing Assessment

Assessment of the LGA newborn begins with a review of the maternal history, which can provide clues as to whether the woman has an increased risk of giving birth to an LGA newborn. Maternal factors that increase the chance of bearing an LGA newborn include diabetes mellitus or glucose intolerance, multiparity, prior history of a macrosomic infant, postterm gestation, maternal obesity, paternal height, gestational weight gain, male fetus, and genetics (Kenner et al., 2020).

At birth, assess the newborn for common characteristics. The typical LGA newborn has a large body and appears plump and full faced. The increase in body size is proportional. However, the head circumference and body length are in the upper limits of intrauterine growth. These newborns have poor motor skills and have difficulty in regulating behavioral states. LGA newborns are more difficult to arouse to a quiet alert state (Mandy, 2019b).

Thoroughly assess the LGA newborn at birth to identify traumatic birth injuries such as fractured clavicles, brachial palsy, facial paralysis, phrenic nerve palsy, skull fractures, or hematomas. Perform a neurologic examination to identify any nerve palsies, looking for abnormalities such as immobility of the upper arm. Observe and document any injuries discovered to allow for early intervention and improved outcomes.

LGA infants are at risk for hypoglycemia related to early depletion of glycogen stores in their liver. Obtain frequent blood glucose levels as ordered to evaluate for hypoglycemia. The clinical signs are often subtle and include lethargy, apathy, drowsiness, irritability, tachypnea, weak cry, temperature instability, jitteriness, seizures, apnea, bradycardia, cyanosis or pallor, feeble suck and poor feeding, hypotonia, and coma. Other disorders, including septicemia, severe respiratory distress, and congenital heart disease, may present with similar findings. In addition, be alert for other common problems, such as polycythemia and hyperbilirubinemia (see Table 23.1).

Nursing Management

Hypoglycemia in a neonate is defined as blood glucose value typically below 35 to 45 mg/dL. The American Academy of Pediatrics (AAP) recommends intervening for a blood glucose less than 40 in the first 4 hours of life, and less than 45 at ages 4 to 24 hours (Abramowski & Hamdan, 2020). It is commonly associated with a variety of neonatal conditions like prematurity, FGR, and maternal diabetes. It may be asymptomatic in some newborns. Essential nursing care activities include early identification of women at risk for diabetes, prevention of hypoglycemia, maintenance of fluid and electrolyte balance, and parental education and support. Screening for hypoglycemia in high-risk LGA infants is essential. Supervised breastfeeding or formula feeding may be initial treatment options in asymptomatic hypoglycemia. However, symptomatic hypoglycemia should always be treated with frequent breast or formula feedings or dextrose gel massaged into the buccal mucosa. If hypoglycemia persists, then intravenous dextrose may be needed. Hypoglycemia has been linked to poor neurodevelopmental outcome, and hence aggressive screening and treatment is recommended (Martin & Rosenfeld, 2019).

Assist in stabilizing the LGA newborn. Monitor blood glucose levels within 30 minutes of birth and repeat the screening every hour. Recheck levels before feedings and also immediately in any infant suspected of having or showing clinical signs of hypoglycemia, regardless of age (Kenner et al., 2020). To help prevent hypoglycemia, initiate feedings, which can be formula or breast milk, supplementing with glucose gel supplementation as needed. Monitor and record intake and output and obtain daily weights to aid in evaluating nutritional intake.

Observe for signs of polycythemia and hyperbilirubinemia and report any immediately to the health care provider so that early interventions can be taken to prevent poor long-term neurologic development outcomes. Polycythemia and hyperviscosity are associated with fine and gross motor delays, speech delays, and neurologic sequelae (Martin et al., 2020). Increasing fluid volume aids in decreasing blood viscosity. Partial exchange transfusion with normal saline may be used to lower hematocrit and decrease blood

viscosity, but this treatment remains controversial (Niss & Ware, 2020). Hydration, early feedings, and phototherapy are used to treat hyperbilirubinemia (see Chapter 24 for more information about hyperbilirubinemia). Provide parental guidance about the treatments and procedures being done and about the need for follow-up care for any abnormalities identified.

GESTATIONAL AGE VARIATIONS

The mean duration of pregnancy, calculated from the first day of the last normal menstrual period, is approximately 280 days, or 40 weeks. Gestational age is typically measured in weeks: a newborn born before completion of 37 weeks is classified as a **preterm newborn** and one born after completion of 42 weeks is classified as a **postterm newborn** (Cunningham et al., 2018). An infant born from the first day of the 38th week through 42 weeks is classified as a term newborn. An additional classification is that of the **late preterm newborn (near term)**—one that is born between 34 0/7 and 36 6/7 weeks' gestation. Late preterm births account for 75% of preterm births (Brady et al. 2020).

- Preterm infant—born before 37 completed weeks of gestation
- Late preterm infant (near term)—34 0/7 to 36 6/7 weeks
- **Full-term** infant—38 through 41 completed weeks of gestation
- Postterm infant—42 weeks or more

Precise knowledge of a newborn's gestational age is imperative for effective postnatal management. Determination of gestational age by the nurse assists in planning appropriate care for the newborn and provides important information regarding potential problems that need interventions. See Chapter 18 for more information on assessing gestational age.

TAKE NOTE!

Although preterm and postterm newborns may appear to be at opposite ends of the gestational age spectrum and are very different in size and appearance, both are at high risk and need special care.

Postterm Newborn

A pregnancy that extends beyond 42 weeks' gestation (294 days) produces a postterm newborn. Historically, approximately 12% of pregnancies resulted in birth after 42 weeks' gestation, but current evidence suggests that morbidity and mortality increase significantly in a prolonged pregnancy, so obstetric interventions to induce labor are employed earlier (King et al., 2019). Other terms used to describe this late birth is a postmature infant. Postterm newborns may be LGA, SGA, or dysmature (newborn weighs less than established normal parameters for estimated gestational age [fetal growth restricted]), depending on placental function. A postmature infant's appearance typically shows the effects of progressive placental insufficiency.

The reason why some pregnancies last longer than others is not completely understood. What is known is that women who experience one postterm pregnancy are at increased risk in subsequent pregnancies. The incidence of prolonged pregnancy, beyond 42 weeks, is approximately 3% (Martin et al., 2019).

The ability of the placenta to provide adequate oxygen and nutrients to the fetus after 42 weeks' gestation is thought to be compromised, leading to perinatal mortality and morbidity. After 42 weeks, the placenta begins aging. Deposits of fibrin and calcium, along with hemorrhagic infarcts, occur and the placental blood vessels begin to degenerate. All of these changes affect diffusion of oxygen to the fetus. As the placenta loses its ability to nourish the fetus, the fetus uses stored nutrients to stay alive, and wasting occurs. This wasted appearance at birth is secondary to the loss of muscle mass and subcutaneous fat. A recent study found that maternal and neonatal complication rates in postterm infants were

less when active interventions were instituted at 39 weeks' gestation. Infants born postterm experience at increased mortality rate as compare to those born at term (Lockwood, 2018).

Nursing Assessment

Important nursing care activities include assessing neonate complications related to placental insufficiency, assessing for birth trauma, maintaining body temperature, and offering emotional support to the mother/partner. A thorough assessment of the postterm newborn upon admission to the nursery provides a baseline from which to identify changes in clinical status. Review the maternal history for any risk factors associated with postterm birth. Also be aware of the common physical characteristics and be able to identify any deviation from the expected. Postterm newborns typically exhibit the following characteristics:

- Dry, cracked, peeling, wrinkled skin
- Vernix caseosa and lanugo are absent
- Long, thin extremities
- Minimal fat
- Creases that cover the entire soles of the feet
- Wide-eyed, alert expression
- Abundant hair on scalp
- Loose skin around thighs and buttocks
- Thin umbilical cord
- Long overgrown fingernails
- Limited vernix and lanugo
- Meconium-stained skin and fingernails (Kenner et al., 2020)

Assess the newborn's gestational age and complete a physical examination to identify any abnormalities. Review the medical record to determine the color of the amniotic fluid when membranes ruptured and observe for a meconium-stained umbilical cord and fingernails to assess for possible meconium aspiration. Careful suctioning at the time of birth and afterward, if the condition dictates it, reduces the incidence of meconium aspiration (Kenner et al., 2020). Also be alert for other typical complications associated with a

postterm newborn, such as perinatal asphyxia (caused by placental aging or oligohydramnios [decreased amniotic fluid]), hypoglycemia (caused by acute episodes of hypoxia related to cord compression which exhausts carbohydrate reserves), hypothermia (caused by loss of subcutaneous fat), and polycythemia (caused by an increased production of red blood cells to compensate for a reduced oxygen environment), and be prepared to initiate early interventions (see Table 23.1).

Nursing Management

The birth of a postterm newborn may create stress for the mother and her family. In most situations, birth of a newborn requiring special care was not anticipated. Postterm newborns are susceptible to several birth challenges secondary to placental dysfunction that place them at risk for asphyxia, hypoglycemia, and respiratory distress. The nurse must be vigilant for complications when managing these newborns.

The postterm newborn is at high risk for perinatal asphyxia, which is usually attributed to placental deprivation or oligohydramnios that leads to cord compression, thereby reducing perfusion to the fetus. Anticipating the need for newborn resuscitation is a priority. The newborn resuscitation team needs to be available in the birthing suite for immediate backup. The newborn may require transport to the neonatal intensive care unit (NICU) for continuous assessment, monitoring, and treatment, depending on his or her status after resuscitation.

Monitor and maintain the postterm newborn's blood glucose levels once stabilized. Early initiation of feedings or dextrose gel will help stabilize the blood glucose levels to prevent CNS sequelae.

Also monitor the postterm newborn's skin temperature; respiration characteristics; results of blood studies, such as arterial blood gases (ABGs) and serum bilirubin levels; and neurologic status. Institute measures to prevent or reduce the risk of hypothermia by eliminating sources of heat loss: thoroughly dry the newborn at birth, wrap him or her in a warmed blanket, and place a stockinette cap on the

newborn's head. Providing environmental warmth via a radiant heat source will help stabilize the newborn's temperature.

Closely assess all postterm newborns for polycythemia which contributes to hyperbilirubinemia due to red blood cell destruction. Providing adequate hydration helps to reduce the viscosity of the newborn's blood to prevent thrombosis. Be alert to the early, often subtle signs to promote early identification and prompt treatment to prevent any neurodevelopmental delays (Martin & Rosenfeld, 2019).

CONSIDER THIS

I had been waiting for this baby since I can remember and now I was told to wait even longer. I was into my third week past my due date and was just told that if I didn't go into labor on my own, the doctor would induce me on Monday. As I walked out of his office into the hot summer sun, I thought about all the comments that would await me at the office: "You're not still pregnant, are you?" "Weren't you due last month?" "You look as big as a house." "Are you sure you aren't expecting triplets?" I started to get into my car when I felt warm fluid slide down my legs. Although I was embarrassed at my wetness, I was thrilled I wouldn't have to go back to the office and drove myself to the hospital. Within hours my wait was finally over with the birth of my son, a postterm infant with peeling skin and a thick head of hair. He was certainly worth the wait!

Thoughts: Although most due dates are within plus or minus 2 weeks, we can't "go to the bank with it" because so many factors influence the start of labor. This woman was anxious about her overdue status, but nature prevailed. The old adage, "When the fruit is ripe, it will fall," doesn't always bring a good outcome: many women need a little push to bring a healthy newborn forth. What happens when the fetus stays inside the uterus too long? What other features are typical of postterm infants?

Preterm Newborn

A preterm newborn is one who is born before the completion of 37 weeks' gestation. The World Health Organization (WHO) defines infants born before 28 weeks' gestation as *extremely preterm* infants, infants born between 28 and 31 6/7 weeks as *very preterm*, and infants born between 32and 36 6/7 weeks as *moderate to late preterm* infants (2020a). There has been an improved survival rate of preterm infants due to advancing technology and improved evidence-based perinatal care. Although the national birth rate has been declining since the 1990s, the preterm birth rate has been climbing rapidly. Approximately 15 million infants are born before the 37th week of gestation each year worldwide, accounting for approximately one in every ten babies born, and the overwhelming majority of high-risk infants (WHO, 2020b). Prematurity is now the leading cause of death worldwide within the first month of life and the second leading cause of all infant deaths.

The etiology of half of all preterm births is unknown (Cunningham et al., 2018). Preterm births take an enormous financial toll, estimated to be in the billions of dollars. They also take an emotional toll on those involved.

Changes in perinatal care practices, including regional care, have reduced newborn mortality rates. Transporting high-risk pregnant women to a tertiary center for birth rather than transferring the neonate after birth is associated with a reduction in neonatal mortality and morbidity (ACOG, 2019). Despite increasing survival rates, preterm infants continue to be at high risk for neurodevelopmental disorders such as cerebral palsy, intellectual disability, intraventricular hemorrhage, congenital anomalies, neurosensory impairment, behavioral problems, and chronic lung disease (March of Dimes, 2012). Making sure that all pregnant women receive quality prenatal care throughout pregnancy is a major method for preventing preterm births.

Preterm newborns face a myriad of possible complications as a result of their fragile health status or the procedures and treatments used. Some of the more common complications in preterm newborns

include respiratory distress syndrome, periventricular–intraventricular hemorrhage, bronchopulmonary dysplasia, retinopathy of prematurity, hyperbilirubinemia, anemia, necrotizing enterocolitis, hypoglycemia, infection or septicemia, delayed growth and development, and mental or motor delays (Fanaroff & Fanaroff, 2019). Several of these complications are described in Chapter 24.

Effects of Prematurity on Body Systems

Since the preterm newborn did not remain in utero long enough, every body system may be immature, affecting the newborn's transition from intra- to extrauterine life and placing him or her at risk for complications. Without full development, organ systems are not capable of functioning at the level needed to maintain extrauterine homeostasis (Martin et al., 2020).

> Recall Anna, who was described at the beginning of the chapter; she gave birth to a newborn at 7 months' gestation. What problems would you anticipate that her newborn might have?

RESPIRATORY SYSTEM

The respiratory system is one of the last body systems to mature. Therefore, the preterm newborn is at great risk for respiratory complications. A few of the problems that affect the preterm newborn's breathing ability and adjustment to extrauterine life include:

- Surfactant deficiency, leading to the development of respiratory distress syndrome
- Unstable chest wall, leading to atelectasis
- Immature respiratory control centers, leading to apnea
- Smaller respiratory passages, leading to an increased risk for obstruction
- Inability to clear fluid from passages, leading to transient tachypnea (Resnik et al., 2019)

CARDIOVASCULAR SYSTEM

The preterm newborn has great difficulty in making the transition from intrauterine to extrauterine life in terms of changing from a fetal to a newborn circulation pattern. Higher oxygen levels in the circulation once air breathing begins spur this transition. If the oxygen levels remain low secondary to perinatal asphyxia, the fetal pattern of circulation may persist, causing blood flow to bypass the lungs. Another problem affecting the cardiovascular system is the increased incidence of congenital anomalies associated with continued fetal circulation—patent ductus arteriosus and an open foramen ovale. In addition, impaired regulation of blood pressure in preterm newborns may cause fluctuations throughout the circulatory system. One of special note is cerebral blood flow, which may predispose the fragile blood vessels in the brain to rupture, causing intracranial hemorrhage (Fanaroff & Fanaroff, 2019).

GASTROINTESTINAL SYSTEM

The goal of nutrition of the preterm infant is to provide nutrients to approximate the rate of growth and composition of weight gain for a normal fetus of the same gestational age (Hay, 2018). Preterm newborns may lack the neuromuscular coordination required to maintain the suck, swallowing, and breathing regimen necessary for sufficient calorie and fluid intake to support growth. Perinatal hypoxia causes shunting of blood from the gut to more important organs such as the heart and brain. Subsequently, ischemia and damage to the intestinal wall can occur. This combination of shunting, ischemia, damage to the intestinal wall, and poor sucking ability places the preterm infant at risk for malnutrition and weight loss.

In addition, preterm newborns have a small stomach capacity, weak abdominal muscles, compromised metabolic function, limited ability to digest proteins and absorb nutrients, and weak or absent suck and gag reflexes. All of these limitations place the preterm newborn at risk for nutritional deficiency and subsequent growth and development delays.

The preterm infant’s ability to coordinate sucking, swallowing, and breathing is challenged. As a result, preterm infants often require

enteral or intravenous feeding. Enteral tube feeding will help to conserve energy even in an infant who is able to suck. The exact nutritional needs of preterm infants depend on their gestational age, postnatal age, weight, route of nutritional intake, growth rate, activity, and thermal environment. Preterm infants that are ill or experiencing stressful situations have higher energy requirements. Preterm infants take time to establish enteral intakes, and parenteral nutrition is typically an integral component of care, but safe amounts of macronutrients, and the optimal amino acid and lipid composition remains an uncertainty (Brady et al., 2020).

Currently, minimal enteral feeding is used to prepare the preterm newborn's gut to overcome the many feeding difficulties associated with gastrointestinal immaturity. It involves the introduction of small amounts, of breast milk or enteral feeding to induce surges in gut hormones that enhance maturation of the intestine. This minute amount of breast milk or formula given via gavage (tube) feeding prepares the gut to absorb future introduction of nutrients. It builds mucosal bulk, stimulates development of enzymes, enhances pancreatic function, stimulates maturation of gastrointestinal hormones, reduces gastrointestinal distention and malabsorption, and enhances transition to oral feedings. All of the expert committees recommend the use of human milk, which reduces the risk of necrotizing enterocolitis, a serious disease of preterm infants in the neonatal period (Boquien, 2018).

RENAL SYSTEM

The renal system of the preterm newborn is immature, reducing the baby's ability to concentrate urine and slowing the glomerular filtration rate. As a result, the risk for fluid retention, with subsequent fluid and electrolyte disturbances, increases. In addition, preterm newborns have limited ability to clear drugs from their systems, thereby increasing the risk of drug toxicity. Close monitoring of the preterm newborn's acid–base and electrolyte balance is critical to identify metabolic inconsistencies. Prescribed medications require

strict evaluation to prevent overwhelming the preterm baby's immature renal system (Brady et al., 2020).

IMMUNE SYSTEM

The preterm newborn's immune system is very immature, increasing his or her susceptibility to infections. A deficiency of IgG may occur because transplacental transfer does not occur until after 34 weeks' gestation. This protection is lacking if the baby was born before this time. In addition, preterm newborns have an impaired ability to manufacture antibodies to fight infection if they were exposed to pathogens during the birth process. Moreover, the preterm newborn's thin skin and fragile blood vessels provide a limited protective barrier, adding to the increased risk for infection. Thus, anticipating and preventing infections is the goal; preventing infections has a better outcome than treating them (Fanaroff & Fanaroff, 2019).

CENTRAL NERVOUS SYSTEM

The preterm newborn is susceptible to injury and insult to the CNS, increasing the potential for long-term disability into adulthood. Like all newborns, preterm newborns have difficulty in temperature regulation and maintaining stability. However, their risk for heat loss is compounded by inadequate amounts of insulating subcutaneous fat; lack of muscle tone and flexion to conserve heat; inadequate brown fat to generate heat; limited muscle mass activity, reducing the possibility of producing their own heat; inability to shiver to generate heat; and an immature temperature-regulating center in the brain (Kenner et al., 2020). It is crucial to prevent cold stress, which would increase the newborn's metabolic and oxygen needs. The goal is to create a neutral thermal environment in which oxygen consumption is minimal, but body temperature is maintained (Fanaroff & Fanaroff, 2019).

In addition, the preterm newborn is especially susceptible to hypoglycemia due to immature glucose control mechanisms,

decreased glucose stores, and a reduced availability of alternative fuels such as ketone bodies.

TAKE NOTE!

Glucose is needed by the brain and central nervous system to maintain and support numerous body system functions.

Nursing Assessment

Preterm newborns are at high risk for numerous problems and require special care. When preterm labor develops and cannot be stopped by medical interventions, plans are necessary for appropriate management of the mother and the preterm newborn, such as transporting them to a regional center with facilities to care for preterm newborns or notifying the facility's NICU. Depending on the degree of prematurity, the preterm newborn may be kept in the NICU for months.

