This work is provided "as is," and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals' examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

shop.lww.com

This book is dedicated to my husband, Glenn, for his unfailing patience, encouragement, love, and gratitude—whose support and sense of humor make it all possible. And also to my children, Brian and Jennifer, and my grandchildren—Alyssa, Leyton, Peyton, Wyatt, Michael, Rylan, Brody, and Veda—who continue to inspire me throughout my life. You make it all worthwhile.

—SUSAN SCOTT RICCI

This text is dedicated to my initial mentor into pediatric nursing, Gayle Maloney. She role-modeled and inspired my passion for excellence in the care of children and families. Thank you to my ever-faithful and consistently dedicated husband, John, and my amazing and delightful children, Christian and Caitlin.

—TERRI KYLE

This book is dedicated to all the children out there and the wonderful nurses who care for them. They inspire me to become a better nurse, educator, and person. This book is also dedicated to my loving and supportive family. My husband, Chris, without whom I could not have reached this accomplishment. My four beautiful girls, Grace, Ella, Lily, and Maya, who have allowed me to learn firsthand about growth and development and who truly amaze me each and every day. My parents, Lene and Kishor Patel, who always taught me I could do whatever I put my mind to. To Terri Kyle, thank you for this opportunity, your endless support, and your incredible vision.

—SUSAN CARMAN

About the Authors

SUSAN SCOTT RICCI earned a diploma in nursing from the Washington Hospital Center School of Nursing, with a BSN and MSN, from Catholic University of America located in Washington, DC, an MEd in Counseling from the University of Southern Mississippi. She is licensed as a Women's Health Nurse Practitioner (APRN) from the University of Florida. She recently renewed her national certification as a Certified Nurse Educator (CNE). She has worked in numerous women's health care settings including labor and birth, postpartum, prenatal, and family planning ambulatory care clinics. Susan is a women's health care nurse practitioner, who has spent 30+ years in practice and in nursing education teaching in LPN, ADN, and BSN programs. She is involved in several professional nursing organizations and holds memberships in Sigma Theta Tau International Honor Society of Nursing, Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN), American Nurses Association (ANA), National Association of OB/GYN Nurses, Who's Who in Professional Nursing, American Nurses Association, and the Florida Council of Maternal–Child Nurses.

With Susan Scott Ricci's wealth of practical and educational experience, it is essential to concentrate on evidence-based nursing practice and reduce the amount of "nice to know" information that is presented to students. As an educator, she recognized the tendency for nursing educators to want to "cover the world" when teaching, rather than focusing on the facts that students need to know for safe practice. With this mission in mind, Susan has directed her energy to the *birth* of these essential facts in this textbook.

She recognizes that instructional time is shrinking as the world of health care is expanding exponentially. Therefore, with the valuable instructional time allotted, she has recognized the urgent need to

present pertinent facts as concisely as possible to promote application of knowledge within nursing practice.

TERRI KYLE earned a Doctorate of Nursing Practice with a focus in Educational Leadership from American Sentinel University, a Master of Science in Nursing (Child Health) from Emory University in Atlanta, Georgia, and Bachelor of Science in Nursing from the University of North Carolina at Chapel Hill. She is a certified pediatric nurse practitioner (primary care), and practicing pediatric nursing for over 35 years, she has had the opportunity to serve children and their families in a variety of diverse settings. Terri also holds the credential of certified nurse educator.

She has experience in inpatient pediatrics, in pediatric and neonatal intensive care units, newborn nursery, specialized pediatric units, and community hospitals. She has worked as a pediatric nurse practitioner in pediatric specialty clinics and primary care. She has been involved in teaching nursing for over 29 years with experience in both graduate and undergraduate education. Terri is a fellow in the National Association of Pediatric Nurse Practitioners and a member of the Sigma Theta Tau International Honor Society of Nursing, the National League for Nursing, and the Society of Pediatric Nurses.

With the limited time allotted to the topic of maternity and pediatric nursing in nursing programs, Terri recognized the need for a textbook that “got to the point.” She strongly believes in a concept-based approach for learning nursing—that is, to teach the basics to students in a broad, contextual format so that they can apply that knowledge in a variety of situations. The concept-based approach to nursing education is time efficient for nursing educators and fosters the acquisition of critical thinking skills leading to clinical reasoning development in student nurses.

SUSAN CARMAN earned a Bachelor of Science in Nursing from the University of Wisconsin-Madison and a Master of Science in Nursing and Master in Business Administration from the University of Colorado-Denver. As a pediatric nurse for more than 25 years, Susan has had the opportunity to care for children in a variety of

diverse settings and in many of the major children's hospitals throughout the United States. She also has provided volunteer nursing care in a variety of settings including the Dominican Republic and India. She has been involved in teaching nursing for the past 15 years and enjoys watching students transform into competent nurses with strong critical thinking skills. She is a member of Sigma Theta Tau and Beta Gamma Sigma.

Preface

Many nursing curricula combine and teach maternity and pediatrics in tandem. This can be viewed as a *natural fit* of two content areas that belong together. Nursing education in general is founded upon the principle of mastering simpler concepts first and incorporating those concepts into the student's knowledge base. The student is then able to progress to problem solving in more complex situations. In today's education climate with reduced class time devoted to specialty courses, it is particularly important for nursing educators to focus on key concepts, rather than attempting to cover everything within a specific topic.

The intent of *Maternity and Pediatric Nursing* is to provide the nurse the basis needed for sound nursing care of women and children. The content in the book will enable the reader to guide women and children toward higher levels of wellness throughout the life cycle. In addition, the focus of the textbook will allow the reader to anticipate, identify, and address common problems and provide timely, evidence-based interventions to reduce long-term sequelae.

This textbook is designed as a practical approach to understanding the health of women and children. The main objective is to help the student build a strong knowledge base and assist with the development of critical thinking skills and clinical reasoning. Women in our society are becoming empowered to make informed and responsible choices regarding their health and that of their children, but to do so they need the encouragement and support of nurses who care for them. This textbook focuses on women and children throughout their lifespan, covering a broad scope of topics with emphasis placed upon common issues. Maternity nursing content coverage is comprehensive yet presented in a concise and straightforward manner. The pediatric nursing content presents the important differences when caring for children compared with caring

for adults. Utilizing the nursing process, a concept-based approach to the care of children and their families provides relevant information in a concise and nonredundant manner.

Since women's health has expanded to include care throughout their lifespan, the emphasis of this textbook is on promoting and maintaining their health. The focus of this 4th edition has now expanded to the global outreach of various cultures and traditions in which nurses will encounter in their daily practice settings. Nurses are key players in the global community who improve the lives of mothers and infants. Safe nursing practice requires skills, knowledge, with application of good evidence-based clinical judgment. It is vital for nurses to understand their clients to help promote an optimal outcome to all women and their families. Childbirth today has returned to a more natural practice, that honors the normal process of birth. Several chapters focus on physiologic births and the nurse's role to accomplish this. With these imperatives in mind, the chapters present an overview of common health conditions encountered by many women and how to care for them. The new content presented can be used as a framework in caring for clients from diverse backgrounds, histories, and cultures.

The focus when caring for children is also to maintain and promote their health, as well as provide developmentally appropriate care whether the child is well or ill. Restoration of a child's health when an illness is experienced is paramount for timely accomplishment of suitable growth and development. Nurses are a prime position for influencing children's health, not only through the direct care they provide to children, but also through the connections they make with caregivers and their ability to educate families to best care for their children. Focusing on conceptual learning, students may develop complex critical thinking leading to the ability to clinically reason within various health care environments. This approach is supported by many of the book's features, such as the reoccurring features: Unfolding Case Studies, Clinical Reasoning Alerts, and Thinking about Development.

Organization

Each chapter of *Maternity and Pediatric Nursing* focuses on a different aspect of maternity and/or pediatric nursing care. The book is divided into eleven units, beginning with general concepts related to maternity and pediatric nursing care, progressing from women's health, pregnancy and birth, through child health promotion and nursing management of alterations in children's health.

Unit I: Introduction to Maternity and Pediatric Nursing

Unit I helps build a foundation for the student beginning the study of the care of women, infants, and children. This unit explores contemporary issues and trends in maternity and pediatric nursing. Perspectives on women's health and pediatric nursing, core concepts of maternal and pediatric nursing, including, family-centered and atraumatic care, and communication, and community-based nursing are addressed.

Unit II: Women's Health Throughout the Lifespan

Unit II introduces the student to selected women's health topics, including structure and function of the reproductive system, common reproductive concerns, sexually transmitted infections, problems of the breast, and benign disorders and cancers of the female reproductive tract. This unit encourages the student to assist women in maintaining their quality of life, reducing their risk of disease, and becoming active partners with their health care professional.

Unit III: Pregnancy

Unit III addresses topics related to normal pregnancy, including fetal development, genetics, and maternal adaptation to pregnancy. Nursing management during normal pregnancy is addressed, encouraging application of basic knowledge to nursing practice. Nursing management includes maternal and fetal assessment throughout pregnancy, interventions to promote self-care and minimize common discomforts, and patient education.

Unit IV: Labor and Birth

Unit IV begins with an explanation of the normal labor and birth process, including maternal and fetal adaptations. This is followed by content focusing on the nurse's role during normal labor and birth, which includes maternal and fetal assessment, pharmacologic and nonpharmacologic comfort measures and pain management, and specific nursing interventions during each stage of labor and birth.

Unit V: Postpartum Period

Unit V focuses on maternal adaptation during the normal postpartum period. Both physiologic and psychological aspects are explored. Paternal adaptation is also considered. This unit also presents related nursing management, including assessment of physical and emotional status, promoting comfort, assisting with elimination, counseling about sexuality and contraception, promoting nutrition, promoting family adaptation, and preparing for discharge.

Unit VI: The Newborn

Unit VI covers physiologic and behavioral adaptations of the normal newborn. It also delves into nursing management of the normal newborn, including immediate assessment and specific interventions as well as ongoing assessment, physical examination, and specific interventions during the early newborn period.

Unit VII: Child bearing at Risk

Unit VII shifts the focus to at-risk pregnancy, childbirth, and postpartum care. Pre-existing conditions of the woman, pregnancy-related complications, at-risk labor, emergencies associated with labor and birth, and medical conditions and complications affecting the postpartum woman are all covered. Treatment and nursing management are presented for each medical condition. This organization allows the student to build on a solid foundation of normal material when studying the at-risk content.

Unit VIII: The Newborn at Risk

Unit VIII continues to center on at-risk content. Issues of the newborn with birthweight variations, gestational age variations, congenital conditions, and acquired disorders are explored. Treatment and nursing management are presented for each medical condition. This organization helps cement the student's understanding of the material.

Unit IX: Health Promotion of the Growing Child and Family

Unit IX provides information related to growth and development expectations of the well child from newborn through adolescence. Although not exhaustive in nature, this unit provides a broad knowledge base related to normal growth and development that the nurse can draw on in any situation. Common concerns related to growth and development and client/family education are included in each age-specific chapter.

Unit X: Children and Their Families

Unit X covers broad concepts that provide the foundation for providing nursing care for children. Rather than reiterating all aspects of nursing care, the unit focuses on specific details needed to provide nursing care for children in general. The content remains focused upon differences in caring for children compared with adults. Topics covered in this unit include atraumatic care, anticipatory guidance, and routine well-child care (including immunization and safety), health assessment, nursing care of the child in diverse settings, including the hospital and at home, concerns common to special needs children, pediatric variations in medication and intravenous fluid delivery and nutritional support, and pain management in children.

Unit XI: Nursing Care of the Child with a Health Disorder

Unit XI focuses on children's responses to health disorders. This unit provides comprehensive coverage of illnesses affecting children and is presented according to broad topics of disorders organized with a body systems approach. It also includes infectious, genetic, and mental health disorders as well as pediatric emergencies. Each chapter follows a similar format in order to facilitate presentation of the information as well as reduce repetition. The chapters begin with a nursing process overview for the particular broad topic, presenting differences in children and how the nursing process applies. The approach provides a general framework for addressing disorders within the chapter. Individual disorders are then addressed with attention to specifics related to pathophysiology, nursing assessment, nursing management, and special considerations. Common pediatric disorders are covered in greater depth than less common disorders. The format of the chapters allows for the building of a strong knowledge base and encourages critical thinking. Additionally, the format is nursing process driven and consistent from chapter to chapter, providing a practical and sensible presentation of the information.

Recurring Features

To provide the instructor and student with an exciting and user-friendly text, a number of recurring features have been developed.

Key Terms

A list of terms that are considered essential to the chapter's understanding is presented at the beginning of each chapter. Each key term appears in boldface, with the definition included in the text. Key terms may also be accessed on thePoint.

Learning Objectives

Learning Objectives included at the beginning of each chapter guide the student in understanding what is important and why, leading the student to prioritize information for learning. These valuable learning

tools also provide opportunities for self-testing or instructor evaluation of student knowledge and ability.

Words of Wisdom

Each chapter opens with inspiring Words of Wisdom (WOW), which offer helpful, timely, or interesting thoughts. These WOW statements set the stage for each chapter and give the student valuable insight into nursing care of women, children, and their families.

Threaded Case Studies

Real-life scenarios present relevant woman, child, and family information that is intended to improve the student's clinical reasoning skills. Questions are threaded throughout the chapter about the scenario provide an opportunity for the student to critically evaluate the appropriate course of action.

New! Clinical Reasoning Alert

The Clinical Reasoning Alert promotes critical thinking in the nursing process on information key to clinical reasoning.

New! Unfolding Patient Stories

New! Unfolding Patient Stories, written by the National League for Nursing, are an engaging way to begin meaningful conversations in the classroom. These vignettes, feature patients from Wolters Kluwer's *vSim for Nursing* | *Health Assessment* (co-developed with Laerdal Medical) and DocuCare products; however, each Unfolding Patient Story in the book stands alone, not requiring purchase of these products. For your convenience, a list of these case studies, along with their location in the book, appears in the "Case Studies in This Book" section later in this front matter.

Evidence-Based Practice

The consistent promotion of evidence-based practice is a key feature of the text. Throughout the chapters, pivotal questions addressed by current research have been incorporated into Evidence-Based Practice displays, which discuss recent evidence-based research findings and provide recommendations for nurses.

Healthy People 2030

Throughout the textbook, relevant *Healthy People 2030* objectives are outlined in box format. The nursing implications or guidance provided in the box serve as a roadmap for improving the health of women, mothers, and children. These objectives reflect the proposed *Healthy People 2030* objectives (current at the time this book went to press).

Atraumatic Care

These highlights, located throughout the pediatric sections of the book, provide tips for providing atraumatic care to children in particular situations in relation to the topic being discussed.

Thinking About Development

The content featured in these boxes in chapters related to the care of children will encourage student to think critically about special developmental concerns relating to the topic being discussed.

Teaching Guidelines

An important tool for achieving health promotion and disease prevention is health education. Throughout the textbook, Teaching Guidelines raise awareness, provide timely and accurate information, and are designed to ensure the student's preparation for educating women, children, and their families about various issues.

Consider This!

In every chapter the student is asked to *Consider This!* These first-person narratives engage the student in real-life scenarios experienced by their clients. The personal accounts evoke empathy and help the student to perfect caregiving skills. Each box ends with an opportunity for further contemplation, encouraging the student to think critically about the scenario.

Take Note!

The *Take Note!* feature draws the student's attention to points of critical emphasis throughout the chapter. This feature is often used to stress vitally important information.

Drug Guides

Drug guide tables summarize information about commonly used medications. The actions, indications, and significant nursing implications presented assist the student in providing optimum care to women, children, and their families.

Common Laboratory and Diagnostic Tests

The Common Laboratory and Diagnostic Tests tables in many of the chapters provide the student with a general understanding of how a broad range of disorders is diagnosed. Rather than reading the information repeatedly throughout the narrative, the student is then able to refer to the table as needed.

Common Medical Treatments

The Common Medical Treatments tables in many of the nursing management chapters provide the student with a broad awareness of how a common group of disorders is treated either medically or surgically. The tables serve as a reference point for common medical treatments.

Nursing Care Plans/Nursing Process Overview

Nursing Care Plans provide concrete examples of each step of the nursing process and are included in numerous chapters. The Nursing Process Overview summarizes issue- or system-related content, thereby minimizing repetition. In the pediatric-related chapters, a nursing process overview highlighted at the beginning of each chapter broadly guides the student in the care of child with a disorder related to a particular system.

Focus on Safety

These boxes are placed intermittently throughout the text to draw the student's attention to potential safety issues. Based on the current National Patient Safety Goals, the box lists steps to assist with meeting of the safety goal.

Comparison Charts

These charts compare two or more disorders or other easily confused concepts. They serve to provide an explanation that clarifies the concepts for the student.

Nursing Procedures

Step-by-step Nursing Procedures are presented in a clear, concise format to facilitate competent performance of relevant procedures as well as to clarify maternity and pediatric variations when appropriate.

Dosage Calculation Box

This box provides a dosage calculation example in each of the alteration/disorder chapters. Reiteration of the significance of accurate dosage calculation assists the student with mastery of this critical concept.

Concept Mastery Alerts

Concept Mastery Alerts clarify maternity and pediatric nursing concepts to improve the reader's understanding of potentially

confusing topics as identified by Misconception Alerts in Lippincott's Adaptive Learning Powered by PrepU. Data from thousands of actual students using this program in courses across the United States identified common misconceptions for the authors to clarify in this new edition.

Icons

WATCH AND LEARN

A special icon throughout the book directs students to free video clips locate on thePoint that highlight growth and development, communicating with children, and providing nursing care to the child in the hospital.

CONCEPTS IN ACTION ANIMATIONS

These unique animations, also located on thePoint, bring physiologic and pathophysiologic concepts to life and enhance student comprehension.

Tables, Boxes, Illustrations, and Photographs

Abundant tables and boxes summarize key content throughout the book. Additionally, beautiful illustrations and photographs help the student to visualize the content. These features allow the student to quickly and easily access information.

Key Concepts

At the end of each chapter, Key Concepts provide a quick review of essential chapter elements. These bulleted lists help the student focus on the important aspects of the chapter.

References and Helpful Websites

References used in the development of the text are provided at the end of each chapter. These listings enable the student to further explore topics of interest. Many online resources are provided on thePoint as a means for the student to electronically explore relevant content material. These resources can be shared with women, children, and their families to enhance patient education and support.

Developing Clinical Judgment

This section located at the end of each chapter assists the student with the development of clinical judgment through:

- **Practicing for NCLEX**—these NCLEX-RN® style questions (multiple choice, multiple response, fill-in-the blank) test the student's ability to utilize critical thinking in the application of the nursing process to chapter material. The questions are styled similarly to the national licensing exam (NCLEX-RN®).
- **Dosage calculation questions**—these applicable problems test the student's ability to accurately determine medication dosages particular to children.
- **Critical thinking exercises**—these exercises serve to stimulate the student to incorporate the current material with previously learned concepts and reach a satisfactory conclusion. The exercises encourage students to think critically, problem solve, and consider their own perspective on given topics.
- **Study activities**—these activities promote student participation in the learning process. This section encourages increased interaction/learning via clinical, online, and community activities.
- **Bringing It All Together: A Case Study**—an additional real-life scenario is presented. Applicable child and family information is meant to improve the student's clinical reasoning skills. The case is further developed through critical thinking questions on thePoint.
- **Answers**—answers to the Developing Clinical Judgment questions are provided to instructors on thePoint.

Teaching–Learning Package

Instructor's Resources

Tools to assist you with teaching your course are available upon adoption of this text on thePoint.

- An **E-Book** on thePoint gives you access to the book's full text and images online.
- A **Test Generator** that features hundreds of questions within a powerful tool to help the instructor create quizzes and tests.
- **PowerPoint presentations** with **Guided Lecture Notes** provide an easy way for you to integrate the textbook with our students' class-room experience, either via slide shows or handouts. Multiple choice and true/false questions are integrated into the presentations to promote class participation and allow you to use i-clicker technology.
- An **Image Bank** lets you use the photographs and illustrations from this textbook in your PowerPoint slides or as you see fit in your course.
- **Case Studies** with related questions (and suggested answers) give students an opportunity to apply their knowledge to a client case similar to one they might encounter in practice.
- **Pre-Lecture Quizzes** (and answers) are quick, knowledge-based assessments that allow you to check students' reading.
- **Discussion Topics** (and suggested answers) can be used as conversation starters or in online discussion boards.
- **Assignments** (and suggested answers) include group, written, clinical, and web assignments.
- Sample **Syllabi** provide guidance for structuring your pediatric nursing courses and are provided for four different course lengths: 4, 6, 8, and 10 weeks.
- **Journal Articles**, updated for the new edition, offer access to current research available in Lippincott Williams & Wilkins journals.

Contact your sales representative or check out LWW.com/Nursing for more details and ordering information.

Student Resources

An exciting set of free resources is available to help students review material and become even more familiar with vital concepts. Students can access all these resources on using the codes printed in the front of their textbooks.

- **NCLEX-Style Review Questions** for each chapter help students review important concepts and practice for NCLEX. **More than 1,400 questions** are included!
- **Multimedia Resources** appeal to a variety of learning styles. Icons in the text direct readers to relevant videos and animations:
  - **Watch and Learn Videos** highlight growth and development, communicating with children, and providing nursing care to the child in the hospital.
  - **Concepts in Action Animations** bring physiologic and pathophysiologic concepts to life and enhance student comprehension.
- A **Spanish–English Audio Glossary** provides helpful terms and phrases for communicating with patients who speak Spanish.
- **Journal Articles** offer access to current research available in Lippincott Williams & Wilkins journals.

Lippincott® CoursePoint+

The same trusted solution, innovation and unmatched support that you have come to expect from *Lippincott CoursePoint+* is now enhanced with more engaging learning tools and deeper analytics to help prepare students for practice. This powerfully integrated, digital learning solution combines learning tools, case studies, virtual simulation, real-time data and the most trusted nursing education content on the market to make curriculum-wide learning more efficient and to meet students where they're at in their learning. And now, it's easier than ever for instructors and students to use, giving them everything they need for course and curriculum success!

Lippincott Coursepoint+ includes:

- Engaging course content provides a variety of learning tools to engage students of all learning styles.

- A more personalized learning approach, including adaptive learning powered by PrepU, gives students the content and tools they need at the moment they need it, giving them data for more focused remediation and helping to boost their confidence.
- Varying levels of case studies, virtual simulation, and access to Lippincott Advisor help students learn the critical thinking and clinical judgment skills to help them become practice-ready nurses.
- Unparalleled reporting provides in-depth dashboards with several data points to track student progress and help identify strengths and weaknesses.
- Unmatched support includes training coaches, product trainers, and nursing education consultants to help educators and students implement CoursePoint with ease.

Contents in Brief

UNIT I INTRODUCTION TO MATERNITY AND PEDIATRIC NURSING

CHAPTER 1 Perspectives on Maternal and Child Health Care
CHAPTER 2 Caring for Women and Children

UNIT II WOMEN'S HEALTH THROUGHOUT THE LIFESPAN

CHAPTER 3 Anatomy and Physiology of the Reproductive Systems
CHAPTER 4 Common Gynecologic Issues
CHAPTER 5 Sexually Transmitted Infections
CHAPTER 6 Disorders of the Breasts
CHAPTER 7 Benign Disorders of the Female Reproductive Tract
CHAPTER 8 Cancers of the Female Reproductive Tract
CHAPTER 9 Violence and Abuse

UNIT III PREGNANCY

CHAPTER 10 Fetal Development and Genetics
CHAPTER 11 Maternal Adaptation During Pregnancy
CHAPTER 12 Nursing Management During Pregnancy

UNIT IV LABOR AND BIRTH

CHAPTER 13 Labor and Birth Process
CHAPTER 14 Nursing Management During Labor and Birth

UNIT V POSTPARTUM PERIOD

CHAPTER 15 Postpartum Adaptations

CHAPTER 16 Nursing Management During the Postpartum Period

UNIT VI THE NEWBORN

CHAPTER 17 Newborn Transitioning

CHAPTER 18 Nursing Management of the Newborn

UNIT VII CHILDBEARING AT RISK

CHAPTER 19 Nursing Management of Pregnancy at Risk: Pregnancy-Related Complications

CHAPTER 20 Nursing Management of the Pregnancy at Risk: Selected Health Conditions and Vulnerable Populations

CHAPTER 21 Nursing Management of Labor and Birth at Risk

CHAPTER 22 Nursing Management of the Postpartum Woman at Risk

UNIT VIII THE NEWBORN AT RISK

CHAPTER 23 Nursing Care of the Newborn with Special Needs

CHAPTER 24 Nursing Management of the Newborn at Risk: Acquired and Congenital Newborn Conditions

UNIT IX HEALTH PROMOTION OF THE GROWING CHILD AND FAMILY

CHAPTER 25 Growth and Development of the Newborn and Infant

CHAPTER 26 Growth and Development of the Toddler

CHAPTER 27 Growth and Development of the Preschooler

CHAPTER 28 Growth and Development of the School-Age Child

CHAPTER 29 Growth and Development of the Adolescent

UNIT X FOUNDATIONS OF PEDIATRIC NURSING

CHAPTER 30 Atraumatic Care of Children and Families
CHAPTER 31 Health Supervision
CHAPTER 32 Health Assessment of Children
CHAPTER 33 Caring for Children in Diverse Settings
CHAPTER 34 Caring for the Special Needs Child
CHAPTER 35 Key Pediatric Nursing Interventions
CHAPTER 36 Nursing Care of the Child with an Alteration in Comfort–Pain Assessment and Management

UNIT XI NURSING CARE OF THE CHILD WITH A HEALTH DISORDER

CHAPTER 37 Nursing Care of the Child with an Infection
CHAPTER 38 Nursing Care of the Child with an Alteration in Intracranial Regulation/Neurologic Disorder
CHAPTER 39 Nursing Care of the Child with an Alteration in Sensory Perception/Disorder of the Eyes or Ears
CHAPTER 40 Nursing Care of the Child with an Alteration in Gas Exchange/Respiratory Disorder
CHAPTER 41 Nursing Care of the Child with an Alteration in Perfusion/Cardiovascular Disorder
CHAPTER 42 Nursing Care of the Child with an Alteration in Bowel Elimination/Gastrointestinal Disorder
CHAPTER 43 Nursing Care of the Child with an Alteration in Urinary Elimination/Genitourinary Disorder
CHAPTER 44 Nursing Care of the Child with an Alteration in Mobility/Neuromuscular or Musculoskeletal Disorder
CHAPTER 45 Nursing Care of the Child with an Alteration in Tissue Integrity/Integumentary Disorder

CHAPTER 46 Nursing Care of the Child with an Alteration in Cellular Regulation/Hematologic or Neoplastic Disorder
CHAPTER 47 Nursing Care of the Child with an Alteration in Immunity or Immunologic Disorder
CHAPTER 48 Nursing Care of the Child with an Alteration in Metabolism/Endocrine Disorder
CHAPTER 49 Nursing Care of the Child with an Alteration in Genetics
CHAPTER 50 Nursing Care of the Child with an Alteration in Behavior, Cognition, or Development
CHAPTER 51 Nursing Care During a Pediatric Emergency

Appendix A Standard Laboratory Values
Appendix B Clinical Paths
Appendix C Cervical Dilation Chart
Appendix D Weight Conversion Charts
Appendix E Breastfeeding and Medication Use
Appendix F Growth Charts
Appendix G Blood Pressure Charts for Children and Adolescents
Index

Contents

About the Authors
Reviewers to the Fourth Edition
Preface

UNIT I Introduction to Maternity and Pediatric Nursing

CHAPTER 1 Perspectives on Maternal and Child Health Care

Introduction

Historical Development

The History of Maternal and Newborn Health and Health Care

The History of Child Health and Child Health Care

Evolution of Maternal and Newborn Nursing

Evolution of Pediatric Nursing

Health Status of Women and Children

Mortality

Morbidity

Factors Affecting Maternal and Child Health

Family

Genetics

Society

Global Society

Culture

Health Status and Lifestyle

Access to Health Care

Improvements in Diagnosis and Treatments
Empowerment of Health Care Consumers
Barriers to Health Care
Legal and Ethical Issues in Maternal and Child Health Care
Abortion
Substance Abuse
Intrauterine Therapy
Maternal–Fetal Conflict
Stem Cell Research
Umbilical Cord Blood Banking
Informed Consent
Assent
Refusal of Medical Treatment
Advance Directives
Client Rights
Confidentiality
Implications for Nurses
CHAPTER 2 Caring for Women and Children
Introduction
Core Concepts of Maternal and Child Health Nursing
Family-Centered Care
Evidence-Based Care
Collaborative Care
Atraumatic Care
Communication
Education
The Continuum of Care Emphasis
Preventative Care
Culturally Competent Nursing Care

The Nursing Process
Standards of Care and Performance
Community-Based Care
Community Health Nursing
Community-Based Nursing
Shift in Responsibilities from Hospital-Based to Community-Based Nursing
Community-Based Nursing Interventions
Community-Based Nursing Challenges
Community-Based Nursing Care Settings for Women and Children

UNIT II Women's Health Throughout the Lifespan

CHAPTER 3 Anatomy and Physiology of the Reproductive Systems
Introduction
Female Reproductive Anatomy and Physiology
External Female Reproductive Organs
Internal Female Reproductive Organs
Breasts
Female Sexual Response
The Female Reproductive Cycle
Ovarian Cycle
Endometrial (Uterine) Cycle
Menstruation
Menstrual Cycle Hormones
Perimenopause
Menopause
Male Reproductive Anatomy and Physiology
External Male Reproductive Organs

Internal Male Reproductive Organs
Male Sexual Response
CHAPTER 4 Common Gynecologic Issues
Introduction
Menstrual Disorders
Amenorrhea
Dysmenorrhea
Abnormal Uterine Bleeding (AUB)
Premenstrual Syndrome (PMS)
Endometriosis
Infertility
Cultural Considerations
Etiology and Risk Factors
Therapeutic Management
Nursing Assessment
Nursing Management
Contraception
Types of Contraceptive Methods
Nursing Management for Choosing a Contraceptive Method
Nursing Assessment
Nursing Analyses
Nursing Interventions
Abortion
Surgical Abortion
Medical Abortion
Menopausal Transition
Therapeutic Management
Nursing Assessment
Nursing Management
CHAPTER 5 Sexually Transmitted Infections

Introduction
Sexually Transmitted Infections and Adolescents
Nursing Assessment
Nursing Management
Infections Characterized by Vaginal Discharge
Vaginal Candidiasis (VC)
Therapeutic Management
Nursing Assessment
Nursing Management
Trichomoniasis
Therapeutic Management
Nursing Assessment
Nursing Management
Bacterial Vaginosis (BV)
Therapeutic Management
Nursing Assessment
Nursing Management
Infections Characterized by Cervicitis
Chlamydia
Therapeutic Management
Nursing Assessment
Gonorrhea
Therapeutic Management
Nursing Assessment
Nursing Management of Chlamydia and Gonorrhea
Infections Characterized by Genital Ulcers
Genital Herpes Simplex
Therapeutic Management
Nursing Assessment
Syphilis

Therapeutic Management
Nursing Assessment
Nursing Management of Herpes and Syphilis
Pelvic Inflammatory Disease (PID)
Therapeutic Management
Nursing Assessment
Nursing Management
Vaccine-Preventable STIs
Human Papillomavirus
Nursing Assessment
Therapeutic Management
Nursing Management
Hepatitis A and B
Therapeutic Management
Nursing Assessment
Nursing Management
Hepatitis C
Zika Virus
Ectoparasitic Infections
Human Immunodeficiency Virus (HIV)
HIV and Adolescents
Clinical Manifestations
Diagnosis
Therapeutic Management
Nursing Management
Preventing Sexually Transmitted Infections
Behavior Modification
Contraception
CHAPTER 6 Disorders of the Breasts
Introduction
Benign Breast Disorders

Fibrocystic Breast Changes
Fibroadenomas
Mastitis
Malignant Breast Disorder
Pathophysiology
Staging of Breast Cancer
Risk Factors
Diagnosis
Therapeutic Management
Implementing Health Promotion and Disease Prevention Strategies
Breast Cancer Screening
Nutrition
CHAPTER 7 Benign Disorders of the Female Reproductive Tract
Introduction
Pelvic Floor Disorders
Pelvic Organ Prolapse
Urinary Incontinence
Benign Growths
Polyps
Uterine Fibroids
Genital Fistulas
Bartholin Cysts
Ovarian Cysts
CHAPTER 8 Cancers of the Female Reproductive Tract
Introduction
Ovarian Cancer
Pathophysiology
Screening and Diagnosis
Therapeutic Management
Nursing Assessment

Nursing Management
Endometrial Cancer
Pathophysiology
Screening and Diagnosis
Therapeutic Management
Nursing Assessment
Nursing Management
Cervical Cancer
Pathophysiology
Screening and Diagnosis
Therapeutic Management
Nursing Assessment
Nursing Management
Vaginal Cancer
Pathophysiology
Therapeutic Management
Nursing Assessment
Nursing Management
Vulvar Cancer
Pathophysiology
Screening and Diagnosis
Therapeutic Management
Nursing Assessment
Nursing Management
CHAPTER 9 Violence and Abuse
Introduction
Intimate Partner Violence
Incidence
Background
Characteristics of Intimate Partner Violence
Types of Abuse

Myths and Facts about Intimate Partner Violence
Abuse Profiles
Violence against Pregnant Women
Violence against Older Women
Nursing Management of Intimate Partner Violence Victims
Sexual Violence
Characteristics of Assailants
Sexual Abuse
Incest
Rape
Female Genital Cutting
Human Trafficking
Summary

UNIT III Pregnancy

CHAPTER 10 Fetal Development and Genetics
Introduction
Fetal Development
Zygotic Stage
Blastocyst Stage
Embryonic Stage
Fetal Stage
Fetal Circulation
Genetics
Advances in Genetics
Inheritance
Patterns of Inheritance for Genetic Disorders
Chromosomal Abnormalities
Genetic Evaluation and Counseling

Nursing Roles and Responsibilities
CHAPTER 11 Maternal Adaptation During Pregnancy
Introduction
Signs and Symptoms of Pregnancy
Subjective (Presumptive) Signs
Objective (Probable) Signs
Positive Signs
Physiologic Adaptations During Pregnancy
Reproductive System Adaptations
General Body System Adaptations
Changing Nutritional Needs of Pregnancy
Nutritional Requirements During Pregnancy
Gluten-Free Diet During Pregnancy
USDA and MyPlate
Maternal Weight Gain
Nutrition Promotion
Special Nutritional Considerations
Psychosocial Adaptations During Pregnancy
Maternal Emotional Responses
Becoming a Mother
Pregnancy and Sexuality
Pregnancy and the Partner
Pregnancy and Siblings
CHAPTER 12 Nursing Management During Pregnancy
Introduction
Preconception and Interconception Care
Risk Factors for Adverse Pregnancy Outcomes
Nursing Management
The First Prenatal Visit
Comprehensive Health History

Physical Examination
Laboratory Tests
Follow-Up Visits
Follow-Up Visit Intervals and Assessments
Fundal Height Measurement
Fetal Movement Determination
Fetal Heart Rate Measurement
Teaching about the Danger Signs during Pregnancy
Assessment of Fetal Well-Being
Ultrasonography
Doppler Flow Studies
Alpha-Fetoprotein Analysis
Marker Screening Tests
Nuchal Translucency Screening
Amniocentesis
Chorionic Villus Sampling
Nonstress Test
Biophysical Profile
Nursing Management for the Common Discomforts of Pregnancy
First-Trimester Discomforts
Second-Trimester Discomforts
Third-Trimester Discomforts
Nursing Management to Promote Self-Care
Personal Hygiene
Clothing
Exercise
Sleep and Rest
Sexual Activity and Sexuality
Employment

Travel
Immunizations and Medications
Nursing Management to Prepare the Woman and Her Partner for Labor, Birth, and Parenthood
Childbirth Education Classes
Nursing Management and Childbirth Education
Options for Birth Settings and Care Providers
Preparation for Breastfeeding or Bottle-Feeding
Final Preparation for Labor and Birth

UNIT IV Labor and Birth

CHAPTER 13 Labor and Birth Process
Introduction
Initiation of Labor
Premonitory Signs of Labor
Cervical Changes
Lightening
Increased Energy Level
Bloody Show
Braxton Hicks Contractions
Spontaneous Rupture of Membranes
True Versus False Labor
Factors Affecting the Labor Process
Passageway
Passenger
Powers
Position (Maternal)
Psychological Response
Philosophy

Partners
Patience
Patient (Client) Preparation: Prenatal Education
Pain Management
Physiologic Responses to Labor
Maternal Responses
Fetal Responses
Stages of Labor
First Stage
Second Stage
Third Stage
Fourth Stage
CHAPTER 14 Nursing Management During Labor and Birth
Introduction
Maternal Assessment During Labor and Birth
Vaginal Examination
Assessing Uterine Contractions
Performing Leopold Maneuvers
Fetal Assessment During Labor and Birth
Analysis of Amniotic Fluid
Analysis of the FHR
Other Fetal Assessment Methods
Promoting Comfort and Providing Pain Management During Labor
Nonpharmacologic Measures
Pharmacologic Measures
Nursing Care During Labor and Birth
Nursing Management during the First Stage of Labor

Nursing Management during the Second Stage of Labor
Nursing Management during the Third Stage of Labor
Nursing Management during the Fourth Stage of Labor

UNIT V Postpartum Period

CHAPTER 15 Postpartum Adaptations
Introduction
Maternal Physiologic Adaptations
Reproductive System Adaptations
Cardiovascular System Adaptations
Urinary System Adaptations
Gastrointestinal System Adaptations
Musculoskeletal System Adaptations
Integumentary System Adaptations
Respiratory System Adaptations
Endocrine System Adaptations
Weight Loss after Childbirth
Sexual Health
Global Health of Childbearing Women
Lactation
Ovulation and Return of Menstruation
Cultural Considerations for the Postpartum Period
Balance of Hot and Cold
Postpartum Cultural Beliefs
Psychological Adaptations
Parental Attachment Behaviors
Maternal Psychological Adaptations

Partner Psychological Adaptations
CHAPTER 16 Nursing Management During the Postpartum Period
Introduction
Social Support and Cultural Considerations
Nursing Assessment in the Postpartum Period
Vital Signs Assessment
Physical Examination
Psychosocial Assessment
Nursing Interventions
Providing Optimal Cultural Care
Promoting Comfort
Assisting with Elimination
Promoting Activity, Rest, and Exercise
Preventing Stress Incontinence
Assisting with Self-Care Measures
Ensuring Safety
Counseling about Sexuality and Contraception
Promoting Maternal Nutrition
Supporting the Woman's Choice of Infant Feeding Method
Teaching about Breast Care
Promoting Family Adjustment and Well-Being
Preparing for Discharge

UNIT VI The Newborn

CHAPTER 17 Newborn Transitioning
Introduction
Physiologic Transitioning
Cardiovascular System Adaptations
Respiratory System Adaptations

Body Temperature Regulation
Hepatic System Function
Gastrointestinal System Adaptations
Renal System Changes
Immune System Adaptations
Integumentary System Adaptations
Neurologic System Adaptations
Behavioral Adaptations
Behavioral Patterns
Behavioral Responses
CHAPTER 18 Nursing Management of the Newborn
Introduction
Nursing Management During the Immediate Newborn Period
Assessment
Nursing Interventions
Nursing Management During the Early Newborn Period
Assessment
Nursing Interventions

UNIT VII Childbearing at Risk

CHAPTER 19 Nursing Management of Pregnancy at Risk: Pregnancy-Related Complications
Introduction
Bleeding During Pregnancy
Spontaneous Abortion
Ectopic Pregnancy
Gestational Trophoblastic Disease
Cervical Insufficiency
Placenta Previa

Placental Abruption
Placenta Accreta Spectrum
Hyperemesis Gravidarum
Pathophysiology
Therapeutic Management
Nursing Assessment
Nursing Management
Hypertensive Disorders of Pregnancy
Chronic Hypertension
Gestational Hypertension
Preeclampsia/Eclampsia
HELLP Syndrome
Gestational Diabetes
Blood Incompatibility
Pathophysiology
Nursing Assessment
Nursing Management
Amniotic Fluid Imbalances
Polyhydramnios
Oligohydramnios
Multiple Gestation
Therapeutic Management
Nursing Assessment
Nursing Management
Prelabor Rupture of Membranes
Therapeutic Management
Nursing Assessment
Nursing Management
CHAPTER 20 Nursing Management of the Pregnancy at Risk: Selected Health Conditions and Vulnerable Populations

Introduction
Diabetes Mellitus
Pathophysiology
Screening
Therapeutic Management
Nursing Assessment
Nursing Management
Cardiovascular Disorders
Congenital and Acquired Heart Disease
Hypertension in Pregnancy
Chronic Hypertension
Respiratory Conditions
Asthma
Tuberculosis
Hematologic Conditions
Iron-Deficiency Anemia
Thalassemia
Sickle Cell Anemia
Autoimmune Disorders
Systemic Lupus Erythematosus
Multiple Sclerosis
Rheumatoid Arthritis
Infections
Cytomegalovirus
Rubella
Herpes Simplex Virus
Hepatitis B Virus
Varicella Zoster Virus
Parvovirus B19
Group B Streptococcus
Toxoplasmosis

Women Who Are HIV-Positive
Vulnerable Populations
Pregnant Adolescents
The Woman of Advanced Maternal Age
The Obese Pregnant Woman
The Pregnant Woman and Substance Abuse
CHAPTER 21 Nursing Management of Labor and Birth at Risk
Introduction
Dystocia
Problems with the Powers
Problems with the Passenger
Problems with the Passageway
Problems with the Psyche
Nursing Assessment
Nursing Management
Nontraditional Families
Preterm Labor
Therapeutic Management
Nursing Assessment
Nursing Management
Post-Term Pregnancy
Nursing Assessment
Nursing Management
Women Requiring Labor Induction and Augmentation
Therapeutic Management
Nursing Assessment
Nursing Management
Vaginal Birth after Cesarean
Intrauterine Fetal Demise
Nursing Assessment

Nursing Management
Women Experiencing an Obstetric Emergency
Umbilical Cord Prolapse
Placenta Previa
Placental Abruption
Uterine Rupture
Anaphylactoid Syndrome of Pregnancy
Women Requiring Birth-Related Procedures
Forceps- or Vacuum-Assisted Birth
Cesarean Birth
CHAPTER 22 Nursing Management of the Postpartum Woman at Risk
Introduction
Postpartum Hemorrhage
Pathophysiology
Nursing Assessment
Nursing Management
Venous Thromboembolic Conditions
Pathophysiology
Nursing Assessment
Nursing Management
Postpartum Infection
Endometritis
Surgical Site Infections
Urinary Tract Infections
Mastitis
Postpartum Affective Disorders
Postpartum Blues
Postpartum Depression
Postpartum Psychosis

UNIT VIII The Newborn at Risk

CHAPTER 23 Nursing Care of the Newborn with Special Needs

- Introduction
- Birth Weight Variations
  - *Small-for-Gestational-Age Newborns*
  - *Large-for-Gestational-Age Newborns*
- Gestational Age Variations
  - *Postterm Newborn*
  - *Preterm Newborn*
- Late Preterm Newborn (“Near Term”)
  - *Dealing with Perinatal Loss*

CHAPTER 24 Nursing Management of the Newborn at Risk: Acquired and Congenital Newborn Conditions

- Introduction
- Acquired Disorders
  - *Hypoxic-Ischemic Encephalopathy*
  - *Transient Tachypnea of the Newborn*
  - *Respiratory Distress Syndrome*
  - *Meconium Aspiration Syndrome (MAS)*
  - *Persistent Pulmonary Hypertension of the Newborn*
  - *Periventricular-Intraventricular Hemorrhage (PIVH)*
  - *Necrotizing Enterocolitis*
  - *Infants of Diabetic Mothers (IDM)*
  - *Birth Injuries*
  - *Newborns of Mothers with Substance Use Disorder (SUD)*
  - *Hyperbilirubinemia*
- Congenital Conditions

Esophageal Atresia and Tracheoesophageal Fistula
Omphalocele and Gastroschisis
Anorectal Malformations
Bladder Exstrophy

UNIT IX Health Promotion of the Growing Child and Family

CHAPTER 25 Growth and Development of the Newborn and Infant
Introduction
Physical Growth
Weight
Length
Head Circumference
Physiologic Changes
Neurologic System
Respiratory System
Cardiovascular System
Gastrointestinal System
Genitourinary System
Integumentary System
Hematopoietic System
Immunologic System
Psychosocial Development
Cognitive Development
Motor Skill Development
Gross Motor Skills
Fine Motor Skills
Sensory Development
Sight

Hearing
Smell and Taste
Touch
Communication and Language Development
Social and Emotional Development
Stranger Anxiety
Separation Anxiety
Temperament
Cultural Influences on Growth and Development
Promoting Healthy Growth and Development
Promoting Growth and Development Through Play
Promoting Early Learning
Promoting Safety
Promoting Nutrition
Promoting Healthy Sleep and Rest
Promoting Healthy Teeth and Gums
Promoting Appropriate Discipline
Addressing Child Care Needs
Addressing Common Developmental Concerns
Colic
Spitting Up
Thumb Sucking, Pacifiers, and Security Items
Teething
CHAPTER 26 Growth and Development of the Toddler
Introduction
Physical Growth
Physiologic Changes
Neurologic System
Respiratory System
Cardiovascular System

Gastrointestinal System
Genitourinary System
Musculoskeletal System
Psychosocial Development
Cognitive Development
Motor Skill Development
Gross Motor Skills
Fine Motor Skills
Sensory Development
Communication and Language Development
Emotional and Social Development
Separation Anxiety
Temperament
Fears
Moral and Spiritual Development
Cultural Influences on Growth and Development
The Nurse'S Role in Toddler Growth and Development
Promoting Healthy Growth and Development
Promoting Growth and Development Through Play
Promoting Early Learning
Promoting Safety
Promoting Nutrition
Promoting Healthy Sleep and Rest
Promoting Healthy Teeth and Gums
Promoting Appropriate Discipline
Addressing Common Developmental Concerns
Toilet Teaching
Negativism
Temper Tantrums

Thumb Sucking and Pacifiers
Sibling Rivalry
Regression
CHAPTER 27 Growth and Development of the Preschooler
Introduction
Physical Growth
Physiologic Changes
Psychosocial Development
Cognitive Development
Moral and Spiritual Development
Motor Skill Development
Gross Motor Skills
Fine Motor Skills
Sensory Development
Communication and Language Development
Emotional and Social Development
Friendships
Temperament
Fears
Cultural Influences on Growth and Development
Promoting Healthy Growth and Development
Promoting Growth and Development Through Play
Promoting Early Learning
Promoting Language Development
Choosing a Preschool/Starting Kindergarten
Promoting Safety
Safety in the Water
Promoting Nutrition
Promoting Healthy Sleep and Rest
Promoting Healthy Teeth and Gums

Promoting Appropriate Discipline
Addressing Common Developmental Concerns
Lying
Sex Education
Masturbation
CHAPTER 28 Growth and Development of the School-Age Child
Introduction
Physical Growth
Physiologic Changes
Neurologic System
Respiratory System
Cardiovascular System
Gastrointestinal System
Genitourinary System
Prepubescence
Musculoskeletal System
Immune System
Psychosocial Development
Cognitive Development
Moral and Spiritual Development
Motor Skill Development
Gross Motor Skills
Fine Motor Skills
Sensory Development
Communication and Language Development
Emotional and Social Development
Temperament
Self-Esteem Development
Body Image
School-Age Fears
Peer Relationships

Teacher and School Influences
Family Influences
Cultural Influences on Growth and Development
The Nurse'S Role in School-Age Growth and Development
Promoting Healthy Growth and Development
Promoting Growth and Development Through Play
Promoting Learning
Promoting Safety
Abuse in Children
Promoting Nutrition
Promoting Healthy Sleep and Rest
Promoting Healthy Teeth and Gums
Promoting Appropriate Discipline
Addressing Common Developmental Concerns
Television, Video Games, and the Internet
School Refusal
Latchkey Children
Stealing, Lying, and Cheating
Bullying
Tobacco and Alcohol Education
CHAPTER 29 Growth and Development of the Adolescent
Introduction
Physiologic Changes Associated with Puberty
Physical Growth
Physiologic Changes
Neurologic System
Respiratory System
Cardiovascular System
Gastrointestinal System

Musculoskeletal System
Integumentary System
Psychosocial Development
Cognitive Development
Moral and Spiritual Development
Motor Skill Development
Gross Motor Skills
Fine Motor Skills
Communication and Language Development
Emotional and Social Development
Relationship with Parents
Self-Concept and Body Image
Importance of Peers
Sexuality
Dating
Cultural Influences on Growth and Development
The Nurse'S Role in Adolescent Growth and Development
Promoting Healthy Growth and Development
Promoting Growth and Development Through Sports and Physical Fitness
Promoting Learning
Promoting Safety
Promoting Nutrition
Promoting Healthy Sleep and Rest
Promoting Healthy Teeth and Gums
Promoting Personal Care
Promoting Appropriate Discipline
Promoting Proper Media Use
Addressing Common Developmental Concerns
Violence

Substance Use

UNIT X Foundations of Pediatric Nursing

CHAPTER 30 Atraumatic Care of Children and Families

Introduction

Preventing/Minimizing Physical Stressors

Utilizing the Child Life Specialist

Minimizing Physical Stress During Procedures

Preventing or Minimizing Child and Family Separation: Providing Child- and Family-Centered Care

Promoting a Sense of Control

Enhancing Communication

Teaching Children and Families

CHAPTER 31 Health Supervision

Principles of Health Supervision

Wellness

Medical Home

Partnerships

Special Issues in Health Supervision

Components of Health Supervision

Developmental Surveillance and Screening

Injury and Disease Prevention

Health Promotion

CHAPTER 32 Health Assessment of Children

Introduction

Health History

Preparing for the Health History

Performing a Health History

Physical Examination

Preparing for the Physical Examination

Steps of the Physical Examination
Performing a Physical Examination
CHAPTER 33 Caring for Children in Diverse Settings
Introduction
Community Health Nursing
Community-Based Nursing
Shifting Responsibilities from Hospital to Community-Based Nursing Care
Role of the Community-Based Nurse
Illness and Hospitalization in Childhood
General Inpatient Unit
Emergency Departments
Pediatric Intensive Care Units
Rehabilitation Units/Facilities
Outpatient Facilities
Physician's Office or Clinic, Health Departments, and Urgent Care Centers
Medically Fragile Day Care Centers
Schools
Home Health Care
Other Community Settings
Children's Reactions to Illness and Hospitalization
Anxiety and Fear
Separation Anxiety
Loss of Control
Factors Affecting Children's Reaction to Illness and Hospitalization
Developmental Level
Previous Experiences

Recent Stresses and Changes and Individual Coping Skills
Parents' Response to Child's Illness and Hospitalization
Family's Reactions to the Child's Illness and Hospitalization
Reactions of Parents
Reactions of Siblings
Factors Influencing Family Reactions
Preparing the Child and Family for Surgery
Providing Preoperative Teaching
Safety During Hospitalization or Procedures
Maintaining the Child's Safety
Use of Restraints
Transport of the Child
Hospitalization in Childhood
Preparing Children and Families for Hospitalization
Admitting the Child to the Facility
Addressing the Effects of Hospitalization Developmentally
Providing Basic Care for the Hospitalized Child
Providing Play, Activities, and Recreation for the Hospitalized Child
Promoting Schoolwork and Education During Hospitalization
Family Members' Needs
Child and Family Teaching
CHAPTER 34 Caring for the Special Needs Child
Introduction
The Medically Fragile Child

Impact of the Problem
Effects of Special Needs on the Child
Effects on the Family
Nursing Management of the Medically Fragile Child and Family
The Dying Child
End-of-Life Decision-Making
Nursing Management of the Dying Child
CHAPTER 35 Key Pediatric Nursing Interventions
Introduction
Medication Administration
Differences in Pharmacodynamics and Pharmacokinetics
Developmental Issues and Concerns
Determination of Correct Dose
Oral Administration
Rectal Administration
Ophthalmic Administration
Otic Administration
Nasal Administration
Intramuscular Administration
Subcutaneous and Intradermal Administration
Intravenous Administration
Providing Atraumatic Care
Educating the Child and Parents
Preventing Medication Errors
Intravenous Therapy
Sites
Equipment
Inserting Peripheral IV Access Devices
IV Fluid Administration

Preventing Complications
Discontinuing the IV Device
Providing Nutritional Support
Enteral Nutrition
Parenteral Nutrition
CHAPTER 36 Nursing Care of the Child with an Alteration in Comfort–Pain Assessment and Management
Introduction
Physiology of Pain
Transduction
Transmission
Perception
Modulation
Types of Pain
Classification by Duration
Classification by Etiology
Classification by Source or Location
Factors Influencing Pain
Age and Gender
Cognitive Level
Temperament
Previous Pain Experiences
Family and Culture
Situational Factors
Developmental Considerations
Infants
Toddlers
Preschoolers
School-Age Children
Adolescents

Common Fallacies and Myths About Pain in Children
Management of Pain
Nonpharmacologic Management
Pharmacologic Management
Management of Procedure-Related Pain
Management of Chronic Pain

UNIT XI Nursing Care of the Child with a Health Disorder

CHAPTER 37 Nursing Care of the Child with an Infection
Introduction
Infectious Process
Fever
Stages of Infectious Disease
Chain of Infection
Preventing the Spread of Infection
Variations in Pediatric Anatomy and Physiology
Common Medical Treatments
Sepsis
Bacterial Infections
Community-Acquired Methicillin-Resistant Staphylococcus Aureus
Scarlet Fever
Diphtheria
Pertussis
Tetanus
Botulism
Osteomyelitis
Septic Arthritis
Viral Infections

Viral Exanthems
Mumps
Zoonotic Infections
Cat-Scratch Disease
Rabies
Lyme Disease
Rocky Mountain Spotted Fever
Parasitic and Helminthic Infection
Sexually Transmitted Infections
CHAPTER 38 Nursing Care of the Child with an Alteration in Intracranial Regulation/Neurologic Disorder
Introduction
Variations in Pediatric Anatomy and Physiology
Brain and Spinal Cord Development
Nervous System
Head Size
Common Medical Treatments
Seizure Disorders
Epilepsy
Febrile Seizures
Neonatal Seizures
Structural Defects
Neural Tube Defects
Anencephaly
Encephalocele
Microcephaly
Chiari Malformation
Hydrocephalus
Intracranial Arteriovenous Malformation
Craniosynostosis
Positional Plagiocephaly

Infectious Disorders
Bacterial Meningitis
Aseptic Meningitis
Encephalitis
Reye Syndrome
Trauma
Head Trauma
Nonaccidental Head Trauma
Near-Drowning
Blood Flow Disruption
Cerebral Vascular Disorders (Stroke)
Chronic Disorders
Headaches
Breath Holding
CHAPTER 39 Nursing Care of the Child with an Alteration in Sensory Perception/Disorder of the Eyes or Ears
Introduction
Variations in Pediatric Anatomy and Physiology
Eyes
Ears
Common Medical Treatments
Infectious and Inflammatory Disorders of the Eyes
Conjunctivitis
Nasolacrimal Duct Obstruction
Eyelid Disorders
Eye Injuries
Visual Disorders
Refractive Errors
Strabismus
Amblyopia

Nystagmus
Infantile Glaucoma
Congenital Cataract
Retinopathy of Prematurity
Visual Impairment
Infectious and Inflammatory Disorders of the Ears
Acute Otitis Media
Otitis Media with Effusion
Otitis Externa
Hearing Loss and Deafness
CHAPTER 40 Nursing Care of the Child with an Alteration in Gas Exchange/Respiratory Disorder
Introduction
Variations in Pediatric Anatomy and Physiology
Nose
Throat
Trachea
Lower Respiratory Structures
Chest Wall
Metabolic Rate and Oxygen Need
Common Medical Treatments
Acute Infectious Disorders
Common Cold
Sinusitis
Influenza
Pharyngitis
Tonsillitis
Infectious Mononucleosis
Laryngitis
Croup
Epiglottitis

Bronchiolitis
Pneumonia
Bronchitis
Tuberculosis
Acute Noninfectious Disorders
Epistaxis
Foreign Body Aspiration
Acute Respiratory Distress Syndrome
Pneumothorax
Chronic Respiratory Disorders
Allergic Rhinitis
Asthma
Chronic Lung Disease
Cystic Fibrosis
Apnea
Tracheostomy
CHAPTER 41 Nursing Care of the Child with an Alteration in Perfusion/Cardiovascular Disorder
Introduction
Variations in Pediatric Anatomy and Physiology
Circulatory Changes from Gestation to Birth
Structural and Functional Differences
Common Medical Treatments
Cardiac Catheterization
Cardiac Catheterization
Congenital Heart Disease
Disorders with Decreased Pulmonary Blood Flow
Tetralogy of Fallot
Tricuspid Atresia
Disorders with Increased Pulmonary Flow
Atrial Septal Defect

Ventricular Septal Defect
Atrioventricular Canal Defect
Patent Ductus Arteriosus
Obstructive Disorders
Coarctation of the Aorta
Aortic Stenosis
Pulmonary Stenosis
Mixed Defects
Transposition of the Great Vessels (Arteries)
Total Anomalous Pulmonary Venous Connection
Truncus Arteriosus
Hypoplastic Left Heart Syndrome
Acquired Cardiovascular Disorders
Heart Failure
Infective Endocarditis
Acute Rheumatic Fever
Cardiomyopathy
Hypertension
Kawasaki Disease
Dyslipidemia
Heart Transplantation
Surgical Procedure and Postoperative Therapeutic Management
CHAPTER 42 Nursing Care of the Child with an Alteration in Bowel Elimination/Gastrointestinal Disorder
Introduction
Variations in Pediatric Anatomy and Physiology
Mouth
Esophagus
Stomach

Intestines
Biliary System
Fluid Balance and Losses
Common Medical Treatments
Stool Diversions
Structural Anomalies of the Gastrointestinal Tract
Cleft Lip and Palate
Meckel Diverticulum
Inguinal and Umbilical Hernias
Inguinal Hernia
Umbilical Hernia
Acute Gastrointestinal Disorders
Dehydration
Vomiting
Diarrhea
Oral Candidiasis (Thrush)
Oral Lesions
Hypertrophic Pyloric Stenosis
Intussusception
Malrotation and Volvulus
Appendicitis
Chronic Gastrointestinal Disorders
Gastroesophageal Reflux Disease
Peptic Ulcer Disease
Constipation and Encopresis
Hirschsprung Disease (Congenital Aganglionic Megacolon)
Short Bowel Syndrome
Inflammatory Bowel Disease
Celiac Disease
Functional Abdominal Pain

Hepatobiliary Disorders
Pancreatitis
Gallbladder Disease
Biliary Atresia
Hepatitis
Cirrhosis and Portal Hypertension
Liver Transplantation
CHAPTER 43 Nursing Care of the Child with an Alteration in Urinary Elimination/Genitourinary Disorder
Introduction
Variations in Pediatric Anatomy and Physiology
Structural Differences
Urinary Concentration
Urine Output
Reproductive Organ Maturity
Common Medical Treatments
Collecting Urine Specimens in Children
Urinary Tract and Renal Disorders
Structural Disorders
Hypospadias/Epispadias
Obstructive Uropathy
Hydronephrosis
Vesicoureteral Reflux
Urinary Disorders
Urinary Tract Infection
Enuresis
Acquired Disorders Resulting in Altered Renal Function
Nephrotic Syndrome
Acute Poststreptococcal Glomerulonephritis
Hemolytic Uremic Syndrome

Renal Failure
Acute Renal Failure
End-Stage Renal Disease
Dialysis and Transplantation
Peritoneal Dialysis
Hemodialysis
Renal Transplantation
Reproductive Organ Disorders
Female Disorders
Labial Adhesions
Vulvovaginitis
Male Disorders
Phimosis and Paraphimosis
Circumcision
Cryptorchidism
Hydrocele and Varicocele
Testicular Torsion
Epididymitis
CHAPTER 44 Nursing Care of the Child with an Alteration in Mobility/Neuromuscular or Musculoskeletal Disorder
Introduction
Variations in Pediatric Anatomy and Physiology
Brain and Spinal Cord Development
Myelinization
Muscular Development
Skeletal Development
Common Medical Treatments
Casts
Traction
External Fixation

Congenital and Developmental Disorders
Neural Tube Defects
Spina Bifida Occulta
Meningocele
Myelomeningocele
Pectus Excavatum
Limb Deficiencies
Polydactyly/Syndactyly
Metatarsus Adductus
Congenital Clubfoot
Osteogenesis Imperfecta
Developmental Dysplasia of the Hip
Torticollis
Tibia Vara (Blount Disease)
Muscular Dystrophy
Spinal Muscular Atrophy
Cerebral Palsy
Acquired Disorders
Rickets
Slipped Capital Femoral Epiphysis
Legg–Calvé–Perthes Disease
Transient Synovitis of the Hip
Scoliosis
Spinal Cord Injury
Fracture
Sprains
Overuse Syndromes
Radial Head Subluxation
CHAPTER 45 Nursing Care of the Child with an Alteration in Tissue Integrity/Integumentary Disorder
Introduction

Variations in Pediatric Anatomy and Physiology
Differences in the Skin between Children and Adults
Common Medical Treatments
Infectious Disorders
Bacterial Infections
Fungal Infections
Inflammatory Skin Conditions
Diaper Dermatitis
Atopic Dermatitis
Contact Dermatitis
Erythema Multiforme
Urticaria
Seborrhea
Psoriasis
Acne
Acne Neonatorum
Acne Vulgaris
Injuries
Pressure Ulcers
Minor Injuries
Burns
Sunburn
Cold Injury
Human and Animal Bites
Insect Stings and Spider Bites
CHAPTER 46 Nursing Care of the Child with an Alteration in Cellular Regulation/Hematologic or Neoplastic Disorder
Introduction
Variations in Pediatric Anatomy and Physiology

Red Blood Cell Production
Hemoglobin
Iron
Childhood Cancer versus Adult Cancer
Common Medical Treatments
Chemotherapy
Radiation Therapy
Hematopoietic Stem Cell Transplantation
Palliative Care
Laboratory and Diagnostic Testing
Caring for the Child with Cancer
Anemia
Iron-Deficiency Anemia
Other Nutritional Causes of Anemia

Introduction to Maternity and Pediatric Nursing

1

Perspectives on Maternal and Child Health Care

WOW

WORDS OF WISDOM

Being pregnant and giving birth is like crossing a narrow bridge: people can accompany you to the bridge, and they can greet you on the other side, but you walk that bridge alone. And the journey doesn't end there: children are the future of a society and special gifts to the world. Changes in our society and world require us to be attentive to and value them and their health.

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Analyze the key milestones in the history of maternal, newborn, and child health and health care.
2. Outline the evolution of maternal, newborn, and pediatric nursing.
3. Compare the past definitions of health and illness with the current definitions, as well as the measurements used to assess health and illness in children.
4. Assess the factors that affect maternal and child health.
5. Differentiate the structures, roles, and functions of the family and how they affect the health of women and children.
6. Evaluate how society and culture can influence the health of women, children, and families.
7. Examine access and barriers to health care and its effect on women, children, and family's health.
8. Identify the ethical and legal issues that may arise when caring for women, children, and families.

Sophia Greenly, a 38-year-old woman pregnant with her third child, comes to the prenatal clinic for a routine follow-up visit. Her mother, Betty, accompanies her because Sophia's husband is out of town. Sophia lives with her husband and two children, ages 4 and 9. She works part-time as a lunch aide in the local elementary school. What factors may play a role in influencing the health of Sophia and her family?

INTRODUCTION

A person's ability to lead a fulfilling life and to participate fully in society depends largely on his or her health status. This is especially true for women, who commonly are responsible for not only their own health, but also that of others: their children and families. Thus, it is important to concentrate on the health of women, children, and families. Children are the future of our society. Their overall health has improved, and rates of death and illness in some areas have decreased but we still must focus on children's health both in the United States and globally. Habits and practices established in childhood have profound effects on health and illness throughout life. As a society, creating a population that cares about women, children and families and promotes preventative and quality health care and positive lifestyle choices is crucial. Nurses play a major role in this task. They are often "in the trenches" advocating on various issues, drawing attention to the importance of health care for children, encouraging focus on education and prevention, and assisting families who lack resources or access to health care and legal issues related to caring for children.

Maternity care is an integrated care process, which consists of different services (prenatal, intranatal, and postnatal), involves different professionals, and covers extended time frames. Maternal and newborn nursing encompasses a wide scope of practice typically associated with childbearing. It includes care of the woman before pregnancy, care of the woman and her fetus during pregnancy, care of the woman after pregnancy, and care of the newborn, usually during the first 6 weeks after birth. The overall goal of maternal and newborn nursing is to promote and maintain optimal health of the woman and her family. Providing quality maternity care includes client satisfaction and achieving best evidence-based outcomes with the fewest interventions. Child health nursing, commonly referred to as pediatric nursing, involves the care of the child from infancy through adolescence. In the United States, the number of children under age 18 years is approximately 73.7 million, accounting for 23% of the population (Federal Interagency Forum on

Child and Family Statistics [FIFCFS], 2018). Since the 1960s, children have decreased as a percentage of the total U.S. population and are projected to slowly decline through 2050 (FIFCFS, 2018). The overall goal of pediatric nursing practice is to promote and assist the child in maintaining optimal levels of health, while recognizing the influence of the family on the child's well-being. This goal involves health promotion and disease and injury prevention as well as assisting with care during illness. The common thread in both of these is the care of the family.

This chapter presents a general overview of the health care of women, children, and families and describes the major factors affecting maternal and child health as well as legal and ethical issues involved in maternal and child health care. Nurses need to be knowledgeable about these concepts and factors to ensure that they provide safe, professional care.

HISTORICAL DEVELOPMENT

The health care of women and children has changed over the years due in part to changes in childbirth methods, devastating epidemics, social trends in our country, economic circumstances, physical environment, safety, exposure to violence, illicit substance misuse, changes in the health care system, and federal and state regulations. By reviewing historical events, nurses can gain a better understanding of the current and future status of maternal and child health and how maternal and pediatric nursing care has evolved.

The History of Maternal and Newborn Health and Health Care

Childbirth in colonial America was a difficult and dangerous experience. During the 17th and 18th centuries, women giving birth often died as a result of exhaustion, dehydration, infection, hemorrhage, or seizures. Death in childbirth was sufficiently common that many colonial women regarded pregnancy with dread (Digital

History, 2019). Approximately 43% of all children died before age 5 (Roser, 2019), compared with the 5.8 infant deaths per 1,000 live births of today (Centers for Disease Control and Prevention [CDC], 2019a). This decrease in infant and child mortality rates reflects centuries of advances in public health, living standards, medical science, technology, and clinical practice.

There was a time when nearly every infant that came into this world was attended by a midwife. Centuries ago, “granny midwives” handled the normal birthing process for most women. They learned their skills through an apprenticeship with a more experienced midwife. Physicians usually were called only in extremely difficult cases, and all births took place at home. The rise of obstetrics in the 1800s drove midwifery to the periphery, but within the last century, midwifery has reemerged as an organized profession, appearing everywhere from home births to hospital labor units. Women who labored and gave birth at home were traditionally attended to by relatives and midwives. Continuous companionship support during childbirth has been demonstrated to yield better outcomes (see Evidence-Based Practice 1.1).

During the early 1900s, physicians attended about half the births in the United States. Midwives often cared for women whom could not afford a doctor. Many women were attracted to hospitals because this showed affluence and they provided pain management, which was not available for home births. In the 1950s, “natural childbirth” practices advocating birth without medication and focusing on relaxation techniques were introduced. These techniques opened the door to childbirth education classes and helped bring the father back into the picture. Both partners could participate by taking an active role in pregnancy, childbirth, and parenting (Fig. 1.1).

EVIDENCE-BASED PRACTICE 1.1

Perceptions and Experiences of Labor Companionship: A Qualitative Evidence Synthesis

STUDY

Companionship during labor refers to support provided to a woman during childbirth and may be provided by a partner, family member, friend, doula or health care professional such as a nurse. A previous Cochrane systematic review concluded that having a continuous labor companion improves outcomes for women and their infants. Labor companions are regarded as an important aspect of improving quality of care for the laboring woman. The purpose of this review was to explore how women, families, and health care workers experience women going through labor and childbirth with a continuous support person present. A total of 51 studies were included in the synthesis.

Findings

Labor companions supported women in four different ways. Companions gave informational support by providing information about childbirth, bridging communication gaps between health workers and women, and facilitating nonpharmacologic pain relief. Companions were advocates, which resulted in their speaking up in support of the woman's needs. Companions provided practical support by encouraging women to move around, providing massage, and holding her hand. Finally, companions gave the woman emotional support, using praise and reassurance to help women feel more in control and confident, and providing continuous presence. Companionship helped women to have a positive birth experience.

Nursing Implications

Based on the research findings, it is important for all laboring women to have a companion throughout her childbirth experience. Nurses can apply this evidence-based research to their practice by encouraging women how important it is to have a support person with them during their laboring timeframe. Women have traditionally been attended by a companion throughout their childbirth experience, but initiatives to foster this have not necessarily respected this tradition. Formal hospital policy changes may be needed in some facilities to allow for companionship during the childbirth experience. Nurses can take a lead role in bringing about these changes.

Box 1.1 shows a time line of childbirth in America. In many ways, childbirth practices in the United States have come full circle, as we see the return of nurse midwives and doulas. Today, childbirth choices are often based on what works best for the mother, child, and family.

FIGURE 1.1. Today fathers and partners are welcome to take an active role in the pregnancy and childbirth experience. **A.** A couple can participate together in childbirth education classes. (Photo by Gus Freedman.) **B.** Fathers and partners can assist the woman throughout her labor and delivery. (Photo by Joe Mitchell.)

The History of Child Health and Child Health Care

In past centuries in the United States, the health of the country was poorer than it is today; mortality rates were high and life expectancy was short. Infectious diseases were rampant, and unsanitary food sources contributed to illness in children. Devastating epidemics of smallpox, diphtheria, scarlet fever, and measles hit children the hardest. During this period, the prevalent view was that children were a commodity; their role was to increase the population and share in the work to be done. This view changed over the years. Public schools were established and the court system began viewing children as minors. The health of children began to receive more and more attention.

BOX 1.1 Childbirth in America: A Time Line

1700s	Men did not attend births because it was considered indecent.
	Women faced birth not with joy and ecstasy but with fear of death.
	Female midwives attended the majority of all births at home.
1800s	There is a shift from using midwives to doctors among middle-class women.
	The word *obstetrician* was formed from the Latin, meaning “to stand before.”
	Puerperal (childbed) fever was occurring in epidemic proportions.
	Louis Pasteur demonstrated that streptococci were the major cause of puerperal fever that was killing mothers after delivery.
	The first cesarean section was performed in Boston in 1894.
	The x-ray was developed in 1895 and was used to assess pelvic size for birthing purposes.
1900s	Twilight sleep (a heavy dose of narcotics and amnesiacs) was used on women during childbirth in the United States.
	The United States was 17th out of 20 nations in infant mortality rates.
	Of all women, 50% to 75% gave birth in hospitals by 1940.
	Nurseries were started because mothers could not care for their baby for several days after receiving chloroform gas.
	Dr. Grantley Dick–Reed (1933) wrote *Childbirth Without Fear,* which reduced the “fear–tension–pain” cycle women experienced during labor and birth.
	Dr. Fernand Lamaze (1984) wrote *Painless Childbirth: The Lamaze Method*, which advocated distraction and relaxation techniques to minimize the perception of pain.
	Amniocentesis was first performed to assess fetal growth in 1966.
	In the 1970s the cesarean section rate was about 5%. In 2011 it rose to 32%, where it stands currently.
	The 1970s and 1980s see a growing trend to return birthing back to the basics—nonmedicated, nonintervening childbirth.
	In the late 1900s, freestanding birthing centers—LDRPs—were designed, and the number of home births began to increase.
2000s	One in three women undergoes a surgical birth (cesarean).
	CNMs once again assist couples at home, in hospitals, or in freestanding facilities with natural childbirths. Research shows that midwives are the safest birth attendants for most women, with lower infant mortality and maternal rates, and fewer invasive interventions such as episiotomies and cesareans.
	Childbirth classes of every flavor abound in most communities.

According to the latest available data, the United States ranks 48th in the world in maternal deaths. The maternal mortality ratio is approximately 28 in 100,000 live births.

According to the latest available data, the United States ranks 55th in the world (compared to 224 other countries) in infant mortality rates. The infant mortality rate is approximately 6.17 in 1,000 live births.

As the end of the 19th century neared, doctors and scientists gained a better understanding of the root causes of illness. This knowledge helped fuel public health efforts such as the campaign for safe milk supply, which lead to pasteurizing milk and to dispensing free milk in some cities (U.S. Department of Agriculture [USDA], 2019). Compulsory vaccination programs began during this time. In the late 1800s some states mandated smallpox vaccination as a condition of school attendance. These public health efforts led to a decrease in infant and child deaths (Maternal and Child Health Bureau [MCHB], Health Resources and Services Administration [HRSA], U.S. Department of Health and Human Services [USDHHS], n.d.).

In the late 19th and early 20th centuries, cities became healthier places to live due to urban public health improvements such as sanitation services, treated municipal water, and improvements in hygiene (MCHB, HRSA, USDHHS, n.d.). Diseases such as diphtheria, cholera, polio, and yellow fever began to take less of a toll on children (MCHB, HRSA, USDHHS, n.d.). The turn of the 20th century brought new knowledge about nutrition, sanitation, bacteriology, pharmacology, medication, and psychology. Penicillin, corticosteroids, and increased numbers of vaccines, which were

developed during this time, assisted with the fight against communicable diseases. Thus, by the end of the 20th century, unintentional injuries surpassed disease as the leading cause of death for children greater than 1-year-old. Today, unintentional injuries remain the number one cause of death among people 1 to 44 years old (National Safety Council [NSC], 2020).

Technologic advances have significantly affected all aspects of health care and led to increased survival rates in children. However, many children who survive illnesses that were previously considered fatal are left with chronic disabilities. For example, before the 1960s, extremely premature infants did not survive because of the immaturity of their lungs. Newer ventilation methods and the use of medications to foster lung development have increased survival rates in premature infants, but survivors are often faced with a myriad of chronic illnesses such as chronic lung disease (bronchopulmonary dysplasia), retinopathy of prematurity, cerebral palsy, or developmental delay. This increased survival has resulted in a significant increase in chronic illness relative to acute illness as a cause of hospitalization and mortality. Chronic diseases are illnesses that last more than 3 months and cannot be prevented by vaccination, cured by medication, and do not disappear. Today, more than 54% of American children are suffering from one or more chronic illnesses (Children's Health Defense, 2019).

In recent years advances in biomedicine have created a trend toward earlier diagnosis and treatment of disorders and diseases. Additionally, genetics have been linked with pathophysiologic processes. For example, female fetuses diagnosed with congenital adrenal hyperplasia, a genetic disorder resulting in a steroid-enzyme deficiency leading to disfiguring anatomic abnormalities of sexual characteristics reducing virilization, are able to receive treatment before birth (Marco et al., 2019). In addition, early genetic defect identification allows for appropriate counseling. Advancements in diagnostic technology and treatment methods continue to improve child health. For example, less invasive ways to monitor blood glucose levels—such as using a transdermal patch that will read

blood glucose levels through the skin—are currently under development (Bruen et al., 2017).

In addition to improvement in technology and biomedicine, a number of national and international organizations have been formed in recent years to protect children's rights both in the United States and worldwide. These organizations focus on such issues as violence and abuse, child labor and soldiering, juvenile justice, child immigrants and orphaned children, and abandonment and homelessness—all of which have a negative impact on children's health. A child whose rights are restored and upheld has an improved opportunity for growth, development, education, and health.

The gains in child health have been huge but, unfortunately, these gains are not shared equally among all children. Certain health concerns, such as poor nutrition, obesity, infections, lead poisoning, digestive issues, and asthma, affect poor children at higher rates and with greater severity than affluent and middle-class children (Woolf et al., 2015). Approximately one in five children today live in families with incomes below the federal poverty line (Child Trends Databank, 2018a). Unintentional injuries continue to be the leading cause of death in children greater than 1 year but children's health remains threatened by illnesses and other health-related conditions in the 21st century (CDC/National Center for Health Statistics [NCHS], 2017). Obesity, environmental toxins, allergies, drug abuse, child abuse and neglect, and mental health problems are among some of the key issues that endanger children's health today.

Evolution of Maternal and Newborn Nursing

The history of maternity nursing is characterized by innovations that became common practice in later years. These innovations include fetal monitoring, mother/baby care, and early postpartum discharge. The driving forces behind changes in care within the social context of the times were scientific/medical developments and families' desires for the best possible childbearing experience.

Before World War II, American women moved from home to the hospital for childbirth in part because they were convinced that setting would improve birth outcomes. Hospitals were the major employers of maternity nurses. Early ambulation and rooming-in induced changes in the focus of care for the growing numbers of mothers and infants. Maternity nurses' focus shifted away from carrying out tasks and performing procedures to teaching mothers about self and infant care. Improved staffing patterns within hospitals meant longer hospital stays for the mothers, which allowed maternity nurses to spend more time with mothers for teaching purposes. Maternity nursing has changed dramatically since the baby boom era. The natural childbirth movement became a catalyst to bring about a change in nursing practice on the postpartum nursing units.

Other innovations that came later included breastfeeding and rooming-in to facilitate maternal–newborn bonding. Maternity nurses were then able to help the new mothers learn better how to care for their infants, to promote breastfeeding and bonding. The mid-1960s and early 1970s ushered in a consumer revolt which brought back home births, prepared childbirth, birth centers, a more humanizing maternity care focus, the father's/partner's involvement in the birthing process, and nurse midwives—which had all but disappeared from the American health system (Martucci, 2018). Maternal–infant bonding became recognized as an essential part of postnatal care, and maternity nurses took a lead role to facilitate it.

With innovations becoming commonplace, maternity nursing practice has become more complex. How maternity nurses' approach present-day challenges of increasing technology of birth, looming threats of litigation, and providing care under time and economic restraints is continuing to evolve.

A **certified nurse midwife (CNM)** has postgraduate training in the care of normal pregnancy and delivery and is certified by the American College of Nurse-Midwives (ACNM). Midwives are primary care providers for women with a special emphasis on pregnancy, childbirth, and reproductive health. They are committed to providing ethical, individualized, evidence-based care for all women throughout their life cycle (ACNM, 2019).

A **doula** is a nonmedical birth companion who provides continuous emotional, physical, and educational support to the woman and family during childbirth and the postpartum period. Doulas do not perform clinical or medical tasks; they are there to comfort and support the mother and to enhance communication between the mother and medical professionals (DONA International, 2019). Many nurses working in labor and birth areas today are credentialed in their specialty so that they can provide optimal care to the woman and her newborn.

Evolution of Pediatric Nursing

In 1870, the first pediatric professorship for a physician was awarded in the United States to Abraham Jacobi, known as the father of pediatrics. For the first time, the medical community realized the need to provide specialized training and education about children to health care providers. In the early 1900s, Lillian Wald established the Henry Street Settlement House in New York City; this was the start of public health nursing. This facility provided medical and other services to poor families. These services included home nurse visits to teach mothers about health care.

During this time, health care personnel were trained to take care of children in hospitals, but parents of hospitalized children were discouraged from visiting to prevent the spread of infection. Restricting parents from being involved in their child's care was also thought to minimize emotional stress.

Nursing in public schools began in 1902 with the appointment of Lina Rogers as a full-time, public-school nurse in New York. A professional course in pediatric nursing was started in the early 1900s at Teachers' College of Columbia University.

In the 1960s, changes in the health care delivery system and shifts in the population's health status led to the development of the nurse practitioner role. Loretta Ford was the founder of the first nurse practitioner program. The 1970s brought cost-control systems from the federal government because of rapid escalation of health care expenditures. In addition, the considerable changes in the U.S.

health care system in the 1980s have affected pediatric nursing and child health care. The emphasis of care was on quality outcomes and cost containment. Some of these changes brought more advanced practice nurses into the field of pediatrics.

In the 1980s, the Division of Maternal–Child Health Nursing Practice of the American Nurses Association developed maternal–child health standards to provide important guidelines for delivering nursing care.

In the 1990s, the Institute of Medicine published reports pointing out the need to improve quality and safety of the American health care system. This led to an increased focus on improving health care outcomes. As the health care environment continued to increase in complexity and patients hospitalized got sicker, programs were created for nurses to obtain a level of expertise and validate mastery of their skills and knowledge by passing a national standardized examination. Registered nurses and nurse practitioners can be certified in their specialty, such as pediatrics. These certifications show a commitment to lifelong learning and the ability to stay up to date in the rapidly changing health care environment. In recent years, pediatric nursing certifications have become increasingly specialized, such as a certified pediatric hematology/oncology nurse or a certified pediatric emergency nurse.

HEALTH STATUS OF WOMEN AND CHILDREN

At one time, health was defined simply as the absence of disease. Health was measured by monitoring the mortality and morbidity of a group. Over the past century, however, the focus on health has shifted to disease prevention, health promotion, and wellness. The definition of health is complex. The World Health Organization (WHO, 2019e) defines health as “a state of complete physical, mental, and social well-being, and not merely the absence of disease or infirmity.”

In 1979, *Healthy People: The Surgeon General’s Report on Health Promotion and Disease Prevention*, now titled *Healthy People,*

presented an agenda for the nation that identified the most significant preventable threats to health. With the series of updates that followed, including the present one (5th edition), *Healthy People 2030,* the United States has a comprehensive health promotion and disease prevention agenda that is working toward improving the quantity and quality of life for all Americans (USDHHS, 2020c). Overarching goals are to attain healthy, thriving lives and eliminate preventable disease, disability, injury, and premature death; achieve health equity, eliminate disparities, and attain health literacy to improve the health of all groups; create physical, economic and social environments that promote good health and well-being for all; and promote healthy development and behaviors across every stage of life; and engage leadership, the public and key constituents to take action and develop policies that will improve the health and well-being of all (USDHHS, 2020c). The principle behind this report is that setting national objectives and monitoring their progress can motivate action and change. In developing the health objectives, the report incorporates input from public health and prevention experts; federal, state, and local governments; more than 2,000 organizations; and the public.

There are specific health topic areas, including women and children's health topics, which serve as a method for evaluation of progress made in public health. These topic areas also serve as focal points to coordinate the national health improvement efforts. For example, one objective under the physical activity topic is to increase the proportion of adolescents who meet current federal physical activity guidelines for aerobic physical activity and for muscle-strengthening activity (USDHHS, 2020d). *Healthy People 2030* monitors specific foundation health measures to assess the progress toward promoting health, preventing disease and disability, eliminating disparities, and improving quality of life (USDHHS, 2020b). (See the Healthy People feature for additional information on these health measures.)

Measuring health status is not always a simple process. For example, some women and children with chronic illnesses do not see themselves as "ill" if their disease is under control. A traditional

method of measuring health is to examine mortality and morbidity data. This information is collected and analyzed to provide an objective description of the nation's health.

Mortality

Mortality is the incidence or number of people who have died over a specific period. This statistic is presented as rates per 100,000 and is calculated from a sample of death certificates. The NCHS, under the DHHS, collects, analyzes, and disseminates the data on America's mortality rates. The CDC collects, stores, and shares their data collected through the Pregnancy Mortality Surveillance System (PMSS).

Maternal Mortality

The **maternal mortality ratio** is the annual number of deaths from any cause related to or aggravated by pregnancy or its management (excluding accidental or incidental causes) during pregnancy and childbirth or within 42 days of termination of pregnancy, irrespective of the duration and site of the pregnancy, per 100,000 live births, for a specified year. These catastrophic complications come at a terrible cost emotionally, financially, and medically. The rate of maternal mortality in the United States has more than doubled in the past few decades, making the United States the only developed nation in the world with an increasing maternal mortality rate. This fact is devastating and deserves national attention because a significant proportion (60%) of these deaths are preventable (Lu, 2018).

In the United States, the maternal mortality ratio is mixed depending on ethnic background. African American women suffer maternal mortality ratios far higher than any other ethnic group. The risk of maternal mortality has remained about three to four times higher among African American women when compared with White women during the past 6 decades. This difference may be due to social determinants of health such as educational level, income, health care access, violence, poverty, and environmental issues.

About 42.4 of 100,000 African American mothers die due to childbirth, as compared with much lower rates in Whites (13) and Hispanics (11.3) (CDC, 2019j; United Health Foundation, 2019a). The federal government has pledged to improve maternal–child-care outcomes and thus reduce mortality ratios for women and children by endorsing the *Healthy People 2030,* but the WHO (2019b) data show that the United States ranks 46th among the 181 countries in the world for maternal mortality. In fact, maternal mortality ratios are higher than almost all European countries, as well as several countries in Asia and the Middle East. For a country that spends more than any other country on health care and more on childbirth-related care than any other area of hospitalization, this is a shockingly poor return on investment (Lu, 2018).

HEALTHY PEOPLE *2030*

Foundation Health Measures

1. Tier 1: Healthy Life Expectancy Measures include:
   - Expected years of life free of activity limitation
   - Expected years of life free of disability
   - Expected years of life in good or better health
2. Tier 2: Summary of Mortality and Population Health Measures include:
   - Life expectancy
   - Activity limitations
   - Disability
   - Respondent assessed health status

Adapted from USDHHS. (2020). *Proposed objectives for inclusion in Healthy People 2030*. https://www.healthypeople.gov/sites/default/files/ObjectivesPublicComment508.pdf.

During the past several decades, mortality and morbidity have dramatically decreased as a result of an increased emphasis on hygiene, good nutrition, exercise, and prenatal care for all women. However, women are still experiencing complications at significant rates. The United States is one of the most medically and technologically advanced nations and has the highest per capita

spending on health care in the world, but our current mortality rates indicate the need for improvement. For example:

- Approximately 700 women die each year in the United States as a result of pregnancy or a childbirth complication (CDC, 2019j). More than 50,000 women experience a life-threatening complication/morbidity.
- Most pregnancy-related complications are preventable. The leading causes of pregnancy-related mortality are hemorrhage, infection, preeclampsia–eclampsia, obstructed labor, and unsafe abortion (CDC, 2019j).

The maternal mortality and morbidity rates for African American women have been three to four times higher than for Whites (Hayes & McNeil, 2019). This major racial disparity has persisted for more than 60 years. African American women have at least double the risk of pregnancy-related death compared with White women. This striking difference in the pregnancy-related mortality ratio is the largest disparity in the area of maternal and child health. Researchers do not entirely understand what accounts for this disparity but some suspected causes of the higher maternal mortality rates for minority women include low socioeconomic status, limited or no insurance coverage, bias among health care providers (which may foster distrust), and quality of care available in the community. Language and legal barriers may also explain why some immigrant women do not receive good prenatal care. Lack of care during pregnancy is a major factor contributing to a poor outcome. Prenatal care is well known to prevent complications of pregnancy and to support the birth of healthy infants but not all women receive the same quality and quantity of health care during pregnancy. Pregnancy-related mortality is on the rise in the United States. African American women had higher degrees of hypertension and lower hemoglobin levels on admission and had presented for prenatal care much later, on average, than White women or not at all (American Heart Association [AHA], 2019b).

The CDC (2019j) has noted that the disparity in maternal mortality rates between women of color and White women represents one of

the largest racial disparities among public health indicators. Eliminating racial and ethnic disparities in maternal–child health care requires enhanced efforts at preventing disease, promoting health, and delivering appropriate and timely care. The CDC has called for more research and monitoring to understand and address racial disparities, along with increased funding for prenatal and postpartum care. Research is needed to identify causes and to design initiatives to reduce these disparities, and the CDC is calling on Congress to expand programs to provide preconception and prenatal care to underserved women.

Fetal Mortality

The **fetal mortality rate** or fetal death rate refers to the spontaneous intrauterine death of a fetus at any time during pregnancy prior to birth per 1,000 live births. Fetal deaths later in pregnancy (>20 weeks' gestation) are also referred to as stillbirths. Fetal mortality may be attributable to maternal factors (e.g., malnutrition, disease, or preterm cervical dilation) or fetal factors (e.g., chromosomal abnormalities or poor placental attachment).

Fetal mortality is a major, but often overlooked, public health problem. The fetal mortality rate in the United States is 6.2 per 1,000 live births. An estimated 1 million fetal deaths at any gestational age occur in the United States each year (Gregory et al., 2020). Much of the public concern regarding reproductive loss has concentrated on infant mortality, as less is known about fetal mortality. However, the impact of fetal mortality on United States families is considerable, as it provides an overall picture of the quality of maternal health and prenatal care.

Neonatal and Infant Mortality

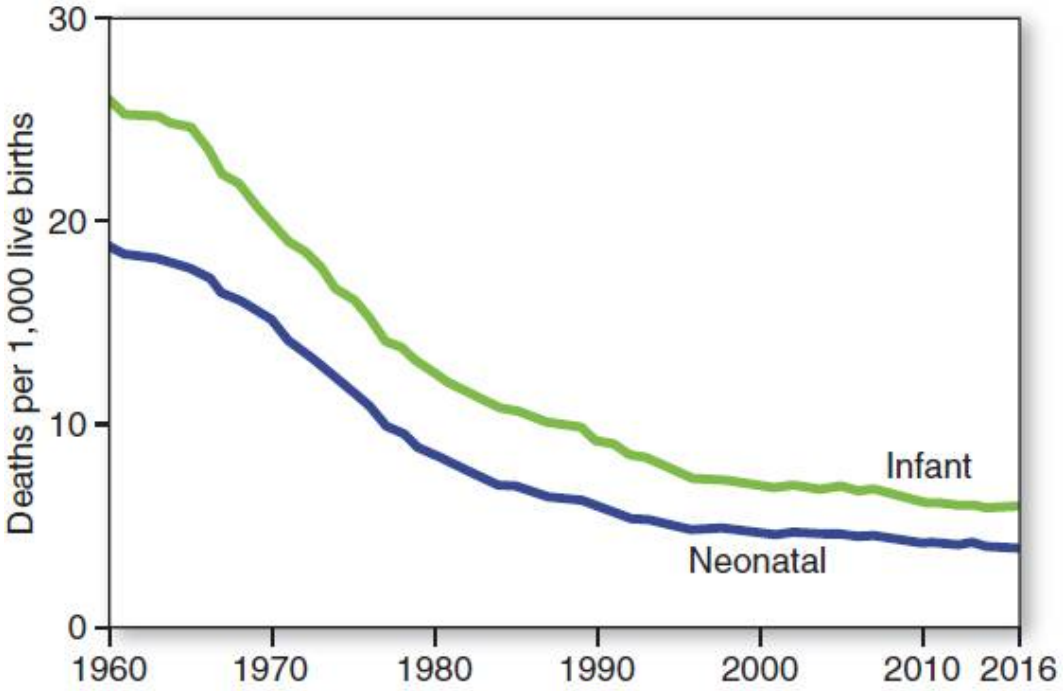
The **neonatal mortality rate** is the number of infant deaths occurring in the first 28 days of life per 1,000 live births. This is their most vulnerable time for survival. Deaths occurring within the first month of life account for two thirds of all infant deaths (United Health Foundation, 2019c). The neonatal mortality rate is less than five per

1,000 live births in the United States (United Nations International Children's Emergency Fund [UNICEF], 2019; World Bank Organization, 2020) (Fig. 1.2). Each year the deaths of 2.5 million babies are linked to complications during birth or within the first month. Furthermore, the burden is inequitably carried by the poor. Evidence-based strategies are urgently needed to reduce the burden of intrapartum-related deaths and effective interventions to address these problems must be incorporated into policy decisions (UNICEF, 2019). The reliability of the neonatal mortality estimates depends on accuracy and completeness of reporting and recording of births and deaths. Underreporting and misclassification are common, especially for deaths occurring early on in life.

Perinatal mortality encompasses late and early neonatal mortality and is defined as the number of stillbirths and deaths in the first week of life per 1,000 live births; it is also a useful indicator. The perinatal mortality is the sum of the fetal mortality and the neonatal mortality. It has remained unchanged for the last few years (Xu et al., 2020).

The **infant mortality rate** is the number of deaths occurring in the first 12 months of life. It is also documented as the number of deaths of infants younger than 1 year of age per 1,000 live births. The infant mortality rate is used as an index of the general health of a country. Generally, this statistic is one of the most significant measures of children's health. The current infant mortality in the United States is 5.8 per 1,000 live births (CDC, 2019a) (Fig. 1.2).

The infant mortality rate varies greatly from state to state as well as between ethnic groups. The United States has one of the highest gross national products in the world and is known for its technologic capabilities, but its infant mortality rate is much higher, in some cases double, than most other developed nations (World Fact Book, 2019). The main causes of early infant death in the United States include problems occurring at birth or shortly thereafter, such as prematurity, low birth weight, congenital and chromosomal anomalies, sudden infant death syndrome (SIDS), respiratory distress syndrome, unintentional injuries, bacterial sepsis, and necrotizing enterocolitis (Murphy et al., 2018).



NOTE: Rates are infant (under 1 year) and neonatal (under 28 days) deaths per 1,000 live births in specified group.
SOURCE: NCHS, National Vital Statistics System, Mortality.

FIGURE 1.2. Infant and neonatal mortality from 1960 to 2016. (Adapted from Xu, J., Murphy, S. L., Kochanek, K. D., Bastian, B., & Arias, E. [Eds.]. [2018]. *Deaths: Final data for 2016. National Vital Statistics Reports*, *67*[5], 1–76. National Center for Health Statistics. https://www.cdc.gov/nchs/data/nvsr/nvsr67/nvsr67_05.pdf)

TAKE NOTE!

Non-Hispanic, African American infants have consistently had higher infant mortality rates than other ethnic groups. This gap continues today (CDC, 2019a).

Congenital anomalies remain the leading cause of infant mortality in the United States (CDC, 2019a). Preterm births and low birth weight are key risk factors for infant death; lower the birth weight, higher the risk of infant mortality. The percentage of infants born preterm in the United States hit a peak in 2006; thus, the effect of preterm-related causes of infant death was increased during this time. From 2007 to 2014, preterm birth rates declined each year but

2015, 2016, and 2017 all brought a rise in the preterm birth rate (CDC, 2019b; Hamilton et al., 2018). This rising trend will need to be closely monitored to understand what is contributing to this increase and what can be done to help decrease the incidence of preterm birth.

After birth, other health promotion strategies can significantly improve an infant's health and chances of survival. Breastfeeding has been shown to reduce rates of infection in infants and to improve their long-term health. Human milk also reduces the risk for allergic and autoimmune diseases, and the risk of obesity and its complications (King et al., 2019). Emphasizing the importance of placing an infant on his or her back to sleep will reduce the incidence of SIDS. In addition, parents/partners should not share a bed with an infant younger than 12 weeks old and should avoid exposing the infant to tobacco smoke (Jordan et al., 2019). Encouraging mothers to join support groups to prevent postpartum depression and learn sound child-rearing practices will improve the health of both mothers and their infants.

Childhood Mortality

The **childhood mortality rate** is the number of deaths per 100,000 population in children 1 to 14 years of age. The childhood mortality rate in the United States has decreased significantly since 1980 but disparities by gender, age, race, and ethnicity persist (Eferevbia et al., 2019). The current mortality rate for children between ages 1 and 4 years is 24.3 per 100,000, with the leading cause of death being unintentional injuries followed by congenital malformations, deformations, and chromosomal abnormalities (CDC/NCHS, 2017). The mortality rate for children of ages 5 to 14 years is 13.6 per 100,000, with the leading cause being unintentional injuries followed by cancer (CDC/NCHS, 2017). Other causes of childhood mortality include suicide, homicide, diseases of the heart, influenza, and pneumonia.

Even as research continues into the preventable nature of childhood injuries, unintentional injury (e.g., motor vehicle accidents,

fires, drowning, bicycle or pedestrian accidents, poisoning, falls) remains a leading cause of mortality and morbidity in children (FIFCFS, 2017). These injuries have far-reaching consequences for children, families, and society in general. Risk factors associated with childhood injuries include young age, male gender, low socioeconomic status, parents who are unmarried or single, low maternal education level, poor housing, parental drug or alcohol abuse, and low support within the family. These deaths can often be prevented through education about the value of using car seats and seat belts, the dangers of driving under the influence of alcohol and other substances, and the importance of pedestrian and bicycle safety, fire safety, water safety, and home safety.

TAKE NOTE!

In the United States, American Indian/Alaska Natives children, followed by African American children, have the highest unintentional injury death rate (Ballesteros et al., 2018).

Morbidity

Morbidity is the measure of the prevalence of a specific illness in a population at a particular time. It is presented in rates per 1,000 population. Morbidity is often difficult to define and record because the definitions used vary widely. For example, morbidity may be defined as visits to the physician or diagnosis for hospital admission. Also, data may be difficult to obtain. Morbidity statistics are revised less frequently because of the difficulty in defining or obtaining the information. The WHO (2019c) has identified four noncommunicable diseases that cause the most worldwide morbidities and mortalities —cardiovascular disease (CVD), cancers, diabetes, and lung diseases.

Women's Health Indicators

Women today face not only diseases of genetic origin, but also diseases that arise from poor personal habits. Even though women represent 51% of the population, only recently have researchers and the medical community focused on their special health needs. The USDHHS adopted the Health and Medicine Division's recommendations that eight preventive services for women be included in the defined list of preventive care services provided without cost sharing under the **Affordable Care Act (ACA)** because they give women access to comprehensive preventive services to achieve health and wellness. For decades, many women struggled to get health insurance coverage for basic needs, but the ACA changed all of that. Unfortunately, many women are unaware about what is covered, and thus don't take advantage of them. The National Women's Law Center (NWLC) has developed resources on well-women visits to ensure that women are able to understand and access the preventive services now available to them under the ACA (NWLC, 2019).

The Population Institute (2018) has conducted a 50-state report card on reproductive health and rights for women and the United States as a whole has been given a D-grade in four broad health indicators: effectiveness, prevention, affordability, and access. They found that there is a growing gap between states that prioritize reproductive health and rights and those that do not.

CVD is the number one cause of death in women, regardless of racial or ethnic group worldwide. Despite increased awareness over the past several decades, more than half of all women do not recognize that heart disease is their number one killer. More women than men die each year from CVD. More than 500,000 women die annually in the United States of CVD—about one death per minute or about one in five women's deaths. More than 23.6 million women die from CVD globally each year (AHA, 2019a; World Heart Federation [WHF], 2019). Women who have a heart attack are more likely than men to die. Heart attacks in women are often more difficult to diagnose than in men because of their vague and varied symptoms. Heart disease is still thought of as a "man's disease," and thus a heart attack may not be considered in the differential

diagnosis 50% of the time when a woman presents to the emergency room with vague symptoms.

Nurses need to look beyond the obvious “crushing chest pain” textbook symptom that heralds a heart attack in men. Risk factors of heart disease differ between men and women in several other ways —for example, menopause (associated with a significant rise in coronary events); diabetes, high cholesterol levels, and left ventricular hypertrophy; and repeated episodes of weight loss and gain (increased coronary morbidity and mortality) (WHF, 2019). Clinical manifestations of a heart attack observed in women include nausea, dizziness, irregular heartbeat, unusual fatigue, sleep disturbances, sweating, indigestion, anxiety, neck, jaw, arm, or shoulder pain, shortness of breath, pain or discomfort in one or both arms, and weakness (American College of Cardiology, 2019). The prevalence, mortality, lack of warning signs in some women, and decreased awareness within this population make it imperative for nurses to assume an active role in assessing these clients, evaluating risk factors, and advocating for prevention of CVD in all women.

Cancer is one of the most significant public health problems in the United States and globally. It is the second leading cause of death among women with breast, colorectal, lung, and cervical cancers contributing to the majority of cancer deaths (8.5 million annually) in women globally (World Cancer Research Fund, 2019). Women have a one-in-three lifetime risk of developing cancer, and one out of every four deaths is from cancer (American Cancer Society [ACS], 2020a). Although much attention is focused on cancer of the reproductive system, lung cancer has the highest mortality rate in women among cancer types. Lung cancer accounts for about 23% of all cancer deaths in women. More people die of lung cancer than of colon, breast, and prostate cancers combined. Lung cancer is largely the result of smoking and second-hand smoke. Lung cancer has no early symptoms, making early detection almost impossible. Thus, lung cancer has the second lowest 5-year survival rate (19%) of any cancer (pancreatic cancer holds first place at 9%); more than 90% of people who get lung cancer die of it (Siegel et al., 2019).

Breast cancer occurs in one in every seven women in a lifetime. It is estimated that in 2020 about 276,480 new cases of invasive breast cancer will be diagnosed among women in the United States. An estimated 42,170 women are expected to die from the disease in 2020 (ACS, 2020e). White women get breast cancer at a higher rate than African American women, but African American women are more likely to get breast cancer before they reach 40, and are more likely to die from it at any age. This is likely because the cancer is more advanced when it is found in African American women, and because survival at every cancer stage is worse among African American women (ACS, 2020a).

Women living in North America have the highest rate of breast cancer in the world. At this time there are about 3.1 million breast cancer survivors in the United States. It is the most common malignancy in women and second only to lung cancer as a cause of cancer mortality in women (ACS, 2020f). Although a positive family history of breast cancer, aging, and irregularities in the menstrual cycle at an early age are major risk factors, other risk factors include excess weight or obesity, not having children, oral contraceptive use, excessive alcohol consumption, a high-fat diet, sedentary lifestyle, and long-term use of hormone therapy after menopause (ACS, 2020f; CDC, 2020b). Breast cancer rates have dropped recently, possibly due to the decreased use of long-term menopausal hormone therapy that occurred after the Women's Health Initiative (WHI) report was released in 2002 and the Million Women Study in 2003 (ACS, 2020f). However, early detection and treatment continue to offer the best chance for a cure, and reducing the risk of cancer by decreasing avoidable risks continues to be the best preventive plan.

Pregnant women are by no means immune to any of the health issues presented thus far. Many women begin a pregnancy with existing health conditions, including hypertension, obesity, CVD, stroke, gallbladder disease, sleep apnea, diabetes, inflammatory processes, autoimmune diseases, anemia, asthma, sexually transmitted infections, depression, or cancer. Although the majority of pregnant women are young and fairly healthy, the incidence of certain chronic health issues in them is increasing secondary to the

obesity epidemic in the United States which impacts more than 90 million adults and 40% of women in the United States. Being overweight or obese is associated with 13 types of cancer, including uterine, breast, and colorectal (CDC, 2019c).

Women's health is a complex issue, and no single policy is going to change the overall dismal state ratings. Although progress in science and technology has helped reduce the incidence of, and improve the survival rates for, several diseases, women's health issues continue to have an impact on our society. By eliminating or decreasing some of the risk factors and causes for prevalent diseases and illnesses, society and science could minimize certain chronic health problems. Focusing on the causes and effects of particular illnesses could help resolve many women's health issues of today.

Childhood Morbidity

In general, 59.2% of children in the United States enjoyed excellent health, and 26.4% had very good health as reported in a summary of health statistics for children in 2018 (Black & Benson, 2019). However, obesity, environmental toxins, allergies, drug abuse, child abuse and neglect, and mental health problems are among some of the key issues that endanger children's health today. Factors that may increase morbidity include homelessness, poverty, low birth weight, chronic health disorders, foreign-born adoption, attendance at day care centers, and barriers to health care. For example, 17% of all children ages 0 to 17 live in poverty and have a higher incidence of disease, limited coordination of health services, and limited access to health care, except for visits to the emergency department (Child Trends Databank, 2019b). However, the poverty rate among African Americans and Hispanics is twice as high as their White peers (Child Trends Data Bank, 2019d). These children are particularly at increased risk for illness.

The most important aspect of morbidity is the degree of disability it produces, which is identified in children as the number of days missed from school or confined to bed. Frequent school

absenteeism has immediate and long-term negative effects on academic performance, graduation rates, adult income, overall health and life expectancy. Control of communicable diseases in children will require public health preventive efforts both at home and at school, which is a primary setting for transmission. Research finds increased illness prevalence and absenteeism with decreasing income status which highlights the need for accessible, affordable resources and interventions at home and school as simple as hand washing hygiene practices (Berendes et al., 2019).

Common health problems in children include respiratory disorders such as asthma; gastrointestinal disturbances, which lead to malnutrition and dehydration; and injuries. Asthma is the leading chronic disease affecting more than 6 million children in the United States (American Lung Association [ALA], 2019). Figure 1.3 shows the major causes of hospitalization by diagnostic category in children in the United States.

As more immunizations become available, common childhood communicable diseases affect fewer children. The tracking of the leading topics from *Healthy People 2030* provides some positive information related to improving children's health. Improvements have occurred in child health but morbidity and disability from some conditions, such as asthma, diabetes, attention-deficit/hyperactivity disorder, and obesity, have increased in recent decades. Also, disparities in health status among children in the United States according to race and socioeconomic status demonstrate widening social inequalities.

One trend in the United States is the increasing number of children with mental health disorders and related emotional, social, or behavioral problems. The American Academy of Pediatrics (AAP) estimates that one in five children in the United States have mental health–related problems yet many receive no professional help and lack access to evidence-based services. ADHD, behavioral problems, anxiety, and depression are the most commonly diagnosed mental disorders in children (AAP, 2019c; Office of Adolescent Health, 2017). These problems may limit the child's educational success. They also increase the child's risk for

significant mental health problems later in life or emotional problems and possible use of firearms, reckless driving, promiscuous sexual activity, and substance abuse during adolescence. Overall, these behavioral, social, and educational problems can interfere with children's social and academic development. Often, insurance does not reimburse for these problems, leading to additional concerns such as lack of treatment. Early diagnosis and appropriate screenings, referrals, and treatment can make a difference in the lives of children with mental health disorders (CDC, 2019h).

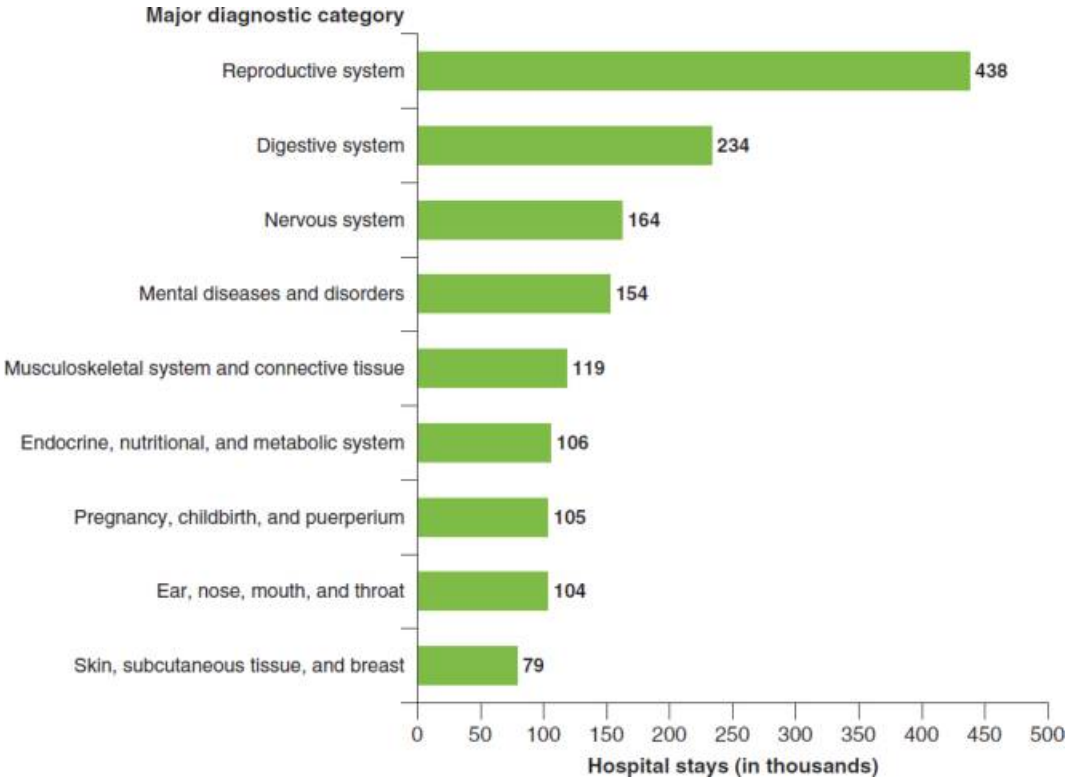


FIGURE 1.3. Top major diagnostic categories for hospitalization in children 1 to 17 years of age, 2012. (Witt, W. P., Weiss, A. J., & Elixhauser, A. [2014]. *Overview of hospital stays for children in the United States, 2012*. HCUP Statistical Brief #187. Agency for Healthcare Research and Quality. http://www.hcup-us.ahrq.gov/reports/statbriefs/sb187-Hospital-Stays-Children-2012.pdf). *Note:* This figure includes all hospital stays but excludes newborns and other neonates with conditions originating in perinatal period, for which there were 3.9 million total hospital stays.

Environmental and psychosocial factors are now an area of concern in children. These include academic difficulties, complex psychiatric disorders, self-harm and harm to others, use of firearms, hostility at school, sexual and physical abuse, substance abuse, bullying online, HIV/AIDS, obesity, violence in the home, and adverse effects of the media.

FACTORS AFFECTING MATERNAL AND CHILD HEALTH

From conception, children are shaped by a myriad of factors, such as genetics and the environment. As members of a family, they are also members of a specific population, community, culture, and society. As they learn and grow, they are affected by multiple, complex, and ever-changing influences around them. For example, dramatic demographic changes in the United States have led to shifts in minority population groups. Globalization has led to an international focus on health. In addition, access to health care and the types of health care available have changed due to modifications in health care delivery and financing. Furthermore, the United States is still grappling with issues such as violence, immigration, poverty, natural disasters, literacy, environmental warming, and homelessness (Our World in Data, 2019). The factors affecting maternal and child health discussed in this section include family, genetics, society, culture, health status and lifestyle, access to health care, improvements in diagnosis and treatments, and empowerment of health care consumers.

These factors may affect the person positively, by promoting healthy growth and development, or negatively, by increasing the person's health risks. Nurses, especially those working with women and children, need to understand how these influences affect the quality of nursing care and health outcomes. They must examine the impact of these variables to gain the knowledge and skills needed to plan effective care, thereby achieving the best possible outcomes for women, children, and families.

Family

The family is considered the basic social unit. The U.S. Census Bureau defines a family consisting of two or more (one of whom is the householder) people living in the same household who are related to the householder by birth, marriage, or adoption (United States Census Bureau, 2019b). Earlier definitions of family emphasize the legal ties or genetic relationships of people living in the same household with specific roles. Given the changing nature of families in today's society, contemporary families are remarkably diverse in structure and process, and the social and demographic changes propelling family diversity are likely to accelerate in the future (Sociology Research, 2019) (Fig. 1.4).

The family greatly influences the development and health of its members. For example, children learn health care activities, health beliefs, and health values from their family. The family's structure, the roles assumed by family members, and social changes that affect the family's life can influence the woman's and child's health status. Families are unique; each one has different views and requires distinct methods for support.

Various theories and models have been generated to explain the concept of family. They have influenced the definition of family, the understanding of the structure and function of the family, and the way family coping and adaptation are assessed. Table 1.1 summarizes some of the major theories related to family.

TAKE NOTE!

The lifestyle of the parents basically is the lifestyle of the children. For instance, parents who are inactive and eat poorly will have children who do the same, and the problems associated with these unhealthy habits, such as diabetes, obesity, and early heart disease, are showing up earlier in children and adolescents. It is important for parents to serve as role models for proper nutrition and physical activity (through sports, hobbies, or other activities).

Family Structure

Family structure is the composition of people who interact with one another on a regular, recurring basis in socially sanctioned ways. It involves how the family unit is organized, which often influences the relationship of the members of the family. Family members can be gained or lost through events such as divorce, marriage, birth, death, abandonment, and incarceration. All of these events can alter the family structure, leading to roles being redefined or redistributed. Table 1.2 provides examples of the types of family structures found in today's society.

A

B

FIGURE 1.4. Nurses must recognize family dynamics when providing health care. There are many different family structures, and they influence the client's needs. **A.** The traditional nuclear family is composed of two parents and their biologic or adopted children. **B.** The extended family includes the nuclear family plus other family members, such as grandparents, aunts, uncles, and cousins. **C.** Gay and lesbian families comprise two people of the same sex sharing a committed relationship with or without children.

TABLE 1.1 Summary of Major Theories Related to Family

Theory	Description	Key Components
Friedman's structural functional theory	Emphasizes the social system of family, such as the organization or structure of the family and how the structure relates to the function.	Identified five functions of families: • Affective function: meeting the love and belonging needs of each member • Socialization and social placement function: teaching children how to function and assume adult roles in society • Reproductive role: continuing the family and society in general • Economic function: ensuring the family has necessary resources with appropriate allocation • Health care function: involving the provision of physical care to keep family healthy
Duvall's developmental theory	Emphasizes the developmental stages that all families go through, beginning with marriage; the longitudinal career of the family is also known as the family life cycle.	Described eight chronologic stages with specific predictable tasks that each family completes: • Marriage: beginning of family • Childbearing stage • Family with preschool children • Family with school-age children • Family with adolescents • Family with young adults • Middle-age parents • Family in later years
Von Bertalanffy: general system theory applied to families	Emphasizes the family as a system with interdependent, interacting parts that	Used to define how families interact with and are influenced by the members of their family

	endure over time to ensure the survival, continuity, and growth of its components; the family is not the sum of its parts but is characterized by wholeness and unity.	and society and how to analyze the interrelationships of the members and the impact that change affecting one member will have on other members.
Family stress theory	Addresses the way families respond to stress and how the family copes with the stress as a group and how each individual member copes.	Described elements of stress as occurring internally within the family (e.g., values, beliefs, structure) that the family can control or change or externally from outside the family (e.g., culture of the surrounding community, genetics, the family's current time or place) over which the family has no control. Described mobilization of family resources resulting in either a positive response of constructive coping or negative response of a crisis. Identified the main determinant of adequate coping based on the meaning of the stressful event to the family and its individual members.
Resiliency model of family stress and family adjustment, and adaptation response model	Addresses the way families adapt to stress and can rebound from adversity.	Identified the elements of risks and protective factors that aid a family in achieving positive outcomes.

Adapted from Friedman, M. M. (1998). *Family nursing: Theory and practice* (4th ed.). Appleton & Lange; Duvall, E. (1977). *Marriage and family development* (5th ed.). J. B. Lippincott; Von Bertalanffy, L. (1968). *General systems theory*. Penguin Press; Boss, P. (2001). *Family stress management: A contextual approach* (2nd

ed.). Sage Publications, Inc.; Patterson, J. (2002). Integrating family resilience and family stress theory. *Journal of Marriage and Family*, *64*(2), 349–360.

The traditional nuclear family is no longer considered the dominant family structure. From 1960 to the present, the percentage of children who were living with their own married parents has decreased steadily (United States Census Bureau, 2019a). The nuclear family is still the most common, but there are millions of households in the United States with a different family structure. By understanding clients' family structure and any changes that may occur, nurses can provide them with support to alleviate or prevent dysfunctional alterations in family coping and adaptation.

TABLE 1.2 Types of Family Structures

Structure	Description	Specific Issues
Nuclear family	Husband, wife, and children living in same household	May include natural or adopted children. Once considered the traditional family structure; now decreased due to trends in divorce rates or other social situations such as nonmarital childbearing.
Binuclear family	Child who is member of two families due to joint custody; parenting is considered a joint venture	Always works better when the interests of the child are put above the parents' needs and desires.
Single-parent family	One parent responsible for care of children	May result from death, divorce, desertion, birth outside marriage, or adoption. Likely to encounter several challenges because of economic, social, and personal restraints; one person as homemaker, caregiver, and financial provider.
Commuter family	Adults in the family living and working apart for professional or financial reasons, often leaving the daily care of children to one parent	Similar to single-parent family, but without as much economic challenge.
Step or blended family	Adults with children from previous marriages or from the new marriage	May lead to family conflict due to different expectations for the child and adults; may have different views and practices related to child care and health.
Extended family	Nuclear family and	Need to determine decision

	grandparents, cousins, aunts, and uncles	maker as well as primary caretaker of the children. May be encouraged and supported by some cultures, such as Hispanic and Asian cultures.
Same-sex family (also called homosexual or gay/lesbian family)	Adults of the same sex living together with or without children	May face prejudice against those with different lifestyles.
Communal family	Group of people living together to raise children and manage household; unrelated by blood or marriage	May face prejudice against those with different lifestyles. Need to determine the decision maker and caretaker of children.
Foster family	A temporary family for children who are placed away from their parents to ensure their emotional and physical well-being	May include foster family's children and other foster children in the home. Foster children are more likely to have unmet health needs and chronic health problems because they may have been living in a variety of settings.
Grandparents-as-parents families	Grandparents raising their grandchildren if parents are unable to do so	May increase the risk for physical, financial, and emotional stress on older adults. May lead to confusion and emotional stress for child if biologic parents are in and out of the child's life.
Adolescent families	Young parents still mastering the developmental tasks of their own childhood	Teenage girls have greater risk for health problems during pregnancy and delivery of premature

	infants, leading to risk of subsequent health and developmental problems. Probably still need support from their family related to financial, emotional, and school issues.

Families today face complex challenges as they try to nurture, develop, and socialize their members. Family structure changes such as divorce, blending families, adoption, or foster care can have wide-ranging and lifelong effects. These special situations require astute assessment and proactive intervention to minimize the risk to the family.

DIVORCED FAMILY

Divorce is a common reason why the family structure changes. Today, more than 50% of marriages end in divorce and many of these marriages include children (Fortin & Downes, 2019). Divorce rates have climbed across the globe and it is estimated that 48% of American children live in divorced single-parent homes by the age of 16 (Devlin, 2020). Divorce can have a great impact on the child, with chronic and devastating results. Typically, divorce is not a single event. Changes have most likely been occurring in the family for years, and children may have been exposed to turmoil, violence, or changes in structure before the actual divorce. Children feel scared and confused by the threat divorce poses on their security. The initial response of children to divorce depends on their age, developmental level, temperament and the circumstances surrounding the divorce. Problems are most apparent the first couple of years immediately following the divorce and children may feel anger, anxiety, guilt, depression, and exhibit noncompliance, however most children show good adjustment a few years after divorce (Fortin & Downes, 2019). Children in divorced families may experience long-term distress and require psychological help two to three times more than children with parents that have remained married (Fortin & Downes, 2019).