A thorough assessment of the preterm newborn upon admission to the nursery provides a baseline from which to identify changes in clinical status. Be aware of the common physical characteristics and be able to identify any deviation from the expected (Fig. 23.2). Common physical characteristics of preterm infants may include:

- Birth weight of less than 5.5 lb
- Scrawny appearance
- Head disproportionately larger than chest circumference
- Poor muscle tone and flexion
- Fontanels wide and soft with overriding sutures
- Minimal subcutaneous fat
- Undescended testes in males
- Plentiful lanugo (soft, downy hair), especially over the face and back
- Poorly formed ear pinna, with soft, pliable cartilage
- Fused eyelids
- Prominent clitoris and labia minora in females
- Soft and spongy skull bones, especially along suture lines

- Matted scalp hair, woolly in appearance
- Absent to a few creases in the soles and palms
- Minimal scrotal rugae in male infants
- Thin, transparent skin with visible veins
- Breast and nipples not clearly delineated
- Abundant vernix caseosa (Kenner et al., 2020)

FIGURE 23.2. Characteristics of a preterm newborn. **A.** Few plantar creases. **B.** Soft, pliable ear cartilage, matted hair, and fused eyelids. **C.** Lax posture with poor muscle tone. **D.** Breast and nipple area barely visible. **E.** Male genitalia with minimal rugae on scrotum. **F.** Female genitalia with prominent labia and clitoris.

Be alert for evidence that might suggest that the preterm newborn is developing a complication (see Table 23.1).

Review the maternal history to identify risk factors for preterm birth and check ante- and intrapartum records for maternal infections to anticipate the need for treatment. Maternal risk factors associated

with preterm birth include a previous preterm delivery, low socioeconomic status, preeclampsia, hypertension, poor maternal nutrition, smoking, multiple gestation, infection, advanced maternal age, and substance abuse.

Assess the newborn's gestational age and assess for FGR if appropriate. Inspect the newborn's skin closely, especially skin color. Assess vital signs, including temperature via skin probe to identify hypothermia or fever, and heart rate for tachycardia or bradycardia. Evaluate the newborn's respiratory effort and respiratory rate. Observe for periods of apnea lasting longer than 20 seconds. Monitor oxygen saturation levels by pulse oximetry to validate perfusion status. Note and report any signs of respiratory distress. Auscultate lung and heart sounds, being especially alert for possible murmur, which would indicate the presence of patent ductus arteriosus in a preterm newborn.

Assess neurologic status by observing the newborn's behavior. Note any restlessness, hypotonia, or weak cry or sucking effort and report unusual findings.

Monitor laboratory studies such as hemoglobin and hematocrit for signs of polycythemia. Screen for hypoglycemia upon admission and then hourly, always observing for nonspecific signs of hypoglycemia such as lethargy, poor feeding, and seizures. Evaluate serum bilirubin concentrations.

Finally, assess the mother and family members. Identify family strengths and coping mechanisms to establish a basis for intervention.

Nursing Management

The birth of a preterm newborn creates a crisis for the mother and family. Multiple studies have found that hospitalization for preterm newborns is often followed by negative mental health/behavioral outcomes, anxiety and depressive disorders, and long-term neurologic sequelae. Emerging evidence suggests that partners/significant others experience high rates of psychological stress in the first few months after a preterm birth. The NICU can be

a stressful environment for parents. Nurses need to identify at risk parents to help direct specific interventions to reduce their stress early on (Ionio et al., 2019). Premature labor and birth are accompanied by feelings of helplessness, isolation, and loss of control (Kenner et al., 2020). Preterm newborns present with immaturity of all organ systems, abundant physiologic challenges, and significant morbidity and mortality globally (Martin et al., 2020). The nurse must be vigilant for complications when managing preterm newborns (Fig. 23.3) (Nursing Care Plan 23.1, at the end of the chapter).

PROMOTING OXYGENATION

Newborns normally start to breathe without assistance and often cry after birth, being stimulated by a change in pressure gradients and environmental temperature. The work of taking that first breath is primarily due to overcoming the surface tension of the walls of the terminal lung units at the gas–tissue interface. Subsequent breaths require less inspiratory pressure since there is an increase in functional capacity and air retained. By 1 minute of age, most newborns are breathing well. A newborn who fails to establish adequate, sustained respiration after birth is said to have **asphyxia** (perinatal acidosis), which is the deprivation of oxygen during the birth process, resulting in fetal hypoxia that can lead to organ damage and brain injury (Blackburn, 2018).

FIGURE 23.3. The physical condition of a preterm newborn demands skilled assessment and nursing care.

The preterm infant lacks surfactant, which lowers surface tension in the alveoli and stabilizes them to prevent their collapse. Even if preterm newborns can initiate respirations, they have a limited ability to retain air due to insufficient surfactant. Therefore, preterm newborns develop atelectasis quickly without alveoli stabilization. The inability to initiate and establish respirations leads to hypoxemia and ultimately hypoxia (decreased oxygen), acidosis (decreased pH), and hypercarbia (increased carbon dioxide). This change in the newborn's biochemical environment may inhibit the transition to

extrauterine circulation, thus allowing fetal circulation patterns to persist (Martin, 2019).

Failure to initiate extrauterine breathing or failure to breathe well after birth leads to hypoxia (too little oxygen in the cells of the body). As a result, the heart rate falls, cyanosis develops, temperature decreases, blood pressure decreases, and respirations are altered (apnea, tachypnea, retractions, grunting, and nasal flaring) and the newborn becomes hypotonic and unresponsive. Although this can happen with any newborn, the risk is higher in preterm newborns.

Resuscitating the Newborn

Neonatal resuscitation skills are essential for all nurses that work in the maternal/child specialty areas. Resuscitation involves much more than knowing the technical skills involved; it requires excellent assessment skills and an understanding of the newborn's physiologic transition from intra- to extrauterine life. Approximately 10% of newborns require some assistance to begin breathing at birth. The goals of neonatal resuscitation are to reestablish adequate respirations, obtain adequate cardiac output, prevent neonatal death and adverse long-term neurodevelopmental sequelae associated with perinatal asphyxia (Ohning, 2019). Anticipation, adequate preparation, accurate evaluation, and prompt initiation of support are critical for successful newborn resuscitation. Have all basic equipment immediately available and in working order. Ensure that the equipment is evaluated daily, and document its condition and any needed repairs. Box 23.2 lists the equipment needed for basic newborn resuscitation.

BOX 23.2 Basic Equipment for Newborn Resuscitation

- A wall vacuum suction apparatus
- Infant-size stethoscopes
- Pulse oximeter
- Epinephrine
- Volume expander
- Intravenous fluids
- A wall source or tank source of 100% oxygen with a flow meter
- A neonatal self-inflating ventilation bag with correct-sized face masks
- A selection of endotracheal tubes (2.5, 3.0, or 3.5 mm) with introducers
- A laryngoscope with a small, straight blade and spare batteries and bulbs
- Ampules of naloxone (Narcan) with syringes and needles
- A wall clock to document timing of activities and events
- A supply of disposable gloves in a variety of sizes for staff to use

Determine the need for resuscitation by performing a rapid assessment using the following questions:

- What is the newborn's heart rate?
- What is the gestational age of this newborn? Was the amniotic fluid clear of meconium?
- Is the newborn breathing or crying now?
- Does the newborn have good muscle tone?

If the answers are "yes" to all questions, then routine care is initiated: provide warmth, clear the airway, dry the newborn, and assess color. If the answer to any of these questions is "no," the newborn should receive one or more of the following actions, according to this sequence:

1. Stabilization—Dry the newborn thoroughly with a warm towel; provide warmth by placing him or her under a radiant heater to prevent rapid heat loss through evaporation; position the head in a neutral position to open the airway; clear the airway with a bulb syringe or suction catheter if secretions are blocking airway; stimulate breathing. At times, handling and rubbing the newborn with a dry towel may be all that is needed to stimulate respirations.
2. Assess for breathing—bag the newborn if not breathing.

3. Place pulse oximeter on the newborn's right hand to determine oxygen saturation.
4. Ventilation if needed.
5. Assess heart rate.
6. Chest compressions if needed.
7. Administration of epinephrine and/or volume expansion if needed (Bon et al., 2018).

The decision to progress from one set of actions to the next and the need for further resuscitative efforts is determined by the assessment of respirations, heart rate, and color (AAP & American Heart Association [AHA], 2016). Nurses need to remember that preterm infants have immature lungs that may be more difficult to ventilate and are also more vulnerable to injury by positive-pressure ventilation. They also have immature blood vessels in the brain that are prone to hemorrhage; thin skin and a large surface area, which contribute to rapid heat loss; increased susceptibility to infection; and increased risk of hypovolemic shock related to small blood volume. Anticipation, adequate preparation, accurate evaluation, and prompt initiation of support are critical for successful neonatal resuscitation.

When performing newborn resuscitation, use the mnemonic "C-A-B"—Compressions—Airway—Breathing (anticipate and establish a patent airway, initiate breathing, maintain the circulation with chest compressions and medications, if needed) to remember the sequence of steps (Box 23.3).

BOX 23.3 C-A-Bs of Newborn Resuscitation

- **C**ompressions
  - Compression rate of 100 to 120 per minute
  - Compression depth–1.5 in for infant
  - Place two fingers on the sternum just below the nipple line.
  - After 30 compressions, administer two sequential breaths.
- **A**irway
  - Place infant's head in slightly extended sniffing position.
  - Suction mouth, then nose if secretions are blocking the airway.
  - Head tilt/chin lift to open airway
- **B**reathing
  - Give rescue breathing in an apneic infant with a pulse.
  - Initiate breathing first by using tactile stimulation.
  - Follow stimulation with positive pressure ventilation (PPV) with a bag-mask device.
  - ETT insertion if newborn remains apneic or PPV doesn't achieve effective ventilation
  - Listen for audible breath sounds.
  - Look for slight chest movement with each breath.

Adapted from American Academy of Pediatrics (AAP) & American Heart Association (AHA). (2016). *Textbook of neonatal resuscitation* (7th ed.). American Academy of Pediatrics.

Resuscitation measures are continued until the newborn has a pulse above 100 bpm, a good healthy cry or good breathing efforts, and a pink tongue. This last sign indicates a good oxygen supply to the brain. Effective chest compression is the key to successful resuscitation (Lamberg, 2018). Throughout the resuscitation period, keep the parents informed of what is happening to their newborn and what is being done and why. Provide support through this initial crisis. Once the newborn is stabilized, encourage bonding by having them stroke, touch, and when appropriate hold the newborn.

Administering Oxygen

Oxygen administration is a common therapy in the neonatal intensive care unit, though the normal oxygen concentration for a preterm infant remains unknown. Use of large concentrations of oxygen and sustained oxygen saturations higher than 95% while on

supplemental oxygen have been associated with the development of retinopathy of prematurity (ROP) and further respiratory complications in the preterm newborn (Martin & Deakins, 2020). For these reasons, oxygen should be used judiciously to prevent the development of further complications. A guiding principle for oxygen therapy is it should be targeted to levels appropriate to the condition, gestational age, and postnatal age of the newborn. Current common practice is to maintain oxygen saturation levels in the high 80s to mid-90s, though a wide variation in practice may still occur. Room air is the preferred gas to be used when initiating positive pressure ventilation during the resuscitation of newborns (Brady & Kamath-Rayne, 2020). Refer to Chapter 39 for a more in-depth discussion of ROP.

Respiratory distress in preterm infants is commonly caused by a deficiency of surfactant, retained fluid in the lungs (wet lung syndrome), meconium aspiration, pneumonia, hypothermia, or anemia. The principles of care are the same regardless of the cause of respiratory distress.

- First, keep the newborn warm, preferably in a warmed isolette or with an overhead radiant warmer, to conserve the baby's energy and prevent cold stress.
- Handle the newborn as little as possible, because stimulation often increases the oxygen requirement.
- Provide energy through calories via intravenous dextrose or gavage or continuous tube feedings to prevent hypoglycemia.
- Treat cyanosis with an oxygen hood or blow-by oxygen placed near the newborn's face if respiratory distress is mild and short-term therapy is needed.
- Record the following important observations every hour or more frequently if indicated and document any deterioration in respiratory status:
  - Respiratory rate, quality of respirations, and respiratory effort
  - Airway patency, including removal of secretions per facility policy
  - Skin color, including any changes to duskiness, blueness, or pallor

- Lung sounds on auscultation to differentiate breath sounds in upper and lower fields
- Equipment required for oxygen delivery, such as:
  - Blow-by oxygen delivered via mask or tube for short-term therapy
  - Oxygen hood (oxygen is delivered via a plastic hood placed over the newborn's head)
  - Nasal cannula (oxygen is delivered directly through the nares) (Fig. 23.4A)
  - Continuous positive airway pressure (CPAP), which prevents collapse of unstable alveoli and delivers high levels of inspired oxygen into the lungs
  - Mechanical ventilation, which delivers consistent assisted ventilation and oxygen therapy, reducing the work of breathing for the fatigued infant (Fig. 23.4B)
- Correct placement of endotracheal tube (if present)
- Oxygen saturation levels via pulse oximetry
- Heart rate, including any changes

FIGURE 23.4. A. A preterm newborn receiving oxygen therapy via a nasal cannula. The newborn also has an enteral feeding tube inserted for nutrition. **B.** A preterm newborn receiving mechanical ventilation.

- Monitor the infant's respiratory status, clinically as well as by oxygen saturation, ABGs, and chest x-ray.
- Oxygen saturation levels via pulse oximetry to evaluate need for therapy modifications based on hemoglobin
- Suction as needed to remove secretions to maintain a patent airway and enhance oxygenation.

- Decrease stimulation; cluster all care to allow for rest.
- Maintain a neutral thermal environment.
- Administration of medication, such as exogenous surfactant
- Offer emotional support and progress reports on infant's condition to family.

If the newborn shows worsening cyanosis or if oxygen saturation levels fall below normal limits, prepare to give additional oxygen as ordered. Evaluate ABG results periodically as ordered. Document any deterioration or changes in respiratory status. Administer exogenous surfactant as ordered. Throughout care, maintain strict asepsis and meticulous hand hygiene in order to reduce the risk of infection (Kenner et al., 2020).

MAINTAINING THERMAL REGULATION

Providing an optimal thermal environment is important. When a newborn becomes chilled, it attempts to conserve body heat by vasoconstriction and thermogenesis by metabolizing brown adipose tissue and increasing oxygen consumption. This increase in energy expenditure reduces the neonate's ability to gain weight. Immediately after birth, dry the newborn with a warmed towel and then place him or her in a second warm, dry towel before performing the assessment. This drying prevents rapid heat loss secondary to evaporation. Newborns that are active, breathing well, and crying are stable and can be placed on their mother's chest ("kangaroo care") to promote warmth and prevent hypothermia. Preterm newborns that are not considered stable may be placed under a radiant warmer or in a warmed isolette after they are dried with a warmed towel.

Typically newborns use nonshivering thermogenesis for heat production by metabolizing their own brown adipose tissue. However, the preterm newborn has an inadequate supply of brown fat because he or she left the uterus early before the supply was adequate. The preterm newborn also has decreased muscle tone and thus cannot assume the flexed fetal position, which reduces the amount of skin exposed to a cooler environment. In addition, preterm newborns have large body surface areas compared to their weight.

This allows an increased transfer of heat from their bodies to the environment.

Typically, a preterm newborn that is having problems with thermal regulation is cool-to-cold to the touch. The hands, feet, and tongue may appear cyanotic. Respirations are shallow or slow, or signs of respiratory distress are present. The newborn is lethargic and hypotonic, feeds poorly, and has a feeble cry. Blood glucose levels are probably low, leading to hypoglycemia, due to the energy expended to keep warm.

When promoting thermal regulation for the preterm newborn:

- Remember the four mechanisms for heat transfer and ways to prevent loss:
  - Convection: heat loss through air currents (avoid drafts near the newborn)
  - Conduction: heat loss through direct contact (warm everything the newborn comes in contact with, such as blankets, mattress, stethoscope)
  - Radiation: heat loss without direct contact (keep isolettes away from cold sources and provide insulation to prevent heat transfer)
  - Evaporation: heat loss by conversion of liquid into vapor (keep the newborn dry and delay the first bath until the baby's temperature is stable)
- Frequently assess the temperature of the isolette or radiant warmer, adjusting the temperature as necessary to prevent hypo- or hyperthermia.
- Utilize plastic wraps and bags, skin-to-skin contact, or transwarmer mattresses if available to keep infants warmer and decrease the incidence of hypothermia.
- Assess the newborn's temperature every hour until stable.
- Observe for clinical signs of cold stress, such as respiratory distress, central cyanosis, hypoglycemia, lethargy, weak cry, abdominal distention, apnea, bradycardia, and acidosis.
- Remember the complications of hypothermia and frequently assess the newborn for signs:
  - Metabolic acidosis secondary to anaerobic metabolism used for heat production, which results in the production of lactic acid
  - Hypoglycemia due to depleted glycogen stores

    - Pulmonary hypertension secondary to pulmonary vasoconstriction
- Monitor the newborn for signs of hyperthermia such as tachycardia, tachypnea, apnea, warm to touch, flushed skin, lethargy, weak or absent cry, and CNS depression; adjust the environmental temperature appropriately.
- Explain to the parents the need to maintain the newborn's temperature, including the measures used; demonstrate ways to safeguard warmth and prevent heat loss (Kenner et al., 2020; Roychoudhury & Yusuf, 2017).

PROMOTING NUTRITION AND FLUID BALANCE

Preterm infants have huge nutritional needs immediately after birth, more than at any other time in their lives. Providing nutrition is challenging for preterm newborns because their needs are great, but their ability to take in optimal amounts of energy/calories is reduced due to their compromised health status. Individual nutritional needs are highly variable.

FIGURE 23.5. Infants who are ill at birth often need supplemental feedings by nasogastric or gastrostomy tubes. (Copyright Caroline Brown, RNC, MS, DEd.)

Depending on their gestational age, preterm newborns receive nutrition orally, enterally, or parenterally via infusion. Several different methods can be used to provide nutrition: parenteral feedings administered through a percutaneous central venous catheter for long-term venous access with delivery of total parenteral nutrition (TPN); or enteral feedings, which can include oral feedings (formula or breast milk), continuous nasogastric tube feedings, or intermittent gavage tube feedings (Fig. 23.5). Gavage feedings are commonly used for compromised newborns to allow them to rest during the feeding process. Many have a weak suck and become fatigued and thus cannot consume enough calories to meet their needs.

Most newborns born after 34 weeks' gestation without significant complications can feed orally. Enteral feeding should start as soon as possible after birth, using mother's colostrum and milk as first choices. Enteral feedings promote gastrointestinal development and growth. Those born before 34 weeks' gestation typically start with

parenteral nutrition within the first 24 hours of life. Then enteral nutrition is introduced and advanced based on the degree of maturity and clinical condition. Ultimately, enteral nutrition methods replace parenteral nutrition. The objective of preterm neonatal nutritional strategies should be to optimize neurodevelopment outcomes rather than growth alone.

To promote nutrition and fluid balance in the preterm newborn:

- Measure daily weight and plot it on a growth curve.
- Monitor intake; calculate fluid and caloric intake daily.
- Assess fluid status by monitoring weight; urinary output; urine specific gravity; laboratory test results such as serum electrolyte levels, blood urea nitrogen, creatinine, and hematocrit; skin turgor; and fontanels (Hay, 2018).
- Be alert for signs of dehydration, such as a decrease in urinary output, sunken fontanels, temperature elevation, lethargy, and tachypnea.
- Continually assess for enteral feeding intolerance; measure abdominal girth, auscultate bowel sounds, and measure gastric residuals before the next tube feeding.
- Encourage and support breastfeeding by facilitating maternal breast pumping.
- Encourage nuzzling at the breast in conjunction with kangaroo care if the newborn is stable.

TAKE NOTE!

When assessing the fluid status of a preterm newborn, palpate the fontanels. Sunken fontanels suggest dehydration; bulging fontanels suggest overhydration.

PREVENTING INFECTION

Preterm infants have an increased susceptibility to infection, thus meticulous attention to infection control is needed as prevention of infection is critical. Nurses need to have a high index of suspicion to recognize infections in preterm infants to prevent poor clinical

outcomes. Infections are the most common cause of morbidity and mortality in the NICU population (Pammi, 2020). Sources of infection in a newborn can be divided into three categories: transplacental acquisition (intrauterine infection); perinatal acquisition during childbirth (intrapartum infection); and hospital acquisition in neonatal period (postnatal infection) from the mother, hospital environment, or staff (Kenner et al., 2020). Nursing assessment and early identification of infectious problems are imperative to improve outcomes.

Preterm newborns are at risk for infection because their early birth deprived them of maternal antibodies needed for passive protection. They are also susceptible to infection because of their limited ability to produce their own antibodies, asphyxia at birth, and thin, friable skin that is easily traumatized, providing an entry portal for microorganisms.

Early detection is crucial. The clinical manifestations can be nonspecific and subtle: apnea, diminished activity, poor feeding, temperature instability, respiratory distress, seizures, tachycardia, hypotonia, irritability, pallor, jaundice, and hypoglycemia. Group B streptococcal infection remains the most common cause of early and late neonatal sepsis (Puopolo et al., 2018). Report any of these to the primary care provider immediately so that treatment can be instituted.

Include the following interventions when caring for a preterm or postterm newborn to prevent infection:

- Assess for risk factors in maternal history that place the newborn at increased risk.
- Strict compliance with handwashing and universal precautions.
- Monitor for changes in vital signs such as temperature instability, tachycardia, or tachypnea.
- Assess oxygen saturation levels and initiate oxygen therapy as ordered if oxygen saturation levels fall below acceptable parameters.
- Assess feeding tolerance, typically an early sign of infection.
- Monitor laboratory test results for changes.
- Avoid using tape on the newborn’s skin to prevent tearing.

- Use equipment that can be thrown away after use.
- Adhere to standard precautions; use clean gloves to handle dirty diapers and dispose of them properly.
- Use sterile gloves when assisting with any invasive procedure; attempt to minimize the use of invasive procedures.
- Remove all jewelry on your hands prior to washing hands; wash hands upon entering the nursery and in between caring for newborns.
- Administer antibiotics as ordered and monitor for therapeutic and adverse effects.
- Avoid coming to work when ill, and screen all visitors for contagious infections.

Remember Anna, who was in a state of shock when she entered the NICU to see her preterm baby for the first time? How could the nurse have prepared her for this event? What information needs to be given at the isolette to reduce her anxiety and fear now?

PROVIDING APPROPRIATE STIMULATION

Preterm infants do not tolerate being overstimulated. Flashing lights, beeping monitors, and constant alarms in the NICU can cause the preterm infant to suddenly pause in breathing, as well as change heart rate, blood pressure, and oxygen levels. Newborn stimulation involves a series of activities to encourage normal development. Research on developmental interventions shows that when preterm newborns, in particular, receive sensorimotor interventions such as rocking, nonnutritive sucking with a pacifier, skin-to-skin contact with parents, containment (swaddling and surrounded by blanket rolls), caffeine therapy, music, nonnutritive sucking, breastfeeding, massage, holding, or sleeping on waterbeds, they gain weight faster, progress in feeding abilities more quickly, and show improved interactive behavior compared to preterm newborns who were not stimulated (Mohamed et al., 2018). Conversely, overstimulation may have negative effects by reducing oxygenation and causing stress. The NICU environment lends itself to persistent and unpredictable sounds that are in stark contrast to the protective sounds inside the

mother. A newborn reacts to stress by flaying the hands or bringing an arm up to cover the face. When overstimulated, such as by noise, lights, excessive handling, alarms, and procedures, and stressed, heart and respiratory rates decrease and periods of apnea or bradycardia may follow (Fanaroff & Fanaroff, 2019).

FIGURE 23.6. A preterm newborn receiving nonnutritive sucking.

Appropriate developmental stimulation that would not overtax the compromised newborn might include kangaroo (skin-to-skin) holding, rocking, soft singing or music, cuddling, gentle stroking of the infant's skin, colorful mobiles, gentle massage, waterbed mattresses, and

nonnutritive sucking opportunities (Fig. 23.6) or providing sucrose if tolerated.

The NICU environment can be altered to provide periods of calm and rest for the newborn by dimming the lights, avoiding tapping on isolettes, lowering the volume and tone of conversations, monitoring noise levels in the NICU periodically, shielding infants from bright lights, moving infants slowly, introducing touch slowly, closing doors gently, setting the telephone ringer to the lowest volume possible, clustering nursing activities, using skin-to-skin care, and covering the isolette with a blanket to act as a light shield to promote rest at night (Pados, 2019).

Encourage parents to hold and interact with their newborn. Doing so helps to acquaint the parents with their newborn, promotes self-confidence, and fosters parent–newborn attachment (Fig. 23.7).

Think back to Anna, the woman who gave birth to a preterm newborn at 7 months' gestation. Anna will be discharged but her newborn will be staying in the NICU for a while. What interventions would be appropriate to facilitate bonding despite their separation? What support can be provided specifically to her family?

FIGURE 23.7. A mother bonding with her preterm newborn.

MANAGING PAIN

Pain is both a sensory and emotional experience. It is well known that preterm infants can feel pain and express it through specific signs and symptoms. Pain control and prevention is imperative for ethical and clinical reasons and is required by the AAP and the Joint Commission as a standard of excellence. Pain is an unpleasant sensory and emotional experience felt by all humans. Unlike adults, infants are incapable of rating their pain on a scale of 0 to 10, and yet from the moment they take their first breath, they are exposed to painful procedures. Newborns feel pain and require the same level of

pain assessment and management as adults. Common indicators of pain in the newborn who is unable to vocalize include facial expressions, crying, withdrawal of body part, total body movements, and physiologic changes such as oxygen saturation and respiratory rate (Eriksson & Campbell-Yeo, 2019). Even though pain may not be expressed verbally in neonates, this does not negate their experiencing it. Untreated pain in newborns may result in increased morbidity and length of stay in the NICU, exaggerated responses to pain in later life, and altered psychosocial development (Walker, 2019). Parents commonly expect that health care providers will use appropriate measures to prevent pain in their newborns, but there are gaps in knowledge about the most effective way to accomplish this.

Recent research findings suggested that infants be given an appropriate-sized pacifier for comfort during painful procedures. Administration of oral sucrose with and without nonnutritive sucking and warmth is also frequently used as a nonpharmacologic intervention for procedural pain relief in neonates (Bucsea & Riddell, 2019). Based on research, nurses need to be more informed about the effectiveness of nonnutritive sucking and other nonpharmacologic measures, their analgesic mechanisms, and how to use and incorporate it into practice (De Clifford-Faugere et al., 2019).

Assessment of pain in the newborn remains a contentious and vexing problem. Newborns in the NICU are subjected to repeated procedures that cause them pain. Newborns, whether preterm, full term, or postterm, do experience pain, but the pain is difficult to validate with consistent behaviors. Considering that ill newborns undergo multiple noxious stimuli from invasive procedures, such as lumbar punctures, heel sticks, venipuncture, line insertions, chest tube placement, specimen collections, endotracheal intubation and suctioning, and mechanical ventilation, common sense would suggest that newborns experience pain from many of these activities and interventions. Historically, pain management in infants was not addressed formally but current guidelines address the nurse’s role in assessing and managing neonatal pain (Kenner et al., 2020). Refer

to Box 23.4 for an overview of the principles of newborn pain prevention and management that all nurses should utilize.

BOX 23.4 Newborn Pain Prevention and Management Guidelines

- Newborn pain frequently goes unrecognized and undertreated.
- Pain assessment is an essential activity prior to pain management.
- Newborns experience pain, and analgesics should be given.
- A procedure considered painful for an adult should also be considered painful for a newborn.
- Developmental maturity and health status must be considered when assessing for pain in newborns.
- Newborns may be more sensitive to pain than adults.
- Pain behavior is frequently mistaken for irritability and agitation.
- Newborns are more susceptible to the long-term effects of pain.
- Adequate pain management may reduce complications and mortality.
- Nonpharmacologic measures can prevent, reduce, or eliminate newborn pain.
- Sedation does not provide pain relief and may mask pain responses.
- A newborn's response to both pharmacologic and nonpharmacologic pain therapy should be assessed within 30 minutes of administration or intervention.
- Health care professionals are responsible for pain assessment and treatment.
- Written guidelines are needed on each newborn unit.

Adapted from Bucsea, O., & Riddell, R. P. (2019). Non-pharmacological pain management in the neonatal intensive care unit: Managing neonatal pain without drugs. Seminars in Fetal and Neonatal Medicine, *24*(4), 101017. https://doi.org/10.1016/j.siny.2019.05.009; De Clifford-Faugere, G., Aita, M., & Le May, S. (2019). Nurses' practices regarding procedural pain management of preterm infants. Applied Nursing Research, *45*, 52–54. https://doi.org/10.1016/j.apnr.2018.11.007; and Zeltzer, L. K., Krane, E. J., & Levy, R. L. (2020). Chapter 76 Pediatric pain management. In R. M. Kliegman, J. St. Geme, N. J. Blum, S. S. Shah, R. C. Tasker, K. M. Wilson, & R. E. Behrman (Eds.), *Nelson textbook of pediatrics* (21st ed., 469–490). Elsevier.

Several psychometric tools are available to assess pain in the newborn. Examples include the Premature Infant Pain Profile (PIPP), which assesses heart rate and oxygen saturation; the CRIES tool (cry, requires oxygen, increased vital signs, expression, and sleeplessness); and the Neonatal Infant Pain Scale (NIPS), which evaluates respiratory patterns. Most are based on facial expressions,

crying patterns, change in vital signs, and body movements (Eriksson & Campbell-Yeo, 2019). See Chapter 36 for a more in-depth discussion of pain assessment and management.

Nurses play a key role in assessing a newborn's pain level. Assess the newborn frequently. Pain is considered the "fifth vital sign" and should be assessed as frequently as the other four vital signs. Differentiate pain from agitation by observing for changes in vital signs, behavior, facial expression, and body movement. Suspect pain if the newborn exhibits the following:

- Sudden high-pitched cry
- Facial grimace with furrowing of brow and quivering chin
- Increased muscle tone
- Oxygen desaturation
- Increase in heart rate
- Body posturing, such as squirming, kicking, arching
- Limb withdrawal and thrashing movements
- Increased blood pressure, pulse, and respirations
- Fussiness and irritability (Zeltzer et al., 2020)

The goals of pain management are to minimize the amount, duration, and severity of pain and to assist the newborn in coping. It is essential that pain-related stress in preterm infants is accurately identified and appropriately managed, and that pain management strategies are evaluated for protective or adverse effects in the long term. Effective pain management strategies for newborns include preventing, limiting, or avoiding noxious stimuli; using nonpharmacologic techniques to reduce pain; and administering pharmacologic agents when appropriate. Nurses play a crucial role in assessing pain, implementing and evaluating interventions to minimize neonatal pain using available resources, especially nonpharmacologic techniques. Box 23.5 lists some of the more commonly used nonpharmacologic pain management techniques for the preterm newborn.

Nonpharmacologic pain management strategies include nonnutritive sucking, breastfeeding, radiant heat to promote warmth, skin-to-skin contact, and sweetened solutions. Pharmacologic

strategies include narcotic analgesics, but they are limited. Morphine and fentanyl, usually administered intravenously, are the most commonly used opioids for moderate to severe pain. Acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs) are effective for mild pain. Benzodiazepines are used as sedatives during painful procedures and can be combined with opioids for more effectiveness. Local or topical anesthetics (e.g., EMLA cream) also may be used before procedures such as venipuncture, lumbar puncture, and intravenous catheter insertion (Fanaroff & Fanaroff, 2019).

BOX 23.5 Nonpharmacologic Techniques to Reduce Pain in the Preterm Newborn

- Gentle handling, rocking, caressing, cuddling, and massaging
- Rest periods before and after painful procedures
- Kangaroo care (skin-to-skin contact) during procedure
- Breastfeeding, if able, to reduce pain from minor procedures
- Use of a facilitated tuck (holding arms and legs in a flexed position)
- Application of topical anesthetics prior to venipuncture or lumbar puncture
- Swaddling and positioning to establish physical boundaries
- Nonnutritive sucking (pacifier dipped in sucrose) prior to procedure
- Minimal use of tape, with gentle removal to avoid skin tears
- Warm blankets for wrapping to facilitate relaxation
- Reduction of environmental stimuli by removing or turning down noxious stimuli such as noise from alarms, beepers, loud conversations, and bright lights
- Distraction, such as with colored objects or mobiles

Adapted from Bucsea, O., Riddell, R. P. (2019). Non-pharmacological pain management in the neonatal intensive care unit: Managing neonatal pain without drugs. Seminars in Fetal and Neonatal Medicine, *24*(4), 101017. https://doi.org/10.1016/j.siny.2019.05.009; Kenner, C., Altimier, L., & Boykova, M. V. (Eds.). (2020). *Comprehensive neonatal nursing care* (6th ed.). Springer Publishing Company.

Be vigilant in assessing for adverse effects (respiratory depression or hypotension) when administering pharmacologic agents for pain management, especially in preterm newborns with neurologic impairment. These negative effects are usually dose and route

related, so be knowledgeable about the pharmacokinetics and therapeutic dosing of any drug administered.

PROMOTING GROWTH AND DEVELOPMENT

In the late 1990s, researchers evaluated the NICU environment in terms of light and sound levels, caregiving activities, and handling of newborns. As a result of this research, many environmental modifications were made to reduce the stress and overstimulation of the NICU, and the concept of developmentally supportive care was introduced. Developmentally supportive care is defined as care of a newborn or infant to support positive growth and development. Developmental care focuses on what newborns or infants can do at that stage of development; it uses therapeutic interventions only to the point that they are beneficial; and it provides for the development of the newborn–family unit (Martin et al., 2020).

Family-centered developmental care is an essential element of neonatal intensive care. It is of particular importance when the infant is vulnerable and at greater risk for poor outcomes complicated by a family unit that is easily challenged by the unique needs of the infant, yet all newborns and their families deserve this philosophy of caregiving. Family-centered developmental care must continue to be tested through research to determine which interventions work, what does not work, and which interventions need further refinement (Park & Kim, 2019).

EVIDENCE-BASED PRACTICE 23.1

Improving Neurodevelopment Outcomes in NICU Patients

STUDY

The NICU is full of stimulation from many sources, including positioning that differs from newborn's intrauterine environment. This overstimulation environment causes stress to the preterm infant and can produce physical and neurologic responses and delays. Their stress responses are manifested by an increase in heart rate, decreased oxygen saturation, poor weight gain, and delayed development. To decrease the incidence of negative outcomes related to prematurity and developmental concerns, the NICU environment can be modified to better mimic the uterus. Developmentally appropriate positioning assists the infant to be more flexed and supported to benefit overall development. The purpose of this study was to measure the effectiveness of developmentally structured positioning on length of NICU stay, weight gain, and tone/flexion compared with neonates without structured positioning. Study design was quasi-experimental with 20 preterm infants were enrolled in the structured positioning intervention group and 50 infants enrolled in the nonintervention group.

Findings

Results showed that the postintervention group had clinically significant weight gain and better tone and flexion scores than the nonintervention group. The length of stay between the two groups was not statistically significant, however, it was expected that the length of stay would decrease with implementation of the positioning intervention.

Nursing Implications

Based on the results of this study, nurses can feel confident in integrating the principles of developmental care into their practice, especially structured positioning to facilitate a positive impact on the infant's neurodevelopmental outcome. The infant's weight gain, tone and flexion scores improved with developmentally structured positioning. With greater structure and consistent attention to developmental care principles, outcomes for preterm infants can improve with consistency in practices among NICU nurses.

Painter, L., Lewis, S., & Hamilton, B. K. (2019). Improving neurodevelopmental outcomes in NICU patients. Advances in Neonatal Care, *19*(3), 236–243. https://doi.org/10.1097/ANC.0000000000000583

Developmental care is a philosophy of care that requires rethinking the relationships between newborns, families, and health care providers. It includes a variety of activities designed to manage the environment and individualize the care of the preterm or high-risk ill newborn based on behavioral observations (see Evidence-Based Practice 23.1).

Developmental care includes these strategies:

- Clustering care to promote rest and conserve the infant's energy
- Flexed positioning to simulate in utero positioning
- Environmental management to reduce noise and visual stimulation
- Kangaroo care to promote skin-to-skin sensation
- Placement of twins in the same isolette or open crib to reduce stress
- Activities to promote self-regulation and state regulation:
  - Surrounding the newborn with nesting rolls/devices
  - Swaddling with a blanket to maintain the flexed position
  - Providing sheepskin or a waterbed to simulate the uterine environment
  - Providing nonnutritive sucking (calms the infant)
  - Providing objects to grasp (comforts the newborn)

- Promotion of parent–infant bonding by making parents feel welcome in the NICU
- Open, honest communication with parents and staff
- Collaboration with the parents in planning the infant's care (Franck & O'Brien, 2019; Painter et al., 2019)

Developmental care can be fostered by clustering the lights in one area so that no lights are shining directly on newborns, installing visual alarm systems and limiting overhead pages to minimize noise, and monitoring continuous and peak noise levels. Nurses can play an active role by serving on committees that address these issues. In addition, nurses can provide direct developmentally supportive care. Doing so involves careful planning of nursing activities to provide the ideal environment for the newborn's development. For example:

- Dim the lights and cover isolettes at night to simulate nighttime.
- Support early extubation from mechanical ventilation.
- Encourage early and consistent feedings with breast milk.
- Administer prescribed antibiotics judiciously.
- Position the newborn as if he or she was still in utero (a nesting fetal position).
- Promote kangaroo care by encouraging parents to hold the newborn against the chest for extended periods each day.
- Coordinate care to respect sleep and awake states.

Throughout the newborn's stay, work with the parents, developing a collaborative partnership so they feel comfortable caring for their newborn. Be prepared to make referrals to community support groups to enhance coping (Andrews & Pinto, 2019).

PROMOTING PARENTAL COPING

Generally, pregnancy and the birth of a newborn are exciting times, but when the newborn has serious, perhaps life-threatening problems, the exciting experience suddenly changes to one of anxiety, fear, guilt, loss, and grief.

Parents of preterm infants spend several months visiting the NICU, constantly worrying about their infant's survival, health and

well-being, having to face the unexpected and struggling with this unexpected event in their lives. Parents are typically unprepared for the birth of a preterm newborn and commonly experience an array of emotions, including disappointment, fear for the survival of the newborn, and anxiety due to the separation from their newborn immediately after birth. Gaining insight into the experience of parents of premature infants can help nurses ensure services more effectively meet the needs of these families. Early interruptions in the bonding process and concern about the newborn's survival can create extreme anxiety and interfere with attachment. Parents often feel vulnerable and incompetent in the NICU high-tech environment and this leads to emotional distress (Ding et al., 2019; Sabnis et al., 2019).

Nursing interventions aimed at reducing parental anxiety include:

- Reviewing with the parents the events that have occurred since birth
- Providing individualized support to parents while in NICU
- Providing simple relaxation and calming techniques (visual imagery, breathing)
- Exploring their perception of the newborn's condition and offering explanations
- Encouraging parental involvement with their newborn in NICU
- Validating their anxiety and behaviors as normal reactions to stress and trauma
- Providing a physical presence and support during emotional outbursts
- Providing anticipatory guidance about taking their infants home
- Exploring the coping strategies they used successfully in the past and encouraging use now
- Motivating fathers to co-parent and support them to establish a father–child relationship
- Encouraging frequent visits to the NICU
- Addressing their reactions to the NICU environment and explaining all equipment used
- Identifying family and community resources available to them (Noergaard et al., 2018)

Preparing for Discharge

Discharge planning typically begins with evidence that recovery of the newborn is certain. However, the exact date of discharge may not be predictable. The goal of the discharge plan is to make a successful transition to home care. Essential elements for discharge are a physiologically stable infant, routine discharge screening and vaccination, a family who can provide the necessary care with appropriate support services in place in the community, and a pediatrician or primary care physician or nurse practitioner available for ongoing care (Gupta et al., 2019; Smith & Stewart, 2019).