Parents need to understand the impact that divorce can have on their children so that they can place the children's interests in the forefront. The loss of a parent through divorce can leave children vulnerable to physical and mental illnesses (D'Onofrio & Emery, 2019). However, by appropriately utilizing family strengths and providing care and attention, children can be helped to deal constructively with divorce (D'Onofrio & Emery, 2019). Parents can use the rules in Box 1.2 to help reduce tension and conflict, thereby minimizing the impact of separation and divorce on their children. Health care providers can offer support, guidance, and resources to help make the strain of divorce easier on the entire family.

SINGLE-PARENT FAMILIES

Single-parent families can result from divorce or separation, death of a spouse, an unmarried woman raising her own child, or adoption by an unmarried man or woman.

Approximately 32% of children younger than age 18 live with unmarried parents, with 21% living with the mother only, 7% living with co-habiting parents, and 4% living with the father only (Livingston, 2018).

Single-parent families have several concerns that can affect the health of the children. Life in a single-parent household can be stressful for both the adult and the children. The single parent may feel overwhelmed with no one to share the day-to-day responsibilities of juggling the care of the children, maintaining a job, and keeping up with the home and finances. These issues may be compounded by other pressures, such as custody problems, decreased time available to spend with children, continuing conflicts between parents who are separated or divorced, or changes in relationships with extended family members.

Communication and support are essential to the optimal functioning of the single-parent family. The parent and children need to be able to express their feelings and work through the problems together. Single parents must provide greater support for their children. Even though a single parent may feel alone they need to ensure they treat their children as children and not a substitute for a partner. Support and comfort need to come from outside resources. Community resources can be helpful. Parents Without Partners, for instance, is an international organization that has over 200 chapters in the United States and Canada. Links to these organizations' websites can be found on thePoint. It provides "single parents and their children with an opportunity for enhancing personal growth, self-confidence and sensitivity towards others by offering an environment for support, friendship, and the exchange of parenting techniques" (Parents Without Partners, 2014).

BOX 1.2 Rules for Divorcing Parents

1. Tell your children about the divorce and the reasons for the divorce in terms that they can understand. Be sure that you and your spouse are present together when telling the children; tell all the children at the same time.
2. Reassure your children that the divorce is not their fault. Repeat this as often as possible and as necessary.
3. Inform the children well in advance of anyone moving out of the house (except when abuse is present or there are concerns for immediate safety).
4. Clearly inform the children about the family structure after the divorce, such as who will live with whom and where; also discuss visitation clearly and honestly.
5. Do not make your children be or act like adults. Seek support from other adults in your life.
6. Do not discuss money or finances with your children.
7. Minimize unpredictable schedules and maintain routines, rules, and discipline, and be consistent in this area.
8. Never force or allow your children to take sides.
9. Avoid belittling your former spouse when the children can hear. However, do not lie to cover up for irresponsible behavior by the other parent.
10. Never put your children in the middle between you and your ex-spouse.
11. Keep each parent involved in the child's life. Write letters, emails, phone calls, and text messages to continue communication. This shows the child they remain important to you even when they are with the other parent.
12. Communicate directly with the other parent. Avoid making the child your messenger.
13. Allow and assist the child to express his or her feelings about the divorce and offer support.

BLENDED FAMILIES

Family life is changing. Two parent households are declining as divorce, remarriage, and cohabitation are on the rise. Although it

creates a structure and stability and reduces some of the financial stresses of single parenthood, making the transition to a blended family takes time. Children may feel jealous of the stepparent or feel disloyal toward the previous biologic parent. There may be competition or rivalry among the stepchildren. The child may fear that the stepparent is interfering with the child's relationship with the parent or taking away his or her source of love, affection, and attention.

Mutual respect and open, honest communication among all individuals involved are key, and this should include the previous biologic parent when possible. Responsibilities for parenting must be shared, including decisions about expectations, limits, and discipline. The continued role of the previous biologic parent and the role of the stepparent in the child's life are important to address.

ADOPTED FAMILIES

Adoption is the process of a nonbiologic parent or parents creating a legal relationship with a child. It is estimated that every year, approximately 120,000 children are adopted in the United States (Schulte, 2019). Adoption can occur domestically (through an agency or intermediary such as an attorney in the family's own area or country), or the family may choose to adopt a child from another country. The child may be of a different culture, race, or ethnicity (Fig. 1.5). Most children in need of adoption in the United States and overseas are not infants. In recent years there have been an increasing number of children adopted from the U.S. child welfare systems and internationally along with an increase in transracial, same-sex parents, and single-parent adoptions and adoption of children with special needs (Schulte, 2019).

The amount of contact between the child and the birth mother can vary greatly. In a closed adoption there is no contact between the adoptive parents, the adopted child, and the birth mother. In an open adoption there is as much contact among the individuals as desired. Regardless of the method used to adopt a child, adoptive families may be faced with unique issues. Some adopted children have

complex medical, developmental, behavioral, educational, and psychological issues. A comprehensive health evaluation needs to be done which includes diagnostic tests, age-appropriate screenings, and behavioral/developmental assessments based on the risks presented by the child's previous living conditions (Jones et al., 2019). They may have been exposed to poverty, neglect, infectious diseases, and lack of adequate food, clothing, shelter, and nurturing, placing them at risk for medical problems, physical growth and development delays or abnormalities, and behavioral, cognitive, and emotional problems. The adoptive parents may know about these problems, but in other situations little if any history may be available.

FIGURE 1.5. An adoptive family with children from a different culture.

Differences in culture, ethnicity, or race can further influence the adopted child's sense of identity (Jones et al., 2012, reaffirmed 2017). Children may be subjected to racism or bigotry. Extended

family members may not accept the child as part of the family. Parents need to emphasize that the adopted child is their child and is as much a part of the family as any other member. Parents need to openly recognize racial differences that exist between them and their child. Parents should encourage and assist the child to learn about their heritage, culture, and ethnic group as part of their socialization process (Jones et al., 2012, reaffirmed 2017; Zhang & Pinderhughes, 2019). Adopted adolescents and adults may feel a need to identify their biologic parents. Children adopted from other countries may travel to the country of their birth, and children adopted domestically may search for biologic relatives. Although this search is an indicator of healthy emotional growth, it can upset the adoptive parents, who may feel rejected.

As the adopted child grows older, he or she may feel the loss of a birth family or may question what he or she did that led to the birth parents' decision to proceed with adoption. Attachment to the adoptive family is important. In order to attach in future relationships children must appropriately grieve past losses. This can be particularly complex and difficult for older children and children previously living in foster care or orphanages.

TAKE NOTE!

Adolescents face vast challenges adjusting to adoption at this age because of the added complexity of identity issues facing this age group (Jones et al., 2012, reaffirmed 2017).

Clear, open, honest communication and discussion are essential to promote a healthy, strong relationship. Support, guidance, and open communication are key for all parties involved. Open acknowledgment of the adoptive relationship helps to nurture trust, security, and a child's self-esteem as he or she learns to understand what it means to be part of a family through adoption (Jones et al., 2012, reaffirmed 2017).

The pediatric nurse needs to be sensitive, understanding, and supportive when interacting with adopted children and their families. “Positive” adoption language should be used. This includes saying “birth parent” when referring to biologic parents instead of “natural” or “real parent” and just parents when talking about adoptive parents (Jones et al., 2012, reaffirmed 2017). Also, do not refer to the child as their “adopted child” or other children as “natural child” (Jones et al., 2012, reaffirmed 2017). When discussing adoption using terms such as “make an adoption plan” instead of “give away” or “give up for adoption” are preferred (Schulte, 2019). The nurse also needs to provide reassurance and understanding regarding missing health information and provide appropriate resources and referrals to resources that are knowledgeable about adoption and sensitive to the issues that may arise. Sources of information and support available are the Center for Adoption Support and Education and the North American Council on Adoptable Children, links to which are provided on thePoint.

FOSTER CARE FAMILY

Foster care is a situation in which a child is cared for in an alternative living situation apart from his or her parents or legal guardians. The child may be placed in this living situation due to difficulties in the family situation, such as abuse, neglect, abandonment, or the parents’ inability to meet the child’s needs, due to illness, substance abuse, or death. The child may be sent to live with relatives (kinship care) or foster parents, who are strangers providing protection and shelter in a state-approved foster home.

There are about 442,995 children in the United States currently living in some form of foster care (U.S. Department of Health and Human Services, Administration for Children & Families, Administration on Children, Youth and Families, Children’s Bureau [USDHHS, ACF, ACYF, CB], 2018). On average, children remain in foster care for nearly 2 years and some are there for 5 or more years (Children’s Rights, 2019). The goal of foster care is to provide temporary services until the child can return home to his or her

family or be adopted. Unfortunately, children may remain in foster care for several years or longer and may be moved from one foster family to another.

Many children who are placed in foster care have been the victims of abuse or neglect. Children in foster care are more likely to exhibit a wide range of medical, emotional, behavioral, dental, educational, or developmental problems (Fortin & Downes, 2019). However, children are very resilient and most children in foster care are determined to live their lives, but they may struggle with certain issues, including the following:

- Unmet health care needs
- Significant mental health problems, such as depression, social problems, anxiety, and posttraumatic stress disorder due to trauma, loss, and unpredictability
- Behavioral problems such as substance use, problems with the law, and self-destructive behaviors
- Interruptions in developmental stages and developmental delay
- Educational obstacles due to frequent moves and educational difficulties
- Self-blame and feelings of guilt
- Hygiene issues
- Feelings of being unwanted
- Feelings of helplessness and powerlessness
- Insecurity about the future
- Ambivalent feelings related to foster parents; feelings of being disloyal to birth parents (American Academy of Child and Adolescent Psychiatry, 2018; Fortin & Downes, 2019)

Individual attention to the child in foster care is essential. A multidisciplinary approach to care that includes the birth parents, foster parents, child, health care professionals, and support services is important to meet the child's needs for growth and development. Nurses play a key role in advocating for the child.

Family Roles and Functions

Regardless of the structure of the family, the role of the family in caring for the child includes not only providing physical and emotional care but also imparting the rules and expected behaviors of society through teaching and discipline techniques. These expected behaviors depend on the culture, values, and beliefs of the family and the child's developmental stage and physical and cognitive abilities. Roles and functions are further defined by each family's own traditions and values and the family's set of standards for interaction within and outside the family. For instance, some families may value privacy more than others. These family members may tend to be more self-protective and secretive.

CAREGIVER–CHILD INTERACTION

The caregiver–child interaction is critical to the survival and healthy development of a young child. Responsive caregiving is essential for positive socioemotional development in children (Fanaroff & Fanaroff, 2019). Typically, the primary caregivers are the parents. Ideally, parents nurture their children and provide them with an environment in which they can become competent, productive, self-directed members of society. For young children in particular, growth, health, and their very personhood itself depend on the ability of the adults in their life to understand and respond to them (Feigelman, 2020).

PARENTAL ROLES

Parenting is an enormous responsibility and takes a lot of time as well as physical and mental energy. Parental roles are vast and numerous. Typical parental roles include nurturer/caregiver, financial provider, decision maker, schedule manager, financial manager, problem solver, counselor, teacher, behavior support and manager, and health manager.

CHANGES IN PARENTAL ROLES OVER TIME

Parental roles evolve due to societal and economic changes as well as individual family changes. Traditionally, the role of provider was assigned to the father. However, with increased numbers of women in the workplace and more households with two parents working, today both parents are often the providers as well as the nurturers to the children. Technologic innovations have provided parents with opportunities to work at home, allowing some parents to maintain the provider role while simultaneously fulfilling the nurturer and health manager roles. Fathers are taking on greater responsibilities related to household management and child care. Also, the number of children being raised by their grandparents is increasing. It is estimated that approximately 3 million older adults are raising their grandchildren now (AARP, 2018). Moreover, as baby boomers age, parents may find themselves caring for both their children and their aging parents.

Recall Sophia, the pregnant woman described at the beginning of the chapter. Identify the parental roles Sophia would assume. How might these roles be different from those of her mother when she was Sophia's age?

PARENTING STYLES

Beginning in the 1960s with Baumrind, a psychologist, and further research in the 1980s by Maccoby and Martin were the basis of the development of four major parenting styles seen in our society: authoritarian, authoritative, permissive, and uninvolved or rejecting–neglecting. The styles are defined by the amount of support and control exerted over the child during parenting. Many parents may use more than one parenting style and may fall somewhere in between styles instead of adhering strictly to one style. Some parents may change parenting styles as the child ages and matures. Whatever the style, sensitive and responsive caregiving is needed to promote appropriate physical, neurophysiologic, and psychological development. Parenting styles vary in levels of warmth and control, which are linked to social-emotional and developmental outcomes for children (Branjerporn et al., 2019). Nurses need to recognize

different parenting styles and provide support to parents by discussing the effects of different parenting models and teaching parenting skills.

Authoritarian

The *authoritarian* parent expects obedience from the child and discourages the child from questioning the family's rules. The parent provides low support and high control over the child (Cherry, 2019). The rules and standards set forth by the parents are strictly enforced and firm. An authoritarian parent provides little or no nurturing or affection. The parents expect the child to accept the family's beliefs and values and demand respect for these beliefs. The parents are the ultimate authority and allow little, if any, participation by the child in making decisions. Behavior that does not adhere to the family's rules and standards is punished. This parenting style is associated with negative effects on self-esteem, happiness and social skills, depressed and lonely, increased aggression, feeling anger, resentment, and defiance (Cherry, 2019).

Authoritative

The *authoritative* or democratic parent shows some respect for the child's opinions. Although parents still have the ultimate authority and expect the child to adhere to the rules, authoritative parents allow children to be different and believe that each child is an individual. They exhibit warmth and consistently, fairly, and firmly enforce the family's rules and standards without emphasizing punishment. Differences are approached with reasoning and discussion rather than by exerting control (Feigelman, 2020). This type of parenting is associated with increased independence, happiness, self-confidence, and socially responsible individuals (Cherry, 2019).

Permissive

Permissive or laissez-faire parents have little control over the behavior of their children. Rules or standards may be inconsistent, unclear, or nonexistent. Permissive parents allow their children to

determine their own standards and rules for behavior. Discipline can be lax, inconsistent, or absent. Parents can be warm, cool, or uninvolved. There are more negative than positive effects associated with this style of parenting. Negative effects include children being impulsive, low happiness, poor school performance, problems with authority, lacking responsibility, and independence (Cherry, 2019). This type of parenting is child-centered, but a nondemanding pattern that make few demands for mature behavior (Checa & Abundis-Gutierrez, 2018).

Neglectful

Uninvolved, neglectful parents are indifferent and low in responsiveness and demands made on children. They do not provide rules or standards. The child's basic needs are often met but the parent is disconnected from the child's life. In some cases, the parents may neglect or reject the child. They can be cold and uninterested in meeting the child's needs. They minimize their interactions and time with the children. This type of parenting is associated with negative effects such as the child lacking interest in school, lacking interest in the future, and lacking emotional and self-control (Cherry, 2019). This type of parenting may also lead to lack of trust, low self-esteem, antisocial behavior, and anger toward others (Cherry, 2019; Rodriquez, 2019).

DISCIPLINE

Much of parenting involves increasing desirable behavior and decreasing or eliminating undesirable behavior, a process generally known as **discipline**. There are various opinions in our society about the best or most effective method of discipline. Each child and family are unique. Discipline that works with one child or within one family may not work for another family. Discipline should focus on the development of the child while ensuring to preserve their self-esteem and dignity. It should be based on age-appropriate expectations with clear, consistent guidelines while offering meaningful choices when

possible. Discipline involves teaching and it is ongoing, not something that is done just when the child misbehaves.

The AAP (Sege et al., 2018) suggests these strategies for effective discipline (see also Teaching Guidelines 1.1):

TEACHING GUIDELINES 1.1
Promoting Effective Discipline

- Set clear, consistent, and developmentally appropriate expected behaviors; offer choices whenever possible.
- Maintain consistency in responding to behaviors; provide encouragement and affection.
- Role-model appropriate behaviors.
- Provide an age-appropriate explanation of the consequence if the child demonstrates unacceptable behavior.
- Always administer the consequence soon after the unacceptable behavior.
- Keep the consequence appropriate to the age of the child and the situation.
- Stay calm but firm without showing anger when administering the consequence.
- Always praise the child for displaying appropriate behavior (positive reinforcement).
- Set the environment to assist the child in accomplishing the appropriate behavior; remove temptations that may lead to inappropriate behavior.
- Reinforce that the child's behavior was "bad" but the child was not "bad."
- Use extinction to reduce or eliminate reinforcement for an inappropriate behavior (e.g., ignore a temper tantrum).

- Maintaining a positive, supportive, nurturing caregiver–child relationship
- Using positive reinforcement to increase desirable behaviors
- Praise good behavior to reinforce it

- Be a role model for good behavior
- Set limits and expectations
- Removing positive reinforcements or using punishment to reduce or eliminate undesirable behaviors

POSITIVE REINFORCEMENT

Attention from parents is a very powerful form of positive reinforcement and can help increase desirable behaviors. The key is to focus on the child's appropriate behaviors rather than emphasize the inappropriate ones. Immediate, consistent, and frequent feedback is crucial. This feedback can be in the form of smiles, praise, special attention, or rewards such as extra privileges or a special token or activity. Providing the feedback immediately is important so that the child learns to associate the feedback with the appropriate behavior, thereby reinforcing the behavior.

EXTINCTION

Another form of discipline is extinction, which focuses on reducing or eliminating the positive reinforcement for inappropriate behavior. Examples are ignoring the temper tantrums of a toddler, withholding or removing privileges, and requiring "time-out." Withholding or removing privileges such as TV, music device, computer, or phone use is most effective for older children and adolescents. The adolescent may be grounded for a short time or not allowed to drive the car. To be effective, the privilege being withheld or removed must be something that the child values.

Time-out is an extinction discipline method that is most effective with toddlers, preschoolers, and early school-age children. It involves removing the child from the problem area and placing him or her in a neutral, nonthreatening, safe area where no interaction occurs between the child and parents or others for a specifically determined period (Fig. 1.6).

TAKE NOTE!

Time out allows the child time to cool down. The amount of time that a child spends in time-out is typically 1 minute per year of age; around the age of 3 the parent could allow the child to dictate their own time-out length, such as saying come back when you feel ready and calm, this allows the child to learn self-management skills (AAP, 2018d).

PUNISHMENT

Discipline is often confused with punishment, but punishment involves a negative or unpleasant experience or consequence for doing or not doing something. Although punishment is sometimes a necessary element of discipline, to be an effective tool it must be coupled with rewards for good behavior (Sege et al., 2018).

FIGURE 1.6. Although he might not like it, quiet solitude helps the child develop inner control.

Punishment may be verbal or corporal. Verbal **punishment** commonly takes the form of reprimands or scolding (the use of disapproving statements). The statements are intended to change or eliminate the inappropriate behavior. Verbal reprimands can be effective in the short term if they are used sparingly and are focused on the child's specific behavior. If verbal reprimands are used

frequently and indiscriminately, they lose their effectiveness, can provoke anxiety in the child, and encourage the child to ignore the parent.

Corporal punishment involves the use of physical pain as a means to decrease inappropriate behavior. The most common form of corporal punishment is spanking (the use of an open hand to the buttocks or an extremity with the intention of modifying behavior without causing injury) (Sege et al., 2018). Spanking decreases as children age but is still used as a discipline strategy in adolescents. Over the past two decades a growing body of research has suggested that corporal punishment can cause an increase in behavior problems, have lasting effects into adulthood, and is ineffective in teaching a child responsibility and self-control (AAP, 2018a).

TAKE NOTE!

Other forms of discipline, if used incorrectly, can also cause problems for the child and interfere with the caregiver–child relationship. For example, disapproval using tone of voice, facial expression, or gestures can be effective in stopping inappropriate behavior, but if the disapproval comes in the form of verbal statements that attack the child rather than the behavior, negative consequences may occur (Sege et al., 2018).

Genetics

Genetics, the study of heredity and its variations, is a field that has applications to all stages of life and all types of diseases. Heredity is the process of transmitting genetic characteristics from parent to offspring. The child's biologic traits, including sex, gender, race, some behavioral traits, and the presence of certain diseases or illnesses, are directly linked to genetic inheritance.

Sex and Gender

The child's sex is established when the sex chromosomes join. A child's sex can influence many aspects, such as physical

characteristics and personal attributes. In addition to the development of male or female genitalia, body development, and hair distribution, some diseases or illnesses can be sex related; for example, scoliosis is more common in females and color blindness in males (Templeton, 2019).

In addition to the specific biologic and physical traits related to the sex of the child there are also social effects related to the gender of the child. The child develops specific gender attitudes and behaviors that are appropriate in his or her own culture. Interactions with family members and peers as well as activities and societal values affect how children perceive themselves as a specific gender (Fig. 1.7).

FIGURE 1.7. Interactions with family members and peers as well as activities and societal values affect how children perceive themselves as a certain gender.

Race

Race refers to the physical features that distinguish members of a particular group, such as skin color, bone structure, or blood type. Some of the physical variations may be normal in a particular race

but may be considered an identifying characteristic of a disorder in other races. For example, epicanthal folds (the vertical folds of skin that partially or completely cover the inner canthi of the eye) are normal in Asian children but may occur with Down syndrome or renal agenesis in other races. In addition, certain malformations and diseases are found more commonly in specific races. For example, sickle cell anemia occurs more often in African Americans (Templeton, 2019).

Public awareness is important in educating diverse race couples at genetic risk about the benefits of screening programs and proactively seeking preconceptual genetic counseling to consider options that could include preimplantation genetic diagnosis (the use of in vitro fertilization technology to screen for unaffected embryos) (Cunningham et al., 2018). The lack of engagement by ethnic minorities might simply reflect a lack of genetic awareness. Nurses can take the lead in assisting couples to gain that needed awareness to be empowered to make intelligent reproductive decisions.

Temperament

Temperament is the manner in which a child interacts with the environment. One's temperament is a collection of traits that stay relatively constant over time. The way a child experiences a particular event will be influenced by his or her temperament, and the child's temperament will influence the responses of others, including the parents, to the child. Early on, infants demonstrate differences in their behavior in response to stimuli. These responses are an integral part of the infant's developing personality and individuality. Although a child's temperament is intrinsic and relatively resistant to change, it does stabilize as the child matures. Knowing a child's temperament can help parents understand and accept the characteristics of the child without feeling responsible for having caused them.

The classic temperament theory proposes children's temperaments may be categorized into three major groups: easy, difficult, and slow to warm up; various temperaments exist that are a

combination of these groups (Levine, 2019). Easy children are even-tempered and have regular biologic functions, predictable behavior, and a positive attitude toward new experiences. Difficult children have irregular biologic functions, are highly active, and intense; they react to new experiences by withdrawing and are frustrated easily. Children in the slow-to-warm-up category are moody and less active and have more irregular reactions; they react to new experiences with mild but passive resistance and need extra time to adjust to new situations (Levine, 2019). Some children will have a mix of these temperament categories.

A child's temperament may cause problems in the family if it conflicts with that of the parents (e.g., a difficult 2-year-old with slow-to-warm-up parents). If parents want and expect their child to be predictable but that is not the child's style, parents may perceive the child to have problems; this conflict may then affect the child's health. The key is not to label the child but to recognize the strengths and limitations of each group. Knowing a child's temperament can help parents understand a child's characteristics and behaviors and allow parents to adjust their parenting style.

Genetically Linked Diseases

New technologies in molecular biology and biochemistry have led to better understanding of the mechanisms involved in hereditary transmission, including those associated with genetic disorders. These advances are now leading to better diagnostic tests and management options.

Reproductive genetic testing, counseling, and other genetic services can be valuable components in the reproductive health care of women and their families. These services have the potential to increase knowledge about possible pregnancy outcomes that may occur if a woman decides to reproduce; to provide reassurance during pregnancy; and to enhance the developing relationship between the woman, her expected child, and others (Norwitz et al., 2019). This awareness can provide each woman with an opportunity to have access to desired genetic services in a way that will improve

her control over the circumstances of her reproductive life, her pregnancies, childbearing, and parenting, within a framework that is sensitive to her needs and values. Nurses can be a vital facilitator in this process and to these services.

Two major areas of study in genetics that are important to pediatrics are cytogenetics and the Human Genome Project. Cytogenetics is the study of genetics at the chromosome level. Since the genetic code was deciphered, much has been learned about the chromosomal structure shared by all human organisms. Chromosomal anomalies, such as trisomies 21, 18, and 13, occur in 0.6% of all live births and negatively affect fetal viability (Marion & Levy, 2019); anomalies are even more common among spontaneous abortions and stillbirths. The Human Genome Project was an international research effort involving the localization, isolation, and characterization of human genes and investigation of the function of the gene products and their interaction with one another. It was considered one of the most ambitious and successful international research collaborations in the history of biology. Completion of this project provided scientists with greatly enhanced information about how DNA shapes species development and genetic diseases to aid in developing new ways to identify, treat, cure, or even prevent them. Chapters 10 and 49 offer a more detailed discussion of genetics.

Society

Society has a major impact on the health of women, children, and families. Major components of a society that influence children and their health include social roles, socioeconomic status, the media, and the expanding global nature of society. Each of these areas may influence a person's self-concept, the communities where they live, their choice of lifestyle, and their health. Nurses need to assess these areas and their influence on the child and family so that individualized strategies can be designed and implemented to enhance the positive effects and minimize the negative effects on the child's and family's health.

Social Roles

Society often prescribes specific patterns of behaviors: certain behaviors are permitted and others are prohibited. These patterns are identified as social roles and can be an important factor in the development of self-concept, and a person's self-concept can have a very positive or a very negative influence on his or her health.

Socioeconomic Status

Health is correlated to people's socioeconomic status (relative position in society) and lifestyle. This includes the family's economic, occupational, and educational levels. Children are raised differently by parents of different educational levels, occupations, and incomes. Low socioeconomic status typically has an adverse influence on an individual's health. Health care costs are continuing to rise, as are health insurance premiums. The family may not be able to afford healthy food, health care, and housing; meals may be unbalanced, erratic, or insufficient. Housing may be overcrowded or have poor sanitation. These families may not understand the importance of preventive care or may simply not be able to afford it. As a result, they may be exposed to health risks such as lead poisoning or may not be immunized against communicable diseases. Studies have documented that children who come from low socioeconomic status are more likely to suffer negative physical and mental health outcomes, such as depression, anxiety, substance use, attempted suicide, obesity, and injuries (American Psychological Association [APA], n.d.).

TAKE NOTE!

A recent research study showed that lower socioeconomic status was associated with increased cortisol levels over time. Children living in low socioeconomic status situations are more vulnerable to anxiety and alterations in their stress-sensitive hypothalamus–pituitary–adrenal axis system. Cortisol plays a role in psychiatric and physical illnesses; therefore, findings of elevated cortisol levels in children from a low socioeconomic status may help explain why low socioeconomic status is negatively related to health (Zhu et al., 2019).

POVERTY

Poverty is a measurement based on the specific monetary income of a family. The poverty threshold is the dollar amount that the U.S. Census Bureau uses to determine whether a family is living in poverty. It is based on the family's size and income (Table 1.3). If the individual's or family's income is below the threshold, then that person or family is said to be living in poverty.

TABLE 1.3 2020 U.S. Poverty Guidelines

Size of Family Unit	48 Contiguous States and D.C.	Alaska	Hawaii
1	$12,760,490	$15,950	$14,680
2	$117,240	$21,550	$19,830
3	$21,720	$27,150	$24,980
4	$26,200	$32,750	$30,130
5	$30,680	$38,350	$35,280

Data from U.S. Department of Health and Human Services (USDHHS). (2020a). *2020 Poverty guidelines*. Retrieved January 15, 2020, from https://aspe.hhs.gov/poverty-guidelines

Despite the many global economic gains that have been made during the past century, poverty continues to grow and the gap between rich and poor is widening. Major gaps continue between the economic opportunities and status afforded to women and those offered to men. A disproportionate share of the burden of poverty rests on women's shoulders, and this undermines their health. However, poverty, particularly for women, is more than monetary deficiency. Women continue to lag behind men in control of cash, credit, and collateral. Other forms of impoverishment may include deficiencies in literacy, health care access, education, skills, employment opportunities, mobility, and political representation, as well as pressures on time and energy linked to their responsibilities. These poverty factors may affect a woman's health. Our nation's

laws, policies, and courts need to recognize the reality of poor women's lives who face ongoing barriers which leave them without the care they need (Borchelt, 2019).

Basic financial stability enhances the general health and well-being of children, and thus an important negative influence on children's health is poverty. Children living in poverty are more likely to have poor health, be retained in a grade or drop out of school, experience violent crimes, and become poor adults (Children's Defense Fund, 2017).

According to the Children's Defense Fund (2017), 13.2 million American children live in poverty, with 6 million living in extreme poverty. The rate of poverty is closely tied to the overall health of the economy; therefore, in times of recession, a rise is usually seen. Family structure is an important factor associated with poverty rates for children. The poverty rate for married-couple families is much less than that for families headed by a single parent. Of the families living below poverty level, 25.7% were single-mother families with no husband present, 12.4% were single-father families with no wife present, and only 4.9% were married couples (Fontenot et al., 2018). Educational level is another important factor: as education increases, unemployment declines and annual income rises. However, a chronic physical or emotional problem in any wage earner may lead to unemployment, and this can cause the family to spiral downward into poverty.

The effects of poverty on children's health can be wide-ranging. The family may be able to afford only substandard housing or a house or apartment in a dangerous neighborhood (e.g., unsanitary conditions, toxins, violence). Poverty may also lead to homelessness.

HOMELESSNESS

During the 2014–2015 school year, approximately 1.2 million children that were enrolled in school were homeless (Children's Defense Fund, 2017). It is impossible to measure homelessness with 100% accuracy. Therefore, looking at trends is important to

demonstrate if progress is being made or not. Close to half of homeless are African American families with children (Children's Defense Fund, 2017).

Homelessness occurs in large urban areas and midsize cities as well as suburban and rural areas. The principal causes of homelessness in families are poverty and lack of affordable housing. Other causes include cutbacks in public welfare programs, mental health issues, and traumatic events such as unemployment, illness, or accidents and personal crises such as divorce, domestic violence, or substance abuse. Children may be forced out of their house or choose to run away and become homeless because they have been abused or neglected, lived in foster homes, or were placed in residential treatment or juvenile detention centers.

In homeless children, the basic need for a stable shelter goes unmet. Homelessness is not conducive to appropriate growth and development in children. Homelessness can have a negative impact on health and well-being in numerous ways, including the following:

- Increased mental health issues such as anxiety, depression, or aggressive behavior
- Higher incidence of chronic health problems and trauma-related injuries
- Poor oral health and hygiene which can cause systemic infections
- Problems related to nutritional deficiencies, affecting fetal or child growth and development
- Participation in behaviors such as illegal substance use or unprotected sex with multiple partners
- Limited access to health care services such as preventive care, prenatal care, or dental care
- Inability to attend school consistently, because the environment is not conducive to learning; may result in learning problems, socialization issues, or behavioral issues (Early Childhood Learning & Knowledge Center, 2019)

Media

Prolonged sitting and watching television or surfing the Internet while pregnant impairs the blood return in the legs and causes swelling.

This immobility may also increase the risk of blood clot formation. Nurses can instruct their pregnant clients that it is important to improve circulation to the legs by not crossing them at the knees and to keep the legs moving by rotating the feet at the ankles. Sitting with the feet up with support to the ankles is also helpful. Changing the sitting position and getting up at least every hour is essential to prevent complications.

Today's children are inundated with various forms of media, such as television, iPhones, iPods, iPads/tablets, video and computer games, social media such as Facebook, Instagram and Snapchat, the Internet, movies, magazines, books, and newspapers (Fig. 1.8). Media has both positive and negative effects on the development of children and much depends on the content to which they are exposed (Chassiakos et al., 2016; Radesky, 2019). Positive effects include exposure to early learning, new knowledge and information including health promotion messages, and increased social contact and support (Chassiakos et al., 2016). Negative effects include adverse health effects on sleep, attention, learning, activity, and mental health (Chassiakos et al., 2016). Some of the images and information are not always in the best interests of children. Children may identify with, and mimic, characters who engage in risk-taking behaviors or lifestyles. Evidence is clear that media exposure can contribute to many different risks and health problems, such as excessive caloric intake, physical inactivity, smoking, early initiation of sexual behaviors, and underage drinking (Chassiakos et al., 2016). Research has established a strong link between media violence and violent, aggressive behavior (Chassiakos et al., 2016). If an image or type of behavior is portrayed as the norm, children may view this as acceptable behavior without examining the potential health risks or other long-term consequences. For example, thinness is portrayed as the body type that is identified with beauty, leading some children to develop unhealthy dieting or other behaviors to develop that body type. For the child who has a body type that does not fit the ideal, depression or self-esteem issues may develop.

FIGURE 1.8. Computer games can be fun and educational, but the child should be monitored while using the computer and other forms of media to minimize negative effects.

Overall, the images children view every day will affect their behavior and possibly their health, and pediatric nurses should take this into account when working with children and their families.

The media's influence relates not only to the content, but also to the total viewing time. For example, excessive TV viewing has been linked to obesity, poor cognitive skills, and irregular sleep patterns. Overuse of computer or video games may lead to poor school performance. Media has become a major factor in children's lives with TV remaining the dominant medium. Media in all forms can affect how children feel, learn, think, and behave (AAP, 2019b). Young children spend more time on media than they do in school. It is the leading activity other than sleeping and can cause less sleep time, delays in learning and social skills, obesity, and behavioral problems (AAP, 2019b). Media can be a positive influence, such as when it offers educational programming or public service messages on the negative effects of substance abuse, smoking, or gang

involvement. Also, public broadcasting networks offer valuable programming.

Obtaining a media history provides helpful and important information. The nurse is encouraged to ask questions regarding the amount of recreational screen time and if the child has a television or Internet-connected device in their bedroom (AAP, 2019b). The AAP recommends families develop a family media plan. This allows a family to develop and individualize family rules and guidelines surrounding media use. The AAP Family Media Use Plan can be accessed at www.healthychildren.org/MediaUse-Plan (Chassiakos et al., 2016). It is important for parents to set limits and know what their children are viewing, whether it is on the TV, computer, iPod, tablet, or phone.

TAKE NOTE!

The AAP discourages the use of media, with the exception of video chatting, in children less than 18 months. In children 18 to 24 months media should be limited to educational programming with adult interaction during the media viewing and no more than 1 hour a day of media for children 2 to 5 years of age. For children greater than 5 years of age the recommendation includes 2 hours or less of sedentary screen time daily and no screens during meals or 1 hour before bed (AAP & Council of Communications and Media, 2016a, 2016b; Chassiakos et al., 2016).

Widespread access to the Internet has fostered a connection to other areas of the world that would not have been possible in previous years. Children are no longer limited to their immediate surroundings, and they have access to a wealth of information. The Internet can be a valuable resource for parents and children to access information, learn new things, and communicate with friends and family. However, online threats exist that can affect the child's health and safety such as sexual predators, pornography, violence, and racism. Parents need to be alert to these hazards and set up safety guidelines (see Teaching Guidelines 1.2).

Global Society

The world is connected in many ways today: people travel from one nation to another easily, new products and immigrants arrive each day, and the Internet makes worldwide communication simple. UNICEF and the WHO lead the world in dealing with the issues effecting children. An estimated 6.3 million children under the age of 15 years die annually around the world (WHO, 2019a). Hundreds of thousands of children born in developing countries and their families are moving to more developed nations such as the United States as refugees, immigrants, or international adoptees. These families become part of this nation.

TEACHING GUIDELINES 1.2

Teaching to Promote Safe Internet Use

- Develop a Family Media Use Plan.
- Determine a time limit that your child can spend on digital media each day or week and maintain consistency in enforcing this time limit.
- Ensure that use of the Internet does not replace or interfere with homework, sleep, physical activity, friends, or household or school activities.
- Tell your child NEVER to share personal information with anyone online unless you are sure of the person and the child has your permission to do so.
- Urge your child NEVER to share his or her password with anyone, even friends.
- Review Internet sites with your child, and explain which sites are appropriate. Use the safety and parental controls offered by your Internet service provider.
- Avoid placing the computer or having digital media in the child's room. Rather, place the computer and encourage digital media use in a public area of your home, such as the den or kitchen, so that you can monitor your child's use.
- Discuss with your child the need for safety while using the Internet. Explain potential hazards in terms the child can understand.
- Advise your child to immediately close any sites or stop any communication that makes him or her confused or uncomfortable. Tell your child NEVER to arrange any face-to-face meetings with persons met online. Urge your child to tell you if he or she encounters such a situation.
- Teach the child NEVER to open e-mail from any unknown senders.
- Be aware of digital media use policies in your child's school.

Nurses need to be aware of the impact of worldwide events, such as natural and man-made disasters, on families. Families can be displaced by events such as hurricanes or wars, placing them at increased risk for problems such as infectious diseases, malnutrition, and psychological trauma.

Young children bear the brunt of the global burden of disease but progress has been made in reducing mortality in children less than 5 years old. More than half of these early child deaths are due to conditions that could be prevented or treated with access to simple, affordable interventions (WHO, 2019a). The UNICEF and the WHO have identified major problems affecting child growth and development and survival:

- Acute respiratory infections, such as pneumonia
- Malnutrition, including micronutrient deficiency
- Overcrowded living conditions leading to air pollution
- HIV/AIDS
- Diarrhea related to lack of clean water and sanitation
- Vaccine-preventable diseases such as measles
- Nonbreastfed children leading to malnourishment
- Malaria
- Preterm birth complications
- Low birth weight
- Poor hygienic practices utilized in homes and public facilities
- Poor health care of pregnant and nursing mothers (WHO, 2019a)

These organizations work to propose ways to eradicate these conditions therefore improving the health of children around the world. Today, families, children, and society as a whole have concerns over world threats and safety. Disasters such as the terrorist attacks of September 11, 2001, the killings at Columbine High School and Sandy Hook Elementary School, and devastating weather events such as Hurricane Katrina and others can have a significant impact on the well-being of women and children. The increase in stressors such as war, terrorism, school violence, and natural disasters puts women, children, and their families at risk for experiencing mental health difficulties. Children who have experienced these events are at risk for issues such as

posttraumatic stress disorder, behavioral problems, depression, anxiety, sleep disturbances, restlessness, irritability, aggression, bullying, physiologic responses such as gastrointestinal symptoms, changes in academic performance, social isolation, and safety and security concerns (Schonfeld et al., 2015). Children's coping abilities may be reduced and alterations in growth and development may be seen. Children's reactions depend on age and developmental level and are highly influenced by the emotional state of their caregivers. Nurses must be aware of the effects of world threats on women and children so that they can assess for alterations and intervene to promote security and stability. Nurses should use the conversation as an opportunity to listen and acknowledge bad things can happen but reassure them many people are working to keep them safe.

Violence

Violence can occur in any setting and can involve any person. Violence against women is a major health concern—it affects millions of lives and costs the health care system an estimated amount more than 5.8 billion dollars annually in the United States (Doi et al., 2019). Violence affects families, women, and children of all ages, ethnic backgrounds, races, educational levels, and socioeconomic levels. Pregnancy is often a time when physical abuse starts or escalates, resulting in poorer outcomes for the mother and the baby. The effects of intimate partner violence (IPV) on maternal health include insufficient or inconsistent prenatal care, poor nutrition, substance abuse, inadequate weight gain, and depression. Adverse neonatal outcomes include low birth weight, preterm birth, placental abruption, uterine rupture, fetal demise, and small-for-gestational-age infants (King et al., 2019). Many of these can lead to maternal or neonatal morbidity or mortality.

BOX 1.3 RADAR

R—Routinely screen every client for abuse.
A—Ask direct, supportive, and nonjudgmental questions.
D—Document all findings.
A—Assess your client's safety.
R—Review options and provide referrals.

There are many opportunities within the current health care system for screening and early intervention during routine prenatal care or during episodic care in a hospital setting. (See Box 1.4 for IPV screening example.) The nurse is responsible for assessing for and following up on any abuse. Due to the potential impact of violence on women, children, and families, it is essential to identify any violent situation via a thorough assessment. All clients should be provided with safety information about violence, even for those who do not disclose an unsafe relationship. All nurses need to include "RADAR" in every client visit (Box 1.3). Nurses serve their clients best not by trying to rescue them, but by helping them build on their strengths and providing support. Essentially, nurses empower their clients to help themselves. Providing referrals to shelters and child advocacy centers and intervening to assist women and children in dealing with this issue are paramount.

VIOLENCE IN THE HOME

Violence in the home environment, known as domestic violence, affects many lives in the United States. The U.S. Bureau of Justice Office on Violence against Women (2019) estimates that one in three women will experience violence against them and more than three women are murdered by their partners each day. This violence is known as intimate partner abuse, family violence, wife beating, battering, marital abuse, or partner abuse, but regardless of the term used, its negative effects are widespread. Refer to Chapter 9 for further information on violence and abuse, including gender-based violence and IPV.

Children exposed to family violence are more likely to be physically, sexually, or emotionally abused themselves (Office on Women's Health, 2019). The federal Child Abuse Prevention and Treatment Act (CAPTA) defines **child abuse and neglect** as "any recent act or failure to act on the part of a parent or caretaker that results in death, serious physical or emotional harm, sexual abuse or exploitation, or an act or failure to act that presents an imminent risk of serious harm to a child" (Children's Bureau, 2019).

An estimated one in seven children have experienced abuse or neglect during their lives, and this is likely an underestimate (CDC, 2020c). Of the number of children identified as being maltreated, the majority were victims of neglect. Child maltreatment has a tremendous impact on broader lifelong health and well-being outcomes, and many will suffer an early death (CDC, 2020c).

TAKE NOTE!

Children of African American, American Indian, Alaska Native descent, or children of multiple races and ethnicities have the highest rates of abuse and neglect (Children's Bureau, 2019).

Children who are exposed to stressors such as domestic violence or who are victims of childhood abuse or neglect are at high risk for short- and long-term problems. These problems manifest differently based on the child's age and developmental ability; the younger the child, and the longer the exposure, the more serious the problems seen. Short-term problems include sleep disturbances, headaches, stomachaches, depression, asthma, fear of harm, inability to experience empathy or guilt, habitual lying, low frustration tolerance, poor judgment, shame, fear about the future, enuresis, aggressive behaviors, such as increased peer aggression and bullying, decreased social competencies, withdrawal, avoidance attachment, developmental regression, fears, anxiety, and learning problems. Long-term problems may include poor school performance, truancy, absenteeism, and difficulty with adult relationships and tasks. There

is a strong correlation between the number of exposures to adverse events and negative behaviors such as early initiation of smoking, sexual activity, and illicit drug use, adolescent pregnancies, and suicide attempts (Edwards, 2019).

TAKE NOTE!

Witnessing and being exposed to violence in childhood results in a higher tolerance, and greater use, of violence as an adult (Franchek-Roa, 2018).

Due to the potential impact of violence on children and families, it is important to perform a thorough assessment to identify violence in the family (Box 1.4). Providing referrals to shelters and child advocacy centers and intervening to assist children in dealing with this issue are key.

Not all children exposed to violence suffer negative consequences. Children have resilience, and preliminary studies have identified protective factors that can help buffer children from the effects of violence and reduce the risk that the child will develop violent behaviors (CDC, 2020d). Examples of protective factors include the following:

BOX 1.4 Assessing for Violence

Questions for the Parent

- Do you ever feel afraid in your home?
- What happens when you and (partner's name) argue?
- Do arguments ever become physical (hitting, kicking, pushing, throwing, or punching/breaking objects)?
- Have you ever been threatened with a weapon (gun, knife, other)?
- Have you ever felt trapped or like a prisoner in your own home? Does your partner ever lock you in/out of the house or take your car keys?
- Have your children ever seen or heard violence in the home?
- Have the police ever been involved due to violence in your home?
- Is the violence ever directed at the children? Does (partner's name) ever hit, kick, push, or yell at your child when he or she is angry?
- How do you and (partner's name) discipline the children?

Questions for the Child

- What happens when Mommy and Daddy (or appropriate partner names) argue/fight? Is there any hitting, pushing, and so forth?
- How do you feel when Mommy and Daddy (or appropriate partner names) fight?
- What happens to you when you get in trouble?

If hitting or other physical forms of discipline occur, ask the following:

- What are you hit with? Where on your body? Does it ever leave a mark/bruise?
- Who hits/kicks you? How often does it happen?

- Feelings of connectedness or a secure attachment to a nonviolent parent or caregiver
- Strong commitment to school and academic performance
- Enhance parenting skills to promote healthy child development
- Involvement in social activities
- Social and community support
- Positive sibling and peer relationships
- Ability to discuss problems with parents or a supportive adult
- Consistent presence of a parent at least once during the day, such as in the morning on awakening, when getting home from school, at dinnertime, or when going to bed
- Positive view of self

- Strong cultural and/or spiritual identity

Thus, interventions need to focus on reducing children's exposure to violence and fostering protective factors.

YOUTH VIOLENCE

Youth violence is "the intentional use of physical force or power to threaten or harm others by young people ages 10 to 24" (CDC, 2020e). A young person can be involved with youth violence as a victim, offender, or witness. Youth violence affects the community as well as the child and family. Studies have shown that youth violence is associated with a disruption in social services, an increase in health care costs, and a decline in property values (CDC, 2020e). Research continues to show that children exposed to violence suffer serious consequences, such as problems with development, behavior, economic health of all community residents, physical and mental health issues, which last a lifetime (CDC, 2020e).

VIOLENT CRIMES

Violent crimes include murder, rape, robbery, and aggravated assault. Statistics from the CDC (2020f) show that for people of ages 10 to 24 years:

- Approximately 13 young people are victims of homicide each day; of those deaths, firearms accounted for the majority of the deaths.
- More than 1,100 youth are treated in emergency departments for injuries due to violence each day.
- Homicide remained the third leading cause of death for youth.

SUICIDE

Suicide is a serious public health problem affecting young people today. Suicide is the second-leading cause of death in people of ages 10 to 34 years, with the majority due to firearms (CDC, 2018a, 2019d). Many more people think about or attempt suicide every year then die from suicide (CDC, 2019d). Of these reported suicides,

boys (77.9%) were much more likely than girls to die from suicide (CDC, 2018a).

TAKE NOTE!

Cultural variations in youth suicide rates are present; non-Hispanic Native American/Alaskan Natives and non-Hispanic Whites have the highest rate of suicide (CDC, 2019d).

SCHOOL VIOLENCE

In recent years, due to several high-profile cases of school shootings, much attention has been directed at school violence and concern for student safety. However, statistically, less than 2% of school-age homicides occur on the way to or from school, at school events, or during school hours (CDC, 2019f). Although students are much less likely to be victims of crime at school than away, some schools continue to have serious crime and violence problems highlighting the importance of school violence prevention. Approximately 9% of high school students reported being involved in a physical altercation at least once in the previous year (CDC, 2019e).

Much of school violence involves bullying, which is repeated negative actions that are clearly malicious and unwarranted, by one or more persons directed at a victim. Bullying is common. One in five high school students report being a target of bullying (CDC, 2019g). Many cases of bullying go unreported, but bullying can affect school performance and social relationships and have long-lasting traumatic effects such as depression, low self-esteem, anxiety, academic problems, dropping out of school, emotional distress, and violence later in adolescence and adulthood (CDC, 2019g). School nurses need to be aware of bullying and offer support, guidance, and intervention when necessary to the students and staff.

Safe schools are essential for proper learning, growth and development, development of healthy relationships, and overall health of our children. Violence in schools has a negative effect not

only on students but also on the school and the entire community. The continued coordination among schools, law enforcement, social services, and mental health systems and the development of effective programs will help to reduce these risk behaviors.

Community

Community encompasses a broad range of concepts, from the nation where a person lives, to a particular neighborhood or group. The surrounding community affects many aspects of a person's health and general welfare. The quality of life within the community has a great influence on a person's ability to develop and become a functional member of society. Community influences include the school, which is a community in itself, and peer groups. The support and assistance offered to women, children, and families from other areas of the community, such as school programs and community centers, can improve the person's overall health and well-being.

SCHOOLS AND OTHER COMMUNITY CENTERS

Children today start school at an earlier age, spend more time in child-care settings, and are involved in various community centers and activities. By age 3 or 4, many children are in a preschool setting for several hours a day. Some children spend more awake time in school and child-care settings than in their family home. Thus, schools and child-care settings have become major influences on children.

School also provides a means of socialization. School rules about attendance and authority relationships and the system of sanctions and rewards based on achievement help to teach children behavioral expectations that they will need for future employment and relationships in the adult world. Although the primary role of schools has always been academic education, today schools are performing more health-related functions. Schools play an important role in promoting healthy behaviors and educating children about proper exercise, nutrition, safety, sex, drugs, and mental health.

FIGURE 1.9. Day care centers provide socialization and support for young children.

Academic success is linked to healthy behaviors. Academic success is a good indicator of child well-being and is a predictor of adult health outcomes (CDC, 2019h). Academic failure is linked to health risk behaviors such as substance use, violence, and physical inactivity. School health programs have positive impacts on health outcomes and health risk behaviors along with educational outcomes (CDC, 2019h).

Because in many families both parents need to work, many children are enrolled in child-care and after-school programs. Thus, the socialization process begins earlier and involves a larger percentage of the child's waking hours (Fig. 1.9).

After-school hours are a critical time where children may participate in risky health behaviors if they are not provided with supervised, structured activity where they can learn and grow. Community centers and after-school programs can provide an opportunity for children to learn new skills, have new experiences,

and develop relationships with caring adults in a safe and supportive environment.

PEER GROUPS

A child's friends can have a major influence, positive or negative, on his or her growth and development. Peer group relationships often begin early and are a large part of the child's world, particularly with school-age children and adolescents. This influence starts in playgroups in preschool or elementary school. The child is confronted with a variety of values and belief systems from interactions with friends. To be accepted, the child must conform to the specific values and beliefs of the group. When these values and beliefs differ from those of the adults in the child's world, conflicts can occur, possibly separating children from the adults and strengthening their sense of belonging to the peer group.

When the child's friends are successful in school or other activities, the growth and development of the child continues in a healthy and positive way. When these groups demonstrate healthy behaviors, the influence is very positive, but peer groups can also exert negative influences on the child. Thus, it is vital to identify the important peer groups in a child's life and the positive or negative behaviors connected with these groups.

Culture

In a world moving quickly toward globalization, nurses must strive to understand diverse cultures. Culture (the view of the world and implementation of a set of traditions that are used by a specific social group in order to pass these traditions along to the next generation) plays a critical role in shaping a woman, child, or family including their health and health practices (Martin et al., 2019). Culture is a complex phenomenon involving the integration of many components such as beliefs, values, language, time, personal space, and view of the world, all of which shape a person's actions and behavior. Individuals learn these patterns of cultural behaviors from their family

and community through a process called **enculturation**, which involves acquiring knowledge and internalizing values (Raval & Walker, 2019).

Culture is learned first in the family, then in school, and then in the community and other social organizations. Culture influences every aspect of development and is reflected in childbearing and child-rearing beliefs and practices designed to promote healthy adaptation (Andrews et al., 2019).

With today's changing demographic patterns, nurses must be able to incorporate cultural knowledge into their interventions so that they can care effectively for culturally diverse women, children, and families. They must be aware of the wide range of cultural traditions, values, and ethics that exist in the United States today. All nurses must establish **cultural competence**, the ability to apply knowledge about a client's culture so that health care interventions can be adapted to meet the needs of the client. Cultural competence refers to the process by which individuals and systems respond respectfully and effectively to people of all cultures, languages, ethnic backgrounds, disabilities, religions, sexual orientation, and other diversity factors in a manner that recognizes, and values the worth of individuals, families, and communities. Cultural humility is a process of self-reflection and discovery in order to build honest and trustworthy relationships. Being culturally competent signifies knowledge of various cultures, whereas cultural humility is an ongoing process recognizing that the person in front of you from a different culture is the expert, not the nurse (Christensen, 2019).

The nurse should know about various cultural groups, ethnicity, culture-based health practices and how they may affect children, as well as the demographics of the local population. The goal is for the nurse to view culture as a point of congruence rather than a potential source of conflict.

The relationship of culture to health care can become obscured by the use of broad group titles. In reality, there are many distinct cultural groups, and within a group there may be many subcultures. Geographic differences also can occur. For example, the Latin Americans living in New York may be quite different from the Latin

Americans living in Florida. Nurses must be aware of these distinct cultural groups so they can provide culturally competent care.

Nurses should also be aware of the traditional health care values and practices that are passed along from one generation to the next. For example, some cultures believe in consulting folk healers, and this belief may have a major influence on children's health. See Table 1.4 for some general beliefs and practices of selected cultural groups. It is crucial that the nurse remembers that diversity exists within cultures and this is as important as the diversity between cultures. Every child is a unique individual with his or her own beliefs, values, and history. Nurses need to avoid stereotyping, which can lead to misconceptions. Stereotyping or labeling can result from **ethnocentrism**, a belief that one's own ethnic group is superior to other ethnic groups. This attitude can lead to a slanted view of the world, and it may hinder the nurse's ability to provide culturally competent care.

Cultural Health Practices

Health practices are often the result of health beliefs derived from a person's culture. For example, do the child and family view health and illness as the result of natural forces, supernatural forces, or the imbalance of forces? Most cultures have remedies that people may use or consider before they seek professional health care. People from some cultures may go to folk healers who they believe can cure certain illnesses. For example, the *curandero* (male) or the *curandera* (female) of the Mexican American community is believed to have healing powers as a gift from God. Asian Americans may consult a practitioner who specializes in traditional Asian therapies such as acupuncture, acupressure, and moxibustion. These folk healers are often very powerful in their community, speak the language, and are very familiar with the culture's spiritual or religious aspects.

If the folk remedies or practices of the folk healers are compatible with the health regimen and support appropriate health practices, these practices and beliefs do no harm; in fact, they may even

benefit the child and family. However, use of a folk healer can lead to a delay in beneficial treatment or create other problems. Some traditional health practices may be misinterpreted as being harmful, and some actually can cause harm. For example, the Vietnamese practice of coining, which involves rubbing the edge of a coin on an oiled symptomatic body area to rid the body of disease, may be misinterpreted as a sign of physical abuse (Marion et al., 2018). This practice also can lead to burns, bruising, or welt-like lesions on the child's skin if it is done frequently. *Azarcon* and *greta,* powders containing high amounts of lead, are used as a folk remedy in Mexico to treat *empacho,* digestive problems such as diarrhea, and indigestion; and in some cases have resulted in lead toxicity (Andrews et al., 2019).

TABLE 1.4 Beliefs and Practices of Selected Cultural Groups

Cultural Group	Beliefs and Practices Affecting Children's Health
African Americans	• Strong extended family relationships; matriarchal (mother as head of household); elder family members valued and respected • Food as a symbol of health and wealth • Use of folk healing and home remedies common to treat body, mind, and spirit • Strong church/religious affiliation
Asian Americans	• Strong loyalty to the family; patriarchal (father head of household); family as the center, with members expected to care for one another; preserving family pride and dignity is important • Use of complementary modalities with Western health care practices • Respect for authority emphasized
Arab Americans	• Women subordinate to men; young individuals subordinate to older persons; Family loyalty is primary • Modesty and cleanliness is a core value • Disease and illness attributed to the will of Allah • Good health associated with eating properly, consuming nutritious foods, and fasting to cure disease
American Indian/Alaska Native	• High value on family and tribe; respect for elders; family as an extended network providing care for newborns and children; women as the verbal decision makers • Celebrations to mark the stages of growth and development • Use of food to celebrate life events and in healing and religious ceremonies • Prefer restoration of physical, mental, and spiritual balance through herbal medicines and healing ceremonies
Hispanics	• Family important; father as the source of strength, wisdom, and self-confidence; mother as the caretaker and decision maker for health • View of children as persons to continue the family and culture • Use of food for celebrations and socialization • Folk medicine practices and prayers, herbal teas, and poultices for illness treatment

Adapted from Adams-Leander, S. (2016). Chapter 5: Transcultural nursing in the community. In C. Rector (Ed.), *Community & public health nursing. Promoting the public's health* (8th ed., pp. 115–149). Wolters Kluwer Health/Lippincott Wilkins & Williams.

TAKE NOTE!

Nurses can help to shape a person's lifelong perceptions of health and health services. An understanding of how the woman's, child's, and family's culture affects their health practices gives the nurse an opportunity to incorporate appropriate and beneficial health practices into the family's cultural milieu, providing sources of strength rather than areas of conflict.

Changing Cultural Demographics

The United States is no longer a melting pot of various cultures and ethnicities but a society with each individual bringing a diversity and richness that enriches the country as a whole. Currently, there are approximately 19 million immigrant children from birth to 17 years old in the United States of which, 51% of the population is White, 14% is Black or African American, 25% is Hispanic, 5% is Asian, and 5% is non-Hispanic other races (FIFCFS, 2017). The Hispanic population has increased substantially over the past decade (FIFCFS, 2017). It is projected by 2050 that 36% of the U.S. population of children will be Hispanic and 36% will be White, non-Hispanic (FIFCFS, 2017). In addition, the increasing number of intermarriages between individuals from different ethnic origins is producing an increasing number of children who have a heritage that represents more than one cultural group.

Immigration

Employment, economic and educational opportunities, expanded human rights, and other types of freedoms and opportunities encourage many foreigners to move to the United States. There are a growing number of immigrants with approximately one in four children in the United States being immigrants or members of an immigrant family (Child Trends Databank, 2018a). More than half of

all immigrant children are of Hispanic origin (Child Trends Databank, 2018). This includes both children born outside the United States or with at least one foreign-born parent. Some communities welcome the new members, but others do not. Partly due to fears of terrorism, the United States is evaluating, enforcing, and changing many of its immigration laws.

Immigration can affect the health, educational, and social services provided in the United States. It also presents issues related to access to care and the types of care that need to be offered. Immigration imposes stresses on women, children, and families, including the following:

- Unique health issues such as communicable and noncommunicable diseases specific to their country or origin, oral health issues, altered nutrition, and growth
- Depression, grief, or anxiety due to migration and adoption of a new culture
- Separation from support systems
- Inadequate language skills
- Differences in social, professional, and economic status between the country of origin and the United States
- Traumatic events such as war that may have occurred in their homeland (AAP, 2019d; Linton et al., 2019)

Inability to speak English can hinder an immigrant's educational attainment, economic opportunities, and ability to join the mainstream of society. One third of children living in the United States speak a language other than English at home (Linton et al., 2019). Immigrant parents who do not speak English may have trouble accessing health care and health insurance, enrolling their children in school or becoming involved in school activities, and accessing work or better-paying jobs.