BOX 23.6 Critical Components of Discharge Planning

- Parental education—involvement and support in newborn care during NICU stay will ensure their readiness to care for the infant at home.
- Evaluation of unresolved medical problems—review of the active problem list and determination of what home care and follow-up is needed.
- Implementation of primary care—completion of newborn screening tests, immunizations, examinations such as funduscopic exam for ROP, and hematologic status evaluation.
- Development of home care plan, including assessment of:
  - equipment and supplies needed for care.
  - in-home caregiver's preparation and ability to care for infant.
  - adequacy of the physical facilities in the home.
  - an emergency care and transport plan if needed.
  - financial resources for home care costs.
  - family needs and coping skills.
  - community resources, including how they can be accessed.

The care of each high-risk newborn after discharge requires careful coordination to provide ongoing multidisciplinary support for the family. The discharge planning team typically includes the parents, primary care physician, neonatologists, neonatal nurses, and a social worker. Other professionals, such as surgical specialists and pediatric subspecialists, occupational, physical, speech, and respiratory therapists, nutritionists, home health care nurses, and a case manager, may be included as needed (Fanaroff & Fanaroff,

2019; Kenner et al., 2020). Critical components of discharge planning are summarized in Box 23.6.

Nurses involved in the discharge process are instrumental in bridging the gap between the hospital and home. When planning for discharge of the high-risk infant, the nurse should:

- Assess the physical status of the mother and the newborn.
- Discuss the early signs of complications and what to do if they occur.
- Reinforce instructions for infant care and safety.
- Stress the importance of proper car seat use.
- Provide instructions for medication administration.
- Reinforce instructions for equipment operation, maintenance, and troubleshooting.
- Teach infant cardiopulmonary resuscitation and emergency care.
- Demonstrate techniques for special care procedures such as dressings, ostomy care, artificial airway maintenance, chest physiotherapy, suctioning, and infant stimulation.
- Provide breastfeeding support or instruction on gavage feedings.
- Assist with defining roles in the adjustment period at home.
- Assess the parents' emotional stability and coping status.
- Provide support and reassurance to the family.
- Report abnormal findings to the health care team for intervention.
- Follow-up with parents to ensure that they have connected with appropriate support systems in the community (Gupta et al., 2019; Kenner et al., 2020).

LATE PRETERM NEWBORN ("NEAR TERM")

The late preterm is a newborn that is born between 34 weeks and 36 6/7 weeks' gestation. Previously, infants born during this time frame were called "near term" or "slightly premature," which was a misnomer because the infants have special care needs. Some of the most common complications for late preterm infants are cold stress, respiratory distress, hypoglycemia, sepsis, cognitive delays, hyperbilirubinemia, and feeding difficulties (Martin & Rosenfeld, 2019). In recent years, the subject of late preterm birth has received

much attention, since this population of preterm newborns represents more than 72% of all preterm births in the United States and continues to increase (Williams & Pugh, 2018). With the sharp rise in the number of cesarean births performed, the incidence of late preterm newborns will also rise. Perinatal nurses need to understand the risks of late preterm births and the unique needs of this population in order to facilitate timely assessment and intervention to improve outcomes. Some of the challenges facing the late preterm newborn include:

- Respiratory distress (related to pulmonary immaturity, lack of adequate surfactant, retained lung fluid, cesarean section)
- Thermoregulation issues (less brown and white, limited ability to flex the trunk and extremities to decrease exposed surface area)
- Hypoglycemia related to the first two challenges (respiratory distress and cold stress)
- Apnea (related to poor respiratory control and immaturity)
- Jaundice and hyperbilirubinemia (related to immature bilirubin conjugation and excretion)
- Feeding challenges related to immature suck and swallowing reflexes
- Sepsis because maternal antibodies are not fully transferred prior to the 37th week
- Neurodevelopmental delay (related to brain and CNS immaturity) (Barfield & Lee, 2020; Huff et al., 2019).

These challenges are similar to those facing the preterm newborn and require similar management. Late preterm newborns have more clinical problems, longer lengths of stay, higher costs when compared with full-term newborns, and increased mortalities (Kenner et al., 2020). Anticipatory guidance for parents of late preterm infants should include recommending an infant cardiopulmonary resuscitation course, educating about sudden infant death syndrome prevention protocol (Back to Sleep), and advising the parents to avoid public places and limit visitors for the first few weeks after being discharged from the hospital. Consistent follow-up medical care, weekly weight checks, and up-to-date immunizations can help late preterm infants avoid complications. Nurses and parents must

be aware of the risks associated with late preterm births to optimize care and outcomes for this group of newborns. For information related to discharge teaching for the family of the late preterm infant, refer to Teaching Guidelines 23.1.

TEACHING GUIDELINES 23.1

Discharging the Late Preterm Infant

When discharge planning for the late preterm infant, validate parents' understanding of:

- dressing the infant appropriately in order to maintain appropriate temperature.
- practicing good handwashing and limiting contact with ill persons.
- maintaining adequate nutritional and fluid intake to promote growth and development; breastfeeding is preferred.
- avoiding secondhand smoke exposure.
- practicing safe sleep practices: avoid soft mattresses or blankets, place infant supine to sleep.
- keeping appointments for health maintenance visits (check-ups) as scheduled.
- notifying the pediatrician or nurse practitioner immediately if the infant:
  - has difficulty breathing or turns blue (call for emergency services in this case).
  - has a temperature below 97° F (36.1° C) or above 100.4° F (38° C).
  - displays a yellow color to the skin (jaundice).
  - feeds poorly.
  - vomits.
  - fails to void for 12 hours, or to pass a bowel movement in 24 hours.
  - acts lethargic, irritable or "just not right".

Preparing for discharge from the neonatal intensive care unit. *Pediatrics*, *143*(6). e20182915. https://doi.org/10.1542/peds.2018-2915; Smith, V. C., & Stewart, J. (2019). Discharge planning for high risk newborns. *UpToDate*. Retrieved June 16, 2020, from https://www.uptodate.com/contents/discharge-planning-for-high-risk-newborns.

TAKE NOTE!

Compared to the term infant, late preterm infants are more likely to be affected by infections, hypothermia, hypoglycemia, respiratory distress, apnea, jaundice, feeding difficulties, and neurodevelopmental delays in the first years of life. They place a significant burden on the health care and educational systems (Huff et al., 2019).

Dealing with Perinatal Loss

Pregnancy is typically a time of joy and anticipation, but nurses are called upon at times to be with women during heartbreaking circumstances. It is estimated that over 7 million perinatal losses occur globally each year. More than 1 million occur within the United States annually (CDC, 2019). Perinatal loss, defined as any pregnancy loss and/or neonatal death up to 1 month of age, continues to be a common occurrence even though major advances have taken place in perinatal health care. The prevalence of perinatal death reflects a very real possibility that all nurses will meet and care for a woman who has experienced the death of a baby (Jordan et al., 2019).

Perinatal loss is a profound experience for the family. Grief is universal, but the response to it, is individual. The loss of a dreamed for pregnancy/infant is both a physiologic event for a woman, as well as an emotional and sociocultural one. It engenders a unique kind of mourning since the infant is so much a part of the parents' identity. Instead of celebrating a new life as they expected, parents are mourning the loss of dreams and hopes and the loss of an extension of themselves. NICU nurses face a difficult situation when caring for newborns who may not survive. Newborn death is incomprehensible to most parents/partners/significant others. They are commonly offered time to see their infant, memory items, and support. This can make the grieving process more difficult because of the denial the parents commonly experience: what is happening "can't be real." Deciding whether to see, touch, or hold the dying newborn is extremely difficult for many parents. Nurses play a major role in

assisting parents/partners/significant others to make their dying newborn “real” to them by providing them with as many memories as possible and encouraging them to see, hold, touch, dress, and take care of the infant and take photographs. These actions help to validate the partners’/significant others’/parents’ sense of loss, relive the experience, and attach significance to the meaning of loss. A lock of hair, a name card, or an identification bracelet may serve as important mementos that can ease the grieving process. The memories created by these interventions can be useful allies in the grieving process and in resolving grief. Nurses have the honor of walking alongside those parents whose infant died must remember that moments/memories matter to them (Heazell et al., 2019; Limbo & Hutti, 2019).

A nurse’s willingness to sit quietly and observe, to remain open and nonjudgmental, and to explore what might be helpful are useful strategies to bridge cultural differences. Statements such as, “Help me understand how your family cares for someone who is dying,” or, “What would be important for me to know about how best to care for your baby’s body?” convey a nurse’s willingness to learn what is most important to each family. Parents’ answers may help guide nurses in providing culturally appropriate care for diverse populations. Nurses who are attentive to learning what is most important to parents, and subsequently work to incorporate such interventions into their care, foster relationships between parents and their infant (Willis, 2019).

Parent–newborn interaction is vital to the normal processes of attachment and bonding. The detachment process involved in a newborn’s death is equally important for parents. Nurses can aid in this process by helping parents to see their newborn through the maze of equipment, explaining the various procedures and equipment, encouraging them to express their feelings about the newborn’s status, and providing time for them to be with their dying newborn. Nurses should use insightful and empathetic communication skills to help parents cope with their loss (Jordan et al., 2019).

A common reaction by many people when learning that a newborn is not going to survive is one of avoidance. Nurses are no exception. It is difficult to initiate a conversation about such a sensitive issue without knowing how the parents are going to react and cope with the impending loss. One way to begin a conversation with the parents is to convey concern and acknowledge their loss. Active listening can give parents a safe place to begin the healing process. The relationship that the nurse establishes with the parents is a unique one, providing an opportunity for both the nurse and the parents to share their feelings.

Be aware of personal feelings about loss and how these feelings are part of one's own life and personal belief system. Actively listen to the parents when they are talking about their experiences. Communicate empathy (understanding and feeling what another person is feeling), respect their feelings, and respond to them in helpful and supportive ways (Cunningham et al., 2018). Table 23.2 highlights appropriate interventions for a family experiencing a perinatal loss before and after a newborn dies.

In a time of crisis or loss, people are often more sensitive to other people's reactions. For example, the parents may be extremely aware of the nurse's facial expressions, choice of words, and tone of voice. Talking quickly, in a businesslike fashion, or ignoring the loss may inhibit parents from discussing their pain or how they are coping with it. Parents may need to vent their frustrations and anger, and the nurse may become the target. Validate their feelings and attempt to reframe or refocus the anger toward the real issue of loss. An example would be to say, "I understand your frustration and anger about this situation. You have experienced a tremendous loss and it must be difficult not to have an explanation for it at this time." Doing so helps to defuse the anger while allowing them to express their feelings.

TABLE 23.2 Assisting Parents to Cope with Perinatal Loss

Before the newborn's death	Respect variations in the family's spiritual needs and readiness. Assess cultural beliefs and practices that may bring comfort; respect culturally appropriate requests for truth telling and informed refusal. Initiate spiritual comfort by calling the hospital clergy if appropriate; offer to pray with the family if appropriate. Encourage the parents to take photographs, make memory boxes, and record their thoughts in a journal. Explore with family members how they dealt with previous losses. Discuss techniques to reduce stress, such as meditation and relaxation. Recommend that family members maintain a healthy diet and get adequate rest and exercise to preserve their health. Participate in early and repeated care conferencing to reduce family stress. Allow family to be present at both medical rounds and resuscitation; provide explanations of all procedures, treatments, and findings; answer questions honestly and as completely as possible. Provide opportunities for the family to hold the newborn if they so choose. Assess the family's support network. Provide suggestions as to how friends can be helpful to the family.
After the newborn's death	Help the family to accept the reality of death by using the word "died." Acknowledge their grief and the fact that their newborn has died. Help the family to work through their grief by validating and listening. Provide the family with realistic information about the causes of death. Offer condolences to the family in a sincere manner.

	Encourage the father to cry and grieve with his partner. Provide opportunities for the family to hold the newborn if they desire.
At the time of the release of the newborn's body	Reassure the family that their feelings and grieving responses are normal. Encourage the parents to have a funeral or memorial service to bring closure. Suggest that the parents plant a tree or flowers to remember the infant. Address attachment issues concerning subsequent pregnancies. Provide information about local support groups. Provide anticipatory guidance regarding the grieving process. Present information about any impact on future childbearing, and refer the parents to appropriate specialists or genetic resources.

Adapted from Heazell, A. E., Wojcieszek, A., Graham, N., & Stephens, L. (2019). Care in pregnancies after stillbirth and perinatal death. *International Journal of Birth and Parent Education*, *6*(2), 23–28; Jordan, R. G., Farley, C. L., & Grace, K. T. (2019). *Prenatal and postnatal care: A woman-centered approach* (2nd ed.). John Wiley & Sons, Inc.; and Kenner, C., Altimier, L., & Boykova, M. V. (Eds.). (2020). *Comprehensive neonatal nursing care* (6th ed.). Springer Publishing Company.

The death of an infant will more than likely be one of the toughest moments in a family's life. Giving families some sense of control in an otherwise hopeless situation can provide some comfort. Some ideas to provide them a sense of control include:

- Ask the family who they wish to have present as the infant dies.
- Give the family a choice of rooms in which they can say good-bye to their infant.
- Provide privacy for the family during this time period by placing a sign on the door.
- Provide ideas for making or selecting memorial items for a memory box.
- The family should never be left to handle their emotions alone unless they request it.

- Respect a family's wishes if they refuse to be with their infant during the dying process or afterward. Everyone grieves differently.

When assisting bereaved parents, start where the parents are in the grief process to avoid imposing your own agenda on them. You may feel uncomfortable at not being able to change the situation or take the pain away. The nurse's role is to provide immediate emotional support and facilitate the grieving process. Supporting and strengthening the family bond in the face of perinatal loss is essential.

Comforting the family after the infant's death is vital to give them a sense of closure and start the healing process. Some things the nurse can do to help the family during this time include:

- Sending the family a card from the nursing staff, signed by all who worked with their infant, within a week of leaving the hospital
- Attending the funeral to allow for a public good-bye and to support others in their time of loss
- Assessing parental desires for special end-of-life rituals, such as spiritual practices
- Inviting parents to annual remembrance ceremonies sponsored by the hospital
- Providing the family with a memory box, which might contain an outfit worn by their infant, a blanket used to cover their infant, a lock of hair, a card with hand and footprints, and a photo with someone holding their infant
- Remembering their infant at various anniversaries by sending a card or calling the family to see how they are doing provides families much-needed comfort
- Donating to a charity in memory of the infant, such as to March of Dimes
- Providing the family with resources that might help them. Information might include listings of local or online support groups as well as grief websites such as Share.org

Being present during this traumatic event for families is tough. Serving infants and their families by bearing witness to their pain and grief is a special privilege. Being present for the family with compassion, comfort, support, and resources during their time of

loss is truly an honorable gesture. Nurses are well positioned to provide clear, compassionate communication and anticipatory guidance to women experiencing perinatal loss. Attending to spiritual needs, harnessing family support, providing mementos, and encouraging reflection through journaling may help women find meaning and new perspectives on their bereavement experience. Nurses are remembered years later for their kindness and guidance of the family members through this adverse event with dignity (Wool & Catlin, 2018).

NURSING CARE PLAN 23.1 Overview of the Care of a Preterm Newborn

Alice, an 18-year-old, felt she had done everything right during her first pregnancy and certainly didn't anticipate giving birth to a preterm newborn at 32 weeks' gestation. When Mary Kaye was born, she had respiratory distress and hypoglycemia and couldn't stabilize her temperature. Assessment revealed the following: newborn described as scrawny in appearance; skin thin and transparent with prominent veins over abdomen; hypotonic with lax, extended positioning; weak sucking reflex when nipple offered; respiratory distress with tachypnea (70 breaths/min), nasal flaring, and sternal retractions; low blood glucose level suggested by lethargy, tachycardia, jitteriness; axillary temperature of 36° C (96.8° F) despite warmed blanket; weight 2,146 g (4.73 lb); length 45 cm (17.72 in).

NURSING ANALYSIS: Ineffective breathing pattern related to immature respiratory system and respiratory distress as evidenced by tachypnea, nasal flaring, sternal retractions, and/or oxygen saturation <87%

OUTCOME IDENTIFICATION AND EVALUATION

Newborn's respiratory status returns to adequate level of functioning as evidenced by rate remaining within 30 to 60 breaths/min, maintenance of acceptable oxygen saturation levels, and minimal to absent signs of respiratory distress.

INTERVENTIONS: *Promoting Optimal Breathing Pattern*

- Assess gestational age and risk factors for respiratory distress *to allow early detection*.
- Anticipate need for bag and mask setup and wall suction *to allow for prompt intervention should respiratory status continue to worsen*.
- Assess respiratory effort (rate, character, effort) *to identify changes*.
- Assess heart rate for tachycardia and auscultate heart sounds *to determine worsening of condition*.
- Observe for cues (grunting, shallow respirations, tachypnea, apnea, tachycardia, central cyanosis, hypotonia, increased effort) *to identify need for additional oxygen*.
- Maintain slight head elevation *to prevent upper airway obstruction*.
- Assess skin color *to evaluate tissue perfusion*.
- Monitor oxygen saturation level via pulse oximetry *to provide objective indication of perfusion status*.

- Provide supplemental oxygen as indicated and ordered *to ensure adequate tissue oxygenation*.
- Assist with any ordered diagnostic tests, such as chest x-ray and arterial blood gases, *to determine effectiveness of treatments*.
- Cluster nursing activities *to reduce oxygen consumption*.
- Maintain a neutral thermal environment *to reduce oxygen consumption*.
- Monitor hydration status *to prevent fluid volume deficit or overload*.
- Explain all events and procedures to the parents *to help alleviate anxiety and promote understanding of the newborn's condition*.

NURSING ANALYSIS: Ineffective thermoregulation related to lack of fat stores and hypotonia as evidenced by extended positioning, low axillary temperature despite warmed blanket/radiant heat source/isolette, respiratory distress, and lethargy

OUTCOME IDENTIFICATION AND EVALUATION

Newborn will demonstrate ability to regulate temperature as evidenced by temperature remaining in normal range (36.5° to 37.5° C) and absent signs of cold stress.

INTERVENTIONS: ***Promoting Thermoregulation***

- Assess the axillary temperature every hour or use a thermistor probe *to monitor for changes*.
- Review maternal history *to identify risk factors contributing to problem*.
- Monitor vital signs, including heart rate and respiratory rate, every hour *to identify deviations*.
- Check radiant heat source or isolette *to ensure maintenance of appropriate temperature of the environment*.
- Assess environment for sources of heat loss or gain through evaporation, conduction, convection, or radiation *to minimize risk of heat loss*.
- Avoid bathing and exposing newborn *to prevent cold stress*.
- Warm all blankets and equipment that come in contact with newborn; place warmed cap on the newborn's head and keep it on *to minimize heat loss*.
- Encourage kangaroo care (mother or father holds preterm infant underneath clothing skin-to-skin and upright between breasts) *to provide warmth*.
- Educate parents on how to maintain a neutral thermal environment, including importance of keeping the newborn warm with a cap and double-wrapping with blankets and changing them frequently to keep dry *to promote newborn's adjustment*.
- Demonstrate ways *to safeguard warmth and prevent heat loss*.