Immigrant families also may arrive in the United States with significant health problems. They may present with diseases that are more common in their country of origin but rarely seen in the United States, such as malaria. The health status of immigrant children may be compromised due to the lack of at-birth and early childhood screenings, which may manifest with problems such as inborn errors

of metabolism, lack of preventive care, no immunizations, and no dental care. Due to financial, language, cultural, and other types of barriers that immigrant families sometimes face, they may not receive the necessary preventive care or receive care for minor conditions until they become more serious. Stresses experienced by immigrant children and their families, such as those associated with relocation, separation, and traumatic events, also can have a negative impact on their psychological health.

Spirituality and Religion

Spirituality is a basic human quality involving the belief in something greater than oneself and a faith that affirms life positively. It is a major influence in many people's lives, providing a meaning or purpose to life and a foundation for and source of love, relationships, and service. Spirituality is considered a universal human phenomenon with an assumption of the wholeness of people and their connectedness to a higher being. During life-changing events and crises, such as a serious illness or the birth of a child with a congenital defect, families often turn to spirituality for hope, comfort, and relief.

The word *religion* is often used interchangeably with spirituality in our society. However, spirituality is a more private and individual belief, whereas religion is an organized way of sharing beliefs and practicing worship. Around 80% of Americans believe in God (Pew Research Center, 2018). Therefore, spirituality and religion are an important focus when working with women, children, and their families. A person's reaction to health and illness may be affected by these beliefs. In some religions, illness is seen as a punishment for sin or wrongdoing. Other religions view illness as a test of strength (Nies & McEwen, 2019).

People appreciate the recognition of, and respect for, their beliefs. Therefore, identifying the individual's and family's religious beliefs and customs is important. People may adhere to special dietary restrictions, rituals such as baptism or Holy Communion, use of amulets or icons, or practices related to dying that can be

incorporated into the plan of care. Using open-ended questions and observing for the use of religious articles during assessment can provide clues to the family's beliefs and practices. Visits from spiritual leaders may also be noted. Table 1.5 identifies some of the ways in which tenets of major religious beliefs may affect children's health.

TAKE NOTE!

Never make assumptions about a family's religious or spiritual affiliation. Although they may belong to a particular religion, family members may not adhere to all of its beliefs or participate in all aspects of the religion. Be alert for clues that would provide insight into their specific beliefs.

Health Status and Lifestyle

Obviously, the general health status of a person and specific lifestyle can influence a person's health. Health status may be a factor soon after birth. Societal shifts, triggered by a greater focus on education and careers, have resulted in a trend toward delayed childbearing in American women. This timing has increased the incidence of multiple births due to the increased use of in vitro fertilization and other assisted reproductive technologies along with women delaying childbearing until they are older. Up to 5% of children in the United States are conceived through assisted reproductive technology currently and this percentage will be increasing (Pierce & Mocanu, 2018). Potential complications of multiple births include prematurity and intrauterine growth restriction, which may lead to chronic health problems in the child. Children with chronic health conditions may also have developmental delays, especially in acquiring skills related to cognition, communication, adaptation, social functioning, and motor functioning. Thus, the beginning health status of a child may affect his or her long-term health and development.

TABLE 1.5 Selected Religious Beliefs Affecting Children's Health

Religion	Beliefs About Health and Illness	Dietary Practices	Beliefs About Birth and Death
Buddhism	Illness from karmic causes (ignorant craving) Illness as an opportunity to develop the soul Ultimate goal of achieving nirvana (state of supreme tranquility, purity, and stability) No restrictions for medications, vaccines, nutritional therapies, or other therapeutic interventions	Moderation in diet encouraged Some sects vegetarian; some branches have strict dietary regulation; therefore, it is important to inquire about client's preferences	No baptism Last rite chanting at bedside soon after death If there is hope for recovery and continuing the pursuit of enlightenment all means of intervention are encouraged Organ donation acceptable Cremation common
Christian Science	Disease viewed as error of human mind that can be dispelled by spiritual truth Health viewed within a spiritual framework; healing through prayer and spiritual regeneration	No special requirements or restrictions Abstinence of alcohol and tobacco and possible tea and coffee	No baptism or last rites Unlikely to seek medical means to prolong life, use of prayer for recovery. Disposal of body in death left to family to decide

	Possible contact of own healing ministry (Christian Science practitioners) if child is hospitalized General opposition to human interventions with drugs or other therapies except for legally required immunizations Usually do not use blood or blood components, seek transplants or act as donors, seek biopsies or physical examination		
Hindu	Illness due to sins committed in previous life Acceptance of most medical practice/care Nonviolent approach to life	Meat consumption forbidden (especially beef) Some are strict vegetarians	No baptism View of death as a step in an ongoing cycle to reach nirvana Certain prescribed rites after death, such as washing the body by family and restrictions on who touches the body Cremation common

Islam	Belief that God cures but will accept treatment Compulsory prayers at dawn, noon, afternoon, after sunset, and after nightfall	Ingestion of pork and pork products and alcohol forbidden Fasting (by boys from age 7, girls from age 9, and adults) required during Ramadan (ninth month of Islamic year) (exceptions for pregnant/nursing mothers, elderly, or very ill)	No baptism Special party (*Aqeeqa*) to celebrate birth Specific burial rituals (rinsing and washing, wrapping, special prayers, and burial)
Judaism (orthodox and conservative)	Illness as possible reason for violating some dietary restrictions No treatments or procedures on Sabbath (which begins 18 minutes before sunset on Friday and ends 42 minutes after sunset on Saturday) or holy days	Ingestion of blood (such as raw meat) prohibited Kosher dietary laws; highly individualized observance Abstinence from ingestion of pork and predatory fowl and no mixing of milk dishes with meat dishes; ingestion of only fish with fins and scales; no shellfish (strict followers) Fasting during Yom Kippur, and matzo replaces leavened bread during Passover week	No baptism Ritual circumcision of male infants on eighth day of life Ritual of washing body after death; family and close friends remain with the deceased for a period of time No cremation
Mormon (Church of Jesus Christ	Belief in divine health via laying on of hands.	Ingestion of caffeinated tea, coffee, and alcohol and use	Baptism at older age (approximately 8 years old); infant blessed by church

of Latter-Day Saints)	Medical therapy not prohibited Common use of herbal folk remedies	of tobacco prohibited Fasting (no food or drink including water) once a month for 24 hours on a designated day, exceptions made (pregnant women, very young or old, and ill)	official after the birth Death believed to be another step in eternal progression Cremation discouraged, but not forbidden
Roman Catholic	Care of sick encouraged Misuse of any substance considered harmful to the body and a sin Eucharist as the food of healing and health	Moderation in diet encouraged Fasting and abstinence from meat and meat products on Ash Wednesday and Good Friday Abstinence on Fridays during Lent, but exceptions made if ill	Infant baptism Sacrament of the sick if prognosis is poor while child is alive; anointing of the sick Burial and treatment of the body with respect and honor Cremation is acceptable in certain circumstances

Developmental Level and Disease Distribution

Developmental level has a major impact on a person's health status. In general, the distribution of diseases or illnesses varies with age. For example, adolescents who become pregnant are at a higher risk for certain complications, such as anemia, hypertension, preterm labor, cephalopelvic disproportion, and postpartum hemorrhage. Pregnant adolescents also experience higher rates of IPV and

substance abuse. Moreover, substance abuse can contribute to low birth weight, intrauterine growth restriction, preterm births, stillbirth, newborn addiction, and sepsis (CDC, 2019i). Women who become pregnant after age 35 are at risk for hypertension, dystocia, and postpartum hemorrhage. Older pregnant women are also more likely to have a pre-existing condition that could complicate the pregnancy. Moreover, fetuses of older pregnant women are at risk for chromosomal abnormalities.

Certain communicable diseases are more commonly associated with certain age groups. Roseola, which is a viral illness resulting in high fevers and rash, is most often seen in infants 6 to 15 months; scarlet fever, a group A streptococci infection, is a disease that primarily affects children between 4 and 8 years of age. The physiologic immaturity of an infant's body systems increases the risk for infection. Ingestion of toxic substances and poisoning are major health concerns for toddlers as they become more mobile and inquisitive. Because preschool and school-age children are generally quite active, they are more prone to injury and accidents. Adolescents are establishing their identity, which may lead them to distance themselves from their family values and traditions for a period of time and conform more to their peers. This journey may lead to risky behaviors, resulting in injuries or other situations that may impair their health.

Nutrition

Nutrition provides the body with the calories and nutrients to sustain life and promote growth, as well as the essentials required to maintain health and prevent illness (Fig. 1.10).

Nutritional deficiencies, such as iron-deficiency anemia, or excesses, such as the increasing incidence of childhood obesity, are still common problems in the United States. Nearly one in five school age children is obese (CDC, 2018b). Effective obesity prevention and treatment interventions targeting children and their families are needed to help curb the obesity epidemic. Some factors contributing to poor nutrition include inadequate food intake, nutritionally unsound

social and cultural food practices, the easy accessibility of processed and nutritionally inadequate foods, lack of nutrition education in homes and schools, and the presence of illness that interferes with ingestion, digestion, and absorption of food.

FIGURE 1.10. A. This pregnant client is eating a healthy meal to ensure adequate nutrition. **B.** The dietary habits established early in life can have a long-lasting impact on the child's health and quality of life.

During pregnancy, a woman needs additional calories to support fetal growth and development as well as to support her own needs, and an adequate intake of folic acid is important to prevent neural tube defects. For the child, inadequate nutrition is associated with lowered cognitive ability, poor or altered emotional and mental health, increased susceptibility to childhood illnesses, and stunted physical growth (Parks et al., 2020). Fast food or junk food that is prevalent in today's society is a key factor in the epidemic of childhood obesity and increases in the prevalence of childhood type 2 diabetes. Nutrition and its effects on health status are integrated throughout this text.

Lifestyle Choices

Lifestyle choices that affect a person's health include patterns of eating; amount and type of exercise; use of tobacco, drugs, or alcohol; and methods of coping with stress. Most health problems that arise today are due to a person's lifestyle. For children, the lifestyle of the parents basically is the lifestyle of the child. Inactive parents who eat poorly commonly have children with the same habits, which can result in diabetes, obesity, and early heart disease. These typically adult problems are being diagnosed more frequently in children and adolescents today. Parents should first self-evaluate their own dietary and activity habits, make changes where necessary, and then strive to encourage healthy eating habits and an appropriate level of physical activity in the child's life through sports, hobbies such as dancing, or family activities.

Environmental Exposure

Environmental pollutants are not only hazardous to the ecosystem, but also can lead to various health problems that affect the human population worldwide irrespective of gender, race, or age. Some environmental exposures can jeopardize health. In utero, the child can be affected by poor maternal nutrition, maternal infections, or maternal use of alcohol, tobacco, and drugs. Nurses caring for pregnant women should be aware of the risks to the fetus posed by certain drugs, chemicals, and dietary agents, as well as maternal illnesses. These agents, known as teratogens, may be linked to birth defects in children. Not all drugs or agents are associated with fetal effects, however, and research is necessary to identify the correlations between teratogens and other variables.

The environment continues to affect a child's health after birth. Exposure to air pollution, tobacco, and water or food contaminants can impair a child's health status. Safety hazards in the home or community can contribute to falls, burns, drowning, or other accidents. Exposure to second-hand smoke and other pollutants, such as from radiation or chemicals, is a health hazard for children. Because children are smaller and still developing, environmental exposures can cause them additional health problems. For example,

lead exposure is a common preventable poisoning in children, especially children less than 6 years of age. Due to their rapidly developing nervous system, young children are more sensitive to the effects of lead. Sources include lead paint, pottery and ceramics, imported toys, lead-contaminated dust, and lead contained in soil and water. Lead exposure can result in developmental and behavioral problems ranging from inattentiveness and hyperactivity to permanent brain damage and death, depending on the level of exposure.

TAKE NOTE!

A recent study found that residual tobacco smoke and carcinogens remain after a cigarette is extinguished (referred to as third-hand smoke). These toxins cling to the smoker's hair and clothes and can be present on any surface in the house, such as carpet and cushions. Residue can linger for weeks to months after smoking has stopped. The smoke may be gone, but the side effects are lasting. Children are particularly susceptible to third-hand smoke since they breathe near, crawl, touch, and mouth contaminated surfaces (Samet & Sockrider, 2019).

Stress and Coping

Stressors such as war, terrorism, school violence, pandemics, climate change, displacement, and natural disasters can have a significant impact on the well-being of women, children, and families. They may decrease a person's coping ability and lead to alterations in growth and development (CDC, 2020f). Exposure to traumatic events and violence may have long-term effects on an individual's psychosocial development and status.

Exposure to stress is not limited to disasters or traumatic events, however. Stress can also include areas such as inadequate finances, family crises such as divorce, inadequate support systems, illness, or violence. Stress can also be associated with the normal problems associated with growth and development, such as entering a new classroom, learning a new skill, or being teased by a classmate. Similar to disasters and traumatic events, the effects of

these stressors can dramatically affect the health status of a woman, child, or family.

Some women and children can adapt and respond to the stress, while others do not. The term **resilience** refers to the qualities that enable a person to cope with significant adverse events or stresses and still function competently (Masten & Barnes, 2018). Various internal and external protective factors promote resiliency. Internal factors include the person's ability to take control and be proactive, to be responsible for his or her own decisions, to understand and accept his or her own limits and abilities, and to be goal directed, knowing when to continue or when to stop. External factors include caring relationships with a family member; a positive, safe learning environment at school (including clubs and social organizations); and positive influences in the community (see the discussion earlier in this chapter about protective factors and violence). Promoting the development of resiliency in children aids in the achievement of positive developmental and health outcomes (National Scientific Council on the Developing Child, 2015).

Recall Sophia, the 38-year-old pregnant woman who has come to the prenatal clinic for a visit. While talking with the nurse, Sophia mentions that her children are very involved in activities. She says, "My husband is busy at work, so I do most of the running around. Sometimes I feel like the people at the drive-thru know me by name! My husband helps out on the weekends, but during the week, it's all me." What factors may be influencing Sophia's health? How might these factors be influencing the health of the children and the family?

Access to Health Care

The health care system, including the delivery and financing of this system, continues to change and evolve. Health insurance coverage is a critical factor in making health care affordable and accessible to women. In the United States, changes in the health care system result from pressures from many directions. These changes reflect shifts in social and economic realities and the results of the biomedical and technologic progress over the past several decades. Every person who seeks health care in any form feels the effects.

Access to health care is affected negatively by lack of health insurance. People without health insurance typically cannot afford to seek health care for maintenance and prevention interventions. The “working poor” may not earn enough money to afford health insurance or medical care, and part-time workers do not always receive benefits such as health insurance. Women are less likely than men to be uninsured due to expansion of ACA, but often have inadequate access to care, receive a lower standard of care, and have poorer outcomes (Kaiser Family Foundation, 2020).

Parents with uninsured children often delay care for their children and are less likely to have a usual place of care for their children (FIFCFS, 2018). The percentage of children without health insurance for 12 months has declined since 2010 to an all-time low of 5% (FIFCFS, 2018). This decrease is largely attributed to the expansion of Medicaid and the Child’s Health Insurance Program (CHIP) (Artiga & Ubri, 2017). Medicaid is a joint federal and state program that provides health insurance to low-income children and their parents. It is state administered and each state has its own set of guidelines. In 1997, Congress passed legislation that led to the creation of the State Children’s Health Insurance Program (S-CHIP) (now known as Children’s Health Insurance Programs [CHIP]). The purpose of this program is to help insure low-income children who are ineligible for Medicaid, but cannot afford private health insurance. This program is also funded jointly by the federal and state governments but administered by the individual states. In recent years Medicaid and CHIP have focused on increasing enrollment by increasing outreach, simplifying enrollment procedures, and retaining eligible enrollees. Legislation, such as The Children’s Health Insurance Program Reauthorization Act of 2009 (CHIPRA) and the ACA, has helped support this (Artiga & Ubri, 2017). Despite these efforts, half of uninsured children are eligible for these public programs but not enrolled (Flores et al., 2017). The number of children enrolled in Medicaid and CHIP programs has dropped significantly recently due to an improving economy and low unemployment rate (Ollove, 2019). Medicaid and CHIP provide a good base of coverage for low-

income children, but unfortunately eligibility for parents is much more limited.

These programs rely on adequate state and federal funding. Therefore, the continued success of these programs depends on future legislation. Tough economic times along with changes in employer-based health insurance will continue to challenge the nation to ensure adequate health care for all children.

Improvements in Diagnosis and Treatments

Because of the tremendous improvements that have been made in technology and biomedicine, disorders and diseases are being diagnosed and treated earlier. The 1990s witnessed a remarkable and productive connection between genetics and various pathophysiologic processes. For example, female fetuses with congenital adrenal hyperplasia, a genetic disorder resulting in a steroid enzyme deficiency that can lead to disfiguring anatomic abnormalities, are beginning to receive treatment before birth. In addition, many genetic defects are being identified so counseling and treatment may occur early. With these improved diagnoses and treatments, nurses may now be caring for people who have survived situations that once would have been fatal, who are living well beyond their life expectancy for a specific illness, or who are functioning with chronic disabilities (Stewart et al., 2019). For example, at one time women with congenital heart disease did not live long enough to become pregnant. However, with new surgical techniques to correct the defects, many of these women survive and become pregnant, progressing through their pregnancy without significant problems.

While positive and exciting, these advances and trends also pose new challenges for the health care community. For example, as health care for premature newborns improves and survival rates increase, the incidence of long-term chronic conditions such as respiratory airway dysfunction or developmental delays has also increased. As a result, nurses are faced with caring for clients at all stages along the health–illness continuum, such as well children,

those who are occasionally ill, and women, children, and families with chronic and sometimes disabling conditions.

Empowerment of Health Care Consumers

Due to the influence of managed care, the focus on prevention, a more educated population, and technologic advances, individuals and families have taken an increased responsibility for their own health. Health consumers are now better informed, and they want to play a greater role in managing health and illness. Families want information about illnesses and they want to participate in making decisions about treatment options. By 2040, nurses can expect to see women steeped in knowledge about their own personal health through access to her own health data to manage their own health to keep chronic illnesses at bay (Heath, 2019). As client advocates valuing family-centered care, nurses are instrumental in promoting this empowerment. To do this, the nurse should respect the family's views and concerns, address all issues and concerns, consider the family members as important participants, and always include the woman, child, and family in the decision-making process.

Barriers to Health Care

Women are major consumers of health care services, in many cases arranging not only their own care but also that of family members. Women make the majority of health care decisions and are responsible for the greatest amount of health care spending. Compared with men, women have more health problems, longer life spans, and more significant reproductive health needs (Segura, 2018). Access to care can be jeopardized by lower incomes and greater responsibilities (juggling work and family). Barriers to health care include lack of finances; sociocultural barriers, including lack of transportation, no babysitters, high health insurance premiums, discrimination, and language; and health care delivery system barriers, including inconvenient clinic hours and poor attitudes by

health care workers. These barriers often discourage clients from seeking health care (Erickson, & Bornstein, 2018).

Finances

Financial barriers are one of the most important factors that limit care. Childbirth is the leading reason for hospitalization in the United States. For both private insurers and Medicaid, hospital maternity and newborn charges exceed those for any other condition. In U.S. hospitals, vaginal and cesarean deliveries cost approximately $10,000 to $17,000 and $16,000 to $25,000, without complications, respectively (Hoffower, 2018). Many women have limited or no health insurance and cannot afford to pay for maternity care. The intent of the ACA is to provide access to health care services for many and reduce federal government spending on health care through a focus on preventive care (Amadeo, 2019). Although Medicaid covers prenatal care in most states, the paperwork and enrollment process can be so overwhelming that many women do not register.

After decades of decline, the percentage of children living in low-income families has again been on the rise. Currently, 39% of children were living in low-income families and 17% were living in poor families (Child Trends Databank, 2019b). Many children and families do not have insurance, do not have enough insurance to cover services obtained, or cannot pay for services. Nurses need to assess for financial barriers to health care and be aware of resources available to help families overcome these barriers.

Sociocultural Barriers

Lack of transportation and the need for both parents to work also pose barriers to seeking health care. It can be difficult to attend all recommended prenatal health care visits or well-child visits, especially if the woman has other small children who must be taken along on the visit. These challenges can reduce the adherence to scheduled appointments and follow-up. Knowledge barriers (e.g., lack of understanding of the importance of prenatal care or

preventive health care), language barriers (e.g., speaking a different language than the health care providers), or spiritual barriers (e.g., religious beliefs discouraging some forms of treatment) also exist.

CONSIDER THIS

I was a 17-year-old pregnant migrant worker needing prenatal care. Although my English wasn't good, I was able to show the receptionist my "big belly" and ask for services. All the receptionist seemed interested in was a social security number and health insurance—neither of which I had. She proceeded to ask me personal questions concerning who the father was and commented on how young I looked. The receptionist then "ordered" me in a loud voice to sit down and wait for an answer by someone in the back, but never contacted anyone that I could see. It seemed to me like all eyes were on me while I found an empty seat in the waiting room. After sitting there quietly for over an hour without any attention or answer, I left.

Thoughts: Why did she leave before receiving any health care service? What must she have been feeling during her wait? Would you come back to this clinic again? Why or why not?

LEGAL AND ETHICAL ISSUES IN MATERNAL AND CHILD HEALTH CARE

Law and ethics are interrelated and affect all of nursing. Professional nurses must understand their scope of practice, standards of care, institutional or agency policies, and state laws. Every nurse is responsible for knowing current information regarding ethics and laws related to their practice. Numerous federal programs have had a major impact on women's and children's health (Table 1.6).

Several areas are of particular importance to the health care of women and children. These include abortion, substance abuse, fetal

therapy, maternal–fetal conflict, stem cell research, umbilical cord blood banking, informed consent, client rights, and confidentiality.

Abortion

Abortion was a volatile legal, social, and political issue even before *Roe v. Wade,* the 1973 Supreme Court decision that legalized abortion. Nearly half of pregnancies among American women are unintended, and about four in 10 of these are terminated by abortion. Nineteen percent of all pregnancies (excluding miscarriages) end in abortion (Guttmacher Institute, 2019b). In September 2000, the U.S. Food and Drug Administration approved mifepristone to be marketed in the United States as an alternative to surgical abortion. Medication abortion using mifepristone or a similar medication accounted for 27% of all nonhospital abortions, and about one quarter of abortions before 9 weeks' gestation (Guttmacher Institute, 2019b).

Abortion has become a hotly debated political issue that separates people into two camps: pro-choice and pro-life. The pro-choice group supports the right of any woman to make decisions about her reproductive functions based on her own moral and ethical beliefs. The pro-life group feels strongly that abortion is murder and deprives the fetus of the basic right to life. Both sides will continue to debate this very emotional issue for years to come.

Medical and surgical modalities are available to terminate a pregnancy, depending on how far the pregnancy has developed. A surgical intervention can be performed up to 12 weeks' gestation; a medical intervention can be performed up to 9 weeks' gestation (King et al., 2019). All women undergoing abortion need emotional support, a stable environment in which to recover, and nonjudgmental care throughout the experience.

Abortion is a complex issue, and the controversy is not only in the public arena; many nurses struggle with the conflict between their personal convictions and their professional duty. Nurses are taught to be supportive client advocates and to interact with a nonjudgmental attitude under all circumstances even when personal and political views differ from those of their clients.

TABLE 1.6 Milestones in Federal Programs in Support of the Health of Women and Children

Date	Action	Impact
1909	First White House Conference on Care of Dependent Children (convened by President Theodore Roosevelt) Prevention of Infant Mortality Association formed	Addressed the poor working and living conditions of many children in the United States. Aimed at improving the lives of children. The Association played a major role in creating a new registration procedure for all infant births and deaths nationally.
1912/1913	U.S. Children's Bureau	Established the first governmental agency to oversee children's health and environmental conditions. Purpose is to research and report all issues pertaining to all children's well-being; to assist states and local government in preventing child abuse and neglect.
1921	Maternity & Infancy (Sheppard–Towner) Act	Provided grants to states to establish maternal and child health divisions in state health departments.
1930	White House Conference on Child Welfare Standards	Produced the Children's Charter, documenting the child's need for health, education, welfare, and protection.
1935	The Social Security Act Introduction of vitamin K to newborns	Established federal–state partnership and provided Aid to Dependent Families and Children (ADFC), maternal–child

		health services, and child welfare services. This discovery led to the prevention of hemorrhagic disease in newborns.
1935	Title V Maternal Child Health block grant	Provides funding for ensuring the health of our nation's mothers and children through grants to states. Serves >2.5 million pregnant women; 4 million infants and 30 million children annually.
1938	Initiation of the March of Dimes	Through research, defeated polio and now improves lives through the prevention of birth defects, prematurity, and infant mortality.
1946	National School Lunch Program	Provides nutritious, well-balanced lunches to children each day at school for free or at low cost. It also provides meal supplements for children in afterschool care and nutrition programs for homeless children.
1946	Centers for Disease Control and Prevention established	The CDC is globally recognized as a leading force in public health expertise.
1962	National Institute of Child Health and Human Development (NICHD)	Supports and performs research on child, maternal, adult, and family health issues.
1964	Head Start Developed	Head Start provides child development programs to

		pregnant women, families, and children from birth to age 5 with the overarching goal of increasing school readiness for children from low-income families.
1965	Medicaid Program under Title XIX of Social Security Act; special programs such as Child Health Assessment Program	Provided state block grants to reduce financial barriers to health care for the poor and special services to pregnant women, young children, and people with disabilities.
1966/1974	Women, Infants, Children (WIC) program	Provided nutritional supplementation and education to low-income families; pregnant, postpartum, and lactating women; and infants and children up to age 5.
1968	Expansion of Lunch & Nutrition Act	Provide food for low-income, school-age children year-round along with low-income children in day care and Head Start programs.
1969	U.S. Children's Bureau moves to Office of Health, Education, & Welfare (HEW)	Established greater presence for the programs.
1972	Head Start to Serve Handicapped Children	Congress mandated that at least 10% of the children enrolled in Head Start must be handicapped children.
1975	Education for All Handicapped Children Act (Public Law 94–142)	Established federally mandated special education in public schools.

	Title XX Social Services	Provided block grants to day care, emergency shelters, counseling, family planning, and other services for children.
1976	Improved Pregnancy Outcome Projects	Raised awareness of the importance of maternal health during pregnancy to reduce infant mortality.
1976	The Supplemental Security Income (SSI) Disabled Children's Program	Provided cash to low-income children with disabilities to help their families manage their health care costs.
1979	National health objectives for 1990	These early efforts resulted in *Healthy People 2010* and *2020. Now 2030 is developed*.
1981	Alcohol, Drug Abuse, & Mental Health block grants	Began funding services for children and adolescents with mental health issues.
	Healthy Mothers, Healthy Babies Coalition	Raised public awareness of prenatal care, good nutrition, avoidance of drugs, and promotion of breastfeeding.
1986	Education of Handicapped Act Amendments (Public Law 99–457)	Established federal funding for states to create statewide, comprehensive, coordinated, and multidisciplinary early-intervention services for handicapped infants and toddlers.
1990	Omnibus Budget Reconciliation Act	Extended Medicaid coverage to all children (6–18 years) with family

		income below 133% of poverty level.
1990	Bright Futures Initiated	Provided a comprehensive set of child health supervision guidelines for health professionals, families, and communities and train these groups to work toward optimal child health.
1991	Healthy Start initiated	Is a community-based program that serves at-risk women to reduce infant mortality during and after their pregnancy.
1993	Family & Medical Leave Act (FMLA)	Allowed eligible employees to take up to 12 weeks of unpaid leave from their jobs every year to care for newborns or newly adopted children or children, parents, or spouses who have a serious health condition; employee can return to previous job or a comparable job with the same conditions.
1994	Back to Sleep Campaign	A national campaign to prevent sudden infant death syndrome (SIDS) by placing infants on their backs to sleep.
1995	Early Head Start Program	Federally funded community-based program for low-income families (infants, toddlers, and pregnant women) that focuses on child development.
1997	Children's Health Insurance	Offers federal assistance to

	Program (CHIP) (formerly known as State Children's Health Insurance Program [SCHIP])	state-based health insurance for low-income families that are not eligible for Medicaid but cannot afford private insurance.
2000	Children's Health Act	Lead to increased research and treatment of health issues concerning children such as autism, asthma, epilepsy, and oral health.
2002	No Child Left Behind Act	To ensure that all children in all classrooms receive research-based curriculum, well-prepared teachers, and a safe learning environment.
2006	Combating Autism Act	Lead to increasing autism awareness by increasing funding for research, surveillance, diagnosis, and treatment.
2007	WIC Food Package Revised	Designed to improve nutritional intake of WIC recipients by supporting and promoting long-term breastfeeding and adding fruits and vegetables, whole grains, soy-based foods, and a variety of culturally appropriate foods.
2008	Newborn Screening Saving Lives Act	Provided increased funding for newborn screening grants and provided more education and outreach, coordination of follow-up care after screening and evaluation of newborn

		screening programs effectiveness.
2009	Children's Health Insurance Program Reauthorization Act	Expanded the program to cover more uninsured children.
2009	American Recovery and Reinvestment Act	Designated money to fund and expand programs such as Head Start, foster care, and the Supplemental Nutrition Assistance Program (Food Stamp Program) as well as creating new jobs and improving services such as community health centers and unemployment benefits during the economic recession.
2010	Affordable Care Act (Patient Protection & Affordable Care Act); Health Care & Education Reconciliation Act	Increases coverage by expanding Medicaid, ends pre-existing conditions exclusion for children; holds insurance companies accountable by ending lifetime coverage limits, requiring insurance companies to publicly justify premium increases; decreases health care costs; increases choice and enhances quality of care for all Americans by covering all preventative care.
2014	Birth to Five: Watch me Thrive	A federal initiative program that promotes developmental and behavioral screening for children with the goal to improve early diagnosis

		and treatment of children with developmental delays.
2018	HEALTHY KIDS (Helping Ensure Access for Little One, Toddlers, and Hopeful Youth by Keeping Insurance Delivery Stable Act)	Extends funding for CHIP through 9/2023 National Conference.

With all the advances in abortion care, this points toward greater nursing involvement. Although this bodes well for woman-centered care, the burden on nurses is likely to increase incrementally. Nurses need to clarify their personal values to be able to provide nonjudgmental care to the woman undergoing an abortion. This may have an adverse effect on the affective attributes or emotions that those nurses possess (King et al., 2019).

The American Nurses Association's updated Code of Ethics for Nurses upholds the nurse's right to refuse to care for a client undergoing an abortion if the nurse ethically opposes the procedure (ANA, 2016). Nurses need to make their values and beliefs known to

their managers before the situation occurs so that alternative staffing arrangements can be made. Open communication and acceptance of the personal beliefs of others can promote a comfortable working environment.

Substance Abuse

Substance abuse for any person is a problem, but when it involves a pregnant woman, substance abuse can cause fetal injury and thus has legal and ethical implications. Substance abuse during pregnancy may cause fetal anomalies, preterm birth, placental abruption, and central nervous system developmental alterations (CDC, 2019i). Many state laws require reporting evidence of prenatal drug exposure, which may lead to charges of negligence and child endangerment against the pregnant woman. It has been found that incarceration, or threat of it, has no effect in reducing cases of alcohol or drug abuse. Criminal prosecution and punitive civil actions discourage women from disclosing substance misuse and pose barriers to essential health and social services (Guttmacher Institute, 2019c). This punitive approach to fetal injury raises ethical and legal questions about the degree of governmental control that is appropriate in the interests of child safety. All pregnant women and women of childbearing age should be screened periodically for alcohol, tobacco, and prescription and illicit drug use. Nurses should employ a flexible approach to the care of women who have substance use problems, and they should encourage the use of all available community resources. Nurses should counsel women about the risks of preconception, antepartum, and postpartum substance abuse in a calm, nonjudgmental manner. Nurses have a critical role as client advocates to protect individual health, human and legal rights of all women (Jessup et al., 2019).

Intrauterine Therapy

Progress in prenatal diagnosis can lead to the diagnosis of severe fetal abnormalities for which previously one would anticipate a fatal

outcome or the development of severe disability despite optimal postnatal care. Intrauterine therapy can now be offered in these selected cases and also in the treatment of fetal obstructive uropathy, intrauterine transfusions for fetal anemia, spina bifida repair, and stem cell transplantation. Intrauterine therapy is a procedure that involves opening the uterus during pregnancy, performing a surgery, and replacing the fetus in the uterus. Although the risks to the fetus and the mother are both great, fetal therapy may be used to correct anatomic lesions (Springer, 2019). Some argue that medical technology should not interfere with nature, and thus this intervention should not take place. Others would argue that the surgical intervention improves the child's quality of life. For many people, these are the subjects of debates and intellectual discussions, but for nurses, these procedures may be part of their daily routine.

Nurses play an important supportive role in caring and advocating for clients and their families. As the use of technology grows, situations will surface more frequently that test a nurse's belief system. Encouraging open discussions to address emotional issues and differences of opinion among staff members is healthy and increases tolerance for differing points of view.

Maternal–Fetal Conflict

In maternity nursing, the ethical principles of beneficence and autonomy provide the fundamental framework that guides the management of all pregnant women. As there is the need for consideration of the fetus, autonomy can become a complex issue, which gives rise to what is sometimes called the **maternal–fetal conflict**.

Fetal care becomes problematic when what is required to benefit one member of the dyad will cause an unacceptable harm to the other. When a fetal condition poses no health threat to the mother, caring for the fetal client will always carry some degree of risk to the mother, without direct therapeutic benefit for her. The ethical

principles of beneficence (“be of benefit”) and nonmaleficence (“do no harm”) can come into conflict.

Because the clients are biologically linked, both, or neither, must be treated alike. It would be unethical to recommend fetal therapy as if it were medically indicated for both clients. Still, given a recommendation for fetal therapy, pregnant women, in most cases, will consent to treatment, which promotes fetal health. When pregnant women refuse therapy, health care providers must remember that the ethical injunction against harming one client in order to benefit another is virtually absolute.

The use of court orders to force treatment on pregnant women raises many ethical concerns. Court orders force pregnant women to forfeit their autonomy in ways not required of competent men or nonpregnant women. There is an inconsistency in allowing competent adults to refuse therapy in all cases but pregnancy. The American College of Obstetricians and Gynecologists (ACOG) advocates counseling and education to convince a mother to follow her doctor’s advice and condemns the use of coercion on a pregnant woman, as this violates the intent of the informed consent process. Faced with a continuing disagreement with a pregnant woman, a physician should turn to an institutional ethics committee. Resorting to the legal system is almost never justified (American College of Physicians Ethics Manual, 2019).

Stem Cell Research

Stem cells constitute one of the most promising tools for regenerative medicine. They can grow into any cell type in the body and have been touted as a potential cure for everything from type 1 diabetes to stroke. The goal of stem cell research is a relief of human suffering, which ethically is good. Benefits of stem cell research include therapies for Parkinson disease, regeneration of diseased body tissues, repair of spinal cord injuries, and the growing of needed organs for transplant.

It would seem morally compelling to explore all the sources that might provide us with them, but the ethical concerns surrounding

stem cell research vary depending on the origin of the stem cells. Adult **stem cells** are found in adults, who can replace old cells by reproducing new ones (e.g., blood and liver cells). Bone marrow transplants are examples of the use of adult stem cells in medical therapy. Embryonic stem cells are derived from the inner cell mass of an early embryo. They aren't without controversy; the process of obtaining these cells results in the destruction of the embryo. However, they hold huge promise to cure diseases and structural defects. Our nation cannot ignore the benefits of access to fetal tissue, when properly regulated procurement can be arranged from consenting donors after fetal loss (Charo et al., 2019).

Some people feel that the destruction of the human embryo constitutes the killing of a human being and reject this practice on religious grounds. Views about when life begins and whether the early embryo is considered a person with moral status are the heart of the ethical deliberations related to embryonic stem cells. Everyone has to decide based on their own personal values and ethical background.

Umbilical Cord Blood Banking

Newborn stem cell banking began more than 25 years ago. It has been estimated that more than 35,000 transplants have been performed in children and adults for the correction of inborn errors of metabolism, hematopoietic malignancies, and genetic disorders of the blood and immune system. Umbilical cord blood, the remaining blood in the umbilical cord at birth, can be collected and be a source of stem cells for an individual in need of a bone marrow transplant and other things later in life. It can also be used for admission laboratory studies in neonates and also for a transfusion if needed (ACOG, 2019). The extraordinary scientific and technologic advance of contemporary medicine constantly leads toward the introduction of new treatments. Umbilical cord blood is a potential vast source of primitive hematopoietic stem and progenitor cells available for clinical application. Cord blood can be used as an alternative source

for bone marrow transplantation and its use is developing into a new field of treatment for pediatric and adult clients.

Blood from a newborn's umbilical cord, once considered a waste product that was routinely discarded along with the placenta, is now considered to contain potentially life-saving stem cells. Banks were initially developed to store cord blood stem cells from newborns, for a fee, for potential future use by the same child or a family member if the child developed disease later in life. Today, there are two types of banks: public banks that store, for free, and private banks. The public banks that store stem cells can be used by anyone needing them, similar to how public blood banks work.

Pregnant women should be aware that stem cells from cord blood cannot currently be used to treat inborn errors of metabolism or other genetic diseases in the same individual from which they were collected because the cord blood would have the same genetic mutation. Cord blood collected from a newborn that later develops childhood leukemia cannot be used to treat that leukemia for much the same reason. Umbilical cord banks are a central component, as umbilical cord tissue providers, in both medical treatment and scientific research with stem cells. But, whereas the creation of umbilical cord banks is seen as successful practice, others perceive it as ethically risky.

The fact that private cord banks offer their services as "biologic insurance" in order to obtain informed consent by promising the parents that the tissue that will be stored to insure the health of their child in the future raises the issue of whether the consent is freely given or given under coercion. Another consideration that must be made in relation to privately owned cord banks involves the ownership of the stored umbilical cord. Conflicts between moral principles and economic interests (many physicians own private blood banks) cause dilemmas in the clinical practice of umbilical cord blood storage and use, especially in privately owned banks (Cord for Life, 2019).

Both the ACOG (2019) and AAP (2019a) have reaffirmed previously issued statements opposing the use of for-profit banks and criticizing their marketing tactics. Instead, they recommended

that parents donate cord blood to public banks, which make it available for free to anyone who needs it. Globally, other organizations have done the same. Private umbilical cord blood banking raises a question of special legal regulation. This practice promises the safe storage of biologic material on the assumption that it may be useful, at a certain moment in future, for its own donor (or for a donor's close family member) for curing serious blood diseases (Brown et al., 2019). Nurses need to provide unbiased education about this topic with all pregnant women and their families to allow informed choices to be made.

Informed Consent

In the United States, clinicians have a clear ethical and legal responsibility to obtain informed consent for tests, treatments and procedures. Most care given in a health care setting is covered by the initial consent for treatment signed when the person becomes a client at that office or clinic, or by the consent to treatment signed upon admission to the hospital or other inpatient facility. Certain procedures, however, require a specific process of informed consent. Procedures that require informed consent include major and minor surgery; invasive procedures such as amniocentesis, internal fetal monitoring, lumbar puncture, or bone marrow aspiration; treatments placing the person at higher risk, such as chemotherapy or radiation therapy; procedures or treatments involving research; application of restraints; and photography involving the person.

Generally, only people over the age of majority (18 years of age) can legally provide consent for health care. Because children are minors, the process of consent involves obtaining written permission from a parent or legal guardian. In cases requiring a signature for consent, usually the parent gives consent for care of children less than 18 years of age except in certain situations (see discussion that follows).

TAKE NOTE!

Never assume that the adult accompanying the child is the parent or legal guardian. Always clarify the relationship of the accompanying adult.

The informed consent process, which must be done before the procedure or specific care, addresses the legal and ethical requirement of informing the person about the procedure. It originates from the right of the child and family to direct their care and the ethical responsibility of health care providers to involve the child and family in health care decisions. Nurses have many roles in the informed consent process. Nurses should involve children and adolescents in the decision-making process to the extent possible, though the parent is still ultimately responsible for giving consent. The physician or advanced practitioner providing or performing the treatment and/or procedure is responsible for informing the child and family about the procedure and obtaining consent by providing a detailed description of the procedure or treatment, the potential risks and benefits, and alternative methods available.

The nurse's responsibility related to informed consent includes the following:

- Determining whether the client or parents or legal guardians understand what they are signing by asking them pertinent questions.
- Ensuring that the consent form is completed with signatures from the client (or parents or legal guardians if the client is a child).
- Serving as a witness to the signature process.

Box 1.5 describes the key elements of informed consent, although laws vary from state to state.

Nurses must become familiar with state laws as well as the policies and procedures of the health care agency. Treating children without obtaining proper informed consent violates their rights, and the physician and/or facility may be held liable for any damages (Ryan & Sinha, 2019).

BOX 1.5 Key Elements of Informed Consent

- The decision maker must be of legal age in that state, with full civil rights, and must be competent (have the ability to make the decision).
- Present information that is simple, concise, and appropriate to the level of education and language of the individual responsible for making the decision.
- The decision must be voluntary, and without coercion, force, or influence of duress.
- Have a witness to the process of informed consent.
- Have the witness sign the consent form.

Special Situations to Informed Consent

There are special situations related to informed consent. If the parent is not available, then the person in charge (relative, babysitter, or teacher) may give consent for emergency treatment if that person has a signed form from the parent or legal guardian allowing him or her to do so. During an emergency situation, a verbal consent via the telephone may be obtained. Two witnesses must be listening simultaneously and will sign the consent form, indicating that consent was received via telephone. Health care providers can provide emergency treatment to a child without consent if they have made reasonable attempts to contact the child's parent or legal guardian (AAP et al., 2011, reaffirmed 2015; Brent, 2019). In urgent or emergent situations, appropriate medical care never should be delayed or withheld due to an inability to obtain consent (AAP et al., 2011, reaffirmed 2015; Brent, 2019). Certain federal laws, such as the Emergency Medical Treatment and Labor Act (EMTALA), require that every client who presents at an emergency department is given a medical examination regardless of informed consent or reimbursement ability (AAP et al., 2011, reaffirmed 2015; Brent, 2019). Table 1.7 gives further information about other special situations.

Exceptions to Parental Consent Requirement

In some states, a **mature minor** may give consent to certain medical treatment. The health care provider must determine that the adolescent (usually over 14 years of age) is sufficiently mature and intelligent to make the decision for treatment. The provider also considers the complexity of the treatment, its risks and benefits, and whether the treatment is necessary or elective before obtaining consent from a mature minor (AAP et al., 2011, reaffirmed 2015).

State laws vary in relation to the definition of an emancipated minor and the types of treatment that may be obtained by an emancipated minor (without parental consent). The nurse must be familiar with the particular state's law. Emancipation may be considered in any of the following situations, depending on the state's laws:

- Membership in a branch of the armed services
- Marriage
- Court-determined emancipation
- Financial independence and living apart from parents
- Pregnancy
- Mother less than 18 years of age

The **emancipated minor** is considered to have the legal capacity of an adult and may make his or her own health care decisions (AAP et al., 2011, reaffirmed 2015; Brent, 2019).

Many states do not require consent or notification of parents or legal guardians when providing specific care to minors. Depending on the state law, health care may be provided to minors for certain conditions, in a confidential manner, without including the parents. These types of care may include pregnancy counseling, prenatal care, contraception, testing for and treatment of sexually transmitted infections and communicable diseases (including HIV), substance abuse, and mental illness counseling and treatment (AAP et al., 2011, reaffirmed 2015; Guttmacher Institute, 2019a). These exceptions allow children to seek help in a confidential manner in situations where they might otherwise avoid care if they were required to inform their parents or legal guardian. Again, laws vary

by state, so the nurse must be knowledgeable about the laws in the state where he or she is licensed to practice.

TABLE 1.7 Special Considerations Related to Informed Consent

Issue	Definition	Nursing Considerations
Child not living with biologic or adoptive parents	Child living: • In foster care • With potential adoptive parent • With a relative	Legally appointed guardian must provide consent. Verify authority and include documentation of legally appointed guardian in child's medical record.
Parent consent after divorce	Ability to give consent for health care rests with parent who has legal custody by divorce degree.	Determine if the parents have joint custody or if there is sole custody by one parent. Even the parent with only physical custody may give consent for emergency care. May need to seek court involvement if there is joint legal custody but parents disagree on care.
Consent for organ donation	For a minor to donate, the parents must be aware of the risks and benefits and must provide emotional support to the child. There should be a close relationship between the donor and recipient, if living-related donation is occurring. The minor must agree to donate without coercion in live organ donation.	Potential donors should be referred to local organ procurement organization. Educate family about policies related to organ donation. Legal guardian or parent consents to organ donation.
Consent for medical experimentation	Requirements include consent of parents, assent of child, and a perceived benefit to the child.	Comply with all federal regulations if federal funds are received (refer to section on assent).

American Academy of Pediatrics, Committee on Hospital Care, Section on Surgery, and Section on Critical Care. (2010, reaffirmed 2019). Pediatric organ donation and transplantation. *Pediatrics*, *125*(4), 822–828. https://doi.org/10.1542/peds.2010-0081; U.S. Department of Health and Human Services. (2016). *Special protections for children as research subjects*. http://www.hhs.gov/ohrp/policy/populations/children.html.

Assent

Assent means agreeing to something. In pediatric health care, the term assent refers to the child's participation in the decision-making process about their health care (AAP & Committee on Bioethics, 2016; Navin & Wasserman, 2019). The age of assent depends on the child's developmental level, maturity, and psychological state. The AAP recommends that children and adolescents be involved in the discussions about their health care and kept informed in an age-appropriate manner (AAP & Committee on Bioethics, 2016; Navin & Wasserman, 2019). As a child gets older, assent or dissent should be given more serious consideration. The pediatric client needs to be empowered by health care providers to the extent of their capabilities and as children mature and develop over time they should become the primary decision maker regarding their own health care (AAP& Committee on Bioethics, 2016; Feigelman, 2020). The AAP recommends that if a health care provider asks the child's opinion about the direction of treatment or participation in research, then the child's view and desires should be seriously considered (AAP & Committee on Bioethics, 2016).

When obtaining assent, first help the child to understand his or her health condition, depending on the child's developmental level. Next, inform the child of the treatment planned and discuss what he or she should expect. Then determine what the child understands about the situation and make sure he or she is not being unduly influenced to make a decision one way or another. Finally, ascertain the child's willingness to participate in the treatment or research (AAP & Committee on Bioethics, 2016; Navin & Wasserman, 2019). Assent is a process and should continue throughout the course of treatment or research protocol.

The converse of assent is **dissent** (disagreeing with the treatment plan), and it may be ethically binding (AAP & Committee on Bioethics, 2016). If the health care provider is not going to honor the pediatric client's dissent, then the argument can be made that the provider should not ask for the client's assent. In some cases, such as in those of significant morbidity or mortality, dissent may need to be overridden. These cases need to be looked at on an individual basis. If the decision is made to move forward with treatment despite the child's dissent, then this decision must be explained to the child in developmentally appropriate terms.

There has been an increased emphasis on including children in research studies. Children are not little adults, but the majority of medicines given to children have only been tested on adults (National Institutes of Health [NIH], 2019). In research studies, investigators and investigation review boards (IRBs) are responsible for ensuring measures are taken to protect the children in the studies. The nurse caring for these children also has the responsibility to ensure protection at all stages of the research process. Nurses can become members of the IRB; they should also become familiar with studies that have been approved in their work setting to help ensure their pediatric clients are protected.

TAKE NOTE!

Whenever possible, obtain assent for participation from the child.

Refusal of Medical Treatment

All clients have the right to refuse medical treatment, based on the American Hospital Association's Bill of Rights. Ideally, medical care without informed consent should be used only when the client's life is in danger. Clients may refuse treatment if it conflicts with their religious or cultural beliefs (Laurie et al., 2019). An example would be a Jehovah's Witness. Individuals of this faith have strong beliefs based upon passages from the Bible that are interpreted as

prohibiting the “consumption” of blood. Their beliefs prevent them from accepting transfusion of whole blood or its primary components. With recent advances and use of biologic hemostats that aid coagulation and reduce blood loss, major surgery can be performed safely in the Jehovah’s Witness who refuses blood transfusion by utilizing these devices (Laurie et al., 2019). In these cases, it is important to educate the client and family about the importance of the recommended treatment without coercing or forcing the client to agree. Sometimes common ground may be reached between the family’s religious or cultural beliefs and the health care team’s recommendations. Communication and education are the keys in this situation.

Generally, parents have broad legal protections to decide on care for their children, even if there may be negative consequences of that decision, unless there is a direct threat to the child’s life. In the case of a child, parental autonomy (the right to decide for or against medical treatment) is a fundamental, constitutionally protected right, but not an absolute one. The general assumption is that parents act in the best interests of their children. Ideally, medical care without informed consent should be given only when the child’s life is in danger. In some cases parents may refuse medical treatment for their child. This refusal may arise when treatment conflicts with their religious or cultural beliefs, and the nurse should be aware of some of these common beliefs. Some religions, such as Christian Science, Pentecostal, Church of the First Born, and Followers of Christ, prefer prayer or faith healing over allopathic medicine (Muggli et al., 2019). The Muslim culture advocates vegan diets and refuses pork-based medicines or treatments. Hindus may refuse beef-based foods and medicines. People from an Islamic background may refuse the use of any potentially addictive substances such as narcotics or medicines containing alcohol (Pozgar, 2020). Sometimes common ground may be reached between the family’s religious or cultural beliefs and the health care team’s recommendations.

TAKE NOTE!

Do not assume what a family's beliefs are based on religious affiliation. Assess each family and child views on an individual basis.

In other cases, parents may refuse treatment if they perceive that their child's quality of life may be significantly impaired by the medical care that is offered. The health care team must appropriately educate the family and communicate with them on a level that they can understand. The child and family should be informed of what to expect with certain tests or treatments. The health care team should make a clinical assessment of the child's and family's understanding of the situation and their reasons for refusing treatment. Active listening may allow the health care provider to address the concerns, fears, or reservations the family may have regarding their child's care.

Refusal of medical care may be considered a form of child neglect. If providing medical treatment may prevent substantial harm and suffering, or save a child's life, health care providers and the judicial system strive to advocate for the child. The state has an overriding interest in the health and welfare of the child and can order that medical treatment to proceed without signed informed consent; this is referred to as *parens patriae* (the state has a right and a duty to protect children). If the parents refuse treatment and the health care team feels the treatment is reasonable and warranted, the case should be referred to the institution's ethics committee. If the issue remains unresolved, or in complex cases, the judicial system may become involved (American Academy of Pediatrics, & Committee on Bioethics, 2016). Nurses should document "informed refusal" just as they would informed consent (AAP, 2018b).

Advance Directives

The Patient Self-Determination Act of 1990 established the concept of advance directives. Advance directives determine the child's and

family's wishes should life-sustaining care become necessary. An advanced directive is a "living will" that describes medical ambitions of the child's end-of-life care. Parents are generally the surrogate decision makers for children. If the child's interests are not served by prolonged survival, then the physician or advanced practitioner should educate the parents about the extent of the child's illness and potential for ongoing quality of life (Pozgar, 2020; Weise et al., 2017). After discussion with other family members, friends, and spiritual advisors, the parents may make the decision to forego life-sustaining medical treatment, either withdrawing treatment or deciding to withhold further treatment or opt not to resuscitate in the event of cardiopulmonary arrest (Weise et al., 2017). Parents of children with complex chronic conditions highly value advanced care planning, early in the illness course. Nurses need to incorporate this to make sure this discussion is introduced early on (DeCourcey et al., 2019).

Life-sustaining care may include antibiotics, chemotherapy, dialysis, ventilation, cardiopulmonary resuscitation, and artificial nutrition and hydration. Some families may choose to withdraw these treatments if they are already in place or to not begin them should the need arise. **Do-not-attempt-resuscitation (DNAR)** orders are in place for some children, particularly the terminally ill. Some institutions have started using the term AND (Allow Natural Death). No matter what term is used, these orders should include specific instructions regarding the child's and family's wishes (e.g., some families may desire oxygen but not chest compressions or code medications). When the child is hospitalized, the DNAR order must be documented in the physician orders and updated according to the facility's policy. DNAR orders may also be in place in the home, but only a few states allow emergency medical services to honor a child's DNAR order in the home. Children with DNAR orders may also still be attending school. In that case, the health care professionals involved should meet with the school officials (the board of education and its legal counsel) to discuss how the DNAR request can be upheld in the school setting. The health care provider should help educate the school about the child's condition, potential

complications, and health care goals (Weise et al., 2017). They should work with the school and family on developing an individualized health care plan that will include what to do instead of CPR, such as comfort measures (Weise et al., 2017).

The Baby Doe regulations, which are an amendment to the United States Child Abuse Protection and Treatment Act, provide specific guidelines on how to treat extremely ill, premature, terminally ill, and/or disabled infants regardless of the parents' wishes (Butts & Rich, 2020).

Health care providers must continue to work with parents of extremely sick or premature infants to ensure they are accurately informed about the condition of their child and the risks and benefits to treatment. Health care providers must also be aware of federal, state, and hospital policy regarding care of very ill, premature, and/or disabled newborns.

The nurse must be knowledgeable about the laws related to health care of children in the state where he or she practices as well as the policies of the health care institution. The nurse must be sensitive to the various ethical situations that he or she may become involved in and should apply knowledge of laws as well as concepts of ethics to provide appropriate care.

Client Rights

The American Hospital Association first established a Patient's Bill of Rights in 1972 as a way to promote the value and dignity of the client. This information is updated periodically. Most health care agencies and professional organizations have developed some type of document that addresses client rights.

Ensuring that client rights are upheld is a key aspect in the care of any client. For the pregnant woman, two clients must be considered —the pregnant woman and her fetus. The American Foundation for Maternal and Child Health developed the Pregnant Patient's Bill of Rights to address specific concerns and situations involving the health and well-being of the mother and her fetus. In addition, the USDHHS has issued laws related to protecting the welfare of

newborns (the Baby Doe law). A child, due to his or her age and developmental level, may lack mature decision-making abilities. Many pediatric institutions have adopted a bill of rights for children's health care specific to that institution. This might include the following rights:

- To be called by name
- To receive compassionate health care in a careful, prompt, and courteous manner
- To know the names of all providers caring for the child
- To have basic needs met and usual schedules or routines honored
- To make choices whenever possible
- To be kept without food or drink when necessary for the shortest time possible
- To be unrestrained if able
- To access information contained in your records within a reasonable time frame
- To have parents or other important persons with the child
- To have personal privacy protected
- To receive care in a safe setting, free from verbal or physical abuse or harassment
- To have an interpreter for the child and family when needed
- To object noisily if desired
- To be educated honestly about the child's health care
- To be respected as a person (not having people talk about the child within earshot unless the child knows what is happening)
- For all health care providers, to respect the child's confidentiality about his or her illness at all times (adapted from Children's Hospital Los Angeles, 2019)

Confidentiality

With the establishment of the Health Insurance Portability and Accountability Act (HIPAA) of 1996, the confidentiality of health care information is now mandated by law. The primary intent of the law is to maintain health insurance coverage for workers and their families when they change or lose jobs. Another aspect of the law requires

the Department of Health and Human Services to establish national standards for electronic transmission of health information. With the increased use of electronic medical records (EMRs) and electronic billing came the increased possibility that personal health information might be inappropriately distributed. Client confidentiality and privacy must be maintained in the same manner as it is with paper documentation. Nurses can ensure that privacy is maintained when using computerized documentation and EMRs by doing the following:

- Always maintain the security of personal log-in information; nurses should never share it with other health care providers or other persons.
- Always log off when leaving the computer.
- Do not leave client information visible on a monitor screen when the computer/monitor is unattended.
- Use safeguards, such as encryption, when using alternative means of communication such as email.

Exceptions to confidentiality exist. For example, suspicion of physical or sexual abuse and injuries caused by a weapon or criminal act must be reported to the proper authorities. Abuse cases are reported to the appropriate welfare authorities, whereas criminal acts are reported to the police. In addition, if the minor is a threat to self, then information may need to be disclosed to protect the child. The health care provider must also follow public health laws that require reporting certain infectious diseases to the local health department (e.g., tuberculosis, hepatitis, HIV, and other sexually transmitted infections). Finally, there is a duty to warn third parties when a specific threat is made to an identifiable person.

Health care providers must strike a balance between confidentiality and required disclosure. Even if disclosure is required it is recommended that the health care provider attempt to gain consent for the disclosure and when possible inform the minor of the limits to confidentiality and consent prior to the initiation of care. Health care provider’s ethical obligations require them to achieve a

delicate balance between contributing to the health care team and protecting client confidentiality (Van Liew, 2019).

IMPLICATIONS FOR NURSES

The health care system is intricately woven into the political and social structure of our society, and nurses should understand social, legal, and ethical health care issues so that they can play an active role in meeting the health care needs of women, children, and families. Nurses need to take a proactive role in advocating for and empowering their clients. For example, nurses can help women to increase control over the factors that affect health, thereby improving their health status. A woman may become empowered by developing skills not only to cope with her environment, but also to change it. Nurses also can assume this mentoring role with children and families, thus helping them to improve their overall health status and health outcomes.

Nurses must have a solid knowledge base about the factors affecting maternal and child health and barriers to health care. They can use this information to provide anticipatory guidance, health counseling, and teaching for women, children, and families. It also is useful in identifying high-risk groups so that interventions can be initiated early on, before problems occur.

When caring for women, children, and families, the nurse operates within the framework of the nursing process, which is applicable to all health care settings. Maternal and child health nursing is ever changing as globalization and the exchange of information expands. Nurses must remain up to date about new technologies and treatments and integrate high-quality, evidence-based interventions into the care they provide.

KEY CONCEPTS

- *Healthy People 2030* presents a national set of health goals and objectives for adults and children that focus on health promotion and disease prevention.
- One method to establish the aggregate health status of women, infants, and children is with statistical data, such as mortality and morbidity rates.
- The infant mortality rate is used as an index of the general health of a country. The infant mortality rate in the United States is higher when compared with other industrialized countries. This high rate may be the result of the increase in low–birth-weight infants born in this country.
- The family is considered the basic social unit. The family greatly influences the development and health of its members. Members learn health care activities, health beliefs, and health values from their family.
- Social roles are often an important factor in the development of one's self-concept, which can have a very positive influence on health or present various limitations and problems, possibly resulting in a negative influence on health.
- Culture influences every aspect of development and is reflected in childbearing and child-rearing beliefs and practices designed to promote healthy adaptation (Andrews et al., 2019).
- Spirituality, a major influence for many individuals, provides a meaning and purpose to life and is a foundation for and a source of love, relationships, and service. Spiritual and religious beliefs and views can provide strength and support to women, children, and their families during times of stress and illness.
- Other factors impacting the health of women and children include genetics, global society, health status and lifestyles, access to health care, and improved diagnosis and treatment. Lack of finances, sociocultural barriers, including lack of transportation, no babysitters, high health insurance premiums, discrimination, and language and health care delivery system barriers, including inconvenient clinic hours and poor attitudes by health care workers can provide barriers to health care.
- Law and ethics are interrelated and affect all of nursing. Professional nurses must understand their scope of practice,

standards of care, institutional or agency policies, and state laws. All clients have the right to refuse medical treatment based on the American Hospital Association's Bill of Rights. For a child, the parents have the legal right to decide for or against medical treatment. Minor children (under the age of 18 years) must have their parents or legal guardians provide consent for health care in most cases.

- In certain states, mature minors and emancipated minors may consent to their own health care and certain health care may be provided to adolescents without parental notification, including contraception, pregnancy counseling, prenatal care, testing and treatment of sexually transmitted infections and communicable diseases (including HIV), substance abuse and mental illness counseling and treatment, and health care required as a result of a crime-related injury.
- The nurse must be knowledgeable about the laws related to health care of women and children in the specific state of nursing practice as well as the specific policies of the health care institution.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. When preparing a presentation for a local woman's group on women's health problems, what would the nurse include as the number-one cause of mortality for women in the United States?

   a. Breast cancer
   b. Childbirth complications
   c. Injury resulting from violence
   d. Heart disease

2. Which factor would most likely be responsible for a pregnant women's failure to receive adequate prenatal care in the United States?

   a. Belief that it is not necessary in a normal pregnancy
   b. Use of denial to cope with pregnancy
   c. Lack of health insurance to cover expenses
   d. Inability to trust traditional medical practices

3. When caring for an adolescent, in which instance must the nurse share information with the parents, no matter which state care is provided in?

   a. Pregnancy counseling
   b. Depression
   c. Contraception
   d. Tuberculosis

4. A single mother asks the nurse for suggestions on disciplining her 2-year-old son. Which suggestion would be most appropriate?

a. Encourage the mother to emphasize the inappropriate behavior.
b. Wait an hour or so before enforcing the discipline.
c. Have the child spend 2 minutes in time-out.
d. Withhold a privilege from the toddler for a week.

5. The nurse is teaching a group of students about the possible effects of immigration on the health status of children. Which response by the group would indicate the need for additional teaching?

a. The children of immigrants have better access to preventive care.
b. The children of immigrants have limited involvement in activities due to the language barrier.
c. The children of immigrants lack adequate support systems.
d. The children of immigrants face increased stressors due to relocation.

6. The nurse is preparing a class for a group of students about homelessness. Which factors contribute to homelessness? Select all that apply.

a. Decrease in the number of people living in poverty
b. Rises in unemployment
c. Exposure to abuse or neglect
d. Cutbacks in public welfare programs
e. Development of community crisis centers

CRITICAL THINKING EXERCISES

1. As a nurse working in a federally funded low-income clinic offering women's health services, you are becoming increasingly frustrated with the number of "no-shows," or appointments missed in your maternity clinic. Some clients come for their initial prenatal intake appointment and never come back. You realize that some just forget

their appointments, but most don't even call to notify you. Many of the clients are high risk and thus are jeopardizing their health and the health of their future child.

   a. What changes might be helpful to address this situation?
   b. Outline what you might say at your next staff meeting to address the issue of clients making one clinic visit and then never returning.
   c. What strategies might you use to improve attendance and notification?
   d. Describe what cultural and customer service techniques might be needed.

2. A couple has adopted an 11-month-old infant girl from China and brought her to the health care facility for a check-up. The couple had no contact with the infant's birth parents. The infant spent 7 months in an orphanage before being adopted. Describe the family structure and the issues that may affect this family.
3. You have been asked by the local school district to speak to a group of middle-school children and their parents about Internet safety. Describe the topics that you should address.
4. A 12-year-old is to undergo research treatment for a serious illness. Explain the concept of assent as it relates to this situation.

STUDY ACTIVITIES

1. Research a current policy, bill, or issue being debated on the community, state, or national level that pertains to the health and welfare of women or children. Summarize the major facts and supporting and opposing arguments, and prepare an oral report on your findings.
2. Within your clinical group, debate the following statement: Should access to health care be a right or a privilege?

3. Visit a local community health center that offers services to women and children from various cultures. Interview the staff about any barriers to health care that they have identified. Investigate what the staff has done to minimize these barriers.

BRINGING IT ALL TOGETHER: A CASE STUDY

Maali, a 19-year-old Arab immigrant, presents at the local prenatal clinic accompanied by her husband Labib. The couple and their 18-month-old daughter, Labiba, have lived with relatives since arriving in America 5 months ago. During the prenatal interview, Maali reports that she is 4 months pregnant and is the primary caregiver for their daughter as well as caring for Labib's sister's toddler son while her sister-in-law is at work during the day.

Go to thePoint to find questions to consider about this case.

Caring for Women and Children

WOW

WORDS OF WISDOM

To recognize diversity in others and respect it, we must first have some awareness of who we are.

KEY TERMS

atraumatic care
case management
community
cultural competence
cultural humility
epidemiology
evidence-based nursing practice
family-centered care
health literacy
levels of prevention
nonverbal communication
population
verbal communication

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Identify the core concepts associated with the nursing management of women, children, and families.
2. Examine the major components and key elements of family-centered care.
3. Explain the different levels of prevention in nursing, providing examples of each.
4. Determine examples of cultural issues that may be faced when providing nursing care.
5. Employ cultural competemility and humility when caring for women, children, and families.
6. Outline the various roles and functions assumed by the nurse working with women, children, and families.
7. Demonstrate the ability to use excellent therapeutic communication skills when interacting with women, children, and families.

8. Apply the process of health teaching as it relates to women, children, and families.
9. Assess the importance of discharge planning and case management in providing nursing care.
10. Evaluate the reasons for the increased emphasis on community-based care.
11. Differentiate community-based nursing from nursing in acute care settings.
12. Critique the variety of settings where community-based care can be provided to women, children, and families.

Maria was home a few days after giving birth to her first child. She had just changed her newborn son and placed him on his stomach for a nap when the community health nurse arrived for a postpartum visit. Because the nurse didn't speak Spanish and Maria didn't speak English, a great deal of gesturing followed. After examining Maria, the nurse then picked up her son and placed him on his back in the crib. How might the nurse have prepared for this home visit? What message did the nurse convey in changing the newborn's position?

INTRODUCTION

Now more than ever, nurses contribute to nearly every health care experience. Historically, people were born at home, cared for when ill at home, and then died at home surrounded by loved ones. Today, these events from birth to death, and every health care emergency in between, will likely involve the presence of a nurse. Involvement of a knowledgeable, supportive, comforting nurse often leads to a positive health care experience. Skilled nursing practice depends on a solid base of knowledge and clinical expertise provided in a caring, holistic manner. Nurses, using their knowledge and passion, help meet the health care needs of their clients throughout the life span, whether the client is a pregnant woman, a fetus, a partner, a child, or

the parents or family members of a child. Nurses fill a variety of roles in helping clients to live healthier lives by providing direct care, emotional support, comfort, information, advice, advocacy, support, and counseling. Nurses are often “in the trenches” advocating on various issues, drawing attention to the importance of health care for women and children, encouraging a focus on education and prevention, and assisting families who lack resources or access to health care.

Changes in health care policy have reignited an interest in community health, in which nurses can serve their communities in a variety of ways. Women, children, and families receive a majority of their health care, both well and ill care, in the community setting. During the past several years, the health care delivery system has changed dramatically. Medicare’s prospective payment system (PPS) for hospitals, introduced in the United States in 1983, replaced cost reimbursement with a system of fixed rates which created incentives for hospitals to control costs. With a focus on cost containment, people are spending less time in the hospital. Clients are being discharged “sicker and quicker” from their hospital beds (Anderson & Roberts, 2019). The health care system has moved from reactive treatment strategies in hospitals to a proactive approach in the community. This has resulted in an increasing emphasis on health promotion and illness prevention within the community.

Nurses play an important role in the health and wellness of a community. Nurses wishing to improve maternal and pediatric outcomes can do so by helping to identify high-risk populations within the community and developing educational programs and outreach initiatives to address the needs of this aggregate. This is an exciting time for nurses delivering out-of-hospital care. The rising trend of delivering care in or near people’s homes and away from acute care facilities will necessitate flexible ways of working and greater integration of community nursing roles (Stanhope & Lancaster, 2020). They not only meet the health care needs of the individual, but also go beyond that to implement interventions that affect the community as a whole. There are many opportunities

within the community to offer information to women and their families about various options and choices for clinical care. Women should be provided this at their appropriate literacy level and language to make decisions about their care in partnership with the health care team. Nurses practice in a variety of settings within a community, such as clinics and physician offices, schools, shelters, churches, health departments, community health centers, and homes. They promote the health of individuals, families, groups, communities, and populations and promote an environment that supports health.

This chapter describes the core concepts of maternal and child health nursing and community and community-based nursing. Nurses need to be knowledgeable about these concepts to ensure that they provide professional care.

CORE CONCEPTS OF MATERNAL AND CHILD HEALTH NURSING

Maternal and child health nursing focuses on providing evidence-based care to the client within the context of the family. This care involves the implementation of an interdisciplinary plan in a collaborative manner to ensure continuity of care that is cost-effective, quality-oriented, and outcome-focused. Nurses can provide this care by focusing on the family, using evidence-based practice (EBP), working collaboratively, providing atraumatic therapeutic care, communicating effectively, providing education, utilizing a continuum of care strategy providing preventative care, and providing culturally competent nursing care.

Family-Centered Care

Family-centered care refers to the collaborative partnership among the individual, family, and caregivers to determine goals, share information, offer support, and formulate plans for health care. It is generally understood to be an approach in which clients and their families are considered integral components of the health care

decision-making and delivery processes. It is based on mutual trust and collaboration between women, children, families, and the health care professional. It is a partnership approach between families and their caregivers that recognizes the strength and integrity of the family.

The philosophy of family-centered care recognizes the family as the constant. The health and functioning of the family affect the health of the client and other members of the family. Family members support one another well beyond the health care provider's brief time with them, such as during the childbearing process or during a child's illness.

Family-centered care requires sensitivity to the client's and family's beliefs and those supporting their culture. This involves listening to the family's needs and a shift of the nurse's authoritarian role to the family to empower them to make their own decisions within the context of a supportive environment. The concept of family-centered care shifts control and power out of the hands of those who give care into the hands of those who receive it.

With family-centered care, support and respect for the uniqueness and diversity of families are essential, along with encouragement and enhancement of the family's strengths and competencies. It is important to create opportunities for families to demonstrate their abilities and skills. Families also can acquire new abilities and skills to maintain a sense of control and empowerment in meeting the needs of the client. Family-centered care promotes greater family self-determination, decision-making abilities, control, and self-efficacy, thereby enhancing the client's and family's sense of empowerment. When implementing family-centered care, nurses seek caregiver input. These suggestions and advice are incorporated into the client's plan of care as the nurse counsels and teaches the family appropriate health care interventions. Today, as nurses' partner with various experts to provide high-quality and cost-effective care, one expert partnership that nurses can make is with the client's family.

The impact of family-centered care can be seen in the models of care delivery for women and children. From the 1980s to the

present, there has been increased access to care for all women (regardless of their ability to pay) and hospital redesigns (labor, delivery, and recovery [LDR] rooms and labor, delivery, recovery and postpartum [LDRP] spaces) aimed at keeping families together during the childbirth experience and to minimize interruptions in breastfeeding dyads (King et al., 2019). This impact also can be seen in the care of children. For example, rooming-in and liberal visiting policies allow parents and other family members to participate in the child's care (Fig. 2.1).

Family-centered care works well in all arenas of health care, from preventive care to long-term care. Using a family-centered approach is associated with positive outcomes such as decreased anxiety, improved pain management, shorter recovery times, and enhanced confidence and problem-solving skills. Communication between the health care team and the family is also improved, leading to greater satisfaction for both health care providers and health care consumers. It is important for nurses to remain neutral to all they hear and see in order to enhance trust and maintain open communication lines with all family members. Nurses need to remember that clients are an expert of their own health, thus nurses should work within the clients' framework when planning health promotion interventions.

FIGURE 2.1. Providing an opportunity for the parent to interact with the child is an important component of family-centered nursing care.

Evidence-Based Care

Evidence-based nursing practice involves the use of research or evidence in establishing a plan of care and then implementing that care. It is a clinical decision-making approach that involves the integration of the best scientific evidence, client values and preferences, clinical circumstances, and clinical expertise to promote best outcomes (Linsley et al., 2019). It is important that nurses develop the skills and knowledge necessary to ask pertinent clinical questions, search for current best evidence, analyze the evidence, integrate the evidence into practice when appropriate, and evaluate outcomes. EBP may lead to a decrease in variations in care while at the same time increasing quality and improving health care.

Scientific research findings help nurses not only stay current in their clinical specialties, but also in their choice of the most effective interventions. Many of the professional organizations Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN),

American Nurses Association (ANA), National League for Nursing (NLN), etc. have developed evidence-based clinical practice guidelines for the safest and effective delivery of family-centered nursing care. Nurses should be diligent in seeking out these evidence-based guidelines to ensure excellence in their daily practice. When EBP is delivered in a context of caring and in a supportive organizational culture, the highest quality of care and best client outcomes can be achieved. The knowledge and skills associated with EBP are essential components of all nursing practice (Craig & Dowding, 2020).

Collaborative Care

Nurses must embrace interprofessional collaborative care because health care reform has transformed health care delivery models that require teamwork. Nurses must transition from working in a silo to working with interprofessional teams. This transition is needed to provide high-quality, safe, and accountable care to achieve positive client outcomes. Collaboration in nursing involves enhanced communication and teamwork and when incorporated into nursing care leads to increased nurse satisfaction, efficient and effective client care, increased staff communication and increased feelings of support (American Association of Critical Care Nurses [AACN], 2019). Nurses are important to improving community health because they act like “bridges” between the health care system and the people they serve (AACN, 2019). Modern health care focuses on an interdisciplinary plan of care designed to meet a client’s physical, developmental, educational, spiritual, and psychosocial needs. An example of this interdisciplinary collaborative type of care is termed case management (refer below to the discussion on discharge planner and case manager).

Atraumatic Care

Children undergo a wide range of interventions, many of which can be traumatic, stressful, and painful. The various settings where the

child receives care can be scary and overwhelming to the child and family. The child and family interact with various health care personnel, which leads to an increased potential for anxiety. A major component of the child health nursing philosophy is the importance of providing atraumatic care. **Atraumatic care** refers to the therapeutic delivery of care that minimizes or eliminates the psychological and physical distress experienced by children and their families in the health care system (Wong, 1995). The key principles of atraumatic care include the following:

- Preventing or minimizing physical stressors
- Preventing or minimizing separation of the child from the family
- Promoting a sense of control

Nurses must be alert for any situation that has the potential for causing distress and should be able to identify potential stressors. Pediatric nurses should minimize separation of the child from the family, should decrease the child's exposure to stressful situations, and should strive to prevent or minimize pain and injury. The importance of providing atraumatic care to children is integrated throughout this text and discussed in detail in Chapter 30.

Communication

Communication is a way of conveying messages to various people using a common system of symbols, signs, or behaviors. Infants start their first communication soon after birth when they cry to convey the message of discomfort or hunger. Effective therapeutic communication with women, children, and families is essential to the provision of quality atraumatic nursing care. Client- and family-centered communication increases satisfaction with nursing care and aids in improving knowledge and health care skills (Arnold & Boggs, 2020). The significance of communication revolves around its effectiveness and the climate in which communication occurs. Trust, respect, and empathy are three factors needed to create and foster effective therapeutic communication between people. (See Chapter

30 for specifics on effective communication when working with children.)

Verbal Communication

Communicating through the use of words, either written or spoken, is termed **verbal communication**. Nurses use verbal communication throughout the day when interacting with clients. Good verbal communication skills are necessary when performing nursing assessments and providing child/family teaching. General guidelines for appropriate verbal communication include the following:

- Use open-ended questions that do not restrict the child's or parents' answers.
- Redirect the conversation to maintain focus.
- Use reflection to clarify the parents' feelings.
- Paraphrase the child's or parents' feelings to demonstrate empathy.
- Acknowledge emotions.
- Demonstrate active listening by using the child's or family's own words.

Remember that most parents are laypersons, so avoid using medical jargon. The abbreviations and shortened terms that health care providers use almost without thinking may sound scary or foreign to children and parents. When medical terminology is necessary, provide a definition using developmentally appropriate language.

Nonverbal Communication

Nonverbal communication, or body language, includes attending to others and active listening. The nurse should listen to the other person's verbal communication from the beginning of the interaction. When women, children, and parents feel they are being heard, trust and rapport are established. Guidelines for appropriate nonverbal communication include the following:

- Relax; maintain an open posture, with the arms uncrossed.
- Sit opposite the family and lean forward slightly.

- Maintain eye contact.
- Nod your head to demonstrate interest.
- Note the child's or parent's posture, eye contact, and facial expressions.

TAKE NOTE!

People of all ages desire to be listened to without interruption.

Active listening is critical to the communication process. Listening may uncover fears or concerns that the nurse may not have discovered through questioning.

Paying attention while children and parents talk is a powerful communication tool. By not listening, the nurse may miss critical information and the family may be reluctant to share further. When interacting with the child and family, determine whether the messages sent by the child's or parents' verbal and nonverbal communication are congruent.

Recall Maria, who recently was discharged from the hospital with her newborn son. How did the nurse communicate with Maria? Did the nurse's actions during the visit promote the development of trust between Maria and the nurse? What might have been done differently to foster trust?

Communicating Across Cultures

In the increasingly diverse global population of today, knowing the best way to respect cultural differences is a must for nurses. Understanding and respecting the client's and family's culture helps foster good communication and improves child and family education about health care. Culture, religion, and spirituality are intertwined concepts that affect the client's and family's communication styles, health status, and health beliefs. It is important to be aware of the family's background, lifestyle, and health care practices to meet their information needs.

Learning about the practices of various cultures is just the beginning; the nurse must assess each family's individual beliefs and practices, not generalize. The best way to assess the family's cultural practices is to ask and then listen. Determine the language spoken at home and observe the use of eye contact and other physical contact. Demonstrate a caring, nonjudgmental attitude and sensitivity to the client's and family's cultural diversity.

WORKING WITH AN INTERPRETER

Attempting to communicate with a family who does not speak English can be one of the most frustrating situations in which health care providers find themselves. In this situation, trained interpreters are an invaluable aid and an essential component of client and family education. Whether working with an interpreter in person or over the phone, it is important to coordinate efforts so that both the family and the interpreter understand the information to be communicated. Working as a team, the nurse questions or informs and the interpreter conveys the information completely and accurately. Well-trained translators can also help prevent cultural missteps and can help guide the health care provider to provide information in a more culturally accepted manner; therefore the use of untrained translators, such as family members or bilingual hospital employees, is not appropriate (Levetown & American Academy of Pediatrics Committee on Bioethics, 2008, reaffirmed 2016; Martin et al., 2019). Box 2.1 presents tips for working with an interpreter to maximize teaching efforts.

BOX 2.1 Tips for Working with an Interpreter

- **Help the interpreter prepare and understand what needs to be done ahead of time.** A few minutes of preparation may save a lot of time and help communication flow more smoothly in the long run.
- **Introduce yourself to both parties.** It is the key to easy communication across the language barrier.
- **Physically place yourselves so that you are facing your client, and your client is facing you.** Place the interpreter physically close to both of you, but not in a position that breaks the line of sight between you and your client.
- **Begin with a minute or two of light conversation to establish a rhythm before getting into the business at hand.** This establishes the quantity of speech in the conversation.
- **Remember, the interpreter is the "communication bridge" and not the "content expert."** The nurse's presence at teaching sessions is vital.
- **Establish a rapport with the interpreter.**
- **Be patient. The interpreter's timing may not match that of others involved.** It often takes longer to say in some languages what has already been said in English; therefore, plan for more time than you normally would.
- **Speak slowly and clearly.** Avoid jargon. Use short sentences and be concise. Avoid interrupting the interpreter.
- **Pause every few sentences so the interpreter can translate your information.** After 30 seconds of speaking, stop and let the interpreter express the information. Talk directly to the family, not the interpreter.
- **Give the family and the interpreter a break.** Sessions that last longer than 20 or 30 minutes are too much for anyone's attention span and concentration.
- **Express the information in two or three different ways if needed.** There may be cultural barriers as well as language and dialect differences that interfere with understanding. Interpreters may often know the correct communication protocols for the family.
- **Use an interpreter to help ensure the family can read and understand translated written materials.** The interpreter can also help answer questions and evaluate learning.
- **Avoid side conversations during sessions.** These can be uncomfortable for the family and jeopardize client–provider relationships and trust.
- **Remember, just because someone speaks another language doesn't mean that he or she will make a good interpreter.** An interpreter who has no medical background may not understand or interpret correctly, no matter how good his or her language skills are.
- **Do not use children as interpreters.** Doing so can affect family relationships, proper understanding, and compliance with health care issues.

Based on Levetown, M., & American Academy of Pediatrics Committee on Bioethics. (2008, reaffirmed 2016). Communicating with children and families: From everyday

interactions to skill in conveying distressing information. Pediatrics, 121(5), e1441–e1460. https://doi.org/10.1542/peds.2008-0565

Several helpful resources and websites are listed on thePoint, including Language Line, which offers telephone interpreters who speak 150 languages, and The Center for Applied Linguistics, Northwest Translators and Interpreters Society, and others.

On the second visit to Maria's home, the nurse brought a Spanish-speaking interpreter who explained the reason for the "back to sleep" position and demonstrated to Maria several other useful positions for feeding and holding. Maria was smiling when the nurse left and asking when she would be back. What made the difference in their relationship the second visit? What interventions demonstrate culturally competent care?

COMMUNICATING WITH DEAF OR HEARING-IMPAIRED CLIENTS AND FAMILIES

Hearing loss is the second largest disability, and an invisible one. Nearly one in 10 Americans has hearing loss, and for those over the age of 65, the ratio climbs to one in three (WHO, 2019). Around 466 million people worldwide have disabling hearing loss and 34 million of these are children (WHO, 2019). Health care providers are under a duty to provide auxiliary aids and services to establish effective communication with their clients. Providing assistance to the hearing impaired in health care settings is critically important because, without assistance through auxiliary aids and services, health service providers run the risk of not understanding the client's symptoms, misdiagnosing the client's health problem, and prescribing inadequate or even harmful treatment (National Association of the Deaf [NAD], 2020).

Hearing-impaired pregnant women are often neglected mostly due to a lack of understanding of how best to care for women with different communication needs. Nurses have a key role in exchanging information and taking the time to understand their needs in order to act as an advocate and help them to overcome the barriers that can be created by deafness. In order to fulfill this role,

nurses need to have an understanding of the problems faced by women with hearing impairment and their partners when accessing maternity services (Arnold & Boggs, 2020).

For the hearing-impaired, determine the method of communication used: lip reading, American Sign Language (ASL), another method, or some combination. If the nurse is not proficient in ASL and the client or family uses it, then an ASL interpreter must be available if another adult family member is not present for translation. According to federal law (Americans with Disabilities Act), deaf clients and deaf family members must be given the ability to communicate effectively with health care providers (Martin et al., 2019; NAD, 2020).

Education

People try at every opportunity to learn skills to increase their opportunity to cope with new situations. Illness and hospitalization are two situations that increase the need for assistance and education. Due to shortened hospital stays and decreased admissions, providing client and family education is a key role for nurses. Many times, teaching begins in the primary care setting and then continues in the community setting, especially the home. In the community-based setting, client teaching is often focused on assisting the client and family to achieve independence.

Regardless of the type of setting, nurses are in a distinct position to help clients and families manage their own health care needs. Clients and families need to be knowledgeable about areas such as their condition, the health care management plan, and when and how to contact health care providers. With the limited time available in all health care arenas, nurses must focus on teaching goals and begin teaching at the earliest opportunity. Education and planning care are essential components of quality client care (Fereidouni et al., 2019).

Client education occurs when nurses share information, knowledge, and skills with clients and families, thus allowing them to take responsibility for their health care. Through client education, clients and families can overcome feeling powerless and helpless

and obtain the confidence and capability to be active members in their plan of care.

Overall, client and family education allow clients and families to make informed decisions, ensures the presence of basic health care skills, promotes recognition of problem situations, promotes appropriate responses to problems, and allows for questions to be answered. When thorough and structured education begins in the hospital setting, it can carry over into the home setting, which can decrease hospital readmissions. Verification sheets can play an important role in aiding bedside nurses to provide early formal education for clients and families being discharged home with a new device so that safe care can be achieved in the home setting (Green et al., 2020).

TAKE NOTE!

To cope effectively with illness, understand and participate in decisions about treatment plans, and maintain and improve health after treatment, clients and their families must have access to the specific knowledge and skills relevant to their conditions (Patient Safety Network, 2019).

Steps of Client and Family Education

The steps of client and family education are similar to the steps of the nursing process. The nurse must assess the client, develop a plan, implement services needed, perform follow-up evaluation, and finally document education. Once the nurse achieves a level of comfort and experience with each of these steps, they all blend together into one harmonious whole that becomes an everyday part of nursing practice. Client education begins with the first client encounter and proceeds through discharge and beyond. Reassessment after each step or change in the process is critical to ensuring success.

ASSESSING TEACHING AND LEARNING NEEDS

Excellent nursing care begins with a thorough assessment of the client. In the same way, client and family education begins with a learning needs assessment that includes the clients and family's learning needs, learning styles and preferences, and potential barriers to learning. Based on the results of the assessment, an individualized plan can be developed to reduce the time and effort required for teaching while maximizing learning for the client and family. Although actual nursing care in pediatrics is given to the child, the educational process is targeted at both the child, when developmentally appropriate, and the adult members of the family. Therefore, it is advisable to conduct a learning needs assessment on both the adult caregivers and the child, when appropriate. Box 2.2 describes the components of a learning needs assessment. This is also a good time to establish rapport with the family, demonstrating your interest in them and your confidence in their ability to learn.

Share the assessment with all members of the interdisciplinary team so that the entire team can support the client's and family's learning. Although assessment generally takes place during the first or second meeting with the client and family, it should also occur with each encounter to check for any changes that may occur.

BOX 2.2 Components of Learning Needs Assessment

Assess

- Learner characteristics: Find out more about the child and family's life and how the child's illness has affected it. Learn more about the child and family's social, cultural, and spiritual values.
- Learner needs and readiness: Including what they want and need to know and what they know already; readiness and willingness to learn; motivation to learn and emotional concerns; capacity to learn such as physical or cognitive abilities including ability to read and developmental level.
- Learning style: Determine how the child and family learn best, as well as preferred learning methods and modalities, such as audio, video, written or modeling.
- Learning barriers: Identify cultural or language barriers, cognitive or physical disabilities, presence of pain, and lack of support network.

Based on Jordan, L. M. (2016). *Healthy Literacy made Simple. The Joint Commission Accreditation Ambulatory Care*. https://www.jointcommission.org/assets/1/18/health-literacy-pcmh.pdf

BOX 2.3 Specific Learning Principles Related to Parents

- **Adults are self-directed.** Adults value independence and want to learn on their own terms. Teaching strategies that include such concepts as role playing, demonstration, and self-evaluation are most helpful. Using this model, nurses can partner with families to ensure that education is interactive and adopt the role of facilitator rather than lecturer.
- **Adults are problem-focused and task-oriented.** Adults learn best when they perceive there is a gap in their knowledge base and want information and skills to fill the gap. Providing a reason to learn can often motivate families that appear slow to comply with their child's care and education.
- **Adults are goal-oriented.** Adults learn best at a time when learning meets an immediate need. Presenting information in an organized, sequential, and timely fashion can often help families understand the importance of learning a particular piece of information or task.
- **Adults value past experiences and beliefs.** Adults bring an accumulated wealth of experiences to each health care encounter; this provides a rich base for new learning. Education should take into account a wide range of backgrounds. Appreciating and using individual differences during teaching encounters can help improve compliance and reduce resistance to educational goals.

Knowles, M. S., Holton III, E. F., & Swanson, R. A. (2015). *The adult learner: The definitive classic in adult education and human resource development* (8th ed.). Routledge.

Malcolm Knowles outlined core learning principles to consider when teaching adults (Culatta, 2020; Knowles et al., 2015). He found that instruction for adults needs to focus more on the process than on the content. Box 2.3 lists adult learner-centered principles.

CULTURAL IMPACT ON ASSESSMENT OF LEARNING NEEDS

In addition to determining the language spoken in the home and use of eye and physical contact, investigate the following during the assessment:

- Who is the person caring for the child at home?
- Who is the authority figure in the family?
- What is the social support structure?

- Are there any special dietary needs and concerns?
- Are any traditional health practices used (e.g., healers, shamans, talismans, folk remedies, and herbs)?
- Are any special clothes or other items used to help maintain health?
- What religious beliefs, ceremonies, and spiritual practices are important?

Learning needs can then be negotiated with the family and met based on the assessment. Issues encountered when teaching immigrant or refugee families might include confusion regarding the use of the English versus the metric scale; preparing formulas and medicines using a “handful” or “pinch” of ingredients rather than specific measurements such as a measuring cup or syringe; access to refrigeration for liquid antibiotics; and breastfeeding practices.

LITERACY ISSUES

The greatest barrier to understanding anything is the inability to read. Adequate literacy skills are essential for client and family education, yet many people in America today have marginal reading capabilities. In the United States, more than 36 million adults cannot read better than the average third grader (ProLiteracy, n.d.).

Even people with adequate literacy skills may have difficulty reading, understanding, and applying information to health care situations (Fig. 2.2). **Health literacy** is the ability to read, understand, and use health care information to make appropriate health care decisions and successfully navigate the health care system (Health Resources & Services Administration [HRSA], 2019). It is not simply having the ability to read the health care information, but also includes listening; displaying oral, analytic, and decision-making skills; using electronic technology; and applying these skills to health care situations. The inability to read and comprehend health care information is an enormous problem for many Americans today, with nearly half of all American adults having limited health literacy (American Academy of Pediatrics [AAP], 2020). Low health literacy affects people of all ages, races, and educational and

income levels and results in increased hospitalizations, decreased health status, and increased health costs (Weiss, 2014).

Medical information is becoming increasingly complex, while the amount of time nurses have to spend with clients is decreasing. Also, when unfamiliar information is introduced or when emotional distress is present, reading ability and understanding are further reduced. Therefore, all health care providers should use universal literacy precautions and focus on providing easy to understand information during every patient encounter.

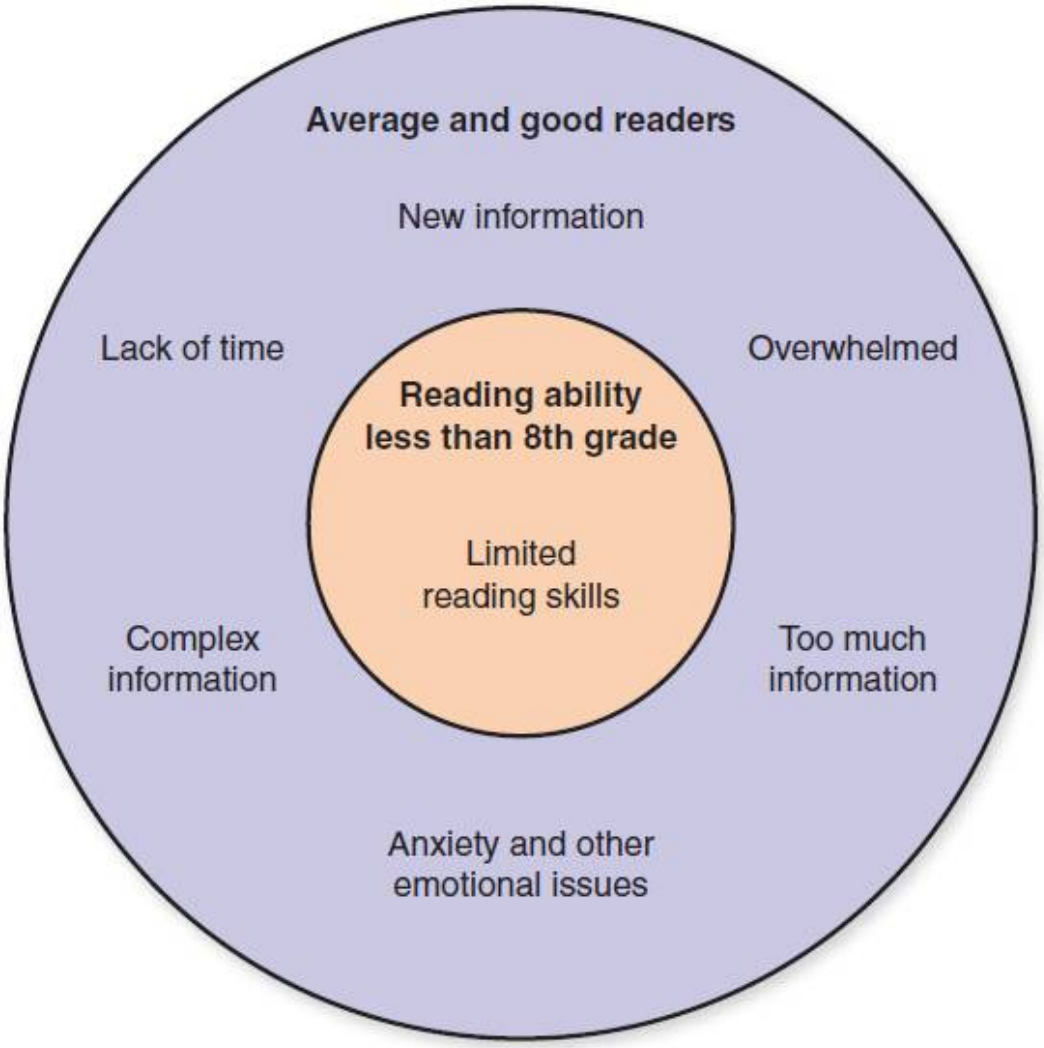

FIGURE 2.2. Factors contributing to poor health literacy.

TAKE NOTE!

Recent Federal programs, such as the Affordable Care Act of 2010, the Department of Health and Human Services' National Action Plan to Improve Health Literacy, and the Plain Writing Act of 2010 have been developed to improve health literacy (Koh et al., 2012).

Poor literacy and health literacy skills are difficult to recognize: appearance, verbal ability, employment status, and educational level cannot reliably detect person's literacy or health literacy abilities. Many people who do not read well go to great lengths to hide their disability. Poor health literacy affects all segments of the population, but certain groups such as the elderly, the poor, members of minority groups, medically underserved, and people who speak English as a second language are at a higher risk (Health Resources & Services Administration [HRSA], 2019). Red flags that might indicate poor literacy skills include the following (Davis et al., 2017; HRSA, 2019):

- Difficulty filling out registration forms, questionnaires, and consent forms; forms are incomplete, incorrect, or inaccurate.
- Frequently missed appointments
- Noncompliance and lack of follow-up with treatment regimens
- History of medication errors
- Responses such as, "I forgot my glasses" or "I'll read this when I get home"
- Inability to answer common questions about their treatment or medicines
- Avoiding asking questions for fear of looking "stupid"

Nurses need to provide understandable and accessible information to all clients, regardless of their literacy or education levels. This would include avoiding medical jargon, breaking down information or instructions into small concrete steps, limiting the focus of a visit to three key points or tasks, and assessing for comprehension. In addition, printed information should be written at or below a 5th to 6th grade reading level with plenty of visual aids or pictures (Wittenberg et al., 2018).

Planning Education

Once the assessment is completed, plan mutually agreed-upon, achievable, individualized learning goals and objectives. It is important that both the teacher and learner believe the goals can be accomplished. Finding common ground and building a bridge between the client's and family's concerns and what the health care team believes they need to know is a critical part of an education plan. This also is an excellent time to consider which client education materials and resources can be used to maximize learning and retention. No single teaching method will suit every client and family. Individualize educational methods to meet the learning needs and abilities of the audience that is being taught. Ensuring instructional methods are chosen based on educational outcomes is a key to success.

Research has shown that 40% to 80% of verbal information given during an office visit is forgotten immediately and almost half of what is retained is incorrect (Brega et al., 2015). Verbal instruction continues to be an important component of patient education but it is not always effective and should be used along with other teaching methods (Marcus, 2014). Using multiple teaching strategies, such as using videos, dolls, play therapy, or computer-based instruction along with written material, at an appropriate reading level for the general population, for future reference is beneficial. Visual aids such as pictures and illustrations are very helpful and can assist those with low literacy.

Planning client and family education should involve input from the entire interdisciplinary team when appropriate. Through good communication and collaboration, team members can work together to empower the child and family to become knowledgeable and skillful caregivers. Leaving behind the traditional path of teacher-centered education and providing family-centered education instead requires thought and skill.

Practical Interventions to Enhance Learning

The assessed needs and planned learning objectives lead to good teaching interventions. Evaluate these interventions frequently to ensure that the child and family are learning and meeting agreed-upon goals. Table 2.1 presents six techniques that can help improve learning.

The American Medical Association and the Agency for Healthcare Research & Quality (AHRQ) recommend practicing universal literacy precautions, which means delivering care as if everyone has low health literacy (Weiss, 2014).

Nurses are in an excellent position to create a “blame-free” environment and offer help. It is entirely appropriate to say to the child or family member, “Many people have a problem reading and remembering the information on this teaching sheet (booklet, manual). Is this ever a problem for you?”

TABLE 2.1 Six Techniques to Improve Learning

Technique	Explanation
Slow down and repeat information often.	Since most of the education in a health care setting is done verbally, repeat important information at least four or five times.
Speak in conversational style using plain, nonmedical language.	When writing directions, write only several words, bullet points, or phrases. Use common, “living-room-type” language containing one or two syllables whenever possible.
Group information and teach it in small amounts using logical steps.	This is especially important when there are large amounts of complex information for the family to learn. Teach for 10–15 minutes, give the learner a break, and return later to teach again.
Prioritize information and teach “survival skills” first.	Due to time constraints and multiple demands on the part of staff, coupled with the rapid turnaround times of health care encounters for clients, there never seems to be enough time to teach. Nurses must provide the client and family with the necessary information to meet their immediate needs. This may include information about the following: • The child’s medical condition • Treatment information • Why the information is important • Possible problems, adverse effects, or concerns • What to do if problems arise • Who to contact for further help, information, or supplies
Use visuals, such as pictures, videos, and models.	Use visual resources to enhance and reinforce learning when available. Drawing simple pictures and charts or using alternative methods such as color-coding often allows learning to occur for families who are having difficulty grasping information or concepts.
Teach using an interactive, “hands-on” approach.	When the learner uses hands-on practice or participates in care, learning occurs more quickly and easily. Learning first on a doll or model can ease anxiety and bolster self-confidence before actually doing care or procedures on the child.
Teach using	Show the learner how to do something, have them show

demonstration, return demonstration, and teach back, tell back.	you what they learned to do, have the learner state in their own words what they know or have learned to do.

The nurse can take several steps to enhance learning, such as:

- Draw pictures or use medical illustrations.
- Use videos.
- Color-code medications or the steps of a procedure.
- Record an audiotape.
- Repeat verbal information often and organize it into small groups.
- Teach a “back-up” family member.

Evaluating Learning

Teaching, even when done well, does not necessarily mean that learning has occurred. Evaluation of learning is critical to ensure that the client and family have actually learned what was taught. In a health care setting, perform an evaluation with each educational encounter and adjust goals and interventions accordingly. The nurse, along with the rest of the interdisciplinary team, is responsible for client and family learning. Help ensure understanding by asking for feedback and offering an opportunity for questions. Also, assessing for signs of confusion, such as increased anxiety, can help evaluate learning. If they have not learned, the health care team ensures that teaching strategies are adjusted so that the client or family does learn.

The ultimate goal of education is a change in behavior on the part of the child and family; this change can occur in their level of knowledge, skill, or both.

Evaluation can occur in several different ways, depending on the topic and the method of teaching. The child or family may:

- demonstrate a skill, often referred to as return demonstration. Learning can quickly and easily be identified using this method.
- repeat back or teach back the information using their own words.

- answer open-ended questions. Open-ended questions provide an opportunity to assess for missing or incorrect information. Open-ended questions are those that cannot be answered with a simple "yes" or "no."

Another option to evaluate learning is to provide a "pretend" scenario for the family, mentally placing them in their own home. Have them verbalize all the steps needed to care for their child, from routine care to handling an emergency situation. They will need to convey information accurately and completely as they walk through the steps necessary to provide care for their child independently at home.

Documenting Education for the Child and Family

Documenting child care and education on the medical record is part of every nurse's professional practice and serves four main purposes. First and foremost, the child's medical record serves as a communication tool that the entire interdisciplinary team can use to keep track of what the child and family has learned already and what learning still needs to occur. Next, it serves to testify to the education the family has received if and when legal matters arise. Thirdly, it verifies standards set by The Joint Commission, Centers for Medicare and Medicaid Services (CMS), and other accrediting bodies that hold health care providers accountable for child and family education activities. Finally, it informs third-party payers of goods and services provided for reimbursement purposes.

Documentation of child and family education is imperative. It is the only way to ensure that the family's educational plan and objectives have been completed and that the family is ready for discharge. Documentation of child and family education should include such topics as the following:

- The learning needs assessment
- Information on the client's medical condition and plan of care
- Goals of client education; the date goal is met
- Teaching method used and how it was received by client and family
- Medications, including drug–drug and drug–food interactions

- Modified diets and nutritional needs
- Safe use of medical equipment
- Follow-up care and community resources discussed

Client and family education play an essential role in promoting safe self-management practice. To ensure that clients and their families attain the required abilities, client and family education needs to be competency based. When developing and applying a competency-based education lesson/program, each nurse must identify essential competencies to be taught, optimal teaching methods, best method to evaluate achievement, and documentation of evidence of learning taken place (Rivers et al., 2019).

The Continuum of Care Emphasis

A “continuum of care” strategy is cost-effective and provides more efficient and effective services. This continuum extends from acute care settings such as hospitals to outpatient settings such as ambulatory care clinics, primary care offices, rehabilitative units, community care settings, long-term facilities, homes, and even schools. For example, the hospital stay is now integrated into a continuum that allows the client to complete therapy at home, school, or other community settings, while reentering the hospital for short periods for specific treatments or illnesses. Nurses play a primary role in providing better follow-up and smoother transitions from one setting to the next.

As a result of improved diagnosis and treatment, the pediatric nurse now cares for children who have survived once-fatal situations, are living well beyond the usual life expectancy for a specific illness, or are functioning and attending school with chronic disabilities. While positive and exciting, these advances and trends pose new challenges for the health care community. For example, as care for premature newborns improves and survival rates have increased, so too has the incidence of long-term chronic conditions such as respiratory airway dysfunction or developmental delays. As a result, pediatric nurses care for children at all stages along the

health–illness continuum, from well children to those who are occasionally ill to those with chronic, sometimes disabling, conditions.

Discharge Planner and Case Manager

Discharge planning involves the development and implementation of a comprehensive plan for the safe discharge of a client from a health care facility and for continuing safe and effective care in the community and at home. **Case management** focuses on coordinating health care services while balancing quality and cost outcomes along the continuum of care. Due to the short length of stays in acute settings and the shift to community settings for clients with complex health needs, discharge planning and case management have become an especially important nursing role in the community (Stanhope & Lancaster, 2020). Often clients requiring community-based care, especially home care, have complex medical needs that require an interdisciplinary team to meet their physical, psychosocial, medical, nursing, developmental, and education needs. The nurse plays an important role in initiating and maintaining the link between team members and the client to ensure that the client and family are receiving comprehensive, coordinated care. Case management is a collaborative process involving assessment, planning, implementation, coordination, monitoring, and evaluation. It involves the following components:

- Advocacy, communication, and resource management
- Facilitates the achievement of client wellness and autonomy
- Adheres to ethical, legal, and regulatory standards
- Client-focused comprehensive care across a continuum
- Coordinated care with an interdisciplinary approach (Commission for Case Management Certification, 2020)

When the nurse effectively functions in the role as a case manager, client and family satisfaction is increased, fragmentation of care is decreased, and outcome measurement for a homogeneous group of clients is possible.

(See Chapter 33 for more information on discharge planning and care coordination for the pediatric population.)

Client Advocate and Resource Manager

Client advocate is another important role of the maternity and pediatric nurse to ensure that the client's and family's needs are being met along the continuum of care. Advocacy also helps ensure that the client and family have available resources and appropriate health care services. For example, the pregnant woman on bed rest at home may need help in caring for her other children, maintaining the household, or getting to her appointments. Children with complex medical needs may require financial assistance through Medicaid or Medicaid waivers, state-run programs that use federal and state money to pay for the health care of individuals with certain medical conditions. They may also need assistance in obtaining needed equipment, additional services, and transportation. Nurses need a basic understanding of community, state, and federal resources to ensure that clients and their families have access to those necessary for them. (See Chapter 33 for more information on advocacy and resource management in the pediatric population.)

Preventative Care

The concept of prevention is a key part of maternal and pediatric nursing. The emphasis on cost reduction also led to an emphasis on preventive care and services. Anticipatory guidance is vital during each health contact with women, children, and families. Education of the family includes everything from keeping the home safe to preventing illness. The focus of health care delivery has moved beyond primary preventive health care (e.g., well-child check-ups, routine physical examinations, prenatal care, and treatment of common acute illnesses) and now encompasses secondary and tertiary care. These are the three **levels of prevention**.

Primary Prevention

It is the responsibility of all nurses to incorporate health promotion and disease prevention activities into their professional roles. The concept of primary prevention involves preventing the disease or condition before it occurs through health promotion activities, environmental protection, and specific protection against disease or injury. Its focus is on health promotion to reduce the person's vulnerability to any illness by strengthening the person's capacity to withstand physical, emotional, and environmental stressors (Wild & McGrath, 2019). It encompasses a vast array of areas, including nutrition, good hygiene, sanitation, immunizations, protection from ultraviolet rays, genetic counseling, bicycle helmets, handrails on bathtubs, drug education for school children, adequate shelter, smoking cessation, family planning, and the use of seat belts (Stanhope & Lancaster, 2020). See Figure 2.3 for examples.

Approximately 300,000 worldwide and about 3,000 children each year in the United States are born with defects of the neural tube—the part of a growing fetus that will become the brain and spinal cord—which can cause severe mental and physical disability or death (CDC, 2017). The lifetime cost to care for a child with spina bifida in the United States is estimated to be $800,000 (CDC, 2017). Prevention of neural tube defects (NTDs), such as anencephaly and spina bifida, is an example of primary prevention. The use of folic acid supplementation daily for 3 months before and 3 months after conception reduces the risk of first occurrence of an NTD. Women who get enough folic acid have more than a 50% reduced risk of having a baby with such a defect (CDC, 2017). All women of childbearing age should take 0.4-mg folic acid daily as soon as they plan to become pregnant and should continue taking it throughout the pregnancy to prevent this devastating condition. Giving anticipatory guidance to parents about poison prevention and safety during play is another example of primary prevention.

A

B

FIGURE 2.3. Levels of prevention. **A.** At the primary prevention level, the nurse provides anticipatory guidance and family teaching. **B.** At the secondary level of prevention, a woman undergoes a mammography screening for early detection of breast problems. **C.** At the tertiary level of prevention, a child with a developmental disability participates in a rehabilitation program.

Secondary Prevention

Secondary prevention is the early detection and treatment of adverse health conditions. This level of prevention is aimed at halting the disease, thus shortening its duration and severity to get the person back to a normal state of functioning. Health screenings are the mainstay of secondary prevention. Pregnancy testing, blood pressure evaluations, cholesterol monitoring, fecal occult blood testing, breast examinations, mammography screening,

colonoscopies for early detection of colon cancer, hearing and vision examinations, and Papanicolaou (Pap) smears are examples of this level of prevention. Such interventions do not prevent the health problem but are intended for early detection and prompt treatment to prevent complications (Kisling & Das, 2019). If the health condition cannot be cured and further complications and disability moves in, then the tertiary level of prevention is needed.

Tertiary Prevention

Tertiary prevention is designed to reduce or limit the progression of a permanent, irreversible disease or disability. It targets both the clinical and outcome stages of a disease. The purpose of tertiary prevention is to restore individuals to their maximum potential (Nies & McEwen, 2019). Tertiary intervention takes place only if the condition results in a permanent disability. Tertiary prevention measures are supportive and restorative. For example, tertiary prevention efforts would focus on minimizing and managing the effects of a chronic illness such as cerebrovascular disease or the chronic effects of sexually transmitted infections (e.g., herpes, human immunodeficiency virus [HIV], and untreated syphilis). Another example would involve working with women who have suffered long-term consequences of violence. Client education is the cornerstone of all disease management programs. The focus of the nurse would be to maximize the woman's strengths through education, to help her recover from the trauma and loss, and to build support systems.

The Nurse's Role in Preventive Care

Applying scientific principles to prevent disease and disability is basic to nursing practice. All health professionals have a special role in health promotion, health protection, and disease prevention. Much of nursing involves prevention, early identification, and prompt treatment of health problems and monitoring for emerging threats that might lead to health problems. Nurses provide health care for

women and children at all three levels of prevention. This care often involves advocacy for services to meet their needs.

Culturally Competent Nursing Care

The United States contains an ever-changing mix of cultural groups. More than 44 million immigrants reside in the United States or about one in seven residents is foreign born (Migration Policy Institute, 2019). The Migration Policy Institute (2019) reports that immigrants accounted for 13.7% of the total 327 million U.S. residents; adding in the U.S.-born children (of all ages) of immigrants means that approximately 90 million people, or one quarter of the overall U.S. population, is either of the first or second generation. This population is made up of numerous diverse cultural backgrounds arriving from every corner of the world into our country daily.

TAKE NOTE!

Over a million immigrants come to the United States each year, and more than half are of childbearing age. By the year 2060, 17% of the nation's population will be comprised of immigrants (Camarota & Zeigler, 2019).

This growing diversity has significant implications for the health care system. For years nurses have struggled with the issues of providing optimal health care that meets the needs of women, children, and their families from varied cultures and ethnic groups. In addition to displaying competence in technical skills, nurses must also become competent in caring for clients from varied ethnic and racial backgrounds. Adapting to different cultural beliefs and practices requires flexibility and acceptance of others' viewpoints. Nurses must listen to clients and learn about their beliefs about health and wellness. To provide culturally appropriate care to diverse populations, nurses need to know, understand, and respect culturally influenced health behaviors. Chapter 1 provides a more detailed

discussion of culture and its impact on the health of women, children, and families.

Nurses must research and understand the cultural characteristics, values, and beliefs of the various people to whom they deliver care so that false assumptions and stereotyping do not lead to insensitive care. Time orientation, personal space, family orientation (patriarchal, matriarchal, or egalitarian), and language are important cultural concepts. Although the location might be different in community-based care, these principles apply to both inpatient and outpatient settings. Utilizing **cultural humility** requires nurses to step outside of themselves to be open to other people's identities, in a way that acknowledges their authority over their own experiences.

Nurses should possess an understanding of the perspectives, traditions, values, practices, and family systems of culturally diverse individuals, families, communities, and populations for whom they provide care, as well as knowledge of the complex variables that affect the achievement of health and well-being (U.S. Department of Health and Human Services Office of Minority Health [USDHHSOMH], 2019). **Cultural competence** is a dynamic process during which nurses obtain and then apply cultural information. Cultural humility goes much deeper than cultural competence because the nurse reverses roles and learns from the client about their diverse culture. Nurses must look at clients through their own eyes and the eyes of clients and family members. Nurses must develop nonjudgmental acceptance of cultural differences in clients, using diversity as a strength that empowers them to achieve mutually acceptable health care goals. Nurses must integrate their client's cultural beliefs and practices into health prescriptions to eliminate or mitigate health disparities and provide client satisfaction. Cultural competence and humility are a dynamic, lifelong learning process. Understanding the process for assessing cultural patterns and factors that influence individual and group differences is critical in preventing overgeneralization and stereotyping. A new term has been coined–*cultural competemility*–which blends the terms cultural competence and cultural humility. It is defined as the synergistic process between cultural humility and cultural competence in which

humility permeates each of the five components of cultural competence (Campinha-Bacote, 2019). This cultural awareness allows nurses to see the entire picture and improves the quality of care and health outcomes (Box 2.4). Cultural competence or humility do not appear suddenly; they must be developed through a series of steps.

CONSIDER THIS

Our medical mission took a team of nurse practitioners into the rural mountains of Guatemala to offer medical services to people who had never had any. One day, a distraught mother brought her 10-year-old daughter to the mission clinic, asking me if there was anything I could do about her daughter's right wrist. She had sustained a wrist fracture a year ago and it had not healed properly. As I looked at the girl's malformed wrist, I asked if it had been splinted to help with alignment, knowing what the answer was going to be. The interpreter enlightened me by saying that this young girl would never marry and have children because of this injury. I appeared puzzled at the interpreter's prediction of this girl's future. It was later explained to me that if the girl couldn't make tortillas from corn meal for her husband because of her wrist disability, she would not be worthy of becoming someone's wife and thus would probably live with her parents the rest of her life.

I reminded myself during the week of the medical mission not to impose my cultural values on the women for whom I was caring and to accept their cultural mores without judgment. These silent self-reminders served me well throughout the week, for I was open to learning about their lifestyles and customs.

Thoughts: What must the young girl be feeling at the age of 10, being rejected for a disability that wasn't her fault? What might have happened if I had imposed my value system on this client? How effective would I have been in helping her if she didn't feel accepted? This incident ripped my heart out, for this young girl will be deprived of a fulfilling family life based on a wrist disability. This is just another example of female suppression that happens all over the world—such a tragedy—and yet a part of their culture, on which nurses should not pass judgment.

Barriers to Cultural Competemility

Illness is culturally shaped in the sense that how we perceive, experience, and cope with disease is based upon our explanations of sickness. Awareness of how this might be of influence—instead of

mere knowledge about the cultural practices or beliefs of specific ethnic groups—and an appreciation of this factor helps nurses deal effectively with cultural issues (Christensen, 2019). When a health care provider lacks knowledge of a client's cultural practices and beliefs or when the provider's beliefs differ from those of the client, the provider may be unprepared to respond when the client makes unexpected health care decisions. System-related barriers can occur if agencies, that have not been designed for cultural diversity, want all clients to conform to the established rules and regulations and attempt to fit everyone into the same mold.

Cultural competemility does not mean replacing one's own cultural identity with another, ignoring the variability within cultural groups, or even appreciating the cultures being served. Instead, nurses skilled at cultural competemility show a respect for difference, an eagerness to learn, and a willingness to accept multiple views of the world. Much of the process of developing cultural competemility involves a reexamination of our values and the influence of these values on our beliefs, which affect our attitudes and actions. At the core of both client centeredness and cultural competemility is the importance of seeing the client as a unique person. It involves letting go of assumptions about an individual based on their culture and creating space for learning who they are as a person—in other words, experience their own ethos (Shepherd et al., 2019). It is important for all nurses to incorporate the client's traditional healing and health practices with conventional medicine by asking such questions as: Do you have treatment preferences you would like me to include in your care plan? Some clients may prefer certain foods or drinks when they are ill. In addition, during fasting and religious seasons, diets may be different and need to be considered during the process of determining the appropriate course of treatment. Some may have a different idea of what caused the illness. Spirituality, culture, and experience may have a significant role in the client's understanding and treatment of the illness.

BOX 2.4 Steps to Developing Cultural Competence and Humility

1. Cultural Self-Awareness
   - Become aware of, appreciate, and become sensitive to the values, beliefs, customs, and behaviors that have shaped one's own culture.
   - Engage in self-exploration beyond one's own culture and "see" clients from different cultures.
   - Health care has a multicultural environment.
   - Practice self-reflection of your own identity.
   - Cultural diversity is awareness of the presence of differences among clients.
   - Examine personal biases and prejudices toward other cultures.
   - Become aware of differences in personal and clients' backgrounds.
2. Cultural Knowledge
   - Obtain knowledge about various worldviews of different cultures, such as through reading about different cultures, attending continuing education courses on different cultures, accessing websites, and attending cultural diversity conferences.
   - Become familiar with culturally/ethnically diverse groups, worldviews, beliefs, practices, lifestyles, and problem-solving strategies.
3. Cultural Skills
   - Learn how to perform a competent cultural assessment.
   - Ask each client about their identity first before starting any interaction.
   - Assess each client's unique cultural values, beliefs, and practices without depending solely on written facts about specific cultural groups.
   - Embracing ethics empowers mutual respect, equality, and trust.
4. Cultural Encounter
   - Listen more than you speak.
   - Engage in cross-cultural interactions with people from culturally diverse backgrounds, such as attending religious services or ceremonies and participating in important family events.
   - Participate in as many cultural encounters as possible to avoid cultural stereotyping.

Cultural competemility: A paradigm shift in the cultural competence verses cultural humility debate. Online Journal of Issues in Nursing, 24(1). DOI:10.3912/OJIN.Vol24No01PPT20

Complementary and Alternative Medicine

In recent years, complementary and alternative medicine (CAM) has become more widely used, and socially and politically accepted in the United States. The federal government formed the National Center for Complementary and Integrative Health (NCCIH) to conduct and support research and education and to provide information on CAM to health care providers and the public. The use of CAM is not unique to a specific ethnic or cultural group: interest in CAM therapies continues to grow nationwide and will affect care of many clients. People from all walks of life and in all areas of the community use CAM. Overall, CAM use is seen more in women than men, and in people with higher educational levels. In the United States, approximately 38% of adults (about four in 10) and approximately 12% of children (about one in nine) are using some form of CAM (NCCIH, 2019). It is well known that CAM, including homeopathy, acupuncture, phytotherapy, hypnosis, and hydrotherapy, is also being used increasingly by midwives for childbirth (King et al., 2019).

CAM includes diverse practices, products, and health care systems that are not currently considered to be part of conventional medicine, such as yoga, meditation, and chiropractors (NCCIH, 2019). *Complementary* medicine is used together with conventional medicine, such as using aromatherapy to reduce discomfort after surgery or to reduce pain during a procedure or during early labor. *Alternative* medicine is used in place of conventional medicine, such as eating a special natural diet to control nausea and vomiting or to treat cancer instead of undergoing surgery, chemotherapy, or radiation that has been recommended by a conventional doctor. *Integrative* medicine combines mainstream medical therapies and CAM therapies for which there is some scientific evidence of safety and effectiveness. These include acupuncture, reflexology, therapeutic touch, meditation, yoga, herbal therapies, nutritional supplements, homeopathy, naturopathic medicine, and many more used for the promotion of health and well-being (Micozzi, 2019).

The philosophy of integrative medicine focuses on treating the whole person, not just the disease. The goal is to treat the mind, body, and spirit all at the same time. History has taught us that in

science application of the results is never determined by a single study, but by the weight of the evidence. It is right that medicine rests upon a foundation that begins with good clinical observations, case reports, and careful interpretations. Replication across scientists, which is the true hallmark of valid science, establishes whether those clinical observations are important and perhaps applicable. While some of the therapies used are nonconventional, a guiding principle within integrative medicine is to use therapies that have some high-quality evidence to support them (Simon, 2019). Integrative medicine combines conventional Western medicine with complementary treatments—all in the effort to treat the whole person. The nurse should avoid judgment and encourage the family to research all approaches that are evidence based that support healthy outcomes. Table 2.2 describes selected CAM therapies and treatments.