NURSING ANALYSIS: Risk for imbalanced nutrition: less than body requirements to meet metabolic needs related to poor sucking and lack of glycogen stores necessary to meet the newborn's increased metabolic demands

OUTCOME IDENTIFICATION AND EVALUATION

Newborn will demonstrate adequate nutritional intake to progressively gain weight toward desired goal, remaining free of signs of hypoglycemia as evidenced by blood glucose levels being maintained above 45 mg/dL, enhanced sucking ability, and appropriate weight gain.

INTERVENTIONS: *Promoting Optimal Nutrition*

- Identify newborn at risk based on behavioral characteristics, body measurements, and gestational age *to establish a baseline and allow for early detection*.
- Assess blood glucose levels as ordered *to determine status and establish a baseline for interventions*.
- Obtain blood glucose measurements upon admission to nursery and every 1 to 2 hours as indicated *to evaluate for changes*.
- Observe behavior for signs of low blood glucose *to allow early identification*.
- Initiate early oral feedings or gavage feedings *to maintain blood glucose levels*.
- If oral or gavage feedings aren't tolerated, initiate an IV glucose infusion *to aid in stabilizing blood glucose levels*.
- Assess skin for pallor and sweating *to identify signs of hypoglycemia*.
- Assess neurologic status for tremors, seizures, jitteriness, and lethargy *to identify further drops in blood glucose levels*.
- Monitor weight daily for changes *to determine effectiveness of feedings*.
- Maintain temperature using warmed blankets, radiant warmer, or warmed isolette *to prevent heat loss and possible cold stress and reduce energy demands*.
- Monitor temperature *to prevent cold stress resulting in decreased blood glucose levels*.
- Offer opportunities for nonnutritive sucking on premature-size pacifier *to satisfy sucking needs*.
- Monitor for tolerance of oral feedings, including intake and output, *to determine effectiveness*.
- Administer IV dextrose if newborn is symptomatic *to raise blood glucose levels quickly*.
- Decrease energy requirements, including clustering care activities and providing rest periods, *to conserve glucose and glycogen stores*.

- Inform parents about procedures and treatments, including rationale for frequent blood glucose levels, *to help reduce their anxiety*.

KEY CONCEPTS

- Variations in birth weight and gestational age can place a newborn at risk for problems that require special care.
- Variations in birth weight include the following categories: small for gestational age, appropriate for gestational age, and large for gestational age. Newborns who are small or large for gestational age have special needs.
- The small-for-gestational-age newborn faces problems related to a decrease in placental function in utero; these problems may include perinatal asphyxia, hypothermia, hypoglycemia, polycythemia, and meconium aspiration.
- Risk factors for the birth of a large-for-gestational-age infant include maternal diabetes mellitus or glucose intolerance, multiparity, prior history of a macrosomic infant, postdates gestation, maternal obesity, male fetus, and genetics. Large-for-gestational-age newborns face problems such as birth trauma due to cephalopelvic disproportion, hypoglycemia, and jaundice secondary to hyperbilirubinemia.
- Variations in gestational age include postterm and preterm newborns. Postterm newborns may be large or small for gestational age or dysmature, depending on placental function.
- The postterm newborn may develop complications after birth, including fetal hypoxia, hypoglycemia, hypothermia, polycythemia, and meconium aspiration.
- Preterm birth is the leading cause of death within the first month of life and the second leading cause of all infant deaths.
- The preterm newborn is at risk for complications because his or her organ systems are immature, thereby impeding the transition from intrauterine life to extrauterine life.
- Newborns can experience pain, but their pain is difficult to validate with consistent behaviors.
- Newborns with gestational age variations, primarily preterm newborns, benefit from developmental care, which includes a variety of activities designed to manage the environment and individualize the care based on behavioral observations.
- Nurses play a key role in assisting the parents and family of a newborn with special needs to cope with this crisis situation, including dealing with the possibility that the newborn may not

survive. Nurses working with parents experiencing a perinatal loss can help by actively listening, understanding the parents' experiences, and communicating empathy.
- The goal of discharge planning is to make a successful transition to home care.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. The nurse documents that a newborn is postterm based on the understanding that he was born after

   a. 38 weeks' gestation.
   b. 40 weeks' gestation.
   c. 42 weeks' gestation.
   d. 44 weeks' gestation.

2. SGA and LGA newborns have an excessive number of red blood cells related to

   a. hypoxia.
   b. hypoglycemia.
   c. hypocalcemia.
   d. hypothermia.

3. Because subcutaneous and brown fat stores were used for survival in utero, the nurse would assess an SGA newborn for which of the following?

   a. Hyperbilirubinemia
   b. Hypothermia
   c. Polycythemia
   d. Hypoglycemia

4. When assessing a preterm newborn, which of the following findings would be of greatest concern?

   a. Milia over the bridge of the nose
   b. Thin transparent skin
   c. Poor muscle tone
   d. Heart murmur

5. When caring for parents experiencing a perinatal loss, which of the following nursing interventions would be most appropriate?

   a. Sheltering the parents from the bad news
   b. Making all the decisions regarding care
   c. Encouraging them to participate in the newborn's care
   d. Leaving them by themselves to allow time to grieve

6. The nurse is providing care to several newborns with variations in gestational age and birth weight. When developing the plan of care for these newborns, the nurse focuses on energy conservation to promote growth and development. Which measures would the nurse include in the nursing plans of care? Select all that apply.

   a. Keeping the handling of the newborn to a minimum
   b. Maintaining a neutral thermal environment
   c. Decreasing environmental stimuli
   d. Initiating early oral feedings
   e. Using thermal warmers in all cribs

7. Which of the following concepts would the nurse incorporate into the plan of care when assessing pain in a newborn with special needs?

   a. Newborns experience pain primarily with surgical procedures.
   b. Preterm newborns in the NICU are at least risk for pain.
   c. Pain assessment needs to be comprehensive and frequent.
   d. A newborn's facial expression is the primary indicator of pain.

8. Evidence-based practice refers to the use of which of the following to validate your practice?

   a. Research findings
   b. Written guidelines

c. Traditional practices
d. Institutional policies

CRITICAL THINKING EXERCISES

1. After fetal distress was noted on the monitor, a postterm newborn was delivered via a difficult vacuum extraction. The newborn had low Apgar scores and had to be resuscitated before being transferred to the nursery. Once admitted, the nurse observed the following behaviors: jitteriness, tremors, hypotonia, lethargy, and rapid respirations.
   a. What might these behaviors indicate?
   b. For what other conditions might this newborn be at high risk?
   c. What intervention is needed to address this newborn's condition?

2. A preterm newborn was born at 35 weeks following a placental abruption due to a car accident. He was transported to the NICU at a nearby regional medical center. After being stabilized, he was placed in an isolette close to the door and placed on a cardiac monitor. A short time later, the nurse notices that he is cool to the touch and lethargic, has a weak cry, and has an axillary temperature of 36° C.
   a. What might have contributed to this newborn's hypothermic condition?
   b. What transfer mechanism may have been a factor?
   c. What intervention would be appropriate for the nurse to initiate?

3. A term SGA newborn weighing 4 lb was brought to the nursery for admission a short time after birth. The labor and birth nurse reports the mother was a heavy smoker and a cocaine addict and experienced physical abuse throughout her pregnancy. After stabilizing the newborn

and correcting the hypoglycemia with oral feedings, the nurse observes the following: acrocyanosis, ruddy color, poor circulation to the extremities, tachypnea, and irritability.

a. What complication might this SGA newborn be manifesting?
b. What factors may have contributed to this complication?
c. What would be an appropriate intervention to manage this condition?

STUDY ACTIVITIES

1. At a community health department maternity clinic, secure permission to interview the parents of a special needs child. Ask about their feelings throughout the experience. How are they managing and coping now?
2. Visit the March of Dimes website and review this group's national campaign to reduce the incidence of prematurity. Are their strategies workable or not? Explain your reasoning.
3. A common metabolic disorder present in both SGA and LGA newborns after birth is _____.
4. A 10-lb LGA newborn is brought to the nursery after a difficult vaginal birth. The nursery nurse should focus on detecting birth injuries such as _____.

BRINGING IT ALL TOGETHER: A CASE STUDY

Taylor was born at 29 weeks. Her premature birth has resulted in an increased risk both for respiratory distress and for hypothermia. Her parents, Susan and Harvey, are interested and involved in Taylor's condition and care but are understandably anxious regarding their first child's health status. She is being cared for by nurses in the neonatal intensive care unit (NICU) of the university-affiliated medical center where she was born.

Go to thePoint to find questions to consider about this case.

Nursing Management of the Newborn at Risk: Acquired and Congenital Newborn Conditions

WOW

WORDS OF WISDOM

Courage and faith in oneself project onto others, giving them the strength to persevere.

KEY TERMS

acute bilirubin encephalopathy
chronic bilirubin encephalopathy
fetal alcohol spectrum disorder (FASD)
gastroschisis
hyperbilirubinemia
hypoxic-ischemic encephalopathy
infant of a diabetic mother (IDM)
kernicterus
meconium aspiration syndrome (MAS)
neonatal abstinence syndrome (NAS)
neonatal sepsis
neural tube defect (NTD)
omphalocele
respiratory distress syndrome (RDS)

LEARNING OBJECTIVES

After completion of the chapter, you will be able to:

1. Describe the most common acquired conditions affecting the newborn.
2. Characterize the nursing management of a newborn experiencing respiratory distress syndrome.
3. Outline the birthing room preparation and procedures necessary to prevent meconium aspiration syndrome in the newborn at birth.
4. Differentiate risk factors for the development of necrotizing enterocolitis.
5. Analyze the impact of maternal diabetes on the newborn and the care needed.
6. Evaluate the assessment and intervention for a newborn experiencing substance withdrawal after birth.
7. Develop assessment and nursing management for newborns sustaining trauma and birth injuries.
8. Review the assessment, interventions, prevention, and management of hyperbilirubinemia in newborns.
9. Summarize the interventions appropriate for a newborn with neonatal sepsis.

10. Formulate a plan of care for a newborn with an acquired or congenital condition.
11. Relate the importance of parental participation in care of the newborn with a congenital or acquired condition, including the nurse's role in facilitating parental involvement.

Kelly, a 27-year-old G2P1, comes to the labor and birth area in active labor. She tells you she is overdue and relieved to finally be giving birth. Her membranes rupture on admission, revealing meconium-stained fluid. What additional nursing assessments need to be carried out now? What risk factors need to be considered when developing Kelly's plan of care?

INTRODUCTION

Advances in prenatal and neonatal medical and nursing care throughout the industrialized world have led to a marked increase in the number of newborns who have survived a high-risk pregnancy, but experience acquired or congenital conditions. These newborns are considered one of our most vulnerable at-risk populations—that is, they are susceptible to morbidity and mortality because of the acquired or congenital disorder. One of the leading health indicators as identified by *Health People 2030* refers to decreasing the number of infant deaths. Acquired and congenital conditions account for a significant percentage of infant deaths. See *Healthy People 2030.*

HEALTHY PEOPLE *2030*

Objective	Nursing Significance
Reduce the rate of fetal deaths at 20 or more weeks of gestation. Reduce the rate of all infant deaths (within 1 year).	• Foster early and consistent prenatal care. • Include education to place infants on their backs for naps and sleep to prevent sudden infant death syndrome (SIDS). • Avoid exposing newborns to cigarette smoke. • Ensure that infants with birth defects receive health care needed in order to thrive.

Adapted from USDHHS. (2020). *Proposed objectives for inclusion in Healthy People 2030.* https://www.healthypeople.gov/sites/default/files/ObjectivesPublicComment508.pdf

During the past several decades' technologic and pharmacologic advances, genomic discoveries, and standardized policies and procedures have significantly improved survival rates for at-risk newborns. However, the risk of morbidity remains an important sequela. For example, some of these newborns are at risk for continuing health problems that require long-term technologic support. Other newborns remain at risk for physical and developmental problems into the school years and beyond. Although challenges exist in application of these advances to improve the newborn's health, the high-risk newborn will increasingly benefit from them in the future. Providing the complex care needed to maintain the child's health and well-being will have a tremendous emotional and economic impact on the family. Nurses are challenged to provide support to mothers and their families when neonatal well-being is threatened.

Acquired disorders typically occur at or soon after birth. They may result from problems or conditions experienced by the woman during her pregnancy or at birth, such as diabetes, maternal infection, or substance abuse, or conditions associated with labor and birth, such as prolonged rupture of membranes or fetal distress. However, there may be no identifiable cause for the disorder.

Congenital disorders can be defined as structural, functional or metabolic abnormalities at birth. According to the Centers for Disease Control and Prevention (CDC, 2020), 3% of all newborns in the United States have birth defect. The most common serious defects worldwide are congenital heart defects, neural tube defects, and Down syndrome (World Health Organization [WHO], 2016). Congenital disorders, which often involve a problem with inheritance, include structural anomalies (commonly referred to as birth defects), chromosomal disorders, and inborn errors of metabolism. Most congenital disorders have a complex etiology, involving many interacting genes, gene products, and social and environmental factors during organogenesis (the origin and development of organs). Some alterations can be prevented or compensated for with pharmacologic, nutritional, or other types of interventions, while others cannot be changed. Only through a better understanding of the complex interplay of genetic, environmental, social, and cultural factors can these devastating and life-changing outcomes be prevented.

The field of genomics and genetic medicine has witnessed an explosion of new knowledge, much of it learned from the Human Genome Project. Advances in understanding of the genetic basis of development and function, as well as the interaction of genes and the environment, continue

to foster new insights into human health. This chapter addresses selected acquired and congenital newborn conditions. In addition, it describes the nurse's role in assessment and management, emphasizing parental education and support. Nurses play a key role in helping the parents cope with the stress of having an ill newborn.

ACQUIRED DISORDERS

Acquired disorders are not passed genetically or caused by hereditary or developmental factors; they are obtained after birth by a reaction to environmental influences outside of the body. Examples of acquired disorders include hypoxic-ischemic encephalopathy (HIE), respiratory distress syndrome (RDS), meconium aspiration syndrome (MAS), persistent pulmonary hypertension of the newborn (PPHN), intraventricular hemorrhage, necrotizing enterocolitis (NEC), retinopathy of prematurity, birth trauma, hyperbilirubinemia, and newborn infections.

Hypoxic-Ischemic Encephalopathy

At birth, the newborn's lungs are filled with fluid. This fluid must be cleared and replaced with air for successful respiration to begin after birth. As the newborn makes the transition to life outside the fluid-filled intrauterine environment, dramatic changes must occur to facilitate newborn respirations. Newborns normally start to breathe with routine warming, drying, airway suctioning, and mild stimulation. Most newborns make this transition such that by 1 minute of age, they are breathing well on their own. A newborn who fails to establish adequate, sustained respiration after birth is said to have asphyxia. Physiologically, asphyxia can be defined as impairment in gas exchange resulting in a decrease in blood oxygen levels (hypoxemia) and an excess of carbon dioxide or hypercapnia that leads to acidosis. It occurs when pulmonary oxygenation is delayed or interrupted. The newborn who experiences asphyxia is at risk for the development of HIE. **Hypoxic-ischemic encephalopathy** is characterized by clinical and laboratory evidence of acute or subacute brain injury due to systemic hypoxemia or reduced cerebral blood flow (Ahlfeld, 2020).

HIE is a leading cause of neonatal brain injury, morbidity, and mortality globally. Approximately 30% of infants with HIE die in the neonatal period, with up to 50% of survivors left with permanent neurodevelopmental abnormalities (Cunningham et al., 2018). Newborns who survive asphyxia

at birth may develop long-term problems such as cerebral palsy, intellectual disability, speech disorders, hearing and/or visual impairment, and learning disabilities (Zanelli et al., 2018).

Pathophysiology

Asphyxia occurs when oxygen delivery is insufficient to meet metabolic demands, resulting in hypoxia, hypercarbia, and metabolic acidosis. Any condition that reduces oxygen delivery to the fetus can result in asphyxia. These conditions may include maternal hypoxia, such as from cardiac or respiratory disease, anemia, or postural hypotension; maternal vascular disease that leads to placental insufficiency, such as diabetes or hypertension; cord problems such as compression or prolapse; and post-term pregnancies, which may trigger meconium release into the amniotic fluid.

Initially, the newborn uses compensatory mechanisms including tachycardia and vasoconstriction to help bring oxygen to the vital organs for a time. However, without intervention, these mechanisms fail, leading to hypotension, bradycardia, and eventually cardiopulmonary arrest.

With failure to breathe well after birth, the newborn will develop hypoxia (too little oxygen in the cells of the body). As a result, the heart rate falls, cyanosis develops, and the newborn becomes hypotonic and unresponsive. Newborn resuscitation is needed to help initiate breathing in newborns that fail to breathe spontaneously at birth.

Nursing Assessment

The key to successful treatment of newborn HIE is early identification and recognition of newborns that may be at risk. Review the perinatal history for risk factors, including:

- Trauma: injury to the central or peripheral nervous system secondary to a long or difficult labor, a precipitous birth, multiple gestation, abnormal presentation, cephalopelvic disproportion, shoulder dystocia, or extraction by forceps or vacuum
- Intrauterine asphyxia: for example, fetal hypoxia secondary to maternal hypoxia, diabetes, hypertension, anemia, cord compression, or meconium aspiration
- Sepsis: acquired bacterial or viral organisms from infected amniotic fluid, maternal infection, or direct contact while passing through the birth canal

- Malformation: congenital anomalies including facial or upper airway deformities, renal anomalies, pulmonary hypoplasia, neuromuscular disorders, esophageal atresia, or neural tube defects
- Hypovolemic shock: secondary to placental abruption, placenta previa, or cord rupture resulting in blood loss to the fetus
- Medication: drugs given to mother during labor that can affect the fetus by causing placental hypoperfusion and hypotension; use of hypnotics, excessive maternal oxytocin administered, analgesics, anesthetics, narcotics, oxytocin, and street drugs during pregnancy (Fanaroff & Fanaroff, 2020)

At birth, assess the newborn immediately. Observe the infant's color, noting any pallor or cyanosis. Assess the work of breathing. Be alert for apnea, tachypnea, gasping respirations, grunting, nasal flaring, or retractions. Evaluate heart rate and note bradycardia. Assess the newborn's temperature, noting hypothermia. Determine the Apgar score at 1 and 5 minutes; if less than 7 at 5 minutes, repeat the assessment at 10 minutes of age. If the initial assessment is poor, begin resuscitation measures until the Apgar score is above 7.

Laboratory or diagnostic testing may be used to identify etiologies for the newborn's asphyxia. For example, a chest x-ray may identify structural abnormalities that might interfere with respiration. A blood culture may identify an infectious process. A blood toxicology screen may detect any maternal drugs in the newborn (Kenner et al., 2020).

Methods of testing to identify the fetus at risk for developing HIE continue to be developed and refined. The perinatal nurse needs to be knowledgeable of each test's purpose, capabilities, limitations, and clinical issues. Appropriate nursing interventions based on this knowledge facilitate the testing process and promote the goal of improved perinatal outcome.

Nursing Management

Management of the newborn experiencing asphyxia includes immediate resuscitation. Ensure that the equipment needed for resuscitation is readily available and in working order. Essential equipment includes a wall suction apparatus, an oxygen source, a newborn ventilation bag, endotracheal tubes (2 to 3 mm), infant warmer, surgical blue towels, a laryngoscope, and ampules of naloxone (Narcan) with syringes and needles for administration. Effective ventilation is essential to successful newborn resuscitation.

Ventilation is frequently initiated with a manual resuscitation bag and face-mask followed by endotracheal intubation if respiratory depression continues (see Chapter 23 for a more detailed discussion of resuscitation).

Dry the newborn quickly with a warm towel and then place him or her under a radiant heater to prevent rapid heat loss through evaporation. Handling and rubbing the newborn with a dry towel may be all that is needed to stimulate the onset of breathing. If the newborn fails to respond to stimulation, then active resuscitation is needed.

The procedure for newborn resuscitation is easily remembered by the "C-A-B" s"—Compressions-Airway-Breathing (see Chapter 23, Box 23.3). Continue resuscitation until the newborn has a pulse above 100 bpm, a good healthy cry, or good breathing efforts and a pink tongue. This last sign indicates a good oxygen supply to the brain (Martin et al., 2020).