TABLE 2.2 Selected Complementary and Alternative Therapies

Therapy	Description
Aromatherapy	Use of essential oils to stimulate the sense of smell for balancing mind, body, and spirit
Homeopathy	Based on the theory of "like treats like"; helps restore the body's natural balance
Acupressure	Restoration of balance by pressing an appropriate point so self-healing capacities can take over
Feng shui (pronounced *fung shway*)	The Chinese art of placement. Objects are positioned in the environment to induce harmony with chi
Guided imagery	Use of consciously chosen positive and healing images along with deep relaxation to reduce stress and to help people cope
Reflexology	Use of deep massage on identified points of the foot or hand to scan and rebalance body parts that correspond with each point
Therapeutic touch	Balancing of energy by centering, invoking an intention to heal, and moving the hands from the head to the feet several inches from the skin
Herbal medicine	The therapeutic use of plants for healing and treating diseases and conditions
Spiritual healing	Praying, chanting, presence, laying on of hands, rituals, and meditation to assist in healing
Chiropractic therapy	Aimed at removing irritants to the nervous system to restore proper function—spinal manipulation done for musculoskeletal complaints
Massage therapy	Therapeutic stroking or kneading of the body to decrease pain, produce relaxation, and/or to improve circulation to that body part

Adapted from Lindquist, R., Tracy, M. F., & Snyder, M. (2018). *Complementary and alternative therapies in nursing* (8th ed.). Springer Publishing Company; Micozzi, M. S. (2019). *Fundamentals of complementary, alternative, and integrative medicine* (6th ed.). Saunders Elsevier; and National Center for Complementary

and Integrative Health (NCCIH). (2019). *The use of complementary and alternative medicine in the United States*. https://www.nccih.nih.gov/

The theoretic underpinnings of complementary and alternative health practices propose that health and illness are complex interactions of the mind, body, and spirit. It is then surmised that many aspects of clients' health experiences are not subject to traditional scientific methods. This field does not lend itself readily to scientific study or to investigation and therefore is not easily embraced by many hard-core scientists (Micozzi, 2019). Much of what is considered to be alternative medicine comes from the Eastern world, folk medicine, and religious and spiritual practices. There is no unifying basic theory for the numerous treatments or modalities, except (as noted previously) that health and illness are considered to be complex interactions among the body, mind, and spirit.

Because of heightened interest in complementary treatments and their widening use, anecdotal efficacy, and growing supporting research evidence, nurses need to be sensitive to and knowledgeable enough to answer many of the questions clients ask and to guide them in a safe, objective way (Lindquist et al., 2018). Nurses have a unique opportunity to provide services that facilitate wholeness. They need to understand all aspects of CAM, including costs, client knowledge, and drug interactions, if they are to promote holistic strategies for clients and families. With all of the enthusiasm in favor of CAM therapies, nurses must not forget their obligation to embrace the principles of EBP and critical evaluation before being misled into therapies that have no scientific basis to justify their use.

The growing use of complementary and alternative therapies during pregnancy and childbirth could be interpreted as a response by women regarding a need for autonomy and active participation in their health care during this time. Studies show that massage, acupuncture, vitamins, and herbs are the most frequently applied methods during pregnancy. In a recent study, only half of the pregnant women revealed their use of CAM to their health care provider during their prenatal visits (Jordan et al., 2019).

Many clients who use complementary or alternative therapies do not reveal this fact to their health care provider. Therefore, one of the nurse's most important roles during the assessment phase of the nursing process is to encourage clients to communicate their use of these therapies to eliminate the possibility of harmful interactions and contraindications with current medical therapies. When assessing clients, ask specific questions about any nonprescription medications they may be taking, including vitamins, minerals, or herbs. Clients should also be asked about any therapies they are taking that have not been ordered by their primary health care provider.

When caring for clients and their families who practice CAM, nurses need to:

- be culturally sensitive to nontraditional treatments.
- acknowledge and respect different beliefs, attitudes, and lifestyles.
- keep an open mind, remembering that standard medical treatments do not work for all clients.
- accept CAM and integrate it if it brings comfort without harm.
- provide accurate information, not unsubstantiated opinions.
- advise clients how they can best monitor their condition using CAM.
- discourage practices only if they are harmful to the client's health.
- instruct the client to weigh the risks and benefits of CAM use.
- avoid confrontation when asking clients about CAM.
- be reflective, nonjudgmental, and open-minded about CAM.

The use of complementary therapies is widespread, especially by women desiring to alleviate the nausea and vomiting of early pregnancy. Ginger powder or tea, Sea-Bands (acupressure), hypnosis, and vitamin B6 are typically used to treat morning sickness (Cunningham et al., 2018). Although these may not cause any ill effects during the pregnancy, most substances ingested cross the placenta and have the potential to reach the fetus, so nurses should stress to all pregnant women that it is better to be cautious when using CAM.

Women at risk for osteoporosis are seeking alternatives to menopausal hormone therapy since the Women's Health Initiative

(WHI) study raised doubts about the benefit of estrogen. Some of the alternative therapies for osteoporosis include soy isoflavones, progesterone cream, magnet therapy, tai chi, mindfulness meditation, yoga, and hip protectors (NCCIH, 2018). In addition, menopausal women may seek CAM therapies for hot flashes. Once again, despite many claims, most of these therapies have not undergone scientific testing and thus could place the woman at risk.

If clients are considering the use of or using CAM therapies, suggest they check with their health care provider before taking any "natural" substance. Offer clients the following instructions:

- Do not take for granted that because a substance is a natural herb or plant product, it is beneficial or harmless.
- Seek medical care when ill.
- Find out the education and credentials of the person suggesting this therapy.
- Always inform the provider if you are taking herbs or other therapies.
- Seek out the findings of scientific studies that validate that therapy's effectiveness.
- Be suspicious of any treatment that says it does not have any side effects.
- Be sure that any product package contains a list of all ingredients and amounts of each.
- Be aware of any treatment that says it can "cure" a difficult to treat disease/condition.
- Be aware that frequent or continual use of large doses of a CAM preparation is not advisable, and harm may result if therapies are mixed (e.g., vitamin E, garlic, and aspirin all have anticoagulant properties).
- Research CAM through resources such as books, websites, and articles (Micozzi, 2019).

All nurses, especially nurses working in the community, must educate themselves about the pros and cons of CAM and be prepared to discuss and help their clients make sense of it all. Expanding our consciousness by understanding and respecting diverse cultures and CAM will enable nurses to provide the best

treatment for clients and their families receiving community-based care. Clients in any setting expect nurses to initiate communication on CAM. Providing clients in the community with evidence-based counseling about CAM is essential for improving client safety and better outcomes.

The Nursing Process

The maternal and pediatric nurse performs all of these tasks using the framework of the nursing process. The nursing process is used to care for the woman, child and family during health promotion, maintenance, restoration, and rehabilitation. It is a problem-solving method based on the scientific method that allows nursing care to be planned and implemented in a thorough, organized manner to ensure quality and consistency of care. The nursing process is applicable to all health care settings and consists of five steps: assessment, nursing analysis (diagnosis), outcome identification and planning, implementation, and outcome evaluation.

1. Assessment. Assessment involves collecting data about the woman, child and family and performing physical assessment during community-based health services, at admission to an acute care setting, at periodic times during the child's hospitalization or care, and during home care visits.
2. Analysis. The nurse analyzes the assessment data to make judgments about the woman's or child's health and developmental status. From this analysis, the nurse develops a list of client issues, concerns, problems, opportunities, or nursing analyses, which differ from medical diagnoses in that they are issues the nurse can address within their scope of practice. This clinical judgment process describes health promotion and health patterns that maternal and pediatric nurses can manage.
3. Planning and expected outcomes. The next step in the process involves developing a plan of care that incorporate goals or expected outcomes that improve the woman's or child's dysfunctional health patterns, promote appropriate health patterns, or provide for optimal developmental outcomes. The plan of care

includes the specific nursing actions that assist in obtaining the outcomes.

4. Implementation. These interventions are implemented, adapted to the child's developmental level and family status, and modified if the woman's or child's response indicates the need. The care plan incorporates the family in addition to the woman or child.
5. Evaluation. The process is continually evaluated and updated during the partnership with the woman, child and family.

Concept Mastery Alert

Assessment

When prioritizing care for children who witnessed a traumatic incident, the nurse must remember that assessment is the first step in the nursing process.

Standardized care plans for specific nursing analyses/client issues or concerns and critical pathways for case management are often used in various maternal and pediatric settings. In general, care plans and critical pathways are becoming more evidence based, using a combination of research, group consensus, and past health care decisions to identify the most effective interventions for the woman, child and family. Evidence-based care planning systems or tools can help bring EBPs to the point of care. These templates can help improve the quality of patient care. The nurse is responsible for individualizing these standardized care plans based on the data collected during the assessment of the woman or child and family and for evaluating the woman's or child's and family's response to the nursing interventions.

Standards of Care and Performance

In any role, the professional nurse is held accountable for nursing actions that adhere to the standards of care. A standard of care is a minimally accepted action expected of an individual of a certain skill or knowledge level and reflects what a reasonable and prudent person would do in a similar situation. Professional standards from

regulatory agencies, state or federal laws, nurse practice acts, and other specialty groups regulate nursing practice in general.

American Nurses Association (ANA), the National Association of Pediatric Nurse Practitioners (NAPNAP), and the Society of Pediatric Nurses (SPN) (2015) have formulated specific standards of care and professional performance for pediatric clinical nursing practice. Standards of Practice include assessment, diagnosis/analysis, outcome identification, planning, implementation, and evaluation (refer to Nursing Process section above for a description of these standards). Standards of professional performance include ethics, education, EBP and research, quality of practice, communication, leadership, collaboration, professional practice evaluation, resource utilization, environmental health, and advocacy.

The AWHONN updated their *Standards for Professional Nursing Practice in the Care of Women and Newborns* in 2019. These standards include assessment, diagnosis/analysis, outcomes, planning, implementation, evaluation (refer to Nursing Process section above for a description of these standards), ethics, culturally congruent practice, communication, collaboration, leadership, education, EBP and research, quality of practice, professional practice evaluation, resource utilization, and environmental health.

These standards are tools that determine if care constitutes adequate, effective, and acceptable nursing practice. They also serve as guides and legal measures for this special area of practice. These standards promote consistency in practice, provide important guidelines for care planning, assist with the development of outcome criteria, and ensure quality nursing care. The ANA–SPN standards specify what is adequate and effective for general pediatric nursing and promote consistency in practice.

Based on the Institute of Medicines competencies for nursing, Quality and Safety Education for Nurses (QSEN) initiatives were developed to be integrated into nursing education. These quality and safety initiatives or competencies help nurses improve the quality and safety of our health care system. Go to thePoint to find QSEN standards mapped to this textbook. National Patient Safety Goals (NPSG) have also been developed by The Joint Commission to

address specific areas of concern regarding patient safety and to help accredited organizations improve patient safety (Joint Commission, 2020). The goals focus on problems that have been identified in health care safety and ways to solve them. Throughout the text, look for the Focus on Safety boxes to learn about pertinent safety goals. Nurses need to understand these competencies and goals and utilize them to improve the quality and safety of their nursing practice.

COMMUNITY-BASED CARE

Community may be defined as a specific group of people, often living in a defined geographical area, who share common interests, who interact with each other, and who function collectively within a defined social structure to address common concerns (Stanhope & Lancaster, 2020). The common features of a community may be common rights and privileges as members of a certain city or common ties of identity, values, norms, culture, language, or social support. Women are caregivers to children, parents, spouses, and neighbors and provide important social support in these roles. The child's community consists of the family, school, neighborhood, youth organizations, and other peer groups.

A person can be a part of many communities during the course of daily life. Examples might include area of residence (home, apartment, shelter), gender, place of employment (organization or home), language spoken (Spanish, Chinese, English), educational background or student status, culture (Italian, African American, Indian), career (nurse, businesswoman, housewife), place of worship (church or synagogue), and community memberships (garden club, YMCA, support group, school PTA, youth organizations, athletic teams).

A **population** is a group of people who share personal or environmental characteristics. Typically, the most common characteristic is geographic location. Populations are made up of human beings within complex social and physical environments. The

betterment of human populations remains the goal of community-based nursing care.

In community-based care, the community is the unit of service. The providers of care are concerned not only with the clients who present for service but also with the larger population of potential or at-risk clients.

Community Health Nursing

Community health nursing focuses on preventing illness and improving the health of populations and communities. Community health nurses work in geographically and culturally diverse settings. They address current and potential health needs of the population or community. They promote and preserve the health of a population and are not limited to particular age groups or diagnoses. Public health nursing is a specialized area of community health nursing.

Epidemiology, the study of the causes, distribution, and control of disease in populations, can help determine the health and health needs of a population and assist in planning health services. Community health nurses perform epidemiologic investigations to help analyze and develop health policy and community health initiatives. Community health initiatives can be focused on the community as a whole or a specific target population with specific needs. *Healthy People 2030* (HP 2030) is an example of national health initiatives developed using the epidemiologic process. HP 2030 ensures that health care professionals evaluate the individual as well as the community. It addresses the link between the individual's health and the health of the community. Nurses play a key role in the health of a community and the individuals who reside in it.

HP 2030 is the fifth edition of national health goals, which were launched in 1979. HP 2030 is a comprehensive health initiatives plan. Nurses can help the nation meet these objectives by educating those in the community on appropriate prevention strategies, such as proper immunization and smoking cessation (see individual chapters for relevant HP objectives and nursing implications). HP

2030 is available online at https://www.healthypeople.gov. Refer to Chapter 1 for more information.

The focus of health care initiatives today is on people and their needs, strengthening their abilities to shape their own lives. The emphasis has shifted away from dependence on health professionals toward personal involvement and personal responsibility, and this gives nurses the opportunity to interact with individuals in a variety of self-help roles. Nurses in the community can be the primary force in identifying the challenges and implementing changes in women's and children's health for the future.

Community-Based Nursing

Community nursing has changed in response to a shift in care from hospitals to home or clinics, brought about by increasing costs to care for an aging population and increasing disease chronicity. Chronic conditions and health inequalities are increasing worldwide. Against this backdrop, the roles of nurses have expanded to strengthen the primary care workforce. The health needs of the society and consumer demand brought about community-based and community-focused services. The movement from an illness-oriented "cure" perspective in hospitals to a focus on health promotion and primary health care in community-based settings has dramatically changed employment opportunities for today's nurses.

This shift in emphasis to primary care and outpatient treatment and management will likely continue. As a result, employment growth in a variety of community-based settings can be expected for properly educated nurses. Community nurses need to be flexible, autonomous, able to adapt care in a community setting, and have a diversity of knowledge and skills to employ.

The Bureau of Labor Statistics, U.S. Department of Labor, Occupational Employment Statistics (2020) found the following trends in registered nurse (RN) employment settings:

- 60% of RNs work in the hospital setting.
- 33% work outside the hospital setting in community-based settings.

- The number of RNs employed in community-based settings has continued to grow largely due to an increase in nurses working in home health care and managed care organizations.

Shift in Responsibilities from Hospital-Based to Community-Based Nursing

Over the past century, changes in health care such as strained health care funding, shorter hospital stays, and cost containment, have led to a shift in responsibilities of care for women and children from the hospital to homes and communities. Many nurses find the shift from acute care nursing to a community setting challenging. Community care, especially home care, is a rapidly growing service in the United States. Nurses play an important role in the treatment and care of clients in the community and need to collaborate with acute care nurses to integrate appropriate community interventions along the continuum of care (Nies & McEwen, 2019). Community-based care has been shown to be a cost-effective method for providing care. It emphasizes wellness and prevention. An increase in disposable income and the increased longevity of people with chronic and debilitating health conditions have also contributed to the continued shift of health care to the community and home setting. Technology has advanced, allowing for improved monitoring of clients in community settings and at home as well as allowing complicated procedures to be done at home, such as intravenous administration of antibiotics, telehealth surveillance, and renal dialysis. Wearable technology, such as a smart watch paired with a smart phone can help assess the well-being of clients in their homes (Frith, 2019).

Another major reason for the increase in community care of children, especially home care, is the understanding that an acute care setting is not an ideal environment for children's development. Caring for children at home and within their community not only improves their physical health but also allows for adequate growth and development while keeping them within their family. When they

are in a familiar environment with the comfort and support of family, there is a better opportunity for improved care and quality of life.

Community-based nursing settings include ambulatory care, home health care, occupational health, school health, and hospice settings (Table 2.3). Clinical practice within the community may also include case management, research, quality improvement, and discharge planning. Nurses with advanced practice and experience may be employed in areas of staff development, program development, and community education.

Community-Based Nursing Interventions

Nursing interventions involve any treatment that the nurse performs to enhance the client's outcome. Nursing practice in the community uses the nursing process and is similar to that in the acute care setting, because assessing, performing procedures, administering medications, coordinating services and equipment, counseling clients and their families, and teaching about care are all part of the care administered by nurses in the community. See Evidence-Based Practice 2.1. Box 2.5 highlights the most common nursing interventions used in community-based nursing practice.

TABLE 2.3 Community-Based Practice Settings

Setting	Description
Ambulatory care	Doctor's offices settings Health maintenance organizations (HMOs) Day surgery centers Freestanding urgent care centers Family planning clinics Birth Centers Mobile mammography centers
Home health care services	High-risk pregnancy/neonate care Maternal/child newborn care Skilled nursing care Hospice care
Health Department services	Maternal/child health clinics Family planning clinics Sexually transmitted infection programs Immunization clinics Substance abuse programs Jails and prisons
Long-term care	Skilled nursing facilities Nursing homes Hospices Assisted living
Other community-based settings	Parish nursing programs Summer camps Childbirth education programs School health programs Occupational health programs

Community-Based Nursing Challenges

Despite the benefits achieved by caring for families in their own homes and communities, challenges also exist. Clients are being discharged from acute care facilities very early in their recovery

course and present with more health care needs than in the past. As a result, nursing care and procedures in the home and community are becoming more complex and time-consuming. Consider the example of a woman who developed a systemic infection, a pelvic abscess, and deep vein thrombosis in her leg after a cesarean birth who is being discharged from the hospital. The nurse's primary focus of care in this situation would be to administer heparin and antibiotics intravenously rather than educating her about child care and follow-up appointments. In the past, this woman would have remained hospitalized for treatment, but home infusion therapy is now less costly and allows the client to be discharged sooner.

This demand on the nurse's time may limit the amount of time spent on prevention measures, education, and the family's psychosocial issues. More time may be needed to help families deal with these issues and concerns. With large client caseloads, nurses may find it difficult to spend the time needed while meeting the time restrictions dictated by their health care agencies. Nurses need to plan the tasks to be accomplished (Box 2.6).

Nurses working in the community have fewer resources available to them compared with the acute care setting. Decisions often have to be made in isolation. The nurse must possess excellent assessment skills and the ability to communicate effectively with the family to be successful in carrying out the appropriate plan of care.

Nurses interested in working in community-based settings must be able to apply the nursing process in an environment that is less structured or controlled than that associated with acute care facilities. Nurses must be able to assimilate information well beyond the immediate physical and psychosocial needs of the client in a controlled acute care setting and deal with environmental threats, lifestyle choices, family issues, different cultural patterns, financial burdens, transportation problems, employment hazards, communication barriers, limited resources, and client acceptance and compliance.

EVIDENCE-BASED PRACTICE 2.1 A Practice-Based Research Database to Study Perinatal Nurse Home Visiting to Pregnant Women with Diabetes

STUDY

Diabetes is a global epidemic and the increasing number of births impacted by hyperglycemia of the mother during pregnancy is causing perinatal morbidity and mortality. Suboptimal glucose control during pregnancy places the health of the woman and her unborn fetus at increased risk. The negative impacts of hyperglycemia on the woman include infections, periodontal disease, hypertension, preeclampsia, birth injuries, and potential of a surgical birth. The fetal exposure to high glucose levels include the risk of preterm birth, congenital anomalies, neonatal hypoglycemia, childhood and adult obesity and type 2 diabetes. This was a descriptive study based on retrospective data collected from 248 perinatal home visit clinical records. Perinatal nurse home visiting can optimize diabetes self-care to improve perinatal outcomes.

Findings

The data collected from the home visits provided a valuable source to validate the clinical role of the perinatal nurse caring for complex medically and socially high-risk pregnant women. The impact on the pregnant women visited was important in reducing perinatal complications.

Nursing Implications

It is important to remember that home visiting is not a single or uniform intervention—it is a mechanism for the delivery of a

variety of interventions directed at different outcomes. Tailoring to the populations served, nurse's home visiting programs are diverse in their goals, based on their target recipient's needs and preferences. Nursing interventions in the community can meet the physiological, psychosocial, and environmental needs of medically high-risk childbearing women with diabetes to optimize their health outcomes.

A practice-based research database to study perinatal nurse home visiting to pregnant women with diabetes. Worldviews on Evidence-Based Nursing, 16(1), 60–69. https://doi.org/10.1111/wvn.12340

BOX 2.5 Community-Based Nursing Interventions

- Health screening—detecting unrecognized or preclinical illness among individuals so they can be referred for definitive diagnosis and treatment (e.g., mammogram or Pap smear, well-child vision, and hearing checks).
- Health education programs—assisting clients in making health-related decisions about self-care, use of health resources, and social health issues such as smoking bans and motorcycle helmet laws (e.g., childbirth education or breast self-examination, child safety programs, poisoning prevention, youth drug awareness programs).
- Medication administration—preparing, giving, and evaluating the effectiveness of prescription and over-the-counter drugs (e.g., hormone replacement therapy in menopausal women, childhood immunizations).
- Telephone consultation—identifying the problem to be addressed; listening and providing support, information, or instruction; documenting advice/instructions given to concerns raised by caller (e.g., consultation for a mother with a newborn with colic, interaction with a parent whose child has a fever or is vomiting).
- Health system referral—passing along information about the location, services offered, and ways to contact agencies (e.g., referring a woman for a breast prosthesis after a mastectomy, arranging for home tutoring for a child with a long-term illness).
- Instructional—teaching an individual or a group about a medication, disease process, lifestyle changes, community resources, or research findings concerning their environment (e.g., childbirth education class, basic life support classes for parents, child safety education classes).
- Nutritional counseling—demonstrating the direct relationship between nutrition and illness while focusing on the need for diet modification to promote wellness (e.g., Women, Infants, and Children [WIC] program; counselor interviewing a pregnant woman or a child and parents who have anemia; eating disorders program).
- Risk identification—recognizing personal or group characteristics that predispose people to develop a specific health problem, and modifying or eliminating them (e.g., genetic counseling of an older pregnant woman at risk for a Down syndrome infant; genetic screening of family members for cystic fibrosis or Huntington disease).

Adapted from Shajani, Z., & Snell, D. (2019). *Wright & Leahey's nurses and families: A guide to family assessment and intervention* (7th ed.). Davis Company.

Although opportunities for employment in community-based settings are plentiful, many positions require a baccalaureate degree. Previous medical–surgical experience in an acute care

setting is typically required by home health agencies because these nurses must function fairly independently within the home environment.

The nurse must also be familiar with and respectful of many different cultures and socioeconomic levels, remaining objective in dealing with such diversity and demonstrating an understanding of and appreciation for cultural differences. Nurses are increasingly working with clients from diverse cultural backgrounds with different cultural values pertaining to their health. Interventions must be individualized to address the cultural, social, and economic diversity among clients in their own environment. Developing an inclusive and respectful mindset toward all clients starts with building strong relationships and understanding, much like breaking down diversity barriers (Fitzgerald & Campinha-Bacote, 2019).

BOX 2.6 Home Care Visitation Planning

- Review previous interventions to eliminate unsuccessful ones.
  - Check previous home visit narrative to validate interventions.
  - Communicate with previous nurse to ask questions and clarify.
  - Formulate plan of interventions based on data received (e.g., client preference of IV placement or order of fluids).
- Prioritize client needs based on their potential to threaten the client's health status.
  - Use Maslow's hierarchy of needs to set forth a plan of care.
  - Address life-threatening physiologic issues first (e.g., an infectious process would take precedence over anorexia).
- Develop goals that reflect primary, secondary, and tertiary prevention levels.
  - *Primary prevention*—Have the client consume adequate fluid intake to prevent dehydration.
  - *Secondary prevention*—Administer drug therapy as prescribed to contain and treat an existing infectious process.
  - *Tertiary prevention*—Instruct the stroke client how to exercise to minimize disability.
- Bear in mind the client's readiness to accept intervention and education.
  - Ascertain the client's focus and how she sees her needs.
  - Address client issues that might interfere with intervention (e.g., if the client is in pain, attempting to teach her about her care will be lost; her pain must be addressed first before she is ready to learn).
- Consider the timing of the visit to prevent interfering with other client activities.
  - Schedule all visits at convenient times per client if possible (e.g., if the client has a favorite television show to watch, attempt to schedule around that event if at all possible).
  - Reschedule a home visit if a client event comes up suddenly.
- Outline nursing activities to be completed during the scheduled visit.
  - Know the health care agency's policy and procedures for home visits.
  - Consider the time line and other visits scheduled that day.
  - Research evidence-based best practices to use in the home to validate your intervention decisions.
- Obtain necessary materials/supplies before making the visit.
  - Assemble all equipment needed for any procedure in advance.
  - Secure any equipment that might be needed if a problem occurs (e.g., bring additional IV tubing and a catheter to make sure the procedure can be carried out without delay).
- Determine criteria to be used to evaluate the effectiveness of the home visit.
  - Revisit outcome goals to determine the effectiveness of the intervention.
  - Assess the client's health status to validate improvement.

- Monitor changes in the client's behavior toward health promotion activities and disease prevention (e.g., verify/observe that the client demonstrates correct hand-washing technique after instruction and reinforcement during the home care visit).

Community-Based Nursing Care Settings for Women and Children

Community-based nursing takes place in a variety of settings, including physician's offices, clinics, health departments, urgent care centers, hospital outpatient centers, schools, camps, churches, shelters, and clients' homes. Nurses provide well care, episodic ill care, and chronic care. They work to promote, preserve, and improve the health of the women, children, and families in these settings.

Due to technologic advances, cost containment, and shortened hospital stays, the home is a common care setting for women, children, and families today. Home care is geared toward the needs of the client and family. Private-duty nursing care is used when more extensive care is needed; it may be delivered hourly (several hours per day) or on a full-time, live-in basis. Periodic nursing visits may be used for intermittent interventions, such as IV antibiotic administration, follow-up with client teaching, and monitoring. The goals of nursing care in the home setting include promoting, restoring, and maintaining the health of the client.

Home care focuses on minimizing the effects of the illness or disability along with providing the client with the means to care for the illness or disability at home. Nurses in the home care setting are direct care providers, educators, advocates, and case managers.

Prenatal Care

Early, adequate prenatal care has long been associated with improved pregnancy outcomes. Adequate prenatal care is a comprehensive process in which any problems associated with pregnancy are identified and treated. Basic components of prenatal care are early and continuing risk assessment, health promotion, medical and psychosocial interventions, and follow-up. Within the community setting, several services are available to provide health care for pregnant women (Box 2.7).

Not all women are aware of the community resources available to them. Most public health services are available for consultation, local hospitals have “hotlines” for questions, and public libraries have pregnancy-related resources as well as Internet access. Nurses can be a very helpful link to resources for all women regardless of their economic status.

BOX 2.7 Maternal–Child Community Health Care Services

- State public health prenatal clinics provide access to care based on a sliding scale payment schedule or have services paid for by Medicaid.
- Federally funded community clinics typically offer a variety of services, which may include prenatal, pediatric, adult health, and dental services. A sliding scale payment schedule or Medicaid may cover costs.
- Hospital outpatient health care services offer maternal–child health services. Frequently they are associated with a teaching hospital in which medical school students, interns, and OB/GYN residents rotate through the clinic services to care for clients during their education process.
- Private OB/GYN offices are available for women with health insurance seeking care during their pregnancies. Some physicians in private practice will accept Medicaid clients as well as private clients.
- Community free clinics offer maternal–child services in some communities for women with limited economic resources (homeless, unemployed).
- Freestanding birth centers offer prenatal care for low-risk mothers as well as childbirth classes to educate couples regarding the birthing process. Most centers accept private insurance and Medicaid for reimbursement services.
- Midwifery services are available in many communities where midwives provide women's health services. They usually accept a multitude of payment plans from private pay to health insurance to Medicaid for reimbursement purposes.
- WIC provides food, nutrition counseling, and access to health services for low-income women, infants, and children. WIC is a federally funded program and is administered by each state. All people receiving Aid to Families with Dependent Children (AFDC), food stamps, or Medicaid are automatically eligible for WIC. WIC serves 53% of all infants born in the United States up to their fifth birthday (USDA Food and Nutrition Service, 2019).
- Childbirth classes offer pregnant women and their partners a series of educational classes on childbirth preparation. Women attend them during their last trimester of pregnancy. Some classes are free and some have a fee.
- Local La Leche League groups provide mother-to-mother support for breastfeeding, nutrition, and infant care problem-solving strategies. All women who have an interest in breastfeeding are welcome to participate in the meetings, which are typically held in the home of a La Leche member.

Technologically advanced care has been shown to improve maternal and child outcomes. Regionalized high-risk care, recommended by the AAP in the late 1970s, aimed to promote uniformity nationwide, covering the prenatal care of high-risk pregnancies and high-risk newborns. The advanced technology found in perinatal regional centers and community-based prenatal surveillance programs have resulted in better risk-adjusted mortality rates. Regionalized systems of perinatal care are recommended to ensure that each mother and newborn achieve optimal outcomes. A classification system for multiple levels of maternal care pertains to birth centers, basic care (level I), specialty care (level II), subspecialty care (level III), and regional perinatal health care centers (level IV). The goal of regionalized maternal care is for high-risk pregnant women to receive care in facilities that are prepared to provide the required level of specialized care, thereby reducing maternal morbidity and mortality rates (American College of Obstetricians and Gynecologists [ACOG], 2019). For example, fetal monitoring and ultrasound technology have traditionally been used in acute care settings to monitor the progress of many high-risk pregnancies. However, with the increased cost of hospital stays, many services were moved to outpatient facilities and into the home. The intent was to reduce health care costs and to monitor women with complications of pregnancy in the home rather than in the hospital. Examples of services offered in the home setting might include the following:

- Infusion therapy to treat infections or combat dehydration
- Hypertension monitoring for women with gestational hypertension
- Fetal monitoring to evaluate fetal well-being
- Portable ultrasound to perform a biophysical profile to assess fetal well-being

As a result, home care has the potential to produce cost savings compared to inpatient care.

Labor and Birth Care

Pregnancy involves numerous choices: cloth or disposable diapers, breastfeeding or bottle-feeding, doctor or midwife, and where to give birth—at a birth center, at home, or at a hospital. Deciding where to give birth depends on the woman's pregnancy risk status. For the pregnant woman who is at high risk as a result of medical or social factors, the hospital is considered the safest place for birth. Potential complications can be addressed because medical technology, skilled professionals, and neonatal services are available. For low-risk women, a freestanding birth center or a home birth is an option.

The choice between a birth center, home birth, or hospital depends on the woman's preferences, her risk status, and her distance from a hospital. Some women choose an all-natural birth with no medications and no medical intervention, whereas others would feel more comfortable in a setting in which medications and trained staff are available if needed. Presenting the facts to women and allowing them to choose in collaboration with their health care provider is the nurse's role. Client safety is paramount but at the same time nurses must protect the woman's right to select birth options and should promote family-centered care in all maternity settings.

BIRTH CENTERS

A birth center is a cross between a home birth and a hospital. Birth centers offer a home-like setting but with close proximity to a hospital in case of complications. Appropriate clients for the birth center might be a woman at term and having a singleton fetus with a vertex (head down) presentation. Midwives often are the sole care providers typically in freestanding birthing centers, with obstetricians as backups in case of emergencies. Birth centers usually have fewer restrictions and guidelines for families to follow and allow for more freedom in making decisions about labor. The rates of cesarean birth and the costs are much lower than those of a hospital (Childbirth Connection, 2020). Midwife-led comprehensive care in a birth center using the same medical guidelines as in standard care in hospitals reduced medical interventions without jeopardizing maternal and

infant health. Birth centers advertise themselves as a natural alternative to a hospital, as well as a place of female empowerment and control (Alliman et al., 2019). The normal discharge time after birth is usually measured in hours (4 to 24 hours), not days.

Birth centers aim to provide a relaxing home environment and promote a culture of normalcy. Currently, we are seeing a rise in the number of birth centers being established, which is essential in the promotion of normality. It is in these birth centers that midwives will learn about normalcy, building the skills needed to support women through labor, rather than managing labor. The current economic climate may result in more efficient use of resources, possibly normalizing birth. Birth is considered a normal physiologic process, and most centers use a noninterventional view of labor and birth. The range of services for the expectant family often includes prenatal care, childbirth education, intrapartum care, and postpartum care, including home follow-up and family planning (Fig. 2.4). One of the hallmarks of the freestanding birth center is that it can provide truly family-centered care by approaching pregnancy and birth as a normal family event and encouraging all family members to participate. Education is often provided by such centers, encouraging families to become informed and self-reliant in the care of themselves and their families (King et al., 2019).

Birth centers provide an alternative for women who are uncomfortable with a home birth but who do not want to give birth in a hospital. Advantages of birth centers include a noninterventional approach to obstetric care, freedom to eat and move around during labor, ability to give birth in any position, and the right to have any number of family and friends attend the birth. Disadvantages are that some centers have rigid screening criteria, which may eliminate healthy mothers from using birth centers; many have rigid rules concerning transporting the mother to the hospital (e.g., prolonged labor, ruptured membranes); and many have no pediatrician on staff if the newborn has special needs or complications after birth (Childbirth Connection, 2020).

FIGURE 2.4. Birthing centers aim to provide a relaxing home environment and promote a culture of normality while offering a full range of health care services to the expectant family. (Photos by Gus Freedman.)

HOME BIRTH

For centuries women have been giving birth to babies in their home. Many feel more comfortable and relaxed when giving birth in their own environment. Women who want no medical interventions and a very family-centered birth often choose to have a home birth. Home births are recommended for pregnant women who are considered to be at low risk for complications during labor and birth (Declercq & Stotland, 2020). Home birth is advantageous because it:

- is the least expensive.
- allows the woman to experience labor and birth in the privacy, comfort, and familiarity of home while surrounded by loved ones.
- allows their partner to remain with them after the birth.
- makes women feel in more in control of their labor process.
- enables women to be able to move freely, eat and drink when/what they want.
- permits the woman to maintain control over every aspect affecting her labor (e.g., positions, attire, support people).
- minimizes interference and unnecessary interventions, allowing labor to progress normally.
- provides continuous one-on-one care by the midwife throughout the childbirth process.
- promotes the development of a trusting relationship with the nurse midwife (American Pregnancy Association, 2019).

A home birth has certain disadvantages, however, including the limited availability of pain medication and danger to the mother and baby if an emergency arises (e.g., placental abruption, uterine rupture, cord prolapse, or a distressed fetus). Delay in getting to the hospital could jeopardize the life of the child or the mother. A backup plan for a health care provider and nearby hospital on standby must be established should an emergency occur. The available evidence suggests that planned home birth is safe with lower rates of perineal lacerations, fewer interventions and surgical births needed for women who are at low risk of complications and are cared for by appropriately qualified and licensed midwives with access to timely transfer to a hospital if required (Caughey & Cheyney, 2019).

Postpartum and Newborn Care

Having a baby is a miracle, but the length of stay in the hospital after childbirth has become a long-standing battle. Reforms in health care financing have reduced hospital stays significantly for new mothers. As a result, community-based nurses play a major role in extending care beyond the hospital setting. When new mothers are discharged from the hospital, most are still experiencing perineal discomfort and uterine cramping. They may still have pain from a surgical incision. They are fatigued and may be constipated. They may feel uncertain about feeding and caring for their newborn. These new mothers need to be made aware of community resources such as telephone consultation by nurses, outpatient clinics, home visits, neighborhood mothers' support groups, and online new parent forums.

TELEPHONE CONSULTATION

Many hospitals offer telephone consultation services by their maternity nurses. The discharged mother is given the phone number of the nursing unit on the day of discharge and is instructed to call if she has any questions or concerns. Because the nurses on the unit are familiar with her birth history and the newborn, they are in a good position to assist her in adjusting to her new role. Although this service is usually free, not all families recognize a problem early or use this valuable informational resource.

OUTPATIENT CLINICS

Outpatient clinics offer another community-based site where the childbearing family can obtain services. Usually the mother has received prenatal care before giving birth and thus has established some rapport with the nursing staff there. The clinic staff is usually willing to answer any questions she may have about her health or that of her newborn. Appointments usually include an examination of the mother and newborn and instructions about umbilical cord care, postpartum and infant care, and nutrition for both mother and infant.

POSTPARTUM HOME VISITS

Shorter length of stay for postpartum mothers and their newborns necessitates vital community follow-up after hospital discharge. Home visits offer services similar to those offered at a scheduled clinic visit, but they also give the nurse an opportunity to assess the family's adaptation and dynamics and the home environment. During the past decade, hospital stays have averaged 24 to 48 hours or less for vaginal births and up to 72 hours for cesarean births (CDC, 2019c). Federal legislation went into effect in 1998 that prohibited insurers from restricting hospital stays for mothers and newborns to less than 2 days for vaginal births or 4 days for cesarean births (CDC, 2019c). These shortened stays have reduced the time available for educating mothers about caring for themselves and their newborns. Community nurses need to ensure there is a seamless continuum of care to support, empower, and educate new mothers and their families to prevent unnecessary hospital readmission or other negative outcomes. Home visiting programs in general seek to promote child health/development, prevent child abuse/neglect, improve maternal well-being, and improve the parental capacity of mothers.

Postpartum care in the home environment usually includes the following:

- Monitoring the physical and emotional well-being of the family members (Fig. 2.5)

FIGURE 2.5. The nurse makes a postpartum home visit to assess the woman and her newborn. During the visit, the nurse assists the mother with breastfeeding.

- Identifying potential or developing complications for the mother and newborn
- Breast care during breastfeeding and engorgement
- Instruction on pelvic floor exercises, nutrition, and self-hygiene care
- Linking the family, as needed, to community social services, housing, and governmental programs
- Bridging the gap between discharge and ambulatory follow-up for mothers and their newborns (King et al., 2019)

SUPPORT GROUPS FOR NEW MOTHERS

Sometimes parenting can make mothers feel like every day is their first day on the job. New mothers should seek support from others that understand what they are going through and can offer support, encouragement and advice when needed. Typically, these groups are locally led by a facilitator with previous experience in motherhood, breastfeeding, and infant care. Usually they are composed of 6 to 12 mothers who share information on breastfeeding techniques, infant sleeping patterns, child care issues, body image issues, and how to integrate the new baby into the family unit. The support group usually meets weekly and provides an avenue of support for new mothers on the same journey.

ONLINE MOTHERHOOD FORUMS/BLOGS

Support groups in online communities provide an anonymous place to exchange information and advice. Previous research has suggested that these groups offer a safe, nonjudgmental forum for new mothers to share experiences and interact anonymously. They serve as a safe, supportive space in which new mothers can better understand their new role of parenting. They offer a viable form of education for new parents, but caution must be used on advice provided on some websites to new mothers (Postpartum Support International, 2020).

HIGH-RISK NEWBORN HOME CARE

With the reduced lengths of stay, high-risk newborns are also being cared for in community settings. High-technology care once was provided only in the hospital. Now, however, the increasing cost of complex care and the influences of managed care have led to the provision of such care at home. Families have become “health care systems” by providing physical, emotional, social, and developmental home care for their technology-dependent infants. Suitable candidates for home care may include preterm infants who continue to need oxygen, low–birth-weight infants needing nutritional or hypercaloric formulas or adjunct feeding methods (e.g., tube

feedings), or infants with hydrocephalus or cerebral palsy. Home care with prepared caregivers might contribute to earlier detection of significant residual/recurrent problems amenable to therapy (March of Dimes, 2019). A wide range of equipment may be used, including mechanical ventilation, electronic apnea monitors, home oxygen equipment, intravenous infusions, respiratory nebulizers, phototherapy, and suction equipment.

All family members must work together to provide 24-hour care. The parents must negotiate with insurers for reimbursement for durable medical equipment, must be able to troubleshoot equipment problems, and must be able to manage inventories of supplies and equipment. In addition, they must be able to assess the infant for problems; determine the problem; decide when to call the nurse, pharmacist, or physical therapist; and interpret and implement prescriptions. Technology in the home requires nurses to focus on the family "home care system" to provide total care to the infant.

Nurses can play a key role in assisting families by preparing them for and increasing their confidence in caring for their infants at home. This adaptation begins before discharge from the hospital. Family members are active participants in the transition-to-home plan. Recognition of parental needs and addressing each area in the discharge plan will ease the transition home.

Assessment of the family's preparedness is essential. The following areas should be explored:

- *Parenting education*—assess the family's knowledge of positioning and handling of their infant, nutrition, hygiene, elimination, growth and development, immunizations needed, and recognition of illnesses. Asking questions in a sensitive manner will assist the nurse in identifying knowledge deficiencies, so they can be reinforced in the nurse's teaching plan.
- *Postpartum care*—determine the mother's concerns in areas of body image, weight loss, sleep/rest needs, discomfort, fatigue, and adjustment to her new role. Asking open-ended questions concerning these areas will help the nurse extract more information to include in the teaching plan. Targeting the mother's areas of

concern will help the nurse focus on needed education to facilitate the mother's transition into her new role as a parent.

- *Support systems*—assess physical and emotional support for the new mother by asking questions about the availability of her immediate family, other relatives, and significant others to help out. If lacking, referrals may need to be made to community parenting programs, cooperative day care, or other community resources needed to assist this family. Exploring these vital areas through sensitive questioning hopefully will convey the nurse's concern for the infant and family while obtaining a thorough assessment of the family's learning needs.

Once preparedness has been assessed, the nurse can intervene as necessary. For example, if the caretakers do not think they are prepared to maintain machinery, technology, medication, or developmental therapy, then the nurse can demonstrate the care to the family. The nurse provides instructions and hands-on experience within a supportive environment until the family's confidence increases. The nurse can also assist the family to anticipate the common problems that might occur (e.g., advising them to avoid running out of supplies, to have enough medication or special formula mixture to last throughout the weekend, and to keep backup batteries for powering machines or portable oxygen). The outcome of the preparedness assessment and intervention is that the safety of the infant is established and maintained.

Nursing for families who are using complex home care equipment requires caring for the infant and family members' physical and emotional well-being as well as providing effective solutions to problems they may encounter. Home health nurses need to identify, mobilize, and adapt a myriad of community resources to support the family in giving the best possible care in the home setting. Preparing families for high-tech care before hospital discharge, with home health nurses continuing and reinforcing that focus, will help ease the burden of managing high-tech equipment in the home.

Women's Health Care

A woman's reproductive years span half her lifetime, on average. This is not a static period, but rather one that encompasses several significant stages. As her reproductive goals change, so do a woman's health care needs. Because of these changing needs, comprehensive community-centered care is critical.

Community-based women's health services have received increased emphasis during the past few decades simply because of economics. Women use more health care services than men, they make as many as 80% of health care decisions, and they represent the majority of the population (Health Grades, 2019). Women spend 66 cents of every health care dollar, and seven of the 10 most frequently performed surgeries in the United States are specific to women (Centers for Medicare & Medicaid Services [CMS], 2019). Examples of community-based women's health care services that can be freestanding or hospital-based include the following:

- Screening centers that offer mammograms, Pap smears, bone density assessments, genetic counseling, ultrasound, breast examinations, complete health risk appraisals, laboratory studies (complete blood count, cholesterol testing, thyroid testing, glucose testing for diabetes, follicle-stimulating hormone [FSH] levels), and electrocardiograms.
- Educational centers that provide women's health lectures, instruction on breast self-examinations and Pap smears, and computers for research.
- Counseling centers that offer various support groups: genetics, psychotherapy, substance abuse, sexual assault, and domestic violence.
- Wellness centers that offer stress reduction techniques, massage therapy, guided imagery, hypnosis, smoking cessation, weight reduction, tai chi, yoga, and women's fitness/exercise classes.
- Alternative/wholeness healing centers that provide acupuncture, aromatherapy, biofeedback, therapeutic touch, facials, reflexology, and herbal remedies.
- Retail centers that offer specialty equipment for rental and purchase, such as breast prostheses.

Women have multiple choices regarding services, settings, and health care providers. In the past most women received health care services from physicians such as obstetricians, gynecologists, and family physicians, but today nurse midwives and nurse practitioners are becoming more prevalent in providing well-women care.

Nurses who work in community-based settings need to be familiar with the many health issues commonly encountered by women within their communities. All nurses who work with women of any age in community-based settings, including the workplace, schools, practitioner offices, and clinics, should possess a thorough understanding of the scope of women's health care and should be prepared to intervene appropriately to prevent problems and to promote health.

Child Health Care

The majority of care for a child occurs in the community setting. The numerous settings may be broad or highly specialized. For example, one setting may provide well-child care as well as illness-related care. Another setting may be limited to providing well-child care; a third setting may be limited to diagnostic evaluation, emergency care, or surgical intervention. Other settings may focus on caring for children with specific conditions or diagnosis, such as diabetes or cancer. See Chapter 33 for specific community-based child health care settings.

Unfolding Patient Stories: Fatime Sanogo • Part 1

Fatime Sanogo, a 23-year-old, is being seen by the nurse in the prenatal clinic. The nurse learns that this is her first pregnancy, she is Muslim, and she recently moved to the United States from Mali, West Africa, with her husband. What cultural factors are important for the nurse to assess that guide culturally humble care during Fatime's pregnancy and preparation for delivery? (Fatime Sanogo's story continues in Chapter 14.)

Care for Fatime and other patients in a realistic virtual environment: vSim for Nursing (**thepoint.lww.com/vSimMaternity**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

KEY CONCEPTS

- Core concepts of maternal and pediatric nursing include family-centered care, evidence-based practice, collaborative care, atraumatic therapeutic care, communication, education, continuum of care strategy including discharge planning, case management, advocacy and resource management, preventative care, and culturally competent care.
- Family-centered care recognizes the concept of the family as the constant. The health and functioning ability of the family influences and impacts the health of the client and other members of the family. Family-centered care recognizes and respects family strengths and individuality, encourages referrals for family support, and facilitates collaboration.
- It is important that nurses develop the skills and knowledge necessary to ask pertinent clinical questions, search for current best evidence, analyze the evidence, integrate the evidence into practice when appropriate, and evaluate outcomes.
- Open, honest lines of communication are essential for nurses. The use of an interpreter may be necessary to ensure effective communication with women, children, and their families in. Maintaining confidentiality and privacy are key.
- A family's knowledge related to the client's health or illness is vitally important. Nurses play a major role in educating women, children, and their families. For children, teaching is provided based on the child's developmental level.
- Discharge planning provides a comprehensive plan for the safe discharge of a client from a health care facility and for continuing safe and effective care in the community. Case management focuses on coordinating health care services while balancing quality and cost outcomes. Both contribute to improved transition from the hospital to the community for women, children, their families, and the health care team.
- Advocacy and resource management help ensure that the client and family have the necessary resources and appropriate health care services available to them.
- Health care delivery has moved from acute care settings out into the community, with an emphasis on health promotion and illness prevention. Community health nursing focuses on prevention and

improvement of the health of populations and communities, addressing current and potential health needs of the population or community, promoting and preserving the health of a population regardless of a particular age group or diagnosis. Community health nurses perform epidemiologic investigations to help analyze and develop health policy and community health initiatives.

- Community-based nurses focus on providing personal care to individuals and families in the community. They focus on promoting and preserving health as well as preventing disease or injury. They help women, children, and their families cope with illness and disease. Community-based nurses are direct care providers as well as advocators and educators. They focus on minimizing and removing barriers to allow the client to develop to his or her full potential.
- Settings for community-based nursing include physicians' offices, clinics, health departments, urgent care centers, clients' homes, schools, camps, churches, and shelters such as abuse, homeless, and disaster shelters. Nurses provide both well, episodic ill care, and chronic care to women, children, and their families.
- There has been a rise in home health care due to shorter hospital stays and cost containment along with an increase in income and longevity of people with chronic and debilitating health conditions. Technology also has improved, which allows clients to be monitored and to undergo complicated procedures at home.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. A community-based nurse is involved in secondary prevention activities. Which activities might be included? Select all that apply.

   a. Fecal occult blood testing
   b. Hearing screening
   c. Smoking cessation program
   d. Cholesterol testing
   e. Hygiene program
   f. Pregnancy testing

2. A woman is to have childbirth at a freestanding birth center. Which would the nurse identify as a major disadvantage associated with this community-based setting?

   a. Increased risk for infection
   b. Increased health care costs
   c. Need to be transferred if an emergency occurs
   d. Increased disruption of family functioning

3. When planning education for a child and parents, what is the first step the nurse should take?

   a. Decide which procedures and medications the child will be discharged on.
   b. Determine the child's and family's learning needs and styles.
   c. Ask the family if they have ever performed this type of procedure.
   d. Tell the child and family what the goals of the teaching session are.

4. The clinic nurse is concerned about the client's ability to understand the instructions given and the health literacy level of her client. Which of the following can the nurse employ to increase the client's understanding of the instructions?

   a. Draw pictures of the procedure and write down the steps to it.
   b. Instruct the client to call the nurse if they have questions.
   c. Discuss the instructions with an elderly family member in addition to the client.
   d. Question the client about their reading level and educational level.

CRITICAL THINKING EXERCISES

1. A 3-year-old girl from Saudi Arabia has become seriously ill while on a visit to the United States. It is projected that she will require a lengthy hospitalization. Describe the steps the nurse should take to communicate with and provide extensive health care teaching to this child's family.
2. A pregnant woman is discharged home from the hospital after admission due to preterm labor. The woman is to be on complete bed rest and will receive home health care through a local agency to assist her and her family and to monitor her health status. As the home health nurse assigned to this woman, what should your nursing assessment include?

STUDY ACTIVITIES

1. Shadow a nurse working in a community setting, such as a women's health clinic, birthing center, camp, home care, or health department. Identify the role the nurse plays in the health of women, children, and families in the setting and in the community.

2. Arrange for a visit to a community health center that offers services to various cultural groups. Interview the staff about the strategies used to overcome communication barriers and different health care practices for the women and children in these groups.
3. Select one of the websites listed on thePoint and explore the information provided. How could a community-based nurse use this information?

BRINGING IT ALL TOGETHER: A CASE STUDY

Bianca, a 23-year-old Hispanic, is about to give birth to her first child, a daughter that will be named Amelia. Her partner, Alejandro, has been supportive of Bianca during her labor and plans to be present during the delivery but seems uneasy about the prospect of caring for his daughter claiming, “I’m not use to being around little babies.” The birthing center focuses on family-centered care and the nurse will plan the care of Bianca and Amelia as well as the support of Alejandro based on that model.

Go to thePoint to find questions to consider about this case.

menarche (men-ahr´kē)
menstruation (men´strū-ā´shŭn)
ovaries
ovulation (ov´yū-lā´shŭn)
penis
progesterone (prŏ-jes´tĕr-ōn)
testes
uterus
vagina
vulva

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Differentiate the structures and functions of the major external and internal female genital organs.
2. Outline the phases of the menstrual cycle, the dominant hormones involved, and the changes taking place in each phase.
3. Identify external and internal male reproductive structures and the function of each in hormonal regulation.

Linda, 49, started menstruating when she was 12 years old. Her menstrual periods have always been regular, but now she is experiencing irregular, heavier, and longer ones. She wonders if there is something wrong or if this is normal.

INTRODUCTION

The reproductive system is a collection of internal and external organs in both males and females that work together for the purpose of procreating. Scientists argue that the reproductive system is among the most important systems in the entire body since it plays a vital role in the survival of the human species. Without the ability to reproduce, a species dies. The female reproductive system produces the female reproductive cells (the eggs, or ova) and contains an organ (**uterus**) in which development of the fetus takes place; the male reproductive system produces the male reproductive cells (the sperm) and contains an organ (**penis**) that deposits the sperm within the female. Nurses need to have a thorough understanding of the anatomy and physiology of the male and female reproductive systems to be able to assess the health of these systems, to promote their health, to care for conditions that might affect the reproductive organs, and to provide client teaching concerning the reproductive system. This chapter reviews the female and male reproductive systems and the menstrual cycle as it relates to reproduction.

FEMALE REPRODUCTIVE ANATOMY AND PHYSIOLOGY

The female reproductive system is composed of both external and internal reproductive organs. It consists of the paired ovaries and oviducts, the uterus, the vagina, the external genitalia, and the mammary glands. All of these structures have evolved for the important functions of ovulation, fertilization of an ovum by a sperm,

support of the developing embryo and fetus, and the birth and care of a newborn.

External Female Reproductive Organs

The external female reproductive organs collectively are called the **vulva** (which means “covering” in Latin). It encompasses both sets of labia (majora and minora), the head of the clitoris, the opening of the urethra, and the opening of the vagina. The vulva serves to protect the urethral and vaginal openings and is highly sensitive to touch to increase the female’s pleasure during sexual arousal (Schillo, 2019). The structures that make up the vulva include the mons pubis, the labia majora and minora, the clitoris and prepuce, the structures within the vestibule, and the perineum (Fig. 3.1).

Mons Pubis

The mons pubis is the elevated, rounded, fleshy prominence made up of fatty tissue that overlays the symphysis pubis. The skin of this fatty tissue is covered with coarse, curly pubic hair after puberty. The mons pubis protects the symphysis pubis during sexual intercourse.

FIGURE 3.1. **A.** The external female reproductive organs. **B.** Normal appearance of external structures. (Photo by B. Proud.)

Labia

The labia majora (large lips), which are relatively large and fleshy, are comparable to the scrotum in males. The labia majora contain sweat and sebaceous (oil-secreting) glands; after puberty, they are covered with hair. Their function is to protect the vaginal opening and provide cushioning during sexual activity. The labia minora (small lips) are the delicate hairless inner folds of skin; they can be very small or up to 2 in wide. They lie just inside the labia majora and surround the openings to the vagina and urethra. The labia minora grow down from the anterior inner part of the labia majora on each side. These lips surround the vaginal opening and extend upward to form protection around both the clitoris and urethra. They are highly vascular and abundant in nerve supply. They lubricate the vulva, swell in response to stimulation, and are highly sensitive.

Clitoris and Prepuce

The clitoris is a small, cylindrical mass of erectile tissue and nerves. It is highly sensitive and is analogous to the head of the male's penis. Unlike the penis, however, the function of the clitoris is purely erogenous. Most of the components of the clitoris are buried under the skin and connective tissue of the vulva. It is located at the anterior junction of the labia minora. There are folds above and below the clitoris. The joining of the folds above the clitoris forms the prepuce, a hood-like covering over the clitoris; the junction below the clitoris forms the frenulum.

TAKE NOTE!

The hood-like covering over the clitoris is the site for female genital mutilation or cutting, which is a cultural ritual still practiced in some countries, including in the United States. It is internationally recognized as a human rights violation against women.

A rich supply of blood vessels gives the clitoris a pink color. Like the penis, the clitoris is sensitive to touch, stimulation, and

temperature and can become erect. For its small size, 9 to 11 cm, it has a generous blood and nerve supply. There are more free nerve endings of sensory reception located on the clitoris than on any other part of the body, and it is therefore unsurprisingly the most erotically sensitive part of the genitalia for most females. Its function is sexual stimulation (Baskin et al., 2018).

TAKE NOTE!

The word clitoris is from the Greek word for "key;" in ancient times the clitoris was thought to be the key to a woman's sexuality.

Vestibule

The vestibule is an oval area enclosed by the two labia minora laterally. It is inside the labia minora and outside of the hymen and is perforated by six openings. Opening into the vestibule are the urethra from the urinary bladder, the vagina, and two sets of glands. The opening to the vagina is called the introitus, and the half-moon–shaped area behind the opening is called the fourchette. Through tiny ducts beside the introitus, Bartholin glands, when stimulated, secrete mucus that supplies lubrication for intercourse. Skene glands are located on either side of the opening to the urethra. They secrete a small amount of mucus to keep the opening moist and lubricated for the passage of urine (Carroll, 2019).

The vaginal opening is surrounded by the hymen. The hymen is a tough, elastic, perforated, mucosa-covered tissue across the vaginal introitus. In a virgin, the hymen may completely cover the opening, but it usually encircles the opening like a tight ring. Because the degree of tightness varies among women, the hymen may tear at the first attempt at intercourse, or it may be so soft and pliable that no tearing occurs. In a woman who is not a virgin, the hymen usually appears as small tags of tissue surrounding the vaginal opening, but the presence or absence of the hymen can neither confirm nor rule out sexual experience (Patton & Thibodeau, 2019).

TAKE NOTE!

Heavy physical exertion, use of tampons, or injury to the area can alter the appearance of the hymen in girls and women who have not been sexually active.

Perineum

The perineum is the most posterior part of the external female reproductive organs. This external region is located between the vulva and the anus. It is made up of skin, muscle, and fascia. The perineum can become lacerated or incised during childbirth and may need to be repaired with sutures. Incising the perineum area to provide more space for the presenting part is called an episiotomy. Although still an obstetric procedure, the use of episiotomy has decreased during the past 25 years worldwide. The procedure should be applied selectively rather than routinely. In Westernized countries, episiotomy rates are far below 30%. An episiotomy can add to postpartum discomfort and perineal trauma and can lead to fecal incontinence (Clesse et al., 2018).

Internal Female Reproductive Organs

The internal female reproductive organs consist of the vagina, uterus, fallopian tubes, and ovaries (Fig. 3.2). These structures develop and function according to specific hormonal influences that affect fertility and childbearing.

Vagina

The **vagina** is a highly muscular and distensible canal situated in front of the rectum and behind the bladder. It is a tubular, fibromuscular organ lined with mucous membrane that lies in a series of transverse folds called rugae. The rugae allow for extreme dilation of the canal during labor and birth. The vagina is a canal that connects the external genitals (vulva) to the cervix. It receives the penis and the sperm ejaculated during sexual intercourse, and it

serves as an exit passageway for menstrual blood and for the fetus during childbirth. The front and back walls normally touch each other so that there is no space in the vagina except when it is opened (e.g., during a pelvic examination or intercourse). In the adult, the vaginal cavity is 3 to 4 in long. Muscles that control its diameter surround the lower third of the vagina. The upper two thirds of the vagina lies above these muscles and can be stretched easily. During a woman's reproductive years, the mucosal lining of the vagina has a corrugated appearance and is resistant to bacterial colonization. Before puberty and after menopause (if the woman is not taking estrogen), the mucosa is smooth due to lower levels of estrogen. Vulvovaginal atrophy, which occurs when estrogen is reduced, can have adverse effects on the health and quality of life for midlife women (Shifren, 2018).

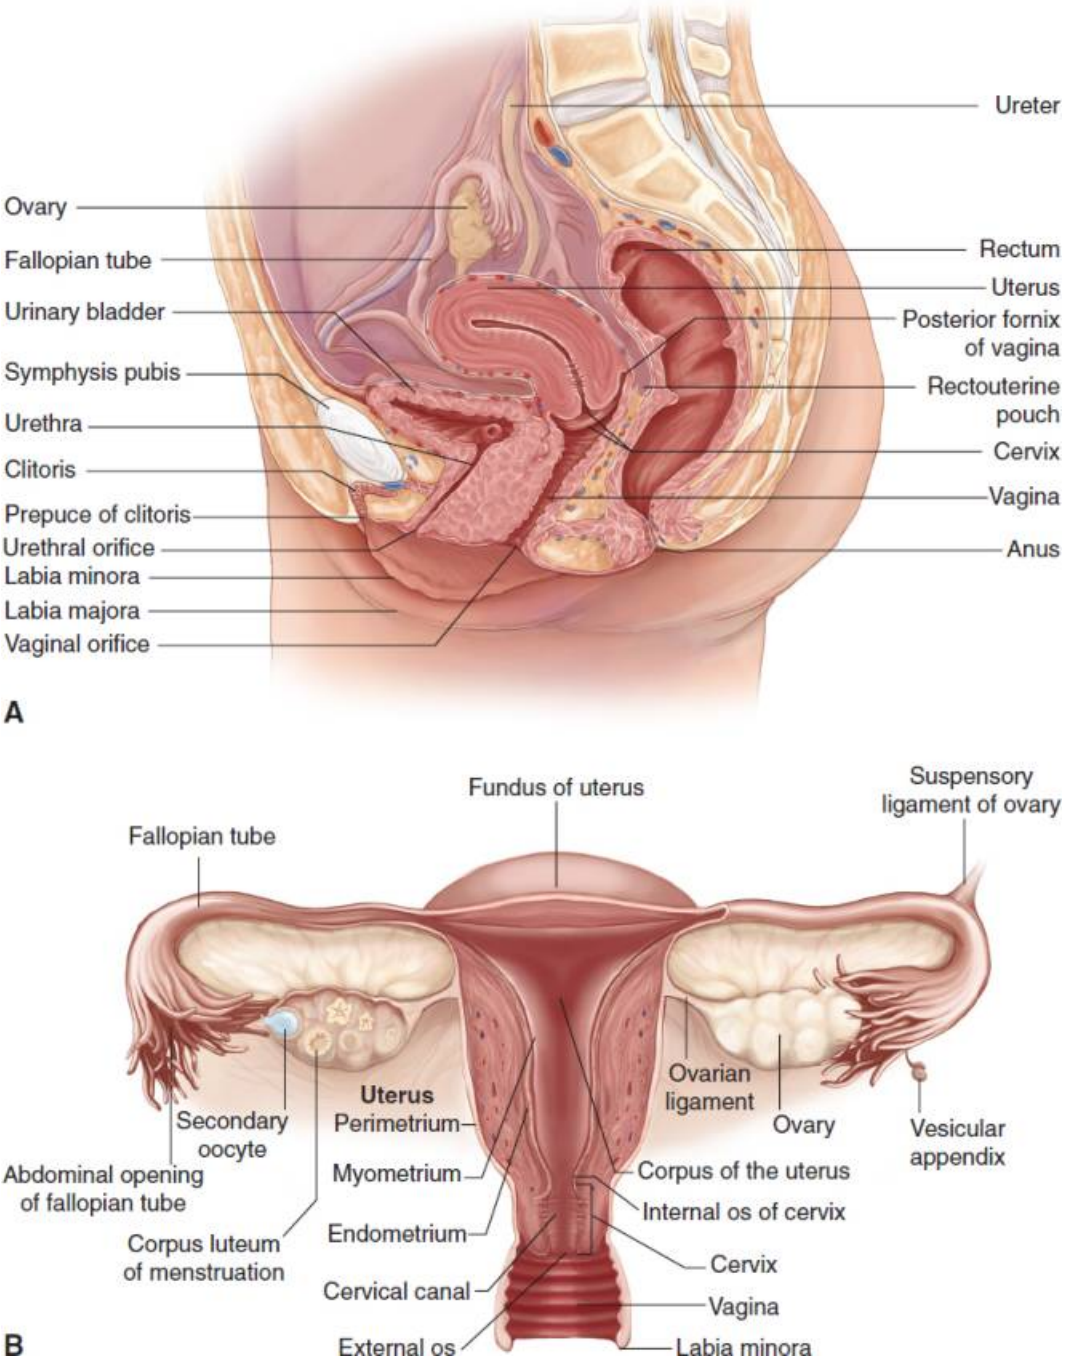

FIGURE 3.2. The internal female reproductive organs. **A.** Lateral view. **B.** Anterior view. (Source: Anatomical Chart Company. [2001]. *Atlas of human anatomy.* Springhouse.)

The vagina has an acidic environment, which protects it against ascending infections. Antibiotic therapy, douching, perineal hygiene

sprays, and deodorants upset the acid balance within the vaginal environment and can predispose women to infections.

Uterus

The uterus is an inverted, pear-shaped muscular organ at the top of the vagina. It lies behind the bladder and in front of the rectum and is anchored in position by eight ligaments, though it is not firmly attached or adherent to any part of the skeleton. A full bladder tilts the uterus backward; a distended rectum tilts it forward. The uterus alters its position by gravity or with change of posture, and it is the size and shape of an inverted pear. It is the site of menstruation, receiving a fertilized ovum, development of the fetus during pregnancy, and contracting to help in the expulsion of the fetus and placenta. Before the first pregnancy, it measures approximately 3 in long, 2 in wide, and 1 in thick. After a pregnancy, the uterus remains larger than before the pregnancy. After menopause, it becomes smaller and atrophies.

The uterine wall is relatively thick and composed of three layers: the endometrium (innermost layer), the myometrium (muscular middle layer), and the perimetrium (outer serosal layer that covers the body of the uterus). The **endometrium** is the mucosal layer that lines the uterine cavity in nonpregnant women. It varies in thickness from 0.5 to 5 mm and has an abundant supply of glands and blood vessels (Schillo, 2019). The myometrium makes up the major portion of the uterus and is composed of smooth muscle linked by connective tissue with numerous elastic fibers. During pregnancy, the upper myometrium undergoes marked hypertrophy, but there is limited change in the cervical muscle content.

Anatomic subdivisions of the uterus include the convex portion above the uterine tubes (the fundus); the central portion (the corpus or body) between the fundus and the cervix; and the cervix, or neck, which opens into the vagina.

CERVIX

The **cervix**, the lower part of the uterus, is sometimes called the neck of the uterus. It opens into the vagina and has a channel that allows sperm to enter the uterus and menstrual discharge to exit. It is composed of fibrous connective tissue. During a pelvic examination, the part of the cervix that protrudes into the upper end of the vagina can be visualized. Like the vagina, this part of the cervix is covered by mucosa, which is smooth, firm, and doughnut-shaped, with a visible central opening called the external os (Fig. 3.3). Before childbirth, the external cervical os is a small, regular, oval opening. After childbirth, the opening is converted into a transverse slit that resembles lips (Fig. 3.4). Except during menstruation or ovulation, the cervix is usually a good barrier against bacteria. The cervix has an alkaline environment, which protects the sperm from the acidic environment in the vagina.

The canal or channel of the cervix is lined with mucus-secreting glands. This mucus is thick and impenetrable to sperm until just before the ovaries release an egg (ovulation). At ovulation, the consistency of the mucus changes so that sperm can swim through it, allowing fertilization. At the same time, the mucus-secreting glands of the cervix actually become able to store live sperm for 2 or 3 days. These sperm can later move up through the corpus and into the fallopian tubes to fertilize the egg; thus, intercourse 1 or 2 days before ovulation can lead to pregnancy. Because some women do not ovulate consistently, pregnancy can occur at varying times after the last menstrual period. During pregnancy the cervix is the vital mechanical barrier which resists compressive and tensile loads generated from a growing fetus. The channel in the cervix is too narrow for the fetus to pass through during pregnancy, but during labor, it stretches to let the newborn through.

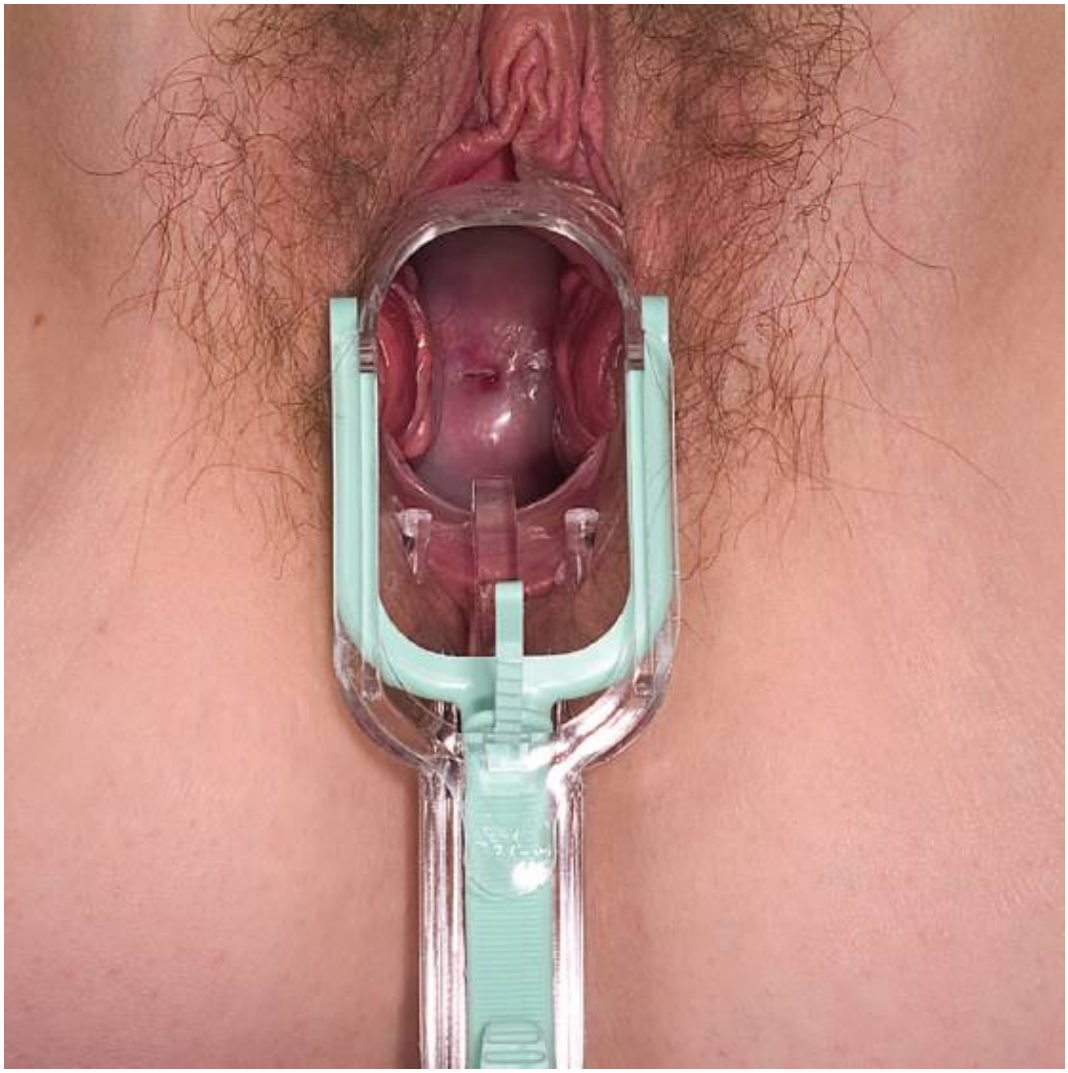

FIGURE 3.3. Appearance of normal cervix. Note: This is the cervix of a multipara female. (Photo by B. Proud.)

CORPUS

The corpus, or the main body of the uterus, is a highly muscular organ that enlarges to hold the fetus during pregnancy. The inner lining of the corpus (endometrium) undergoes cyclic changes as a result of the changing levels of hormones secreted by the ovaries; it is thickest during the part of the menstrual cycle in which a fertilized egg would be expected to enter the uterus and is thinnest just after menstruation. If fertilization does not take place during this cycle, most of the endometrium is shed and bleeding occurs, resulting in the monthly period. If fertilization does take place, the embryo

attaches to the wall of the uterus, where it becomes embedded in the endometrium (about 1 week after fertilization); this process is called implantation (Carroll, 2019). Menstruation then ceases during the 40 weeks (280 days) of pregnancy. During labor, the muscular walls of the corpus contract to push the baby through the cervix and into the vagina.

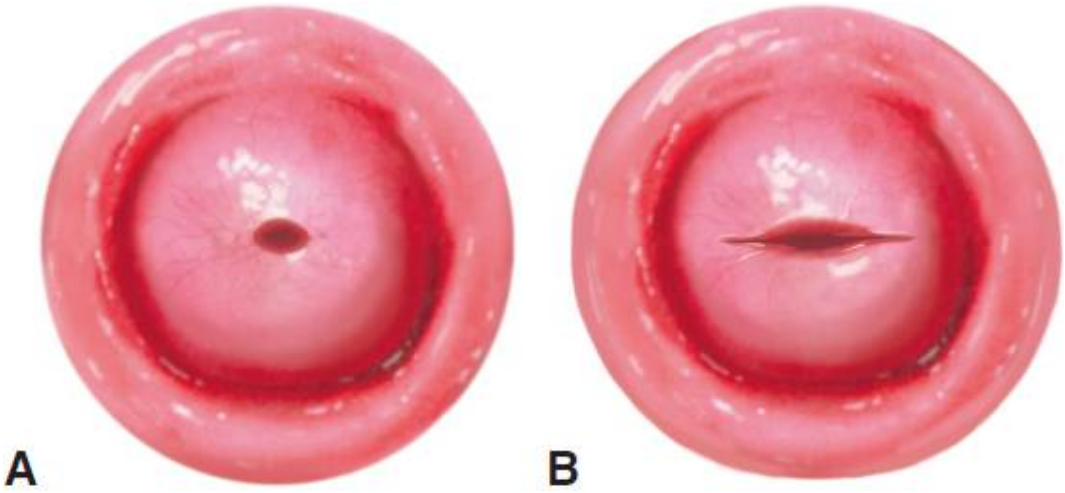

FIGURE 3.4. **A.** Nulliparous cervical os. **B.** Parous cervical os.

Fallopian Tubes

The **fallopian tubes**, also known as oviducts, are hollow, cylindrical structures that extend 2 to 3 in from the upper edges of the uterus toward the ovaries. Each tube is about 7 to 10 cm long (4 in) and approximately 0.7 cm in diameter. The end of each tube flares into a funnel shape, providing a large opening for the egg to fall into when it is released from the ovary. Cilia (beating, hair-like extensions on cells) line the fallopian tube and the muscles in the tube's wall. The fallopian tubes convey the ovum from the ovary to the uterus and sperm from the uterus toward the ovary. This movement is accomplished via ciliary action and peristaltic contraction. If sperm are present in the fallopian tube as a result of sexual intercourse or artificial insemination, fertilization of the ovum can occur in the distal portion of the tube. If the egg is fertilized, it will divide over a period

of 4 days while it moves slowly down the fallopian tube and into the uterus, where it implants into the uterine lining.

Ovaries

The **ovaries** are a set of paired glands resembling unshelled almonds that are the organs of gamete production in the female. They are set in the pelvic cavity below and to either side of the umbilicus. They are usually pearl-colored, oblong, and have a lumpy surface. They are homologous to the testes. Each mature ovary weighs from 2 to 5 g and is about 4 cm long, 2 cm wide, and 1 cm thick (Schillo, 2019). The ovaries are not attached to the fallopian tubes but are suspended nearby from several ligaments, which help hold them in position. The development and the release of the ovum and the secretion of the female hormones **estrogen** and **progesterone** are the two primary functions of the ovary. The ovaries link the reproductive system to the body's system of endocrine glands, as they produce the ova (eggs) and secrete estrogen and progesterone cyclically. After an ovum matures, it passes into the fallopian tubes.

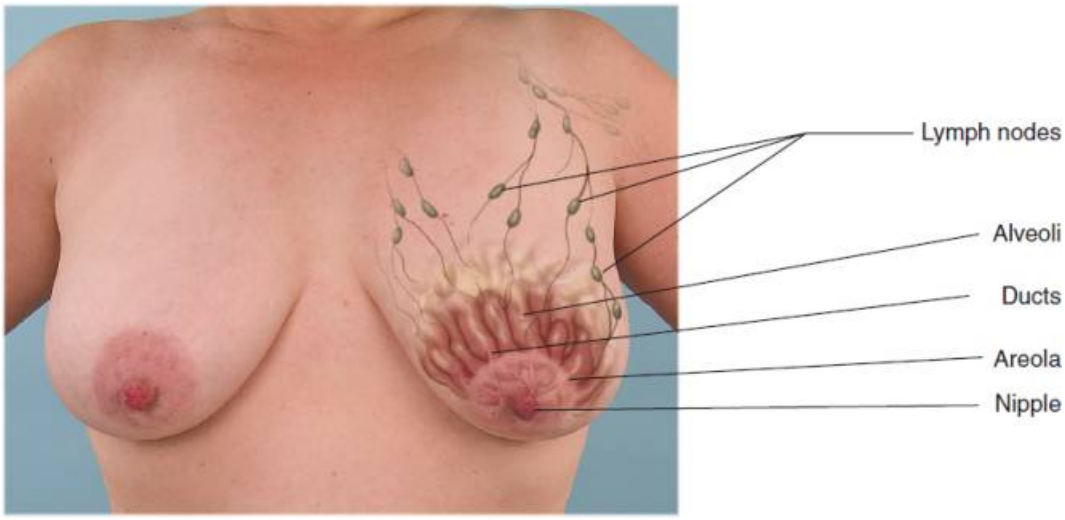

FIGURE 3.5. Anatomy of the breasts. (Photo by B. Proud.)

Breasts

The two mammary glands, or **breasts**, are accessory organs of the female reproductive system that are specialized to secrete milk following pregnancy. They overlie the pectoralis major muscles and extend from the second to the sixth ribs and from the sternum to the axilla. Each breast has a nipple located near the tip, which is surrounded by a circular area of pigmented skin called the areola. Each breast is composed of approximately nine lobes (the number can range between four and 18), which contain glands (alveolar) and a duct (lactiferous) that leads to the nipple and opens to the outside (Fig. 3.5). The lobes are separated by dense connective and adipose tissues, which also help support the weight of the breasts (Carroll, 2019).

During pregnancy, placental estrogen and progesterone stimulate the development of the mammary glands. Because of this hormonal activity, the breasts may double in size during pregnancy in preparation for milk production. At the same time, glandular tissue replaces the adipose tissue of the breasts.

Following childbirth and the expulsion of the placenta, levels of placental hormones (progesterone and lactogen) fall rapidly, and the action of prolactin (milk-producing hormone) is no longer inhibited. Prolactin stimulates the production of milk within a few days after childbirth, but in the interim, dark yellow fluid called colostrum is secreted. Colostrum contains more minerals and protein but less sugar and fat than mature breast milk. Colostrum secretion may continue for approximately a week after childbirth, with gradual conversion to mature milk. Colostrum is rich in maternal antibodies, especially immunoglobulin A (IgA), which offers protection for the newborn against enteric pathogens.

Female Sexual Response

Sexual arousal is a physiologic response to internal and external stimuli and is mediated by both the central and peripheral nervous systems. The sexual response in both females and males is governed primarily by the nervous system rather than by hormones. It is characterized by changes in sensation, tissue contractility,

vasocongestion, and lubrication. The sexual response starts in a state of sexual neutrality, and the person's sexual desire is more of a reciprocal response than a spontaneous one (Goldstein et al., 2018). The sexual cycle is usually thought of as having five phases: desire, excitement, plateau, orgasm, and resolution:

1. *Desire:* Starts with a desire for sexual intimacy, also known as *libido*.
2. *Excitement:* Both men and women have a heightened sexual awareness. When a female is sexually aroused, her brain coordinates a patterned sexual response cycle consisting of increased heart rate, respiratory rate, blood pressure, and general level of excitement (Meston & Stanton, 2018). With sexual stimulation, tissues in the clitoris and breasts and around the vaginal orifice fill with blood and the erectile tissues swell. At the same time, the vagina begins to expand and elongate to accommodate the penis. As part of the whole vasocongestive reaction, the labia majora and minora swell and darken. As sexual stimulation intensifies, the vestibular glands secrete mucus to moisten and lubricate the tissues to facilitate insertion of the penis. Hormones play an integral role in the female sexual response as well. Adequate estrogen and testosterone must be available for the brain to sense incoming arousal stimuli. Research indicates that estrogen preserves the vascular function of female sex organs and affects genital sensation. It is also believed to promote blood flow to these areas during stimulation. Testosterone is needed to stimulate sexual desire in women. Recent research findings also suggest that testosterone therapy improves sexual desire, arousal, orgasm frequency, and satisfaction in women (Kapoor et al., 2018).
3. *Plateau:* The heart rate, blood pressure, level of muscle tension, and respiration rate all increase. During this phase, the penile erection intensifies and the vagina constricts around the penis. Continued stimulation of the clitoris and penis with movement leads to the next phase of the sexual response, the *orgasmic phase.*
4. *Orgasm:* Orgasm is an intense sensation of pleasure achieved by stimulation of erogenous zones. Women experience rhythmic contractions of the pelvic muscles and vaginal walls. In men, ejaculation occurs during the orgasmic phase, and both sexes

experience a peak of sexual pleasure at orgasm. Typically, the woman feels warm and relaxed after an orgasm. Within a short time after orgasm, the two physiologic mechanisms that created the sexual response, vasocongestion and muscle contraction, rapidly dissipate. The orgasmic experience varies from person to person and from time to time in the same person. Women do not have a refractory period after each orgasm and can therefore experience multiple orgasms. Clitoral sexual response and the female orgasm are not affected by aging. Some orgasms are intense, some are quiet, and some are gentle (Goldstein et al., 2018).

5. *Resolution:* At the completion of the sexual episode, the brain and body return to an unaroused state, which is termed *sexual resolution*. During this phase, the heart rate, blood pressure, and respirations slow; the muscles relax. Frequently, fatigue sets in for both people.

THE FEMALE REPRODUCTIVE CYCLE

The female reproductive cycle is a complex process that encompasses an intricate series of chemical secretions and reactions to produce the ultimate potential for fertility and birth. The female reproductive cycle is a general term that includes the ovarian cycle, the endometrial (uterine) cycle, the hormonal changes that regulate them, and the cyclical changes in the breasts. The endometrium, ovaries, pituitary gland, and hypothalamus are all involved in the cyclic changes that help prepare the body for fertilization. Absence of fertilization results in **menstruation**, the monthly shedding of the uterine lining. Menstruation marks the beginning and end of the monthly cycle. Menopause is the naturally occurring cessation of menstrual cycles.

The menstrual cycle results from a functional hypothalamic–pituitary–ovarian axis and a precise sequencing of hormones that lead to ovulation. The ovarian cycle, during which ovulation occurs, and the endometrial cycle, during which menstruation occurs, are divided at midcycle by ovulation. **Ovulation** occurs when the ovum is released from its follicle; after leaving the ovary, the ovum enters the

fallopian tube and journeys toward the uterus. If a sperm cell fertilizes the ovum during its journey, pregnancy occurs (Fig. 3.6).

Ovarian Cycle

The ovarian cycle is the series of events associated with a developing oocyte (ovum or egg) within the ovaries. Whereas men manufacture sperm daily, often into advanced age, women are born with a single lifetime supply of ova that are released from the ovaries gradually throughout the childbearing years. In the female ovary, 1 million oocytes are present at birth, and about 200,000 to 400,000 follicles are still present at puberty. Typically, a woman ovulates one oocyte per month over an approximately 40-year reproductive lifespan. This accounts for the loss of 400 to 500 follicles. By age 35, she will have fewer than 100,000 follicles, and by menopause, her follicular supply will be nearly depleted (Strauss et al., 2019). The ovarian cycle begins when the follicular cells (ovum and surrounding cells) swell and the maturation process starts. The maturing follicle at this stage is called a graafian follicle. The ovary raises many follicles monthly, but usually only one follicle matures to reach ovulation. The ovarian cycle consists of three phases: the follicular phase, ovulation, and the luteal phase.

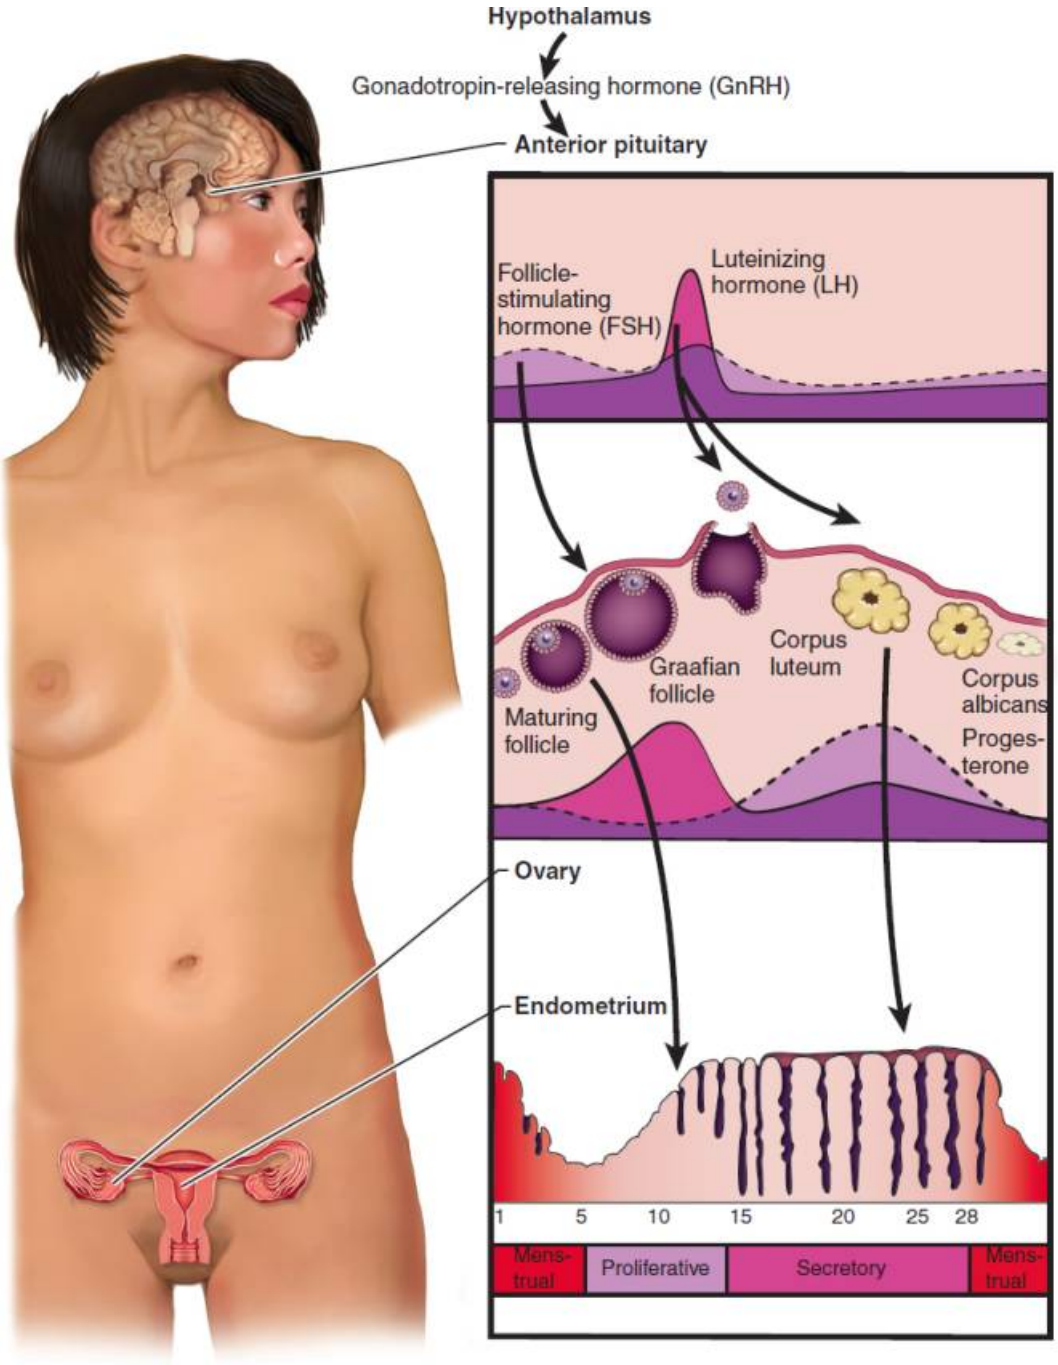

FIGURE 3.6. Menstrual cycle summary based on a 28-day (average) menstrual cycle.

Follicular Phase

This phase is so named because it is when the follicles in the ovary grow and form a mature egg. The goal of this phase is to produce an

ovum for fertilization. This phase starts on day 1 of the menstrual cycle and continues until ovulation, approximately 10 to 14 days later. The follicular phase is not consistent in duration because of the time variations in follicular development. These variations account for the differences in menstrual cycle lengths (Strauss et al., 2019). The hypothalamus is the initiator of this phase. Increasing levels of estrogen secreted from the maturing follicular cells and the continued growth of the dominant follicle cell induce proliferation of the endometrium and myometrium. This thickening of the uterine lining supports an implanted ovum if pregnancy occurs.

Prompted by the hypothalamus, the pituitary gland releases **follicle-stimulating hormone (FSH)**, which stimulates the ovary to produce five to 20 immature follicles. Each follicle houses an immature oocyte or egg. The follicle that is targeted to mature fully will soon rupture and expel a mature oocyte in the process of ovulation. A surge in **luteinizing hormone (LH)** from the anterior pituitary gland is responsible for affecting the final development and subsequent rupture of the mature follicle.

Ovulation

Ovulation is the appropriately timed release of a mature, developmentally competent oocyte from the ovary into the oviduct, where fertilization takes place. At ovulation, a mature follicle ruptures in response to a surge of LH from the pituitary gland, releasing a mature oocyte. The LH surge is the trigger that sets in motion and coordinates both the final stages of oocyte maturation, as well as follicular rupture. No one single event causes ovulation. This approximately occurs on day 14 in a 28-day cycle. When ovulation occurs, there is a drop in estrogen. Typically, ovulation takes place approximately 10 to 12 hours after the LH peak and 24 to 36 hours after estrogen levels peak (Richards & Ascoli, 2018). The distal ends of the fallopian tubes become active near the time of ovulation and create currents that help carry the ovum into the uterus. The lifespan of the ovum is only about 24 hours; unless it meets a sperm on its journey within that time, it will die.

During ovulation, the cervix produces thin, clear, stretchy, slippery mucus that is designed to capture the man's sperm, nourish it, and help the sperm travel up through the cervix to meet the ovum for fertilization. Ovulation symptoms also include vaginal spotting, an increase in vaginal discharge giving the woman a "feeling of wetness," increased libido leading to more desire to be intimate, a slight rise in basal body temperature, and lower abdominal cramping.

The one constant, whether a women's cycle is 28 days or 120 days, is that ovulation takes place at least 14 days before menstruation (Robker et al., 2018).

TAKE NOTE!

About one in five women can feel a pain on one side of the abdomen around the time the egg is released. This midcycle pain is called mittelschmerz.

CONSIDER THIS

We had been married for 2 years when my husband and I decided to start a family. I began thinking back to my high school biology class and tried to remember about ovulation and what to look for. I also used the internet to find the answers I was seeking. As I was reading, it all started to come into place. During ovulation, a woman's cervical mucus increases and she experiences a wet sensation for several days midcycle. The mucus also becomes stretchable during this time. In addition, body temperature rises slightly and then falls if no conception takes place. Armed with this knowledge, I began to check my temperature daily before arising and began to monitor the consistency of my cervical mucus. I figured that monitoring these two signs of ovulation could help me discover the best time to conceive. After 6 months of trying without results, I wondered what I was doing wrong. Did I really understand my body's reproductive activity?

Thoughts: What additional suggestions might the nurse offer this woman in her journey to conception? What community resources might be available to assist this couple? How does knowledge of the reproductive system help nurses care for people who are trying to become pregnant?

Luteal Phase

The luteal phase begins at ovulation and lasts until the menstrual phase of the next cycle. It typically occurs on days 15 through 28 of a 28-day cycle. After the follicle ruptures as it releases the egg, it closes and forms a corpus luteum. The corpus luteum secretes increasing amounts of the hormone progesterone, which interacts with the endometrium to prepare it for implantation. At the beginning of the luteal phase, progesterone induces the endometrial glands to secrete glycogen, mucus, and other substances. These glands become tortuous and have large lumens due to increased secretory activity. The progesterone secreted by the corpus luteum causes the temperature of the body to rise slightly until the start of the next period. A significant increase in temperature, usually 0.5° to 1°F, is

generally seen within a day or two after ovulation has occurred; the temperature remains elevated until 3 days before the onset on the next menstruation (Strauss et al., 2019). This rise in temperature can be plotted on a graph and gives an indication of when ovulation has occurred. In the absence of fertilization, the corpus luteum begins to degenerate and consequently ovarian hormone levels decrease. As estrogen and progesterone levels decrease, the endometrium undergoes involution. FSH and LH are generally at their lowest levels during the luteal phase and highest during the follicular phase.

Endometrial (Uterine) Cycle

The endometrial (uterine) cycle occurs in response to cyclic hormonal changes. The four phases of the endometrial cycle are the proliferative phase, secretory phase, ischemic phase, and menstrual phase.

Proliferative Phase

The proliferative phase of the endometrial cycle corresponds to the follicular phase of the ovarian cycle. It starts with enlargement of the endometrial glands in response to dramatically increasing amounts of estrogen. The blood vessels become dilated and the endometrium increases in thickness from 0.5 to 5 mm in height and increases eightfold in thickness in preparation for implantation of the fertilized ovum (Oyelowo & Johnson, 2018). Cervical mucus becomes thin, clear, stretchy, and more alkaline, making it more favorable to sperm to enhance the opportunity for fertilization. The proliferative phase starts on about day 5 of the menstrual cycle and lasts to the time of ovulation. This phase depends on estrogen stimulation resulting from ovarian follicles, and this phase coincides with the follicular phase of the ovarian cycle.

Secretory Phase

The secretory phase begins at ovulation to about 3 days before the next menstrual period. Under the influence of progesterone released

by the corpus luteum after ovulation, the endometrium becomes thickened and more vascular (growth of the spiral arteries) and glandular (secretion of more glycogen and lipids). These dramatic changes are all in preparation for implantation if it is to occur. This phase typically lasts from day 15 (after ovulation) to day 28 and coincides with the luteal phase of the ovarian cycle. In the absence of fertilization by day 23 of the menstrual cycle, the corpus luteum begins to degenerate and consequently ovarian hormone levels decrease. As estrogen and progesterone levels decrease, the endometrium undergoes involution.

Concept Mastery Alert

Proliferative Versus Secretory Phases of the Uterine Cycle

During the proliferative phase, the ovarian follicles are producing increased amounts of estrogen, and the endometrium prepares for possible fertilization with pronounced growth. The secretory phase begins at the time of ovulation. If the ovum is not fertilized, then the corpus luteum degenerates and hormone levels fall, ultimately resulting in menstruation.

Ischemic Phase

If fertilization does not occur, the ischemic phase begins. Estrogen and progesterone levels drop sharply during this phase as the corpus luteum starts to degenerate. Changes in the endometrium occur with spasm of the arterioles, resulting in ischemia of the basal layer. The ischemia leads to shedding of the endometrium down to the basal layer, and menstrual flow begins.

Menstrual Phase

The menstrual phase begins as the spiral arteries rupture secondary to ischemia, releasing blood into the uterus, and the sloughing of the endometrial lining begins. If fertilization does not take place, the corpus luteum degenerates. As a result, both estrogen and progesterone levels fall, and the thickened endometrial lining sloughs away from the uterine wall and passes out through the vagina. The beginning of the menstrual flow marks the end of one

menstrual cycle and the start of a new one. Most women report menstrual bleeding for an average of 3 to 7 days. The amount of menstrual flow varies but averages 1 oz or a range of approximately 2/3 to 2 2/3 oz in volume per cycle (Schillo, 2019).

Menstruation

Menstruation is a term derived from the Latin word *mensis*, meaning "month." It is the normal, predictable physiologic process whereby the inner lining of the uterus (endometrium) is expelled by the body. Typically, this occurs monthly. Menstruation has many effects on girls and women, including emotional and self-image changes. In the United States, the average age at **menarche** (the start of menstruation in females) is 12 years with a range between eight and 18 (AAP, 2019). Genetics is the most important factor in determining the age at which menarche starts, but geographic location, nutrition, weight, general health, nutrition, cultural and social practices, the girl's educational level, attitude, family environment, and beliefs are also important (Jarrell, 2018).

Pubertal events preceding the first menses have an orderly progression: thelarche, the development of breast buds; adrenarche, the appearance of pubic and then axillary hair followed by a growth spurt; and menarche (occurring about 2 years after the start of breast development). In healthy pubertal girls, the menstrual period varies in flow heaviness and may remain irregular in occurrence for up to 2 years following menarche. After that time, the regular menstrual cycle should be established. Most women will experience 300 to 400 menstrual cycles within their lifetimes (Jarrell, 2018). Normal, regular menstrual cycles vary in frequency and blood loss (Oyelowo & Johnson, 2018). Irregular menses can be associated with irregular ovulation, polycystic ovary syndrome, type 2 diabetes, weather conditions, stress, disease, thyroid disorders, and hormonal imbalances (Goldstein, Clayton et al., 2019).

Think back to Linda, who was introduced at the beginning of the chapter. What questions might need to be asked to assess her condition? What laboratory work might be anticipated to validate her heavier flow?

Although menstruation is a normal process, various world cultures have taken a wide variety of attitudes toward it, seeing it as everything from a sacred time to an unclean time. Folk culture surrounding menstrual-related matters has considerable implications for symptom expression and treatment-seeking behavior. Recent research findings imply the need for education to help adolescent girls manage menstrual symptoms and increase awareness of the benefit of treating them. Given that menstrual-related information comes from mothers, family, and social culture, negative attitudes toward monthly cycles can be formed in young impressionable girls. Nurses, through formal instruction or casual one-on-one discussions, can open doors to many conversations with young girls to help shape good menstrual attitudes and a more positive image of this natural physiologic process (Szulecki, 2018).

TAKE NOTE!

Knowledge about menstruation has increased significantly and attitudes have changed. What was once discussed only behind closed doors is discussed openly today.

Menstrual Cycle Hormones

The menstrual cycle involves a complex interaction of hormones. The predominant hormones include gonadotropin-releasing hormone (GnRH), FSH, LH, estrogen, progesterone, and prostaglandins. Box 3.1 summarizes menstrual cycle hormones.

Gonadotropin-Releasing Hormone

GnRH is secreted from the hypothalamus in a pulsatile manner throughout the reproductive cycle. It pulsates slowly during the

follicular phase and increases during the luteal phase. GnRH induces the release of FSH and LH to assist with ovulation.

BOX 3.1 Summary of Menstrual Cycle Hormones

- LH rises and stimulates the follicle to produce estrogen.
- As estrogen is produced by the follicle, estrogen levels rise, inhibiting the output of LH.
- Ovulation occurs after an LH surge damages the estrogen-producing cells, resulting in a decline in estrogen.
- The LH surge results in establishment of the corpus luteum, which produces estrogen and progesterone.
- Estrogen and progesterone levels rise, suppressing LH output.
- Lack of LH promotes degeneration of the corpus luteum.
- Cessation of the corpus luteum means a decline in estrogen and progesterone output.
- The decline of the ovarian hormones ends their negative effect on the secretion of LH.
- LH is secreted, and the menstrual cycle begins again.

Follicle-Stimulating Hormone

FSH is secreted by the anterior pituitary gland and is primarily responsible for the maturation of the ovarian follicle. FSH secretion is highest and most important during the first week of the follicular phase of the reproductive cycle.

Luteinizing Hormone

LH is secreted by the anterior pituitary gland and is required for both the final maturation of preovulatory follicles and luteinization of the ruptured follicle. As a result, estrogen production declines and progesterone secretion continues. Thus, estrogen levels fall a day before ovulation, and progesterone levels begin to rise.

Estrogen

Estrogen is secreted by the ovaries and is crucial for the development and maturation of the follicle. Estrogen is predominant

at the end of the proliferative phase, directly preceding ovulation. After ovulation, estrogen levels drop sharply as progesterone dominates. In the endometrial cycle, estrogen induces proliferation of the endometrial glands. Estrogen also causes the uterus to increase in size and weight because of increased glycogen, amino acids, electrolytes, and water. Blood supply is expanded as well.

Progesterone

Progesterone is secreted by the corpus luteum. Progesterone levels increase just before ovulation and peak 5 to 7 days after ovulation. During the luteal phase, progesterone induces swelling and increased secretion of the endometrium. This hormone is often called the hormone of pregnancy because of its calming effect (reduces uterine contractions) on the uterus, allowing pregnancy to be maintained.

Prostaglandins

Prostaglandins are primary mediators of the body's inflammatory processes and are essential for the normal physiologic function of the female reproductive system. They are a closely related group of oxygenated fatty acids that are produced by the endometrium with a variety of effects throughout the body. Although they have regulatory effects and are sometimes called hormones, prostaglandins are not technically hormones because they are produced by all tissues rather than by special glands (Smith, 2018). Prostaglandins increase during follicular maturation and play a key role in ovulation by freeing the ovum inside the graafian follicle. Large amounts of prostaglandins are found in menstrual blood. Current research suggests that the pathogenesis of menstrual cramps and pain is due to prostaglandin F2a (PGF2a), a potent myometrial stimulant and vasoconstrictor, in the secretory endometrium. Elevated prostaglandin levels are found in the endometrial fluid of women with dysmenorrhea (painful menses), and this correlates with their degree of pain. Nonsteroidal antiinflammatory drugs are the primary choice of treatment for menstrual cramps (Smith, 2018).

Perimenopause

Perimenopause or menopausal transition and menopause are biologic markers of the transition from young adulthood to middle age. It is the period between the onset of irregular menstrual cycles and the last menstrual period. Neither of these is a symptom or disease but rather a natural maturing of the reproductive system.

During the perimenopausal years (2 to 8 years prior to menopause), women may experience physical changes associated with decreasing estrogen levels, which may include vasomotor symptoms of hot flashes, irregular menstrual cycles, sleep disruptions, forgetfulness, irritability, mood disturbances, decreased fertility, weight gain and bloating, changing bleeding patterns, headaches, decreased vaginal lubrication, night sweats, fatigue, vaginal atrophy, and depression (Delamater & Santoro, 2018). Vasomotor symptoms (hot flashes and night sweats) are the most common complaints for which women seek treatment. Several therapies can be considered to help manage these complaints. Choosing an appropriate treatment approach for the management of these symptoms requires careful assessment of the risk-to-benefit ratio of each evidence-based management option as well as individual client preference (Delamater & Santoro, 2018).

Menopause

Menopause is a universal and irreversible part of the overall aging process involving a woman's reproductive system after which she no longer menstruates. This naturally occurring phase of every woman's life marks the end of her childbearing capacity. The average age of natural menopause—defined as 1 year without a menstrual period—is 50 to 51 years old but varies among different individuals and populations (Casper, 2019). As the average life expectancy for women increases, the number of women reaching and living during menopause has escalated. Most women can expect to spend more than one third of their lives beyond menopause. It is usually marked

by atrophy of the breasts, uterus, fallopian tubes, and ovaries (Bachmann, 2018).

Many women pass through menopause without disruptive symptoms. These women remain active and in good health with little interruption of their daily routines. Other women experience vasomotor symptoms, which give rise to sensations of heat, cold, sweating, headache, insomnia, and irritability. A recent study found that women experiencing menopausal symptoms reported significantly lower health-related quality of life and significantly high work impairment when compared to women without menopausal symptoms.

Genitourinary syndrome of menopause describes the constellation of lower urogenital signs and symptoms associated with a low-estrogen state. Physiologically, this syndrome manifests with symptoms of vaginal dryness, irritation, and itching; decreased lubrication during intercourse; dyspareunia; dysuria; and urinary frequency and urgency. This is often underdiagnosed and undertreated (Santoro & Lin, 2018).

Previously, hormone therapy was the mainstay of menopause pharmacotherapy, but with the results of the Women's Health Initiative trial and the Heart and Estrogen Replacement Study (HERS) (2020), the use of hormone therapy has become controversial. Many women have turned to nontraditional remedies to manage their menopausal symptoms. Common complementary and alternative medicine (CAM) remedies used for the treatment of menopausal symptoms include black cohosh, dong quai, St. John's wort, hops, wild yam, ginseng, evening primrose oil, and acupuncture. Evidence supporting the efficacy and safety of most CAM remedies for relief of menopausal symptoms is limited. Many reports concerning their efficacy and safety are not supportive of the claims made (Adams et al., 2018). Nurses can play a major role in assisting menopausal women by educating and counseling them about the multitude of options available for disease prevention and treatments for menopausal symptoms during this time of change. Menopause should be an opportunity for women to strive for healthy,

long lives, and nurses can help to make this opportunity a reality. See Chapter 4 for more information about menopause.

Recall Linda, who was experiencing changes in her menstrual patterns. Which hormones might be changing, and which systems might they affect? What approach should the nurse take to enlighten Linda about what is happening in her body?

MALE REPRODUCTIVE ANATOMY AND PHYSIOLOGY

The male reproductive system, like that of the female, consists of those organs that facilitate reproduction. The male organs are specialized to produce and maintain the male sex cells, or sperm; to transport them along with supporting fluids to the female reproductive system; and to secrete the male hormone testosterone. The organs of the male reproductive system include the penis, scrotum, two testes (where sperm cells and testosterone are made), and accessory organs (epididymis, vas deferens, seminal vesicles, ejaculatory duct, urethra, bulbourethral glands, and prostate gland).

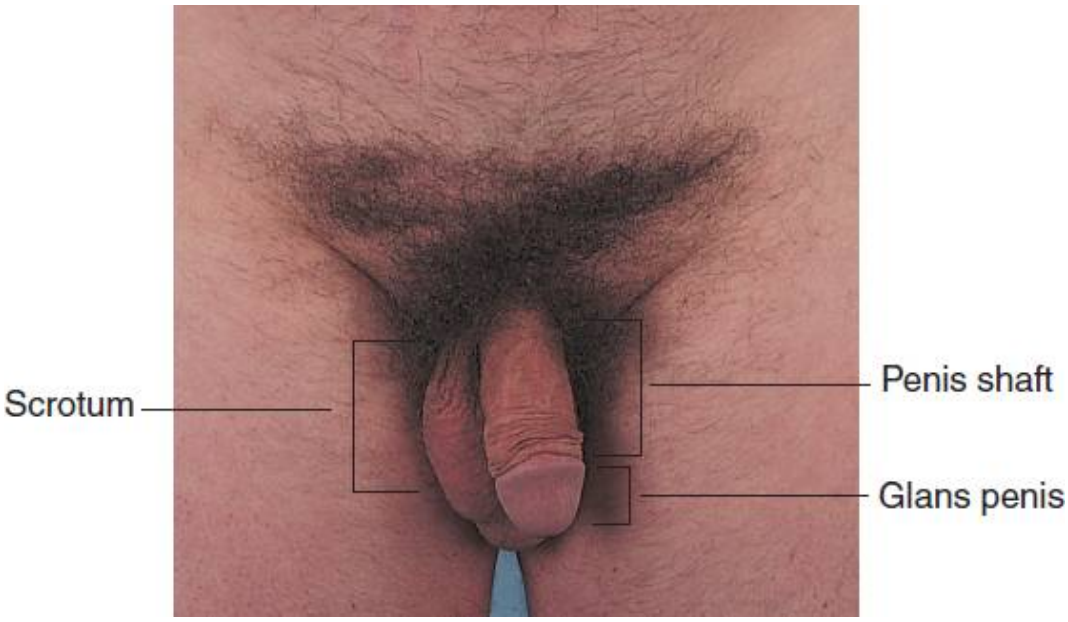

FIGURE 3.7. The external male reproductive organs. (Photo by B. Proud.)

External Male Reproductive Organs

The penis and the scrotum form the external genitalia in the male (Fig. 3.7).

Penis

The penis is the organ for copulation and serves as the outlet for both sperm and urine. The penis becomes engorged with blood during sexual arousal and is inserted into the female vagina during intercourse. The skin of the penis is thin without hair. The prepuce (foreskin) is a circular fold of skin that extends over the glans unless it is removed by circumcision shortly after birth. The urinary meatus, located at the tip of the penis, serves as the external opening to the urethra (Fig. 3.8). The penis is composed mostly of erectile tissue. Most of the body of the penis consists of three cylindrical spaces (sinuses) of erectile tissue. The two larger ones, the corpora cavernosa, are side by side. The third sinus, the corpus spongiosum, surrounds the urethra. Erection results when nerve impulses from

the autonomic nervous system dilate the arteries of the penis, allowing arterial blood to flow into the erectile tissues of the organ.

Scrotum

The scrotum is the thin-skinned sac that surrounds and protects the testes. The scrotum also acts as a climate-control system for the testes, because they need to be slightly cooler than body temperature to allow for normal sperm development. The scrotum is covered with hair starting in puberty. The cremaster muscles in the scrotal wall relax or contract to allow the testes to hang farther from the body to cool or to be pulled closer to the body for warmth or protection (Carroll, 2019). A medial septum divides the scrotum into two chambers, each of which encloses a testis.

FIGURE 3.8. The urinary meatus. (Photo by B. Proud.)

Internal Male Reproductive Organs

The internal structures include the testes, the ductal system, and accessory glands (Fig. 3.9).

Testes

The **testes** are oval bodies the size of large olives that lie in the scrotum; usually the left testis hangs a little lower than the right one. These nut-like structures are analogous to ovaries in the female, and two testes are present in males. The testes have two functions: producing sperm and synthesizing testosterone (the primary male sex hormone). Sperm is produced in the seminiferous tubules of the testes. Similar to the female reproductive system, the anterior pituitary releases the gonadotropins, FSH and LH. These hormones stimulate the testes to produce testosterone, which assists in maintaining spermatogenesis, increases sperm production by the seminiferous tubules, and stimulates production of seminal fluid (Schillo, 2019). The epididymis, which lies against the testes, is a coiled tube almost 20 ft long. It collects sperm from the testes and provides the space and environment for sperm to mature (Fig. 3.10).

The Ductal System

The vas deferens is a cord-like duct that transports sperm from the epididymis. One such duct travels from each testis up to the back of the prostate and enters the urethra to form the ejaculatory ducts. Other structures, such as blood vessels and nerves, also travel along with each vas deferens and together form the spermatic cord. The urethra is the terminal duct of the reproductive and urinary systems, serving as a passageway for semen (fluid containing sperm) and urine. It passes through the prostate gland and the penis and opens to the outside.

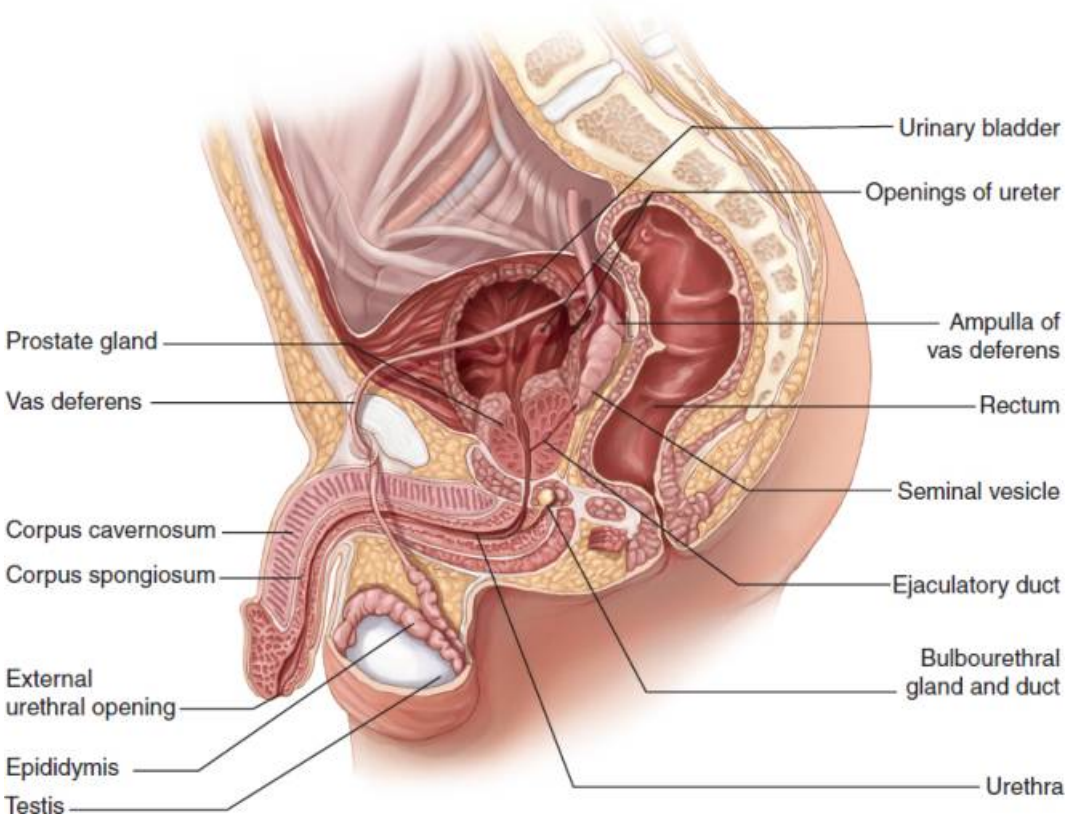

FIGURE 3.9. Lateral view of the internal male reproductive organs. (Source: Anatomical Chart Company. [2001]. *Atlas of human anatomy*. Springhouse.)

Accessory Glands

The seminal vesicles, which produce nutrient-dense seminal fluid, and the prostate gland, which produces alkaline prostatic fluid, are both connected to the ejaculatory duct leading into the urethra. The paired seminal vesicles are convoluted pouch-like structures lying posterior to and at the base of the urinary bladder in front of the rectum. They secrete an alkaline fluid that contains fructose, vitamin C, proteins, and prostaglandins. The fructose supplies energy to the sperm on its journey to meet the ovum, and the prostaglandins assist in sperm mobility.

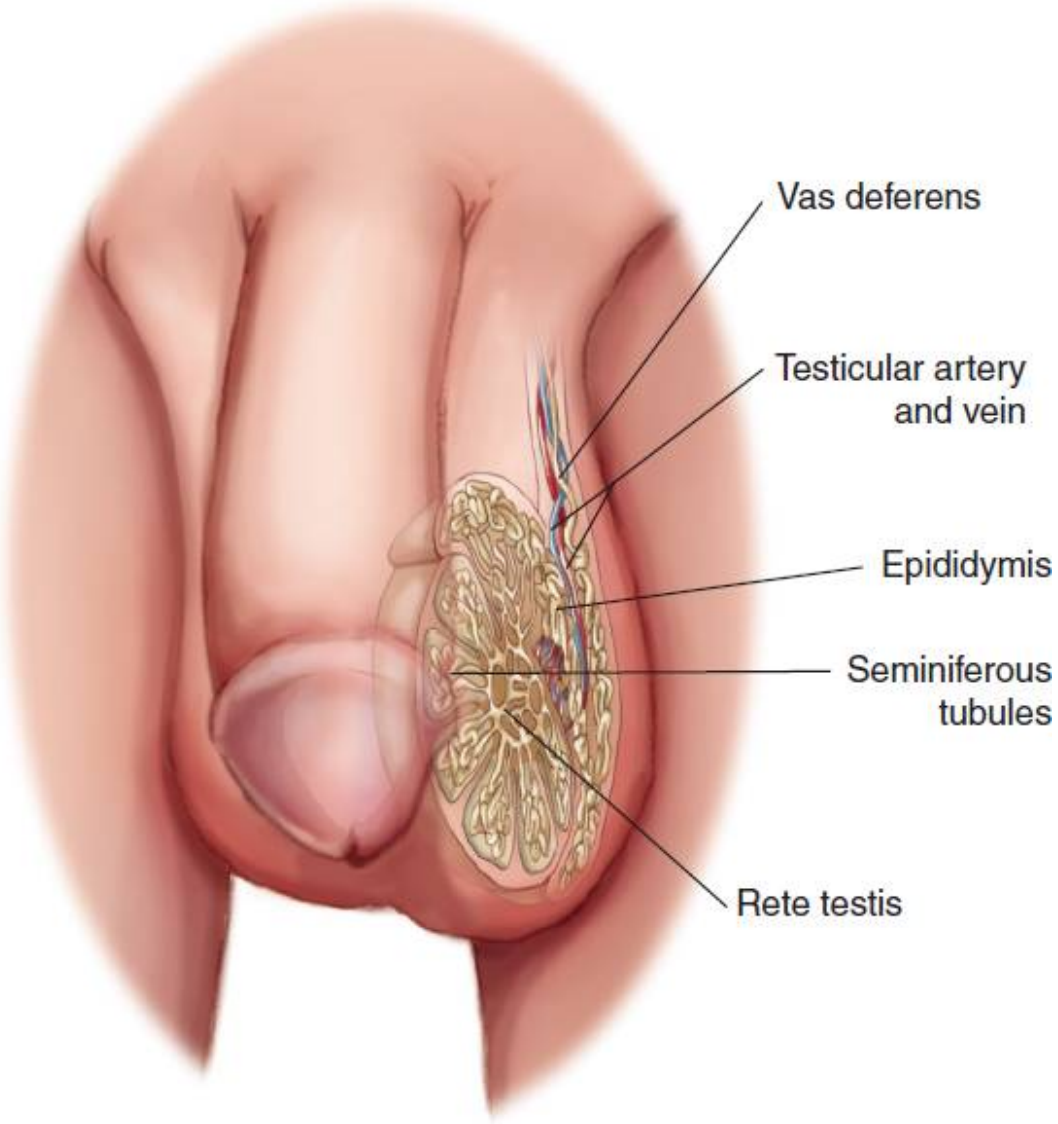

FIGURE 3.10. Internal structures of a testis.

The prostate gland lies just under the bladder in the pelvis and surrounds the middle portion of the urethra. Usually the size of a walnut, this gland enlarges with age. The prostate and the seminal vesicles above it produce fluid that nourishes the sperm. This fluid provides most of the volume of semen, the secretion in which sperm are expelled during ejaculation. Other fluid that makes up the semen comes from the vas deferens and from mucous glands in the head of the penis. The prostate gland also produces prostate-specific antigen (PSA), a glycoprotein that thins semen and cervical mucus,

allowing sperm to travel within the female reproductive tract more easily. PSA levels are elevated when prostatic cancer is present, and these levels are used as a marker for diagnosis and treatment (Webster et al., 2018).

The bulbourethral glands (Cowper glands) are two small structures about the size of peas, located inferior to the prostate gland. They are composed of several tubes with epithelial linings that secrete a mucus-like fluid. It is released in response to sexual stimulation and lubricates the head of the penis in preparation for sexual intercourse. Additionally, it neutralizes the acidity of the urethra to protect sperm during their journey out of the body during ejaculation. Their existence is said to be constant, but they gradually diminish in size with advancing age.