TAKE NOTE!

According to the American Academy of Pediatrics (AAP) and American Heart Association (AHA) Neonatal Resuscitation Program, resuscitation efforts may be stopped if the newborn exhibits no detectable heart rate after 10 minutes of continuous and adequate resuscitation (AAP & AHA, 2016).

Provide continued observation and assessment of the newborn that has been successfully resuscitated. Monitor the newborn's vital signs and oxygen saturation levels closely for changes. Maintain a neutral thermal environment to prevent hypothermia, which would increase the newborn's metabolic and oxygen demands. Check the blood glucose level and observe for signs of hypoglycemia; if this develops, it can further stress the newborn.

The need for resuscitative measures can be extremely upsetting for the parents/partners/significant others. Explain to them the initial resuscitation activities being performed and offer ongoing explanations about any procedures being done, equipment being used, or medications given. Provide presence and support to them throughout the procedure and give frequent updates about procedures being used on their newborn.

Therapeutic hypothermia is a promising neuroprotective intervention for newborns with moderate to severe HIE and has currently been incorporated in many neonatal intensive care units (NICUs). This therapy prevents further damage known as reperfusion injury, which occurs when normal oxygenation and blood flow are restored too quickly to the brain's

cells. After oxygen deprivation, rapid oxygenation can cause more inflammation. Hypothermia treatment works to stabilize the brain's cells and prevent or limit damaging inflammation (Blackburn, 2018). Some infants with encephalopathy will benefit from hypothermia therapy though some will still develop significant adverse outcomes. Cooling the whole body to 33.5°C within the first 6 hours of birth and continuing for a period of up to 72 hours, may slow progression of HIE (Schump, 2018). To enhance the outcome, specific diagnostic predictors are needed to identify newborns likely to benefit from hypothermia treatment (Davies et al., 2019). This treatment decision must be made a collaborative one with the parents' full understanding of the risks involved. With the addition of therapeutic hypothermia as a treatment modality for HIE, many newborns are given the opportunity for a better outcome. Nurses are in a unique position to detect parent anxiety and to maintain therapeutic communication that may help support them through this crisis.

Provide physical and emotional support to the parents through the initial crisis and throughout the newborn's stay. When the newborn is stable, allow parents to spend time with their newborn to promote bonding (Fig. 24.1). Point out the newborn's positive attributes (color, activity, healthy cry) and give frequent updates on his or her status. Role-model techniques for holding, interacting with, and caring for the newborn will assist to decrease the parents' anxiety.

Nurses need to remember developmental care practices for infants with HIE. A team approach incorporating developmental goals and intervention strategies into the nursing care of these infants is essential for optimal developmental outcome. Therapeutic management must always be appropriate for the infant's health status and gestational age. An understanding of the scientific basis for intervention and the therapeutic management techniques for newborns that are sick, recuperating, or convalescing will help the nurse to promote optimal development when caring for the asphyxiated infant (Resnik et al., 2019).

FIGURE 24.1. A father and sibling interacting with his newborn once the newborn's condition has stabilized.

Remember Kelly, the young woman described at the beginning of the chapter? Her son is intubated and tracheal suctioning is performed. Positive-pressure ventilation is also started with a self-inflating bag and 50% oxygen. Ventilation is continued for 1 minute and then gradually discontinued. The heart rate is now 120 bpm, and spontaneous respirations are noted. When free-flow oxygen is administered, the newborn begins to cry and turn pink. What continued care is needed in the special care nursery? What explanation should be offered to Kelly regarding her son?

Transient Tachypnea of the Newborn

Transient tachypnea of the newborn (TTN) is a self-limiting condition characterized by inadequate or delayed clearance of lung fluid leading to transient pulmonary edema. The newborn experiences a mild degree of respiratory distress that requires minimal intervention. It usually occurs within a few hours of birth and resolves by 72 hours of age. TTN occurs in approximately 1% to 2% of all live births and incidence is higher in males than females (Jha & Makker, 2020).

Lower gestational age, cesarean birth, a perinatal hypoxic stress event, and male sex are independent risk factors for TTN. Performing elective cesarean sections no earlier than 39 weeks' gestation may decrease the risk of TTN. Labor before a cesarean section is not sufficient to decrease

the frequency of TTN, even after 37 weeks' gestation, whereas vaginal birth appears to be protective against it (Martin & Rosenfeld, 2019).

Pathophysiology

Most newborns make the transition from fetal to newborn life without incident. During fetal life, the lungs are filled with a serous fluid because the placenta, not the lungs, is used for nutrient and gas exchange. During and after birth, this fluid must be removed and replaced with air. An infant born by cesarean birth is at risk of having excessive pulmonary fluid as a result of not having experienced all the stages of labor. Passage through the birth canal during a vaginal birth compresses the thorax, which helps remove the majority of this fluid. Pulmonary circulation and the lymphatic drainage remove the remaining fluid shortly after birth. TTN occurs when the liquid in the lung is removed slowly or incompletely.

Nursing Assessment

Astutely observe the newborn with respiratory distress because TTN is a diagnosis of exclusion. Initially it might be difficult to distinguish this condition from RDS or group B streptococcal pneumonia, since the clinical picture is similar. However, the symptoms of transient tachypnea rarely last more than 72 hours and if they do, further investigation is warranted (Ahlfeld, 2020).

HEALTH HISTORY AND PHYSICAL EXAMINATION

Review the perinatal history for risk factors related to TTN such as absence of labor, cesarean birth, precipitous delivery, prolonged labor, fetal macrosomia, infants born early, male gender, or maternal asthma and maternal smoking. Those factors are associated with a higher risk of TTN (Martin et al., 2020).

Closely assess the newborn for signs of TTN. Within the first few hours of birth, observe for tachypnea, expiratory grunting, retractions, labored breathing, nasal flaring, and mild cyanosis. Mild to moderate respiratory distress is present by 6 hours of age; with respiratory rates as high as 100 to 140 breaths per minute. Also inspect the newborn's chest for hyperextension or a barrel shape. Auscultate breath sounds, which may be slightly diminished secondary to reduced air entry (Fanaroff & Fanaroff, 2020).

LABORATORY AND DIAGNOSTIC TESTING

To aid in the diagnosis, a chest x-ray may be done. It usually reveals mild symmetric lung overaeration and prominent perihilar interstitial markings and streaking. These findings correlate with lymphatic engorgement of retained fetal fluid. In addition, an arterial blood gas (ABG) assessment is important to ascertain the degree of gas exchange and acid–base balance. It typically demonstrates mild hypoxemia, mildly elevated CO2, and a normal pH (Martin & Rosenfeld, 2019).

Nursing Management

Management of TTN is supportive. As the retained lung fluid is absorbed by the infant's lymphatic system, the pulmonary status improves. Nursing management focuses on providing adequate oxygenation and determining whether the newborn's respiratory manifestations appear to be resolving or persisting. Provide supportive care while the retained lung fluid is reabsorbed. Administer intravenous (IV) fluids and/or gavage feedings until the respiratory rate decreases enough to allow safe oral feeding. Provide supplemental oxygen via a nasal cannula or oxygen hood to maintain adequate oxygen saturation. Maintain a neutral thermal environment with minimal stimulation to minimize oxygen demand.

Provide ongoing assessment of the newborn's respiratory status. As TTN resolves, the newborn's respiratory rate declines to 60 breaths per minute or less, the oxygen requirement decreases, and the chest x-ray shows resolution of the perihilar streaking. Provide reassurance and progress reports to the parents to help them cope with this crisis.

Respiratory Distress Syndrome

It is the 21st century, yet newborns are still at risk for dying from a respiratory condition that robs them of their first breaths: respiratory distress syndrome (RDS). Despite improved survival rates and advances in perinatal care, many high-risk newborns are at risk for respiratory problems, particularly **respiratory distress syndrome**, a breathing disorder resulting from lung immaturity and lack of alveolar surfactant, which keeps the air sacs in the lungs from collapsing and allows them to inflate easily. Without surfactant, the alveoli collapse at the end of expiration. Since the link between RDS and surfactant deficiency was

discovered more than 30 years ago, tremendous strides have been made in understanding the pathophysiology and treatment of this disorder. The introduction of prenatal steroids to accelerate lung maturity and the development of synthetic surfactant can be credited with the dramatic improvements in the outcome of newborns with RDS (Ahlfeld, 2020).

RDS affects an estimated 1% of newborns in the United States annually. The incidence declines with degree of maturity at birth. It occurs in 50% of preterm newborns born at 26 to 28 weeks' gestation, in 30% of those born at 30 to 31 weeks, and 5% of newborns born after 37 weeks (Dyer, 2019). Intensive respiratory care, usually with mechanical ventilation, is necessary.

Pathophysiology

Lung immaturity and surfactant deficiency contribute to the development of RDS. Surfactant is a complex mixture of phospholipids and proteins that adheres to the alveolar surface of the lungs. Anatomically, the immature lung cannot support oxygenation and ventilation, because the alveolar sacs are insufficiently developed, causing a deficient surface area for gas exchange. Physiologically, the amount of surfactant is insufficient to prevent collapse of unstable alveoli. Surfactant forms a coating over the inner surface of the alveoli, reducing the surface tension and preventing alveolar collapse at the end of expiration.

In the affected newborn, surfactant is deficient or lacking, and this deficit results in stiff lungs and alveoli that tend to collapse, leading to diffuse atelectasis. The work of breathing is increased because increased pressure similar to that required to initiate the first breath is needed to inflate the lungs with each successive breath. Hypoxemia and acidemia result, leading to vasoconstriction of the pulmonary vasculature. Right-to-left shunting occurs and alveolar capillary circulation is limited, further inhibiting surfactant production. As the disease progresses, fluid and fibrin leak from the pulmonary capillaries, causing hyaline membranes to form in the bronchioles, alveolar ducts, and alveoli. Hyaline membranes produce a ground-glass appearance in the lung membranes that can be seen on x-rays. These membranes further decrease gas exchange. These factors decrease the total surface area of the gas exchange membrane. The end result is hypoxemia, academia, and a worsening respiratory distress. A vicious cycle is created, compounding the problem (Cunningham et al., 2018).

Nursing Assessment

Nursing assessment focuses on keen observation to identify the signs and symptoms of respiratory distress. In addition, assessment aids in differentiating RDS from other respiratory conditions, such as TTN or group B streptococcal pneumonia.

HISTORY AND PHYSICAL EXAMINATION

Review the history for risk factors associated with RDS. The most common risk factor for the development of RDS is premature birth. Additional risk factors particularly in the term infant include cesarean birth in the absence of preceding labor (related to the lack of thoracic squeezing), male gender, previous birth of an infant with RDS, perinatal asphyxia, cold stress, and maternal diabetes, which produces high levels of insulin which inhibit surfactant production (Resnik et al., 2019).

TAKE NOTE!

Prolonged rupture of membranes, gestational or chronic maternal hypertension, maternal narcotic addiction, and use of prenatal corticosteroids reduce the newborn's risk for RDS because of the physiologic stress imposed on the fetus. Chronic stress experienced by the fetus in utero accelerates the production of surfactant before 35 weeks' gestation and thus reduces the incidence of RDS at birth (Kenner et al., 2020).

The newborn with RDS usually demonstrates signs at birth or within a few hours of birth. Observe the infant for expiratory grunting, shallow breathing, nasal flaring, chest wall retractions (Fig. 24.2), seesaw respirations, and generalized cyanosis. Auscultate the heart and lungs, noting tachycardia (rates above 150 to 180), fine inspiratory crackles, and tachypnea (rates above 60 breaths per minute).

The Silverman–Anderson Index is an assessment scoring system that can be used to evaluate five parameters of work of breathing as it assigns a numerical score for each parameter. Each category is scored as "0" for normal, "1" for moderate impairment, or "2" for severe impairment. Parameters assessed are retractions of the upper chest, lower chest, and xiphoid; nasal flaring; and expiratory grunt. Normally functioning infants should have a cumulative score of 0, whereas critically ill and severely depressed infants will have scores closer to 10 (Fig. 24.3).

FIGURE 24.2. Sternal retractions are a sign of respiratory distress requiring immediate intervention, such as mechanical ventilation and other monitoring devices. (Copyright Caroline Brown, RNC, MS, DEd.)

LABORATORY AND DIAGNOSTIC TESTING

The diagnosis of RDS is based on the clinical picture, a lung ultrasound, or x-ray findings and arterial blood gases that show hypoxemia and acidosis. A chest x-ray or lung ultrasound reveals hypoaeration, underexpansion, bell-shaped thorax, and a diffuse ground-glass pattern (Corsini et al., 2019).

Nursing Management

If untreated, RDS will worsen. In many infants respiratory symptoms decline after 72 hours, paralleling the production of surfactant in the alveoli (Fanaroff & Fanaroff, 2020). The newborn needs supportive care until surfactant is produced. Effective therapies for established RDS include conventional mechanical ventilation, continuous positive airway pressure (CPAP), or positive end-expiratory pressure (PEEP) to prevent volume loss

during expiration, and surfactant therapy. The use of exogenous surfactant replacement therapy to stabilize the newborn's lungs until postnatal surfactant synthesis matures has become a standard of care, but not necessarily evidence based. Knowledge of the surfactant proteins and lipids produced by the epithelial II cells were critical in the development of surfactant-replacement preparations used to treat RDS. This preparation has dramatically improved morbidity and mortality in preterm infants (Ahlfeld, 2020; Blackburn, 2018).

Despite recent advances in the perinatal management of neonatal RDS, controversies still exist. Strong evidence exists for the role of a single course of prenatal steroids in RDS prevention, but the potential benefit and long-term safety of repeated courses are unclear. A Cochrane review concluded that the incidence of RDS was reduced in infants born before 48 hours and between 1 and 7 days of treatment of mothers with prenatal corticosteroids, but not those born <24 hours of administration (Sotiriadis et al., 2018). Many practices involved in preterm neonatal stabilization at birth are not evidence based, including oxygen administration and positive-pressure lung inflation, and they may at times be harmful. A main breakthrough in treating RDS came was the development of surfactant replacement. Surfactant replacement therapy is crucial in the management of RDS, but the best preparation, optimal dose and timing of administration at different gestations has not been scientifically established. Respiratory support in the form of mechanical ventilation may also be lifesaving, but can cause bronchopulmonary dysplasia, and protocols should be directed at avoiding mechanical ventilation where possible by using nasal CPAP or nasal ventilation. Another mainstay of treatment for RDS is inhaled nitric oxide which improves oxygenation, reduces pulmonary inflammation and helps reduce the risk of chronic lung disease. For newborns with RDS to have best outcomes, it is essential that they have optimal supportive care, including maintenance of a normal body temperature, proper fluid management, good nutritional support, and support of the circulation to maintain adequate tissue perfusion (Kenner et al., 2020).

As recommended, care of the newborn with RDS is primarily supportive and requires a multidisciplinary approach to obtain the best outcomes. Therapy focuses on improving oxygenation and maintaining optimal lung volumes. Expect to transfer the newborn to the NICU soon after birth. Apply the basic principles of newborn care, such as thermoregulation, cardiovascular and nutritional support, normal glucose level maintenance,

and infection prevention, to achieve the therapeutic goals of reducing mortality and minimizing lung trauma.

Anticipate the administration of surfactant replacement therapy, prophylactically or as a rescue approach. With prophylactic administration, surfactant is given within minutes after birth, thus providing replacement surfactant before severe RDS develops. Rescue treatment is indicated for newborns with established RDS who require mechanical ventilation and supplemental oxygen. The earlier the surfactant is administered, the better the effect on gas exchange. Following surfactant administration, the newborn must be closely monitored, and preparation for reduced need for oxygen and ventilation should be anticipated (Resnik et al., 2019).

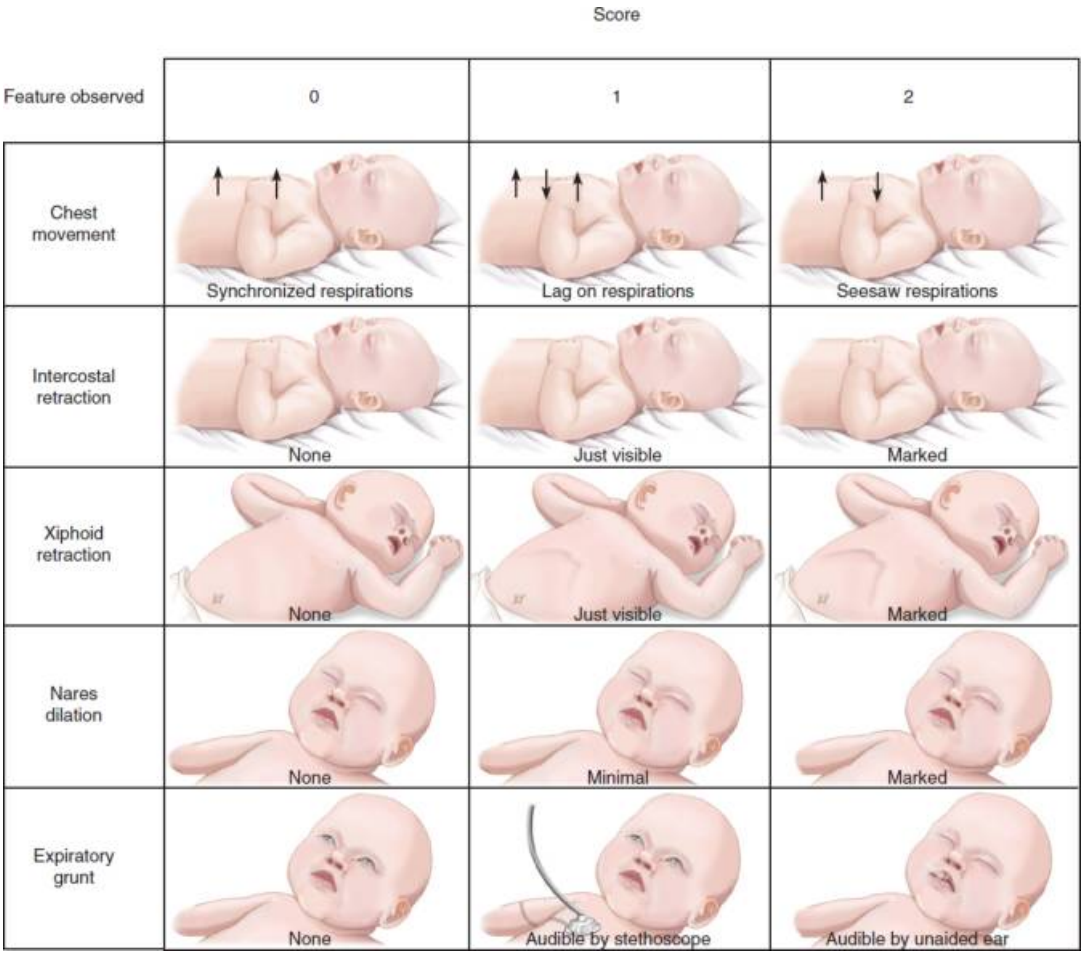

FIGURE 24.3. Assessing the degree of respiratory distress. (Adapted from Hedstrom, A. B., Gove, N. E., Mayock, D. E., & Batra, M. (2018). Performance of the Silverman Andersen Respiratory Severity Score in predicting pCO2 and respiratory support in newborns: a prospective cohort study. *Journal of Perinatology, 38*(5), 5055–5011. https://doi.org/10.1038/s41372-018-0049-3)

Administer the prescribed oxygen concentration via nasal cannula. Anticipate the need for ventilator therapy, which has greatly improved in the past several years, with significant advances in conventional and high-frequency ventilation therapies (Fig. 24.4). Recent studies show no difference in outcomes for newborns who received early treatment with high-frequency oscillatory ventilation or positive end-expiratory pressure compared with those receiving conventional mechanical ventilation. They are both equally effective (Bamat et al., 2019). Although mechanical ventilation has increased survival rates, it is also a contributing factor to bronchopulmonary dysplasia, pulmonary hypertension, and retinopathy of prematurity (Cunningham et al., 2018).

FIGURE 24.4. A newborn with RDS receiving mechanical ventilation.

In addition, support the newborn with RDS using the following interventions:

- Continuously monitor the infant's cardiopulmonary status via invasive or noninvasive means (e.g., arterial lines or auscultation, respectively).
- Monitor oxygen saturation levels continuously; assess pulse oximeter values to determine oxygen saturation levels.
- Closely monitor vital signs, acid–base status, and arterial blood gases.
- Administer broad-spectrum antibiotics if blood cultures are positive.

- Administer sodium bicarbonate or acetate as ordered to correct metabolic acidosis.
- Provide fluids and vasopressor agents as needed to prevent or treat hypotension.
- Test blood glucose levels and administer dextrose as ordered for prevention or treatment of hypoglycemia.
- Cluster caretaking activities to avoid overtaxing and compromising the newborn.
- Place the newborn in the prone position to optimize respiratory status and reduce stress.
- Perform gentle suctioning to remove secretions and maintain a patent airway.
- Assess level of consciousness to identify intraventricular hemorrhage.
- Monitor x-ray studies to detect atelectasis or air leak.
- Maintain a neutral thermal environment to reduce metabolic and oxygen needs.
- Provide sufficient calories via gavage and IV feedings.
- Maintain adequate hydration and assess for signs of fluid overload.
- Provide information to the parents about treatment modalities; give thorough but simple explanations about the rationales for interventions.
- Encourage the parents to participate in care (Fanaroff & Fanaroff, 2020; Kenner et al., 2020).

Provide ongoing assessment and be alert for complications. These may include air leak syndrome, bronchopulmonary dysplasia (chronic lung disease), patent ductus arteriosus, congestive heart failure, intraventricular hemorrhage, retinopathy of prematurity, NEC, complications resulting from IV catheter use (infection, thrombus formation), and developmental delay or disability (Ahlfeld, 2020).

Meconium Aspiration Syndrome (MAS)

MAS is a cause of respiratory failure in term and post-term infants. Meconium is a viscous dark green substance composed primarily of water and other gastrointestinal secretions that can be noted in the fetal gastrointestinal tract as early as 10 to 16 weeks' gestation (Ahlfeld, 2020). It is expelled as the newborn's first stool after birth. Meconium is sterile and does not contain bacteria, the primary factor that differentiates it from stool. Intrauterine distress can cause passage of meconium into the amniotic fluid before birth. Factors that promote the passage in utero include placental

insufficiency, maternal hypertension, preeclampsia, fetal hypoxia, transient umbilical compression, oligohydramnios, and maternal drug abuse, especially of tobacco and cocaine. Meconium can be aspirated before or during labor and after birth. Because meconium is rarely found in the amniotic fluid prior to 36 weeks' gestation, it mainly impacts infants born at term and post-term (Blackburn, 2018). It is usually expelled as the newborn's first stool after birth.

Meconium aspiration syndrome occurs when the newborn inhales particulate meconium mixed with amniotic fluid into the lungs while still in utero or on taking the first breath after birth. Meconium staining of the amniotic fluid, with the possibility of aspiration, occurs in approximately 10% to 15% of births after 36 weeks' gestation (Resnik et al., 2019). Aspiration induces airway obstruction, surfactant dysfunction, hypoxia, and chemical pneumonitis with inflammation of pulmonary tissues. Severe MAS can lead to persistent pulmonary hypertension and death. The use of surfactant and inhaled nitric oxide has led to the decreased mortality and the need for extracorporeal membrane oxygenation (ECMO).

Pathophysiology

The pathophysiology of MAS is complex, and the timing of the insult resulting in aspiration remains controversial. Meconium may be passed in utero secondary to hypoxic stress. Hypoxia induces the fetus to gasp or attempt to breathe. The fetus may bear down and pass meconium into the amniotic fluid or he or she may experience a vagal reflex that causes relaxation of the anal sphincter, allowing meconium to be passed into the amniotic fluid. The fetus then sucks or swallows this amniotic fluid in utero, or the infant may aspirate meconium with the first breath after birth as air rushes into the lungs.

Although the etiology is not well understood, the effects of meconium can be harmful to the fetus. Meconium alters the amniotic fluid by reducing antibacterial activity and subsequently increasing the risk of perinatal bacterial infection. Additionally, meconium is very irritating because it contains enzymes from the fetal pancreas.

When aspirated into the lungs, meconium blocks the bronchioles, causing an inflammatory reaction as well as a decrease in surfactant production. Gas exchange is impaired and atelectasis occurs. A ball-valve effect occurs when air is inspired into the alveoli but cannot be fully expired secondary to reduced airway diameter. Significant respiratory distress is

followed by persistent pulmonary hypertension, right-to-left shunting of blood, and patent ductus arteriosus. Management focuses on appropriate oxygenation, ventilation, improvement of persistent pulmonary hypertension, and maintenance of systemic circulation, which is largely symptomatic and supportive (Calkovska et al., 2019).

Nursing Assessment

Review prenatal and birth records to identify newborns that may be at high risk for meconium aspiration. Predisposing factors for MAS include post-term pregnancy; breech presentation, forceps, or vacuum extraction births; nulliparity; ethnicity (Pacific Islander, Indigenous Australian, African American); intrapartum fever; low Apgar score; prolonged or difficult labor associated with fetal distress in a term or post-term newborn; maternal drug abuse, especially of tobacco and cocaine; maternal infection/chorioamnionitis; maternal hypertension or diabetes; oligohydramnios; fetal growth restriction; prolapsed cord; or acute or chronic placental insufficiency (Kenner et al., 2020).

Assess the amniotic fluid for meconium staining when the maternal membranes rupture. Green-stained amniotic fluid suggests the presence of meconium in the amniotic fluid and should be reported immediately. After birth, note any yellowish-green staining of the umbilical cord and nails and skin. This staining indicates that meconium has been present for some time.

Consider Kelly, the 27-year-old woman who gave birth to a son who required resuscitation. What findings would lead the nurse to suspect that her son aspirated meconium? What risk factors in Kelly's history would support the diagnosis of meconium aspiration syndrome?

TAKE NOTE!

The *Textbook of Neonatal Resuscitation* (2016) does not recommend routine endotracheal suctioning for nonvigorous infants born through meconium-stained amniotic fluid, as was standard procedure in the past. After birth, the infant should be handed to a neonatal team for evaluation and treatment. Use of orogastric suctioning to prevent MAS is not supported by evidence from current research. Guidelines suggest not stimulating infants born with meconium staining with vigorous sucking, to avoid aspiration (Edwards et al., 2019).

Observe the newborn for a barrel-shaped chest with an increased anterior-posterior (AP) chest diameter (similar to that found in a client with chronic obstructive pulmonary disease), prolonged tachypnea, progression from mild to severe respiratory distress, intercostal retractions, end-expiratory grunting, and cyanosis (Ahlfeld, 2020). Auscultate the lungs, noting coarse crackles and rhonchi.

Chest x-rays show patchy, fluffy infiltrates unevenly distributed throughout the lungs and marked hyperaeration mixed with areas of atelectasis. ABG analysis will indicate metabolic acidosis with a low blood pH, decreased PaO2, and increased PaCO2 (Martin et al., 2020). Direct visualization of the vocal cords for meconium staining using an appropriate size laryngoscope is needed to confirm the presence of meconium below the larynx.

Nursing Management

Nursing management focuses on ensuring adequate tissue perfusion and minimizing oxygen demand and energy expenditure. Caring for the newborn with meconium aspiration begins in the birthing unit when the birth attendant identifies meconium-stained amniotic fluid with membrane rupture during labor. Upon delivery of the newborn's head, before the newborn takes the first breath, the nasal cavity and then the posterior pharynx are gently wiped to decrease the potential for aspiration. If the newborn is significantly depressed at birth, secondary clearing of the lower airways by direct tracheal suctioning may be necessary. Repeated suctioning and stimulation are limited to prevent overstimulation and further depression. In pregnancies complicated by meconium-stained amniotic fluid, suctioning of the hypopharynx before the birth of the infant's shoulders and postnatal suction of vigorous infants have been used in an effort to clear the airway and decrease the incidence and the severity of MAS. Based on the results of two large randomized controlled studies, international guidelines from scientific societies for intrapartum and postpartum management of pregnancies with meconium-stained amniotic fluid have radically changed. Intrapartum suction and postnatal intubation and suction of vigorous infants are no longer recommended (AAP & AHA, 2016). Usually the newborn is transferred to the NICU for close monitoring.

Maintain a neutral thermal environment, including placing the newborn under a radiant warmer or in a warmed isolette, to prevent hypothermia. In

addition, minimize handling to reduce energy expenditure and oxygen consumption that could lead to further hypoxemia and acidosis.

Administer oxygen therapy as ordered via nasal cannula or with positive-pressure ventilation. Monitor oxygen saturation levels via pulse oximetry to evaluate the newborn's response to treatment and to detect changes. Increased pulmonary pressures associated with meconium aspiration may cause blood to be shunted away from the lungs. The newborn may exhibit uneven pulmonary ventilation, with hyperinflation in some areas and atelectasis in others. This leads to poor perfusion and subsequent hypoxemia, which in turn may increase pulmonary vasoconstriction, resulting in a worsening of hypoxemia and acidosis.

Expect to administer hyperoxygenation to dilate the pulmonary vasculature and close the ductus arteriosus or nitric oxide inhalation to decrease pulmonary vascular resistance, or to use high-frequency oscillatory ventilation to increase the chance of air trapping (Fanaroff & Fanaroff, 2020). In addition, administer vasopressors and pulmonary vasodilators as prescribed and administer surfactant as ordered to counteract inactivation by meconium. Monitor ABG results for changes and assist with measures to correct acid–base imbalances to facilitate perfusion of tissues and prevent pulmonary hypertension (Cunningham et al., 2018). If these measures are ineffective, be prepared to assist with the use of ECMO, a modified type of heart–lung machine.

In addition, perform the following interventions:

- Cluster newborn care to minimize oxygen demand.
- Maintain an optimal thermal environment to minimize oxygen consumption.
- Prevent and treat any complications such as hypotension, metabolic acidosis, or anemia.
- Incorporate developmental care practices when applicable.
- Pay special attention to systemic blood volume and blood pressure to reduce right-to-left shunting through the patent ductus.
- Administer broad-spectrum antibiotics to treat chemical pneumonitis.
- Continuously monitor the newborn's condition (cardiac and respiratory status, oximetry).
- Provide continuous reassurance and support to the parents throughout the experience (Ahlfeld, 2020; Garcia-Prats, 2020).

Persistent Pulmonary Hypertension of the Newborn

PPHN, previously referred to as persistent fetal circulation, is a cardiopulmonary disorder characterized by marked pulmonary hypertension that causes right-to-left extrapulmonary shunting of blood and hypoxemia. It occurs when the newborn's circulatory system does not have normal transition after birth due to the failure of pulmonary vascular relaxation PPHN can occur idiopathically or as a complication of perinatal asphyxia, MAS, maternal smoking, maternal obesity, hypocalcemia, maternal asthma, pneumonia, congenital heart defects, metabolic disorders such as hypoglycemia, hypothermia, hypovolemia, hyperviscosity, acute hypoxia with delayed resuscitation, sepsis, and RDS. It occurs in approximately two newborns per 1,000 live births of term, near-term, or post-term infants. Current research findings link increased risk of developing PPHN to exposure to selective serotonin reuptake inhibitors (SSRIs) (antidepressants) in late pregnancy (Ng et al., 2019). Treatment of depression with antidepressants is complicated by the mother's needs. Careful consideration must be given to the risks, benefits, and alternatives of utero medication exposure, and this should be discussed with the woman.

Pathophysiology

Elevated pulmonary vascular pressures normally occur during fetal life and decrease partially in response to an increase in oxygen tension at birth when the newborn takes the first breath. However, interference with this ability to breathe allows pulmonary pressures to remain increased. Hypoxemia and acidosis also occur, leading to vasoconstriction of the pulmonary artery. These events cause an elevation in pulmonary vascular resistance. Normally, the decrease in pulmonary artery pressure and pulmonary vascular resistance with breathing leads to the closure of the ductus arteriosus and foramen ovale. However, with PPHN pulmonary vascular resistance is elevated to the point that venous blood is diverted to some degree through fetal shunts (i.e., the ductus arteriosus and foramen ovale) into the systemic circulation, bypasses the lungs, and results in systemic arterial hypoxemia.

Nursing Assessment

Assess the newborn's status closely. A newborn with persistent pulmonary hypertension demonstrates tachypnea within 12 hours after birth. Observe

for marked cyanosis, grunting, respiratory distress with tachypnea, and retractions. Auscultate the heart, noting a systolic ejection harsh sound (tricuspid insufficiency murmur), and measure blood pressure for hypotension resulting from both heart failure and persistent hypoxemia (Kenner et al., 2020). Measure oxygen saturation via pulse oximetry and report low values. Prepare the newborn for an echocardiogram, which will reveal right-to-left shunting of blood that confirms the diagnosis.

Nursing Management

Nursing management focuses on ensuring adequate tissue profusion and minimizing oxygen demand and energy expenditure. When caring for the newborn with persistent pulmonary hypertension, pay meticulous attention to detail, with continuous monitoring of the newborn's oxygenation and perfusion status and blood pressure. The goals of therapy include improving alveolar oxygenation, inducing metabolic alkalosis by administering sodium bicarbonate, correcting hypovolemia and hypotension with the administration of volume replacement and vasopressors, and anticipating use of ECMO when support has failed to maintain acceptable oxygenation (Stark & Eichenwald, 2019).

Provide immediate resuscitation after birth and administer oxygen therapy as ordered. Early and effective resuscitation and correction of acidosis and hypoxia are helpful in preventing persistent pulmonary hypertension. Monitor arterial blood gases frequently to evaluate the effectiveness of oxygen therapy. Provide respiratory support, which frequently necessitates the use of mechanical ventilation. Administer prescribed medications, monitor cardiopulmonary status, cluster care to reduce stimulation, and provide ongoing support and education to the parents.

TAKE NOTE!

Almost any procedure, such as suctioning, weighing, changing diapers, or positioning, can precipitate severe hypoxemia due to the instability of the pulmonary vasculature. Therefore, minimize the newborn's exposure to stimulation as much as possible.

Periventricular-Intraventricular Hemorrhage (PIVH)

The immaturity of the preterm infant's brain makes it vulnerable to injury. The area most vulnerable is the periventricular area. The periventricular area is the rim of brain tissue that lines the outside of the lateral ventricles. Each ventricular area contains a rich network of capillaries which are extremely fragile and can rupture easily. The tremendous physiologic stress during the birth process can cause these vessels to rupture and bleed into the periventricular area (PVH). If the bleeding persists, the expanding volume of blood dissects into the adjacent lateral ventricles leading to an intraventricular hemorrhage (IVH). PIVH occurs in up to 45% of infants with birth weight less than 1,500 g and/or born at less than 35 weeks' gestation. It is uncommon in term neonates, but may occur with birth trauma or asphyxia (Annibale & Hill, 2019). The overall incidence of PIVH has decreased over time as a result of improved perinatal care, increased use of prenatal corticosteroids, and surfactant to treat RDS. Complications resulting from PIVH include hydrocephalus, seizure disorder, periventricular leukomalacia (an ischemic injury resulting from inadequate perfusion of the white matter adjacent to the ventricles), cerebral palsy, learning disabilities, vision or hearing deficits, cognitive impairment or death (van Bel et al., 2019).

Pathophysiology

The pathogenesis of PIVH is attributed to the intrinsic weakness of germinal vasculature and to the fluctuation in the cerebral blood flow. Genetics appear to play a role in this condition (Blackburn, 2018). The preterm newborn is at greatest risk for IVH because cerebral vascular development is immature, making it more vulnerable to injury. The earlier the newborn is, the greater the likelihood for brain damage. While all areas of the brain can be injured, the periventricular area is the most vulnerable (Merhar & Thomas, 2020).

Each ventricular area contains a rich network of capillaries that are very thin, fragile, and easily ruptured. The causes of rupture vary and include fluctuations in systemic and cerebral blood flow, increases in cerebral blood flow from hypertension, IV infusions, seizure activity, increases in cerebral venous pressure due to vaginal delivery, hypoxia, and respiratory distress. With a preterm birth, the fetus is suddenly transported from a well-controlled uterine environment into a highly stimulating one. This tremendous physiologic shock can cause hemorrhage within the first 72 hours post birth (Annibale & Hill, 2019).

Nursing Assessment

The signs of IVH vary significantly and some infants may display no clinical signs. Approximately 50% of PIVH occurs by 24 hours of age, and 90% by 72 hours of age (Shipley et al., 2019). Assess for risk factors such as:

- Preterm birth
- Low birth weight
- Acidosis
- Asphyxia
- Unstable blood pressure
- Seizures
- Elevated INR in the first 48 hours
- Thrombocytopenia
- Prolonged labor
- Nonadministration of vitamin K at birth
- Acute blood loss or hypovolemia
- Respiratory distress with mechanical ventilation, intubation, apnea, hypoxia, or suctioning
- Use of hyperosmolar solutions or rapid volume expansion

Evaluate the newborn for an unexplained drop in hematocrit, pallor, apnea, and poor perfusion as evidenced by respiratory distress and oxygen desaturation. Note seizures, lethargy or other changes in level of consciousness, bulging fontanel, weak sucking, metabolic acidosis, high-pitched cry, or hypotonia. Palpate the anterior fontanel for tenseness. Assess vital signs, noting bradycardia and hypotension. Evaluate laboratory data for changes indicating metabolic acidosis or glucose instability. Frequently a bleed can progress rapidly and result in shock and death. Prepare the newborn for cranial ultrasonography, the diagnostic tool of choice to detect hemorrhage (Fanaroff & Fanaroff, 2020).

Nursing Management

Prevention of preterm birth is essential in preventing PIVH. Identify risk factors that can lead to hemorrhage, and focus care on interventions to decrease the risk of hemorrhage. For example, institute measures to prevent perinatal asphyxia and birth trauma and provide developmental care in the NICU. If a preterm birth is expected, having the mother deliver at a tertiary care facility with an NICU would be most appropriate.

Care of the newborn with PIVH is primarily supportive. Correct anemia, acidosis, and hypotension with fluids and medications. Administer fluids slowly to prevent fluctuations in blood pressure. Avoid rapid volume expansion to minimize changes in cerebral blood flow. Keep the newborn in a flexed, contained position with the head elevated to prevent or minimize fluctuations in intracranial pressure. Continuously monitor the newborn for signs of hemorrhage, such as changes in the level of consciousness, bulging fontanel, seizures, apnea, and reduced activity level. Also, measuring head circumference daily to assess for expansion in size is essential in identifying complications early.

Minimize handling of the newborn by clustering nursing care, and limit stimulation in the newborn's environment to reduce stress. Also reduce the newborn's exposure to noxious stimuli to avoid a fluctuation in blood pressure and energy expenditure. Provide adequate oxygenation to promote tissue perfusion but controlled ventilation to decrease the risk of pneumothorax. Developmental care principles include avoiding lifting the lower extremities above the midline with diaper changes, giving rapid fluid boluses, and high oxygen and ventilation, as these can increase the chance of more cranial hemorrhage (Kenner et al., 2020).

Support for the parents to cope with the diagnosis and potential long-term sequelae is essential. The long-term neurodevelopmental outcome is determined by the severity of the bleed. Provide education and emotional support for the parents throughout the newborn's stay. Discuss expectations for short- and long-term care needs with the parents and assist them in obtaining the necessary support from appropriate community resources (Merhar & Thomas, 2020).

Necrotizing Enterocolitis

NEC is an inflammatory disease of the bowel which can cause ischemic and necrotic injury in the gastrointestinal tract. It is the most common and most serious acquired gastrointestinal disorder among hospitalized preterm neonates and is associated with significant acute and chronic morbidity and mortality. NEC occurs in approximately 10% of infants who weigh less than 1,500 g, with mortality rates up to 50% (Brown, 2020). Attempts to improve gastrointestinal function and reduce the risk of NEC include enteral antibiotics, judicious administration of parenteral fluids, human milk feedings, antenatal corticosteroids, enteral probiotics (*Lactobacillus acidophilus*), and slow continuous drip feedings (Caplan, 2019).

Pathophysiology

The pathophysiology of NEC is not clearly understood and is thought to be multifactorial in nature. Current research points to three major pathologic mechanisms that lead to NEC: bowel hypoxic-ischemia events, perinatal stressors, an immature intestinal barrier, abnormal bacterial colonization, and formula feeding. The intestine of a preterm infant is characterized underdeveloped immune defenses and compromised mucosal barrier function. As a result, the immune intestine is susceptible to bacterial colonization by opportunistic pathogens, which follows oral feeding, which in turn incites an inflammatory response (Martin et al., 2020).

During perinatal or postnatal stress, oxygen is shunted away from the gut to more important organs such as the heart and brain. Ischemia and intestinal wall damage occur, allowing bacteria to invade. High-solute feedings allow bacteria to flourish. Mucosal or transmucosal necrosis of part of the intestine occurs. Although any region of the bowel can be affected, the distal ileum and proximal colon are the region's most commonly involved. NEC usually occurs between 3 and 12 days of life, but it can occur weeks later in some newborns (Blackburn, 2018). The most effective prevention strategy for NEC is the use of human milk. It is well documented that newborns exclusively breastfed have a reduced risk of NEC.

Nursing Assessment

NEC can be devastating, and astute assessment is crucial. Assessing the newborn for the development of NEC includes the health history and physical examination as well as laboratory and diagnostic testing. The onset of NEC is heralded by the development of feeding intolerance, abdominal distention, and bloody stools in a preterm infant receiving enteral feedings. As the disease worsens, the infant develops signs and symptoms of septic shock (respiratory distress, temperature instability, lethargy, hypotension, and oliguria). Nurses need to be suspicious of this condition in caring for this preterm infant.

HEALTH HISTORY AND PHYSICAL EXAMINATION

Assess the newborn's history for risk factors associated with NEC. In addition to preterm birth, prenatal and postnatal predisposing risk factors are highlighted in Box 24.1.

Also observe the newborn for common signs and symptoms, which may include:

- Cardiorespiratory baseline changes
- Feeding intolerance
- Abdominal distention and tenderness
- Bloody or hemoccult-positive stools
- Diarrhea and vomiting
- Delayed gastric emptying
- Respiratory distress

BOX 24.1 Predisposing Factors for the Development of Necrotizing Enterocolitis

Prenatal Factors

- Preterm labor
- Prolonged rupture of membranes
- Preeclampsia
- Maternal sepsis
- Amnionitis
- Uterine hypoxia

Postnatal Factors

- Respiratory distress syndrome
- Patent ductus arteriosus
- Congenital heart disease
- Exchange transfusion
- Low birth weight
- Low Apgar scores
- Umbilical catheterization
- Hypothermia
- Gastrointestinal infection
- Hypoglycemia
- Asphyxia

- Metabolic acidosis
- Temperature instability
- Decreased or absent bowel sounds
- Signs of sepsis
- Occult/gross blood in stool
- Lethargy
- Apnea
- Shock (Brown 2020)

Always keep the possibility of NEC in mind when dealing with preterm newborns, especially when enteral feedings are being administered. Note respiratory distress, cyanosis, lethargy, decreased activity level, temperature instability, feeding intolerance, diarrhea, bile-stained emesis, or grossly bloody stools. Assess blood pressure, noting hypotension. Evaluate the neonate's abdomen for distention, tenderness, and visible loops of bowel. Measure the abdominal circumference, noting an increase. Determine residual gastric volume prior to feeding; when it is elevated, be suspicious for NEC (Kenner et al., 2020).

LABORATORY AND DIAGNOSTIC TESTING

Common laboratory and diagnostic tests ordered for assessment of NEC include:

- Kidney, ureter, and bladder (KUB) of the abdomen x-ray: confirms the presence of pneumatosis intestinalis (air in the bowel wall) and persistently dilated loops of bowel
- An abdominal x-ray to demonstrate dilated bowel loops, abnormal gas patterns, air bubbles that occur from bacteria, and thickened bowel walls
- Blood values: may demonstrate metabolic acidosis, increased white blood cells, thrombocytopenia, neutropenia, electrolyte imbalance, or disseminated intravascular coagulation (DIC) (Sanchez & Kadrofske, 2019)

Nursing Management

Nursing management of the newborn with NEC focuses on maintaining fluid and nutritional status, providing supportive care, and teaching the family about the condition and prognosis. Therapeutic management initially consists of bowel rest and antibiotic therapy. Serial kidney, ureter, and bladder x-rays and C-reactive protein levels are used to assess the resolution or progression of NEC. If medical treatment fails to stabilize the newborn or if free air is present on a left lateral decubitus film (where the infant is lying down on the left side), surgical intervention will be necessary to resect the portion of necrotic bowel while preserving as much of the intestinal length as possible. Surgery for NEC usually requires the placement of a proximal enterostomy until the anastomosis site is ready for reconnection. After surgery, post-op supportive care includes fluids, TPN, antibiotics, and bowel rest for 10 to 14 days.

MAINTAINING FLUID AND NUTRITIONAL STATUS

If NEC is suspected, immediately stop enteral feedings until a diagnosis is made. Administer IV fluids initially to restore proper fluid balance. If ordered, administer total parenteral nutrition (TPN) to keep the newborn supported nutritionally. Give prescribed IV antibiotics to prevent sepsis from the necrotic bowel (if surgery is required, antibiotics may be needed for an extended period of time). Institute gastric decompression as ordered with an orogastric tube attached to low intermittent suction. Carefully monitor intake and output. Restart enteral feedings once the disease has resolved (normal abdominal examination and KUB negative for pneumatosis) or as determined postoperatively by the surgeon.

PROVIDING SUPPORTIVE CARE

Manage pain by administering analgesics as ordered. Infection control is important, with an emphasis on careful handwashing. In addition, implement these interventions in an ongoing manner:

- Check stools for evidence of blood and report any positive findings.
- Measure the abdominal girth.
- Monitor blood pressure for hypotension.
- Palpate the abdomen for tenderness and rigidity.
- Auscultate for normal bowel sounds in all four quadrants.
- Monitor blood gases and oxygen saturation.
- Observe the abdomen for redness or shininess, which indicates peritonitis.
- Offer emotional support for parents/partners/significant others.

EDUCATING THE FAMILY

The diagnosis of NEC may cause significant family anxiety. Listen to the family's worries and fears. Answer their questions honestly. Inform the family that medically treated NEC is usually limited to a short period and resolves within 48 hours of stopping oral feedings, but surgically treated NEC can be a much lengthier process. The amount of bowel that has necrosed, as determined during the bowel resection, significantly increases the likelihood of long-term medical problems. Short bowel syndrome may result from a large resection (short bowel syndrome is discussed in Chapter 42). Reassure the family that although some infants have more involved cases of NEC, the improved parenteral nutrition formulations have improved the outcomes for these infants. Provide education about ostomy

care if surgery is required (refer to Chapter 42 for a discussion of ostomy care). Promote interaction with their newborn. Nursing actions of active engagement with parents and the sick infant (providing NICU orientation and physical care), providing cautious guidance (offering information and instruction on infant care), and their subtle presence (overseeing parent's interaction with their infant) all contribute to fostering a positive, trusting relationship with parents (Gephart & Quinn, 2019; Kenner et al., 2020).

Infants of Diabetic Mothers (IDM)

An **infant of a diabetic mother** (IDM) is one born to a woman with pregestational (pre-existing type 1 or 2) or gestational diabetes (diabetes diagnosed during pregnancy) (see Chapter 20 for additional information). The newborn of a diabetic woman is at high risk for numerous health-related complications, especially hypoglycemia. Gestational diabetes mellitus (GDM) from all causes of diabetes is the most common medical complication of pregnancy and is increasing in incidence, particularly as type 2 diabetes continues to increase worldwide. Despite advances in perinatal care, IDMs remain at risk for a multitude of physiologic, metabolic, and congenital complications such as preterm birth, macrosomia, asphyxia, respiratory distress, hypoglycemia, hypocalcemia, hyperbilirubinemia, polycythemia and hyperviscosity, hypertrophic cardiomyopathy, and congenital anomalies, particularly of the central nervous system. Overt type 1 diabetes around conception produces marked risk of neural tube defects, cardiac defects, and caudal regression syndrome; later in gestation, severe and unstable type 1 maternal diabetes carries a higher risk of intrauterine growth restriction, asphyxia, and fetal death. IDMs born to mothers with type 2 diabetes are more commonly obese (macrosomic) with milder conditions of the common problems found in IDMs. IDMs from all causes of GDM also are predisposed to later-life risk of obesity, diabetes, and cardiovascular disease (Brown, 2020).

Impact of Diabetes on the Newborn

For more than a century, it has been known that diabetes during pregnancy can have severe adverse effects on fetal and newborn outcomes. Infants of diabetic mothers have increased morbidity and mortality in the perinatal period. The incidence of major congenital anomalies is much greater for these newborns than for other newborns (Riskin & Garcia-Prats, 2020).

Poor glycemic control in the first trimester, during organogenesis, is thought to be a major reason for congenital malformations. The most common types of malformations in infants of diabetic mothers involve the cardiovascular, skeletal, central nervous, gastrointestinal, and genitourinary systems. Cardiac anomalies are the most common (Martin & Rosenfeld, 2019).

Infants of diabetic mothers can be large for gestational age (LGA) or small for gestational age (SGA), depending on the vascular impact of this chronic systemic disease on the mother prior to and during the pregnancy. Fetal macrosomia occurs in up to 45% of diabetic pregnancies because of hyperinsulinemia (Brown, 2020). LGA infants (>90th percentile on growth chart) are longer and weigh more than 4,000 g with the majority of the excess weight composed of fat. They also have increased organ weights (organomegaly) and excessive fat deposits on their shoulders and trunk, contributing to the increased overall body weight and predisposing them to shoulder dystocia, brachial plexus injury, fracture, neonatal depression, or cesarean birth. These oversized newborns frequently require cesarean births for cephalopelvic disproportion and dysfunctional labor patterns. They are frequently hypoglycemic in the first few hours after birth (Fanaroff & Fanaroff, 2020). SGA infants (<10th percentile on growth chart) of diabetic mothers usually suffer from intrauterine malnutrition and have few glucose reserves to tolerate the rigors of labor and birth. Uteroplacental circulation is often impaired, leading to poor growth patterns and hypoxemia. Despite their increased or decreased size and weight, they may be remarkably frail, showing behaviors similar to those of a preterm newborn. Thus, birth weight may not be a reliable criterion of maturity.

Pathophysiology

The large size of the IDM arises secondary to exposure to high levels of maternal glucose crossing the placenta into the fetal circulation. Maternal hyperglycemia acts as a fuel to stimulate increased production of fetal insulin, which in turn promotes somatic growth within the fetus. The fetus responds to these high levels by producing more insulin, which acts as a growth factor in the fetus (Brown, 2020). How the fetus will be affected and the problems that the newborn experiences depend on the severity, duration, and control of the diabetes in the mother during the pregnancy. Table 24.1 summarizes the common problems that may occur in infants of diabetic mothers.

TABLE 24.1 Common Problems of Infants of Diabetic Mothers

Condition	Description	Effects
Macrosomia	Newborn with an excessive birth weight; arbitrarily defined as a birth weight >4,000 g (8 lb 8 oz) to 4,500 g (9 lb 9 oz) or >90% for gestational age Complication in 10% of all pregnancies in the United States	Increased risk for shoulder dystocia, traumatic birth injury, birth asphyxia • Risks for newborn hypoglycemia and hypomagnesemia, polycythemia, and electrolyte disturbances • Increased maternal risk for surgical birth, postpartum hemorrhage and infection, and birth canal lacerations • Increased risk of developing type 2 diabetes later in life for both • Higher weight and accumulation of fat in childhood and a higher rate of obesity in adults
Respiratory distress syndrome (RDS)	Cortisol-induced stimulation of lecithin/sphingomyelin (phospholipids) necessary for lung maturation is antagonized due to the high insulin environment within the fetus due to mother's hyperglycemia Less mature lung development than expected for gestational age. Decrease in the phospholipid phosphatidylglycerol (PG), which stabilizes surfactant, compounding risk	Most commonly, breathing normally at birth but developing labored, grunting respiration with cough and a hoarse complaining cry within a few hours with chest retractions and varying degrees of cyanosis • IDMs with vascular disease seldom develop RDS because the chronic stress of poor intrauterine perfusion leads to increased production of steroids, which accelerates lung maturation.
Hypoglycemia	Glucose is the major source of energy for organ function. Typical characteristics: • Poor feedings • Jitteriness • Lethargy • High-pitched or weak cry • Apnea • Cyanosis and seizures	Low blood glucose levels are problematic during early post birth period due to abrupt cessation of high-glucose maternal blood supply and the continuation of insulin production by the newborn. Limited ability to release glucagon and catecholamines, which normally stimulate glucagon

	Some newborns are asymptomatic.	breakdown and glucose release Prolonged and untreated hypoglycemia leads to serious, long-term adverse neurologic sequelae such as learning disabilities and mental retardation.
Hypocalcemia and hypomagnesemia	Hypocalcemia (drop in calcium levels) is manifested by tremors, hypotonia, apnea, high-pitched cry, and seizures due to abrupt cessation of maternal transfer of calcium to the fetus, primarily in the third trimester and experiencing birth asphyxia. Associated hypomagnesemia is directly related to the maternal level before birth. About half of IDMs affected.	Newborn is at risk for a prolonged delay in parathyroid hormone production and cardiac dysrhythmias.
Polycythemia	Venous hematocrit of >65% in the newborn Increased oxygen consumption by IDM secondary to fetal hyperglycemia and hyperinsulinemia Increased fetal erythropoiesis secondary to intrauterine hypoxia due to placental insufficiency from maternal diabetes Hypoxic stimulation of increased red blood cell (RBC) production as compensatory mechanism	Increased viscosity, resulting in poor blood flow predisposing newborn to decreased tissue oxygenation and development of microthrombi
Hyperbilirubinemia	Usually seen within the first few days after birth, manifested by a yellow appearance of the sclera and skin Excessive red cell hemolysis necessary to break down increased RBCs in	If untreated, high levels of unconjugated bilirubin may lead to **kernicterus** (neurologic syndrome that results in irreversible damage) with long-term sequelae that include cerebral palsy, sensorineural

	circulation due to polycythemia Resultant elevated bilirubin levels Excessive bruising secondary to birth trauma of macrosomic infants, further adding to high bilirubin levels	hearing loss, and mental retardation.
Congenital anomalies	Occur in up to 10% of infants of diabetic mothers, accounting for 30–50% of perinatal deaths. Incidence is greatest among small-for gestational-age newborns. Overall, infants of diabetic mothers have three times the usual incidence of congenital anomalies compared to newborns from the nondiabetic general population.	Most common anomalies: • Coarctation of the aorta • Atrial and ventricular septal defects • Transposition of the great vessels • Sacral agenesis • Hip and joint malformations • Anencephaly • Spina bifida • Caudal dysplasia • Hydrocephalus

Nursing Assessment

Assessment begins in the prenatal period by identifying women with diabetes and taking measures to control maternal glucose levels (see Chapter 20 for information on management of the pregnant woman with diabetes).

PHYSICAL EXAMINATION

At birth, inspect the newborn for the following characteristic features. See also Figure 24.5.

- Puffy, rosy cheeks with a ruddy skin color
- Short neck (some describe "no-neck" appearance)
- Buffalo hump over the nape of the neck
- Massive shoulders with a full intrascapular area

- Distended upper abdomen due to organ overgrowth
- Excessive subcutaneous fat tissue, producing fat extremities

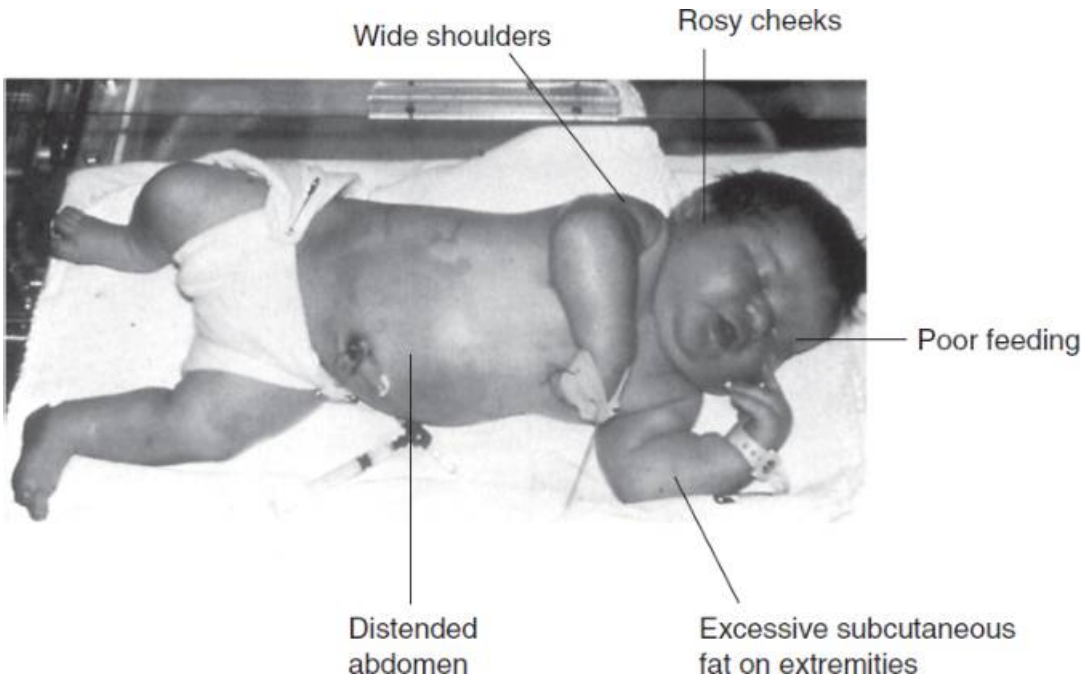

FIGURE 24.5. Characteristics of an infant of a diabetic mother. A macrosomic infant of a diabetic mother (IDM) has head circumference and length that are at the 90th percentile; the IDM's body weight greatly exceeds the 90th percentile. The IDM has considerable fat deposition in the shoulder and intrascapular area. (McDonald, M. G., Seshia, M. M. K. [2016]. *Avery's neonatology: Pathophysiology & management of the newborn* [7th ed.]. Wolters Kluwer.)

Be alert for hypoglycemia, which may occur immediately after birth or within an hour. Assess blood glucose levels, which should remain above 40 mg/dL. Closely assess the newborn for signs of hypoglycemia, including listlessness, hypotonia, apathy, poor feeding, apneic episodes with a drop in oxygen saturation, cyanosis, temperature instability, pallor and sweating, tremors, irritability, and seizures.

Assess the newborn for signs of birth trauma involving the head (tense, bulging fontanels, cephalhematoma, skull fractures, and facial nerve paralysis), shoulders and extremities (posturing, paralysis), and skin (bruising). Inspect the newborn for compromised oxygenation by examining the skin for cyanosis, pallor, mottling, and sluggish capillary refill. Take the newborn's temperature frequently and provide a neutral thermal environment to prevent cold stress, which would increase the glucose utilization and contribute to the hypoglycemic state.

TABLE 24.2 Critical Laboratory Values for Infants of Diabetic Mothers

Hypoglycemia	<40 mg/dL
Hypocalcemia	<7 mg/dL
Hypomagnesemia	<1.5 mg/dL
Hyperbilirubinemia	>12 mg/dL (term infant)
Polycythemia	>65% (venous hematocrit)