Male Sexual Response

Testosterone is deeply involved in every step of the male sexual response. Regardless of the type of sexual stimulation, the physiologic response in both men and women is similar and usually follows a five-phase pattern as described in women earlier:

1. *Desire:* Starts with a desire for sexual intimacy. This can also be termed “libido.”
2. *Excitement:* The man experiences sexual arousal with either thoughts or physical sexual stimuli which cause specific changes such as the heart beating faster, blood pressure rising, the testicles enlarging, and more blood flowing into the penis, creating an erection.
3. *Plateau:* This is the phase between excitement and orgasm in which the head of the penis enlarges and becomes more purplish in color. The glands secrete semen into the urethra, and it becomes challenging to stop from having an orgasm.
4. *Orgasm:* This is a total body response. The tension that built up during the previous two phases is released. It triggers a series of muscle spasms in the legs, stomach, arms, back, and penis. The feelings are intense and pleasurable. Ejaculation of semen occurs at this time.

5. *Resolution:* The body returns to the physiologic nonstimulated state. The blood flows away from the penis and erection ceases; an overall feeling of relaxation ensues, and the testes and scrotum return to their normal size (Seizert, 2018).

Sexual behavior involves the participation of autonomic and somatic nerves and the integration of numerous spinal sites in the central nervous system (CNS). The penile portion of the process that leads to erections represents only a single component. Penile erections are an integration of complex physiologic processes involving the CNS, peripheral nervous system, and hormonal and vascular systems (Schillo, 2019). With sexual stimulation, the arteries leading to the penis dilate and increase blood flow into erectile tissues. At the same time, the erectile tissue compresses the veins of the penis, reducing blood flow away from the penis. Blood accumulates, causing the penis to swell and elongate, producing an erection. As in women, the culmination of sexual stimulation is an orgasm, a pleasurable feeling of physiologic and psychological release.

Orgasm is accompanied by emission (movement of sperm from the testes and fluids from the accessory glands) into the urethra, where the sperm and fluids are mixed to form semen. As the urethra fills with semen, the base of the erect penis contracts; this increases pressure. This pressure forces the semen through the urethra to the outside (ejaculation). During ejaculation, the ducts of the testes, epididymis, and vas deferens contract and cause expulsion of sperm into the urethra, where the sperm mixes with the seminal and prostatic fluids. These substances, together with mucus secreted by accessory glands, form the semen, which is discharged from the urethra.

KEY CONCEPTS

- The female reproductive system produces the female reproductive cells (the eggs, or ova) and contains an organ (uterus) where the fetus develops. The male reproductive system produces the male reproductive cells (the sperm) and contains an organ (penis) that deposits the sperm within the female.
- The internal female reproductive organs consist of the vagina, the uterus, the fallopian tubes, and the ovaries. The external female reproductive organs make up the vulva. These include the mons pubis, the labia majora and minora, the clitoris and prepuce, structures within the vestibule, and the perineum.
- The breasts are accessory organs of the female reproductive system that are specialized to secrete milk following pregnancy.
- The main function of the reproductive cycle is to stimulate growth of a follicle to release an egg and prepare a site for implantation if fertilization occurs.
- Menstruation, the monthly shedding of the uterine lining, marks the beginning and end of the cycle if fertilization does not occur.
- The ovarian cycle is the series of events associated with a developing oocyte (ovum or egg) within the ovaries.
- At ovulation, a mature follicle ruptures in response to a surge of LH, releasing a mature oocyte (ovum).
- The endometrial cycle is divided into four phases: the follicular or proliferative phase, the luteal or secretory phase, the ischemic phase, and the menstrual phase.
- The menstrual cycle involves a complex interaction of hormones. The predominant hormones are GnRH, FSH, LH, estrogen, progesterone, and prostaglandins.
- The organs of the male reproductive system include the penis, scrotum, two testes (where sperm cells and testosterone are made), and accessory organs (epididymis, vas deferens, seminal vesicles, ejaculatory ducts, urethra, bulbourethral glands, and prostate gland).

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. The predominant anterior pituitary hormone that orchestrates the menstrual cycle is

   a. thyroid-stimulating hormone (TSH).
   b. follicle-stimulating hormone (FSH).
   c. corticotropin-releasing hormone (CRH).
   d. gonadotropin-releasing hormone (GnRH).

2. Which glands are located on either side of the female urethra and secrete mucus to keep the opening moist and lubricated for urination?

   a. Cowper
   b. Bartholin
   c. Skene
   d. Seminal

3. What event occurs during the proliferative phase of the menstrual cycle?

   a. Menstrual flow starts
   b. Endometrium thickens
   c. Ovulation occurs
   d. Progesterone secretion peaks

4. Which hormone is produced in high levels to prepare the endometrium for implantation just after ovulation by the corpus luteum?

   a. Estrogen
   b. Prostaglandins
   c. Prolactin

d. Progesterone

5. Sperm maturation and storage in the male reproductive system occur in the

a. testes.
b. vas deferens.
c. epididymis.
d. seminal vesicles.

6. The nurse is preparing to teach a class to a group of middle-aged women regarding the most common vasomotor symptoms experienced during menopause and possible modalities of treatment available. Which are common vasomotor symptoms?

a. Chronic fatigue and confusion
b. Forgetfulness and irritability
c. Night sweats and hot flashes
d. Decrease in sexual response and appetite

CRITICAL THINKING EXERCISES

1. The school nurse was asked to speak to a 10th-grade biology class about menstruation. The teacher felt that the students did not understand this monthly event and wanted the nurse to dispel some myths about it. After the nurse explains the factors influencing the menses, one girl asks, “Could someone get pregnant if she has sex during her period?”

a. How should the nurse respond to this question?
b. What factor regarding the menstrual cycle was not clarified?
c. What additional topics might this question lead to that might be discussed?

STUDY ACTIVITIES

1. Should sex education be taught in public schools, and if so, what topics should be addressed? Debate the pros and cons of teaching this, and outline which topics should be covered.
2. Respond to the following as a topic sentence: “When I was growing up, talking about sexual matters with my parents was _____ because _____. Now the situation is _____.”
3. List the predominant hormones and their functions in the menstrual cycle.
4. The ovarian cycle describes the series of events associated with the development of the _____ within the ovaries.
5. Sperm cells and the male hormone testosterone are made in which structures? Select all that apply.

   a. Vas deferens
   b. Penis
   c. Scrotum
   d. Ejaculatory ducts
   e. Prostate gland
   f. Testes
   g. Seminiferous tubules
   h. Bulbourethral glands

BRINGING IT ALL TOGETHER: A CASE STUDY

A 53-year-old woman came to see her women’s health nurse practitioner for her annual examination. She had a hysterectomy 20 years ago for a prolapsed uterus and has been healthy up until now. She had a long list of symptoms that had been bothering her, but until recently just chalked them up to the aging process. She told the nurse practitioner that she was experiencing insomnia, weight gain around her middle abdomen despite not consuming additional calories, painful intercourse, and hot flashes that were increasing in frequency throughout the day and night.

She had been taking black cohosh for these distressing symptoms for the past several months but was not experiencing any relief. She was concerned that something awful was wrong with her since this natural herb was not reducing her symptoms and they seemed to be getting worse.

Go to thePoint to find questions to consider about this case.

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Examine common gynecologic concerns in terms of symptoms, diagnostic tests, and appropriate interventions.
2. Evaluate risk factors and outline appropriate client education needed in common gynecologic disorders.
3. Delineate the nursing management needed for women experiencing common gynecologic disorders.
4. Compare and contrast the various contraceptive methods available and their overall effectiveness.
5. Explore the challenges associated with induced abortion in our society today.
6. Analyze the physiologic and psychological aspects of menopausal transition.

Izzy, a 27-year-old, presents to her health care provider complaining of progressive severe pelvic pain associated with her monthly periods. She has to take off work and “dope up” with pills to endure the pain. In addition, she has been trying to conceive for over a year without any luck.

INTRODUCTION

Good health throughout the life cycle begins with the individual. Women today can expect to live well into their 80s and need to be proactive in maintaining their own quality of life. Women must take steps to reduce their risk of disease and need to become active partners with their health care professionals to identify problems early, when treatment may be most successful (Teaching Guidelines 4.1). Nurses can assist women in maintaining their quality of life by helping them become more attuned to their bodies and their bodies’ clues and can use the assessment period as an opportunity for teaching and counseling. Nurses are in a prime position to offer

information that provides women with the tools needed to maintain healthy lifestyles and assist in altering behaviors that may cause harm or illness.

TEACHING GUIDELINES 4.1

Tips for Being an Active Partner in Managing Your Health

- Become an informed consumer. Read, ask, and search.
- Know family history and know factors that put you at high risk for different disorders.
- Maintain a healthy lifestyle and let moderation be your guide.
- Schedule regular medical check-ups and screenings for early detection.
- Ask your health care provider for a full explanation of any treatment.
- Seek a second medical opinion if you feel you need more information.
- Know when to seek medical care by being aware of disease symptoms.

Common reproductive issues addressed in this chapter that nurses might encounter in caring for women include menstrual disorders, infertility, contraception, abortion, and the menopausal transition.

MENSTRUAL DISORDERS

Menstrual patterns can be an indicator of overall health and self-perception of well-being. Many women sail through their monthly menstrual cycles with little or no concerns. With few symptoms to worry about, their menses are like clockwork, starting and stopping at nearly the same times every month. For others, the menstrual cycle causes physical and emotional symptoms that initiate visits to their health care providers for consultation. The following menstruation-related conditions will be discussed in this section: amenorrhea, dysmenorrhea, abnormal uterine bleeding (AUB),

premenstrual syndrome (PMS), premenstrual dysphoric disorder (PMDD), and endometriosis. To gain an understanding of menstrual disorders, nurses should know the word parts used to describe them (Box 4.1).

BOX 4.1 Menstrual Disorder Vocabulary

- *meno* = menstrual related
- *metro* = time
- *oligo* = few
- *a* = without, none or lack of
- *rhagia* = excess or abnormal
- *dys* = not or pain
- *rhea* = flow

Amenorrhea

Amenorrhea simply means absence of menses. It is a symptom, not a diagnosis. Amenorrhea is normal in prepubertal, pregnant, postpartum, and postmenopausal females. It usually indicates a defect somewhere in the hypothalamic–pituitary–ovarian–uterine axis to induce cyclic changes in the endometrium that normally result in menses. All of these parts of the body must function properly and in harmony for a menstrual cycle to occur. Amenorrhea is categorized as either primary or secondary. Primary amenorrhea is defined as either the:

1. absence of menses by age 15, with absence of growth and development of secondary sexual characteristics; or
2. absence of menses by age 16, with normal development of secondary sexual characteristics (Creighton et al., 2018).

Of girls living in the United States, 98% menstruate by age 15 (Oyelowo & Johnson, 2018). Recent data suggest that pubertal development, and hence menarche, continues to begin earlier in American girls than it did decades ago (Rebar, 2018). Once menarche has occurred, cycles may take up to 2 years to become regular, ovulatory cycles. Secondary amenorrhea is the absence of

regular menses for three cycles or irregular menses for 6 months in women who have previously menstruated regularly.

Nurses need to consider the causes of amenorrhea as due to one of four factors: ovarian failure; congenital absence of the uterus and vagina; GnRH deficiency; or constitutional delay of puberty. Outflow area problems are obstructive in nature and can be found on physical exam, while ovarian, pituitary, and central nervous system problems involve disruptions in the hypothalamic–pituitary–ovarian–uterine axis that controls the neuroendocrine processes required for a normal menstrual cycle and are generally found through laboratory analysis (Knaus et al., 2018).

Etiology

Primary amenorrhea has multiple causes, including:

- Extreme weight gain or loss
- Congenital abnormalities of the reproductive system
- Stress from a major life event
- Excessive exercise
- Eating disorders (anorexia nervosa or bulimia)
- Cushing disease
- Polycystic ovary syndrome
- Hypothyroidism
- Turner syndrome—defective development of the gonads (ovary or testes)
- Imperforate hymen
- Chronic illness—diabetes, thyroid disease, depression
- Pregnancy
- Cystic fibrosis
- Congenital heart disease (cyanotic)
- Ovarian or adrenal tumors

Causes of secondary amenorrhea can include:

- Pregnancy
- Breastfeeding
- Chronic prolonged stress
- Pituitary, ovarian, or adrenal tumors
- Depression

- Hyperthyroid or hypothyroid conditions
- Malnutrition
- Hyperprolactinemia
- Rapid weight gain or loss
- Chemotherapy or radiation therapy to the pelvic area
- Vigorous exercise, such as long-distance running
- Kidney failure
- Colitis
- Chemotherapy, irradiation
- Use of tranquilizers or antidepressants
- Postpartum pituitary necrosis (Sheehan syndrome)
- Early menopause (Klein et al., 2019)

Therapeutic Management

Therapeutic intervention depends on the cause of the amenorrhea. The treatment of primary amenorrhea involves the correction of any underlying disorders and estrogen replacement therapy to stimulate the development of secondary sexual characteristics if they are absent (Welt & Barbieri, 2018). If a pituitary tumor is the cause, it might be treated with drug therapy, surgical resection, or radiation therapy. Surgery might be needed to correct any structural abnormalities of the genital tract. Dopamine agonists are effective in treating hyperprolactinemia. In most cases, treatment can restore normal ovarian endocrine function and ovulation (Casanueva & Ghigo, 2018).

Therapeutic interventions for secondary amenorrhea can include:

- Cyclic progesterone, when the cause is anovulation, or **oral contraceptives (OCs)**
- Bromocriptine to treat hyperprolactinemia
- Nutritional counseling to address anorexia, bulimia, or obesity
- GnRH, when the cause is hypothalamic failure
- Thyroid hormone replacement, when the cause is hypothyroidism (Solnik, 2018)

Nursing Assessment

Nursing assessment for the young girl or woman experiencing amenorrhea includes a thorough health history, physical examination, and laboratory and diagnostic tests of selected hormone levels to help to identify any underlying causes.

HEALTH HISTORY AND PHYSICAL EXAMINATION

A thorough history and physical examination are needed to determine the etiology. The history should include questions about the women's menstrual onset and patterns; eating and exercise habits; presence of psychosocial stressors; body weight changes; past illnesses; hospitalizations and surgeries; obstetric history; use of prescription and over-the-counter drugs; recent or past lifestyle changes; and history of present illness with an assessment of any body changes.

The physical examination should begin with an overall assessment of the woman's nutritional status and general health. A sensitive and gentle approach to the pelvic examination is critical in young women. Height, weight, and body mass index (BMI) should be taken, along with vital signs. Hypothermia, bradycardia, hypotension, and reduced subcutaneous fat may be observed in women with anorexia nervosa. Facial hair and acne might be evidence of androgen excess secondary to a tumor. The presence or absence of axillary and pubic hair may indicate adrenal and ovarian hyposecretion or delayed puberty. A general physical examination may uncover unexpected findings that are indirectly related to amenorrhea. For example, hepatosplenomegaly, which may suggest a chronic systemic disease or an enlarged thyroid gland, might point to a thyroid disorder as well as a reason for amenorrhea (Rebar, 2018). Examination of the breasts also deserves careful attention because breast development is a reliable indicator of estrogen production. The Tanner stages of breast development should be noted also. The Tanner stages include:

- Stage I—Papilla elevation only (tip of nipple is raised)
- Stage II—Breast buds palpable and areolae enlarge at approximately 11 years old

- Stage III—Elevation of breast contour; areolae enlarge at approximately 12 years old
- Stage IV—Areolae forms secondary mound on the breast at approximately 13 years old
- Stage V—Adult breast contour; areola recesses to breast contour (Edelman & Kudzma, 2018)

Information gained from the history and physical exam can clearly exclude certain diagnostic possibilities, but first impressions can be deceiving and lead to errors in judgment. A methodical, systematic approach to identify the etiology of amenorrhea is best.

LABORATORY AND DIAGNOSTIC TESTS

Common laboratory tests that might be ordered to determine the cause of amenorrhea include:

- Karyotype (might be positive for Turner syndrome)
- Ultrasound to detect ovarian cysts
- Quantitative human chorionic gonadotropin (hCG) test to rule out pregnancy
- Thyroid function studies to determine thyroid disorder
- Prolactin level (an elevated level might indicate a pituitary tumor)
- Follicle-stimulating hormone (FSH) level (an elevated level might indicate ovarian failure)
- Luteinizing hormone (LH) level (an elevated level might indicate gonadal dysfunction)
- 17-ketosteroids (an elevated level might indicate an adrenal tumor) (Pagana et al., 2019)

Nursing Management

Counseling and education are primary interventions and appropriate nursing roles. Address the diverse causes of amenorrhea, the relationship to sexual identity, possible infertility, and the possibility of a tumor or a life-threatening disease. Evidence is mounting that loss of menstrual regularity is a risk factor for later development of osteoporosis and hip fractures, so treatment to restore regular menstrual cycles is essential (Creighton et al., 2018). In addition,

inform the woman about the purpose of each diagnostic test, how it is performed, and when the results will be available to discuss with her. Listening sensitively, interviewing, and presenting treatment options are paramount to gain the woman's cooperation and understanding.

Nutritional counseling is also vital in managing this disorder, especially if the woman has findings suggestive of an eating disorder. The relationship between eating disorders and menstrual dysfunction has been identified in research studies. Careful evaluation of menstrual status is warranted for all women with eating disorders. Timely intervention is important because shorter duration of illness is associated with improved outcomes (Rebar, 2018). Although not all causes can be addressed by making lifestyle changes, emphasize maintaining a healthy lifestyle for the best possible outcomes (Teaching Guidelines 4.2).

TEACHING GUIDELINES 4.2

Tips for Maintaining a Healthy Lifestyle

- Balance energy expenditure with energy intake to maintain ideal weight range.
- Modify your diet to maintain ideal weight to avoid becoming overweight.
- Avoid excessive use of alcohol and mood-altering or sedative drugs.
- Avoid cigarette smoking to prevent cardiovascular disease and lung cancer.
- Identify areas of emotional stress and seek assistance to resolve them.
- Consume adequate fiber to promote regularity
- Balance work, recreation, and rest to reduce anxiety and stress in life.
- Maintain a positive outlook regarding any diagnoses and prognoses.
- Protect yourself from too much sun exposure.
- Participate in ongoing care and screenings to monitor any medical conditions.
- Maintain bone density through:
  - Calcium intake (1,200 to 1,600 mg daily)
  - Vitamin D (600 to 1,000 IU/daily)
  - Weight-bearing exercise (30 minutes or more daily)
  - Hormone therapy (HT) for low-risk women

Centers for Disease Control and Prevention (CDC). (2019c). *Healthy living*. Retrieved June 16, 2020, from https://www.cdc.gov/healthyliving/index.html; MedlinePlus. (2018). *Healthy living*. Retrieved April 29, 2020, from https://medlineplus.gov/healthyliving.html.

Dysmenorrhea

Dysmenorrhea refers to painful menstruation and is a highly prevalent problem among menstruating women. This condition has also been termed *cyclic perimenstrual pain*. Usually pain starts along

with the start of bleeding and lasts for 48 to 72 hours (Smith, 2018). The term *dysmenorrhea* is derived from the Greek words *dys*, meaning “difficult, painful, or abnormal,” and *rrhea*, meaning “flow.” Based on results of large epidemiologic studies, it is estimated that it may affect up to 85% of menstruating women. It is the leading cause of absenteeism of work and school, and has adverse effects on women’s quality of life (Matthewman et al., 2018). Another recent research study linked early smoking (younger than 13 years old) to an increased risk for more severe dysmenorrhea (Dwivedi, 2018). Uterine contractions occur during all periods, but in some women, these cramps can be frequent and very intense. It has a major impact on a woman’s quality of life, work productivity, and health care utilization. Dysmenorrhea is a symptom, not a full diagnosis. It is classified as primary (spasmodic) or secondary (congestive) (Oyelowo & Johnson, 2018).

Etiology

Primary dysmenorrhea refers to painful menstrual bleeding in the absence of any identified underlying pelvic pathology. It is caused by increased prostaglandin production by the endometrium in an ovulatory cycle. This hormone causes contraction of the uterus, and levels tend to be higher in women with severe menstrual pain than in women who experience mild or no menstrual pain. Dysmenorrhea is caused by the activation of the prostaglandin and leukotriene cascade in the uterine wall. These levels are highest during the first 2 days of menses, when symptoms peak (Fulghesu, 2018). This results in increased rhythmic uterine contractions from vasoconstriction of the small vessels of the uterine wall. This condition usually begins within a few years of the onset of ovulatory cycles at menarche.

Secondary dysmenorrhea is painful menstruation due to pelvic or uterine pathology. It may be caused by endometriosis, pelvic adhesions, adenomyosis, fibroids, pelvic inflammatory disease (PID), an intrauterine system, cervical stenosis, or congenital uterine or vaginal abnormalities. Adenomyosis involves the ingrowth of tissue

similar to that of the endometrium into the uterine musculature. Endometriosis involves ectopic implantation of tissue similar to that of the endometrium in other parts of the pelvis and throughout the body. It is most commonly diagnosed in the third or fourth decade of life and affects approximately 10% of women of reproductive age. The pain tends to get worse rather than better over time (American College of Obstetricians and Gynecologists [ACOG], 2018b). Endometriosis is the most common cause of secondary dysmenorrhea and is associated with pain beyond menstruation, dyspareunia, low back pain, heavy or irregular bleeding, bloating, nausea and vomiting, and infertility (ACOG, 2018b). The most effective treatment involves removing the underlying pathology, but there is no cure.

> Think back to Izzy from the chapter opener. Is her pelvic pain complaint a common one with women?

Therapeutic Management

The goal of treatment is to provide adequate pain relief to allow the woman to perform her usual activities. Current treatment mainly includes surgery and ovarian suppressive agents (OCs, progestins, GnRH antagonists, levonorgestrel-releasing intrauterine systems, and androgenic agents). Hormonal treatment is often associated with unwanted side effects and recurrence of symptoms when stopped. Severe dysmenorrhea can be distressing, adversely affecting social and occupational activities. Treatments vary from over-the-counter remedies to hormonal control. However, for some women, satisfactory pain relief is difficult to achieve, and they increasingly seek alternative options. Complementary therapies such as massage therapy, acupuncture (needles used to stimulate certain points of the body to balance the flow of energy within the body), and acupressure (the use of fingers and hands to stimulate acupoints to maintain the balance of energy) are gaining popularity as different ways to cope with the cyclic discomfort.

Therapeutic intervention is directed toward pain relief and building coping strategies that will promote a productive lifestyle. General measures for management include client education and reassurance. Treatment is supportive and should be guided by individual needs. Treatment measures usually include treating infections if present; suppressing hormones if endometriosis is suspected and cannot be treated with surgery by administering low-dose OCs; administering prostaglandin inhibitors to reduce the pain; administering Depo-Provera to suppress ovulation, which thins the endometrial lining of the uterus with subsequent reduction of fluid contents of the uterus during menses; and initiating lifestyle changes (Oyelowo & Johnson, 2018). Table 4.1 lists select treatment options for dysmenorrhea.

Nursing Assessment

As with any gynecologic complaint, a thorough focused history and physical examination are necessary to make the diagnosis of primary or secondary dysmenorrhea. With primary dysmenorrhea, the history usually reveals the typical cramping pain with menstruation, and the physical examination is completely normal. With secondary dysmenorrhea, the history discloses cramping pain (possibly starting at an early age) with a pelvic abnormality, a history of infertility, heavy menstrual flow, irregular cycles, and little response to nonsteroidal antiinflammatory drugs (NSAIDs), OCs, or both (Smith, 2018).

HEALTH HISTORY AND CLINICAL MANIFESTATIONS

Note the past medical history, including any chronic illnesses and family history of gynecologic concerns. Determine medication and substance use, such as prescription medications, contraceptives, anabolic steroids, tobacco, and marijuana, cocaine, or other illegal drugs. A detailed sexual history is essential to assess for inflammation and scarring (adhesions) secondary to PID. Women

with a previous history of PID, sexually transmitted infections (STIs), low consumption of fruits and vegetables, depression, high stress level, multiple sexual partners, history of smoking, or unprotected sex are at increased risk (Magowan et al., 2019).

TABLE 4.1 Treatment Options for Dysmenorrhea

Therapy Options	Dosage	Comments
Nonsteroidal antiinflammatory agents (NSAIDs)		NSAIDs prevent prostaglandin synthesis by inhibiting COX-1 and COX-2 conversion, reducing cramping.
Ibuprofen (Advil, Motrin, Midol)	400–800 mg TID	Take with meals. Do not take with aspirin.
Naproxen (Anaprox, Naprelan, Naprosyn, Aleve)	250–500 mg TID	Avoid alcohol. Watch for signs of GI bleeding. Same as above
Hormonal contraceptives		Decrease prostaglandin synthesis; second-line treatment
Low-dose oral contraceptives	Taken daily—extended-cycle formulas (84 d on, 7 d off)	Take active pills for an extended time to reduce number of monthly cycles.
Depo-medroxyprogesterone (DMPA), Depo-Provera	150 mg IM every 12 wks	Within 9–12 mo of DMPA therapy, 75% of women will experience amenorrhea.
Levonorgestrel-releasing IUS (Mirena)	Inserted into uterine cavity and may remain for up to 5 yrs	Inhibits ovulation and decreases thickness of endometrium Inhibits uterine contractions and reduces pain from menstrual cramps
Selective estrogen receptor modulators (SERMS)	Used for women not responding to NSAIDs and oral contraceptives; dosage is individualized	Adverse effects include hot flashes, nausea and vomiting, and risk of thromboembolism.
Raloxifene		Research is needed to

hydrochloride (Evista); tamoxifen citrate (Nolvadex)	validate effectiveness, doses, side effects, and contradictions.
Complementary therapies Thiamine (vitamin B) Vitamin E (tocopherols) Magnesium Omega-3 fatty acids (fish oil)	Gives sense of control over life, but not necessarily validated by scientific research studies
Lifestyle changes Daily exercise Limited salty foods Weight loss Smoking cessation Relaxation techniques	

American College of Obstetricians and Gynecologists (ACOG). (2018b). *Endometriosis*. Retrieved June 16, 2020, from https://www.acog.org/Patients/FAQs/Endometriosis; Knaus, J. V., Jachtorowycz, M. J., Adajar, A. A., & Tam, T. (2018). *Ambulatory gynecology*. Springer Publishers; Nothnick, W. B., Marsh, C., & Alali, Z. (2018). Future directions in endometriosis research and therapeutics. *Current Women's Health Reviews*, *14*(2), 189–194.

During the initial interview, the nurse might ask some of the following questions to assess the woman's history of dysmenorrhea:

- At what age did your menstrual cycles start?
- Have your cycles always been painful, or did the pain start recently?
- When in your cycle do you experience the pain?
- How would you describe the pain you feel?
- Are you sexually active?
- What impact does your cycle have on your physical and social activity?
- When was the first day of your last menstrual cycle?
- Was the flow of your last menstrual cycle a normal amount for you?
- Do your cycles tend to be heavy or last longer than 5 days?
- Are your cycles generally regular and predictable?

- What have you done to relieve your discomfort? Is it effective?
- Has there been a progression of symptom severity?
- Do you have any other symptoms?

Assess for clinical manifestations of dysmenorrhea. Affected women experience sharp, intermittent spasms of pain, usually in the suprapubic area. Pain may radiate to the back of the legs or the lower back. Pain usually develops within hours of the start of menstruation and peaks as the flow becomes heaviest during the first day or two of the cycle (Smith, 2018). Systemic symptoms of nausea, vomiting, diarrhea, fatigue, fever, headache, and/or dizziness are fairly common. Explore the history for physical symptoms of bloating, water retention, weight gain, headache, muscle aches, abdominal pain, food cravings, or breast tenderness.

PHYSICAL EXAMINATION

The physical examination performed by the health care provider centers on the bimanual pelvic examination. This examination is done during the nonmenstrual phase of the cycle. Explain to the woman how it is to be performed, especially if it is her first pelvic examination. Prepare the woman in the examining room by offering her a cover gown to put on and covering her lap with a privacy sheet on the examination table. Remain in the examining room throughout the examination to assist the health care provider with any procedures or specimens and to offer the woman reassurance.

LABORATORY AND DIAGNOSTIC TESTS

Common diagnostic tests that may be ordered to determine the cause of dysmenorrhea can include:

- Complete blood count to rule out anemia
- Urinalysis to rule out a bladder infection
- Pregnancy test (hCG level) to rule out pregnancy
- Cervical culture to exclude STI
- Erythrocyte sedimentation rate to detect an inflammatory process
- Stool guaiac test to exclude gastrointestinal bleeding or disorders

- Pelvic and/or vaginal ultrasound to detect pelvic masses or cysts
- Diagnostic laparoscopy and/or laparotomy to visualize pathology that may account for the symptoms (Pagana et al., 2019)

What diagnostic tests might be ordered to diagnose Izzy's pelvic pain?

Nursing Management

Educating the client about the normal events of the menstrual cycle and the etiology of her pain is paramount in achieving a successful outcome. Although dysmenorrhea itself is not life threatening, it can have a profound negative impact on a woman's day-to-day life. The nurse should keep this in mind and not minimize this condition. Explaining the normal menstrual cycle will teach the woman the correct terms to use so she can communicate her symptoms more accurately; this will also help dispel myths. Provide the woman with monthly graphs, charts, or apps to record menses, the onset of pain, the timing of medication, relief afforded, and coping strategies used. This involves the woman in her care and provides objective information so therapy can be modified if necessary. Educate women about the associated risk factors for dysmenorrhea which include attempts to lose weight, depression or anxiety, disruption of social networks, heavy menses, nulliparity, and smoking (Dwivedi, 2018).

The nurse should explain in detail the dosing regimen and the side effects of the medication therapy selected. Commonly prescribed drugs include NSAIDs such as ibuprofen (Motrin, Advil) or naproxen (Naprosyn). These drugs alleviate dysmenorrhea symptoms by decreasing intrauterine pressure and inhibiting prostaglandin synthesis, thus reducing pain (Ritter et al., 2020). The primary goal of NSAID therapy for dysmenorrhea is to preempt the production of prostaglandins; thus, starting the medication prophylactically and using sufficient doses to maximally suppress prostaglandin production are essential. If pain relief is not achieved in two to four cycles, a low-dose combination OC may be initiated. Client teaching and counseling should include information about how to take pills, side effects, and danger signs to watch for.

Nonmedical approaches such as healthy levels of exercise; behavioral interventions (biofeedback, hypnosis, relaxation); and dietary or herbal supplements are commonly used by women in an effort to relieve the pain of dysmenorrhea. The data on the effectiveness of such interventions remain inconclusive (Dwivedi, 2018). Encourage the woman to apply a heating pad or warm compress to alleviate menstrual cramps. Additional lifestyle changes that the woman can make to restore some sense of control and active participation in her care are listed in Teaching Guidelines 4.3.

TEACHING GUIDELINES 4.3
Tips for Managing Dysmenorrhea

- Exercise to increase endorphins and suppress prostaglandin release.
- Limit salty foods to prevent fluid retention.
- Increase water consumption to serve as a natural diuretic.
- Increase fiber intake with fruits and vegetables to prevent constipation.
- Use heating pads or warm baths to increase comfort.
- Take warm showers to promote relaxation.
- Sip on warm beverages, such as decaffeinated green tea.
- Keep legs elevated while lying down or lie on your side with knees bent.
- Use stress management techniques to reduce emotional stress.
- Practice relaxation techniques to enhance ability to cope with pain.
- Stop smoking and decrease alcohol use which causes vasoconstriction.

Abnormal Uterine Bleeding (AUB)

Disturbances of menstrual bleeding manifest in a wide range of presentations. **Abnormal uterine bleeding (AUB)** is the umbrella term used to describe any deviation from normal menstruation or from a normal menstrual cycle pattern. It can occur in women of any age with a prevalence of 10% to 30% among women of reproductive age (Wouk & Helton, 2019). The key characteristics are that regularity, frequency, volume or heaviness of flow, and duration of flow are abnormal, but each of these may exhibit considerable variability.

AUB is a disorder that occurs most frequently in women at the beginning and end of their reproductive years. It is common and somewhat debilitating in women of reproductive age. AUB is defined as painless endometrial bleeding that is prolonged, excessive, and irregular, and not attributed to any identified underlying structural or systemic disease. The International Federation of Gynecology and Obstetrics (FIGO) recommends the use of the term “AUB” to describe any aberration of menstrual volume, regulation, duration, and/or frequency in a women who isn’t pregnant. FIGO also recommends to discard such terminology as “menorrhagia,” “metrorrhagia,” and “dysfunctional uterine bleeding,” as they are controversial, confusing, and poorly defined (FIGO, 2018). AUB is frequently associated with anovulatory cycles, which are common for the first year after menarche and associated with immaturity of the hypothalamic–pituitary–ovarian axis. It also occurs later in life as women approach menopause and experience irregular menstrual cycles.

The pathophysiology of AUB is related to a hormone disturbance. With anovulation, estrogen levels rise as usual in the early phase of the menstrual cycle. In the absence of ovulation, a corpus luteum never forms and progesterone is not produced. The endometrium moves into a hyperproliferative state, ultimately outgrowing its estrogen supply. This leads to irregular sloughing of the endometrium and excessive bleeding (Elmaogullari & Aycan, 2018).

If the bleeding is heavy enough and frequent enough, anemia can result.

Etiology

The most common causes of AUB can be classified using the PALM-COEIN acronym:

- PALM (structural)
  - Polyp
  - Adenomyosis
  - Leiomyosis
  - Malignancy
- COEIN (other)
  - Coagulopathy
  - Ovulatory dysfunction
  - Endometrial
  - Iatrogenic
  - Not yet classified (FIGO, 2018; Wouk & Helton, 2019)

Therapeutic Management

Treatment of AUB depends on the cause of the bleeding, the age of the client, and whether or not she desires future fertility. When known, the underlying cause of the disorder is treated. Otherwise, the goal of treatment is to normalize the bleeding, correct anemia, prevent or diagnose early cancer, and restore quality of life. Once malignancy and pelvic pathology have been ruled out, medical treatment is an effective first-line therapeutic option (Knaus et al., 2018).

Treatment options for AUB include combined OCs, which help to regulate the timing and intensity of each cycle; Depo-Provera, a progestin-only birth control injection that reduces the thickness of the endometrial lining; NSAIDs, which can reduce bleeding and modulate pain; tranexamic acid (antifibrinolytic); GnRH analogs; danazol; and levonorgestrel-releasing intrauterine system (LNG IUS) (Ghlichloo & Gerriets, 2019; Singh et al., 2018).

Management of AUB might include medical care with pharmacotherapy or insertion of a hormone-secreting intrauterine system. OCs are used for cycle regulation as well as for contraception. They help prevent the risks associated with prolonged, unopposed estrogen stimulation of the endometrium. NSAIDs and progestin therapy (progesterone-releasing IUS [Mirena] or Depo-Provera) decrease menstrual blood loss significantly (Skidmore-Roth, 2020). Drug categories used in the treatment of AUB include:

- *Estrogens:* cause vasospasm of the uterine arteries to decrease bleeding.
- *Progestins:* used to stabilize an estrogen-primed endometrium.
- *OCs:* regulate the cycle and suppress the endometrium.
- *NSAIDs:* inhibit prostaglandins in ovulatory menstrual cycles.
- *Progesterone-releasing IUSs:* suppress endometrial growth.
- *Androgens:* create a high-androgen/low-estrogen environment that inhibits endometrial growth.
- *Antifibrinolytic drugs:* (tranexamic acid) prevent fibrin degradation to reduce bleeding.
- *Iron replacement therapy:* replenish iron stores lost during heavy bleeding.

If the client does not respond to medical therapy, surgical intervention might include dilation and curettage (D&C), endometrial ablation, uterine artery embolization, or hysterectomy. Surgery should be considered for women for whom medical treatment has failed, cannot be tolerated, or is contraindicated (Oyelowo & Johnson, 2018). Endometrial ablation is an alternative to hysterectomy, but both would only be for the woman who no longer desires fertility as both procedures can cause infertility. Techniques used for ablation include laser, electrosurgery excision procedure, freezing, heated fluid infusion, or thermal balloon ablation. Most women will have reduced menstrual flow following endometrial ablation, and up to half will stop having periods. Younger women are less likely than older women to respond to endometrial ablation. Recent scientific evidence supports that up to one quarter of clients treated with endometrial ablation require repeat ablation or

subsequent hysterectomy to stop AUB. Hysterectomy should be considered a last resort for AUB (ACOG, 2018a).

Nursing Assessment

A thorough history should be taken to differentiate between AUB and other conditions that might cause vaginal bleeding, such as pregnancy and pregnancy-related conditions (abruptio placentae, ectopic pregnancy, abortion, or placenta previa); systemic conditions such as Cushing disease, blood dyscrasias, liver disease, renal disease, or thyroid disease; and genital tract pathology such as infections, tumors, or trauma. Review of medications should include use of contraceptives, unopposed estrogen, levothyroxine, and anticoagulants (Watkins, 2018).

Assess for clinical manifestations of AUB, which commonly include vaginal bleeding between periods, irregular menstrual cycles (usually less than 28 days between cycles), infertility, mood swings, hot flashes, vaginal tenderness, variable menstrual flow ranging from scanty to profuse, obesity, acne, stress, anorexia, thyroid disease, and diabetes. Signs of polycystic ovary syndrome might be present, because it is associated with unopposed estrogen stimulation, elevated androgen levels, and insulin resistance, and it is a common cause of anovulation (Azziz, 2018).

Measure orthostatic blood pressure and orthostatic pulse; a drop in pressure or pulse rate may occur with anemia. With the nurse assisting, the health care provider performs a pelvic examination to identify any structural abnormalities.

Common diagnostic/lab tests that may be ordered to determine the cause of AUB include:

- Complete blood count to detect anemia
- Prothrombin time to detect blood dyscrasias
- Pregnancy test to rule out a spontaneous abortion or ectopic pregnancy
- Thyroid-stimulating hormone level to screen for hypothyroidism
- Transvaginal ultrasound to measure endometrium
- Pelvic ultrasound to view any structural abnormalities

- Endometrial biopsy to check for intrauterine pathology
- D&C for diagnostic evaluation

Nursing Management

Educate the client about normal menstrual cycles and the possible reasons for her abnormal pattern. Inform the woman about treatment options. Do not simply encourage the woman to “live with it.” Instruct the client about any prescribed medications and potential side effects. For example, if high-dose estrogens are prescribed, the woman may experience nausea. Teach her to take antiemetics as prescribed and encourage her to eat small, frequent meals to alleviate nausea. Adequate follow-up and evaluation are essential for women who do not respond to medical management. See Nursing Care Plan 4.1: Overview of a Woman with Abnormal Uterine Bleeding.

TAKE NOTE!

Chronic anovulation can result in infertility and the long-term problem of hyperandrogenism. Severe anemia can also result secondary to prolonged or heavy menses. Depression and embarrassment may be secondary to the irregular and heavy bleeding. Endometrial cancer can occur associated with prolonged buildup of the endometrial lining without menstrual bleeding (Singangutti, 2018).

Premenstrual Syndrome (PMS)

Premenstrual syndrome (PMS) describes a constellation of recurrent physical, emotional, and behavioral symptoms that occur during the luteal phase or last half of the menstrual cycle and resolve with the onset of menstruation. A majority of women in their reproductive years experience a variety of premenstrual symptoms that can alter their behavior and well-being. Women have between 400 and 500 menstrual cycles over their reproductive years, and since premenstrual distress symptoms peak during 4 to 7 days prior to menses, consistently symptomatic women may spend up to 10

years of their lives in a state of compromised physical functioning and/or psychological well-being; thus, it constitutes a major health problem for women. The syndrome occurs across all age groups, though it is most common among those 12 to 45 years old (Zendehdel & Elyasi, 2018).

NURSING CARE PLAN 4.1 Overview of a Woman with Abnormal Uterine Bleeding

Stacy, a 52-year-old obese woman, comes to her gynecologist with the complaint of heavy erratic bleeding. Her periods were fairly regular until about 4 months ago, and since that time, they have been unpredictable, excessive, and prolonged. Stacy reports she is tired all the time, can't sleep, and feels "out of sorts" and anxious. She is fearful she has cancer.

NURSING ANALYSIS: Fear related to current signs and symptoms possibly indicating a life-threatening condition

OUTCOME IDENTIFICATION AND EVALUATION

The client will acknowledge her fears as evidenced by statements made that fear and anxiety have been lessened after explanation of diagnosis.

INTERVENTIONS: *Reducing Fear and Anxiety*

- Distinguish between anxiety and fear *to determine appropriate interventions*.
- Check complete blood count and assess for possible anemia secondary to excessive bleeding t*o determine if fatigue is contributing to anxiety and fear*. Fatigue occurs because the oxygen-carrying capacity of the blood is reduced.
- Reassure client that symptoms can be managed *to help address current concerns*.
- Provide client with factual information and explain what to expect *to assist client with identifying fears and help her cope with her condition*.
- Provide symptom management *to reduce concerns associated with the cause of bleeding*.
- Teach client about early manifestations of fear and anxiety *to aid in prompt recognition and to minimize escalation of anxiety*.
- Assess client's use of coping strategies in the past and reinforce use of effective ones *to help control anxiety and fear*.
- Instruct client in relaxation methods, such as deep-breathing exercises and imagery, *to provide her with additional methods for controlling anxiety and fear*.

NURSING ANALYSIS: Lack of knowledge related to perimenopausal transition and its management

OUTCOME IDENTIFICATION AND EVALUATION

The client will demonstrate understanding of her symptoms as evidenced by making health-promoting lifestyle choices, verbalizing appropriate health care practices, and adhering to measures and complying with therapy.

INTERVENTIONS: *Providing Client Education*

- Assess client's understanding of menopausal transition and its treatment *to provide a baseline for teaching and developing a plan of care*.
- Review instructions about prescribed procedures and recommendations for self-care, frequently obtaining feedback from the client *to validate adequate understanding of information*.
- Outline link between anovulatory cycles and excessive buildup of uterine lining in menopausal transition women *to assist client in understanding the etiology of her bleeding*.
- Provide written material with pictures *to promote learning and help client visualize what is occurring with her body during menopausal transition*.
- Inform client about the availability of community resources, and make appropriate referrals as needed *to provide additional education and support*.
- Document details of teaching and learning *to allow for continuity of care and further education if needed*.

ACOG defines PMS as "the cyclic occurrence of symptoms that are sufficiently severe to interfere with some aspects of life, and that appear with consistent and predictable relationship to menses" (ACOG, 2018d). A woman experiencing PMS may have a wide variety of seemingly unrelated symptoms; for that reason, it is difficult to define and more challenging to diagnose. PMS affects millions of women during their reproductive years. Approximately 80% of women will experience cyclic fluctuations in mood, sleep, breast pain, headache, edema, social withdrawal, and sense of well-being related to their menstrual cycles (Family Practice Notebook, 2018). The exact causes of PMS are not known. It is thought the mood symptoms are related to the interaction between hormonal events and neurotransmitter function, specifically serotonin. Tissues throughout the body are sensitive to hormone levels that change throughout a woman's cycle. Studies suggest that rising and falling levels of hormones (e.g., estrogen and progesterone) may also influence serotonin in the brain which affects mood (Casper, 2019). Not all women respond to serotonin reuptake inhibitors (SSRIs;

Prozac, Paxil, Zoloft), however, which implies that other mechanisms may be involved (Skidmore-Roth, 2020).

As defined by the American Psychiatric Association, PMDD is a more severe variant of PMS affecting 5% to 8% of premenopausal women. Experts compare the difference between PMS and PMDD to the difference between a mild tension headache and a migraine. Risk factors identified that predispose to PMS and PMDD are age between 25 and 35 years, a psychiatric history, a family history of PMDD, unhealthy living habits, and stressful life events. PMDD is characterized by both physical and psychiatric symptoms that impact women significantly during the luteal phase of her menses (Appleton, 2018). PMDD markedly interferes with work, school, social activities, and relationships with others.

Therapeutic Management

Treatment of PMS is often frustrating for both clients and health care providers. Clinical outcomes can be expected to improve as a result of recent consensus on the diagnostic criteria for PMS and PMDD, data from clinical trials, and the availability of evidence-based clinical guidelines.

The management of PMS or PMDD requires a multidimensional approach because these conditions are not likely to have a single cause, and they appear to affect multiple systems within a woman's body; therefore, they are not likely to be amenable to treatment with a single therapy (Reid & Soares, 2018). To reduce the negative impact of premenstrual disorders on a woman's life, education along with reassurance and anticipatory guidance are needed for women to feel they have some control over this condition.

TAKE NOTE!

Because there are no diagnostic tests that can reliably determine the existence of PMS or PMDD, the woman herself must decide that she needs help for these symptoms. The woman must embrace multiple therapies and become an active participant in her treatment plan to find the best level of symptom relief.

Therapeutic interventions for PMS and PMDD address the symptoms since the exact causes of this condition are still unknown. Treatments may include vitamin supplements, dietary changes, exercise, lifestyle changes, and medications (Box 4.2). Pharmacotherapies (particularly SSRIs and serotonin-norepinephrine reuptake inhibitors) represent the first-line treatment for the mood and behavioral symptoms of PMDD. Other medications may include other antidepressant and antianxiety drugs, diuretics, antiinflammatory medications, analgesics, synthetic androgen agents, OCs, and GnRH agonists to regulate menses. Unlike the approach to the treatment of depression, antidepressants need not be given daily, but may be effective when used cyclically, only in the luteal phase, or even limited to the duration of the symptoms.

BOX 4.2 Treatment Options for PMS and PMDD

- Lifestyle changes
  - Reduce stress
  - Exercise three to five times a week
  - Eat a balanced diet and increase water intake
  - Decrease caffeine intake
  - Stop smoking and limit the intake of alcohol
  - Attend a PMS or women's support group
  - Vitamin and mineral supplements
  - Multivitamin daily
  - Vitamin E, 400 units daily
  - Calcium, 1,200 to 1,600 mg daily
  - Magnesium, 200 to 400 mg daily
- Medications
  - NSAIDs taken a week prior to menses
  - OCs (low dose)
  - Antidepressants (SSRIs)
  - Anxiolytics (taken during luteal phase)
  - Diuretics to remove excess fluid
  - Progestins
  - GnRH agonists
  - Danazol (androgen hormone inhibits estrogen production)

Alevizou, F., Vousoura, E., & Leonardou, A. (2018). Premenstrual dysphoric disorder: a critical review of its phenomenology, etiology, treatment and clinical status. Current Women's Health Reviews, 14(1), 59–66; Appleton, S. M. (2018). Premenstrual syndrome: Evidence-based evaluation and treatment. Clinical Obstetrics and Gynecology, 61(1), 52–61; and Oyelowo, T., & Johnson, J. (2018). *A guide to women's health* (2nd ed.). Jones & Bartlett Learning.

COMPLEMENTARY AND ALTERNATIVE THERAPIES

No single treatment is universally recognized as effective, and many clients often turn to therapeutic approaches outside of conventional medicine. Many women use dietary supplements and herbal remedies for their menstrual health and bleeding disorders, though there has been little research to demonstrate their efficacy. Alternative treatments for treating PMDD include calcium supplementation, vitex agnus castus (chaste tree berry), Hypericum

perforatum (St. John's wort), Angelica sinensis (dong quai), Paeonia lactiflora (Chinese peony), and cognitive, behavioral, and relaxation therapies. Some other alternative therapies include the use of yoga, magnesium, vitamin B6, evening primrose oil, ginkgo biloba, viburnum, dandelion, stinging nettle, burdock, raspberry leaf, and skullcap (Fisher et al., 2018). Although research has not conclusively validated the efficacy of these alternative therapies, it is important for the nurse to be aware of the alternative products that many women choose to use.

Concept Mastery Alert

Treatments for Premenstrual Syndrome

Possible treatment options for PMS include reduction of caffeine intake, vitamin and mineral supplements, diuretic therapy, and NSAIDs. Medication therapy that has been found to be helpful for clients with PMS are antidepressants and anxiolytics.

Nursing Assessment

Although little consensus exists in the medical literature and among researchers about what constitutes PMS and PMDD, the physical and psychological symptoms are real. The extent to which the symptoms debilitate or incapacitate a woman is highly variable.

More than 150 symptoms are assigned to PMS, but irritability; food cravings; mood swings; tearfulness; depression; sleep disturbances; edginess; headache; back pain; fatigue; bloating; edema of the face, abdominal area, and extremities; difficulty concentrating; binge eating; breast tenderness; tension; and dysphoria (a profound state of unease and anxiety) are the most prominent and consistently described (Chelmow et al., 2019). To establish the diagnosis of PMS, elicit a description of cyclic symptoms occurring before the woman's menstrual period. The woman should chart her daily symptoms for two cycles. These data will help demonstrate symptoms clustering around the luteal phase of ovulation with resolution after bleeding starts. Ask the woman to bring her list of symptoms to the next appointment. Symptoms can be categorized using the following:

- A—*anxiety:* difficulty sleeping, tenseness, mood swings, and clumsiness
- C—*craving:* cravings for sweets, salty foods, chocolate
- D—*depression:* feelings of low self-esteem, anger, dysphoria
- H—*hydration:* weight gain, abdominal bloating, breast tenderness, ankle swelling
- O—*other:* hot flashes or cold sweats, nausea, change in bowel habits, aches or pains, dysmenorrhea, acne breakout (Oyelowo & Johnson, 2018)

The ACOG diagnostic criteria for PMS include at least one of the following affective and somatic symptoms during the 5 days before menses in each of the three previous cycles:

- Affective symptoms: depression, angry outbursts, irritability, anxiety
- Somatic symptoms: breast tenderness, abdominal bloating, edema, headache
- Symptoms relieved from days four to 13 of the menstrual cycle (ACOG, 2018d)

In PMDD, the main symptoms are mood disruption such as depression, sadness, anxiety, tension, and persistent anger or irritability. Physical symptoms such as headache, joint and muscle pain, lack of energy, bloating, and breast tenderness are also present (Appleton, 2018). It is estimated that up to 75% of reproductive-age women experience premenstrual symptoms that meet the ACOG criteria for PMS and up to 8% meet the diagnostic criteria for PMDD (Oyelowo & Johnson, 2018).

According to the American Psychiatric Association, a woman must have at least five of the typical symptoms to be diagnosed with PMDD (Marfuah, 2018). These must occur during the week before and a few days after the onset of menstruation and must include one or more of the first four symptoms:

- Affective lability: sadness, tearfulness, irritability
- Anxiety and tension
- Persistent or marked anger or irritability
- Depressed mood, feelings of hopelessness
- Difficulty concentrating
- Sleep difficulties

- Increased or decreased appetite
- Increased or decreased sexual desire
- Chronic fatigue
- Headache
- Constipation or diarrhea
- Breast swelling and tenderness (Reid & Soares, 2018)

Nursing Management

Educate the client about the management of PMS or PMDD. Advise her that lifestyle changes often result in significant symptom improvement without pharmacotherapy. Encourage women to eat a balanced diet that includes nutrient-rich foods to avoid hypoglycemia and associated mood swings. Encourage all women to participate in aerobic exercise three times a week to promote a sense of well-being, decrease fatigue, and reduce stress. Administer calcium (1,200 to 1,600 mg/day), magnesium (400 to 800 mg/day), and vitamin B6 (50 to 100 mg/day) as prescribed. In some studies, these nutrients have been shown to decrease the intensity of PMS symptoms. NSAIDs may be useful for painful physical symptoms, and spironolactone (Aldactone) may help with bloating and water retention. Herbs such as vitex agnus castus (chaste tree berry), evening primrose, and SAM-e (a dietary supplement used to enhance mood) may be recommended; though not harmful unless the woman has a contraindication, not all herbs have enough clinical or research evidence to document their efficacy. Nutritional treatments include a diet low in salt, alcohol, caffeine, and sugar (Aleizou et al., 2018).

Explain to the client the relationship between cyclic estrogen fluctuation and changes in levels of serotonin levels and how the different management strategies help maintains serotonin levels, thus improving mood symptoms. It is important to rule out other conditions that might cause erratic or dysphoric behavior. If the initial treatment regimen does not work, explain to the woman that she should return for further testing. Behavioral counseling and stress management might help women regain control during these stressful

periods. Reassuring the woman that support and help are available through many community resources and support groups can be instrumental in her acceptance of this monthly disorder. Nurses can be a calming force for many women experiencing PMS or PMDD. A holistic approach, including lifestyle modifications, pharmacotherapy, herbal therapies, acupuncture, and cognitive behavioral therapy, is most beneficial for symptom reduction, improvement in daily functioning, and quality of life.

TAKE NOTE!

Adolescents and women who experience more extensive emotional symptoms with PMS should be evaluated for PMDD because they may require antidepressant therapy.

Endometriosis

Endometriosis is a complex syndrome characterized by an estrogen-dominant chronic inflammatory process that affects primarily pelvic tissues, including the ovaries. It is caused when tissue similar to that of the endometrium implants outside of the uterus, most commonly throughout the abdominal cavity (Bulun et al., 2019). It is one of the most common gynecologic diseases, affecting more than 6 million women in the United States, about 11% of the adult women population (Patel et al., 2018). Endometriosis tissue is commonly found attached to the ovaries, fallopian tubes, the outer surface of the uterus, the bowels, the area between the vagina and the rectum (rectovaginal septum), and the pelvic side wall (Fig. 4.1) though lesions have been found in locations as far from the uterus as the brain. The places where the tissue attaches are called implants, or lesions. These lesions create their own blood supply and respond to hormones released during the menstrual cycle in the same way as the endometrial lining within the uterus.

At the beginning of the menstrual cycle, when the lining of the uterus is shed and menstrual bleeding begins, endometriosis implants swell and bleed as well. In short, the woman with

endometriosis experiences several “mini-periods” throughout her abdomen, wherever this endometriosis tissue exists. In addition to cyclic bleeding outside the uterus, pelvic pain that can be debilitating, scarring, and adhesion formation occur throughout the pelvis. Symptoms begin as early as adolescence and may settle after menopause.

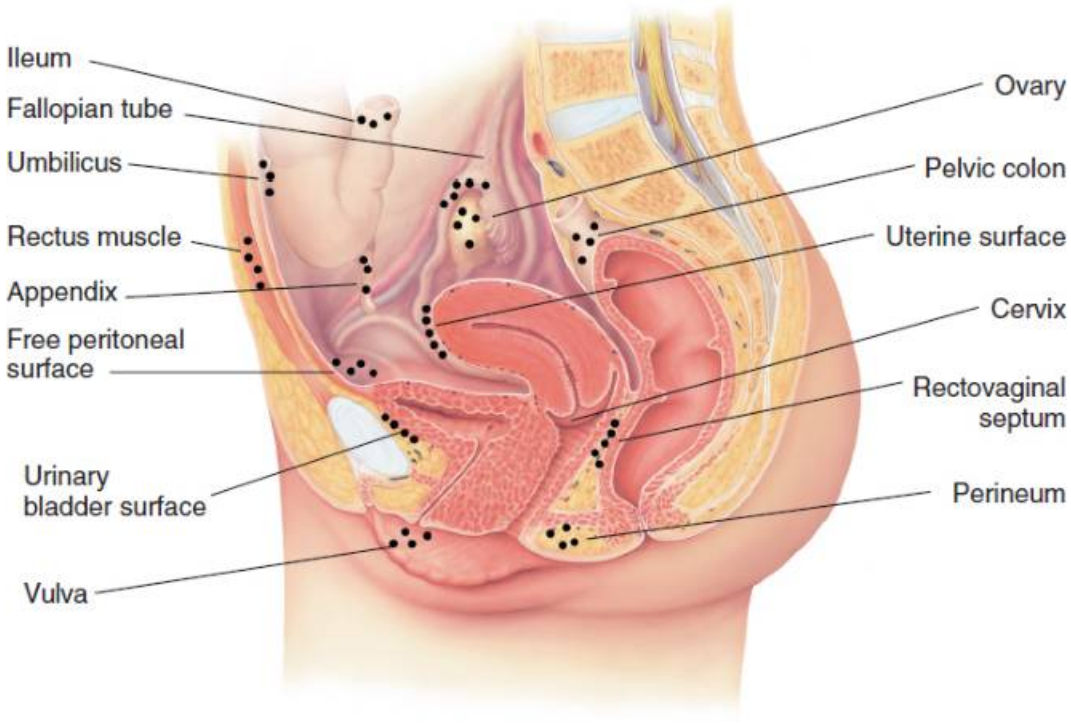

FIGURE 4.1. Common sites of endometriosis formation. (Asset provided by Anatomical Chart Co.)

Think back to Izzy, with her progressive pelvic pain and infertility concerns. After a pelvic examination, her health care provider suspects she has endometriosis.

Etiology and Risk Factors

It is not currently known why endometriosis tissue implants and grows in other parts of the body. Several theories exist, but to date none has been scientifically proven. However, several factors tend to be correlated with a diagnosis of endometriosis:

- The aging process

- Lean body size
- Smoking or exposure to second-hand smoke
- Family history of endometriosis in a first-degree relative
- Short menstrual cycle (less than 28 days)
- Long menstrual flow (more than 1 week)
- High dietary fat consumption
- Infertility
- Young age of menarche (younger than 12)
- Few (one or two) or no pregnancies (Shafrir et al., 2018)

Therapeutic Management

Therapeutic management of the client with endometriosis falls into three categories: pain relief, hormonal suppression, and surgery. The plan must take into consideration the following factors: severity of symptoms, desire for fertility, degree of the disease, and the client's therapy goals. Currently, a definitive diagnosis of endometriosis is only possible via laparoscopy and visualization of the lesions; to date, no imaging modality can prove the presence of lesions. Treatment of endometriosis involves surgery to remove the lesions. Ovarian suppressive agents (OCs, progestins, long-acting GnRH analogs, and androgenic agents like danazol) can manage symptoms. Approximately only half of women with endometriosis experience pain relief from existing medical or surgical treatments (NICHD, 2018) for some time. The gold standard for endometriosis treatment is laparoscopic excision surgery while pain-relieving drugs and hormone suppressants can address symptoms. Alternative therapies may be used, including acupuncture and supplementation with vitamins, minerals, and fish oil (Nothnick et al., 2018). Because endometriosis has no cure and surgery with an endometriosis specialist is not widely accessible, surgery with a general gynecologist may only control symptoms temporarily. Women with endometriosis frequently experience only short-term relief. Endometriosis-associated pelvic pain can be managed by suppression of ovulatory menses and estrogen production, cyclooxygenase inhibitors, and surgical removal of pelvic lesions.

Many pain relief and hormonal suppression therapies have significant adverse effects and limits on the duration of therapy (Table 4.2 and Evidence-Based Practice 4.1).

TABLE 4.2 Treatment Options for Endometriosis

Therapy Options	Comment
Surgical Intervention	
Conservative surgery	Removal of implants/lesions using laser, cautery, or small surgical instruments for excision. This intervention may reduce pain and allow pregnancy to occur in the future but may need to be repeated.
Definitive surgery	Abdominal hysterectomy with or without bilateral salpingo-oophorectomy. Will eliminate bleeding but will leave a woman unable to become pregnant in the future. Pain may not resolve if extrauterine lesions are not completely removed.
Medication Therapy	
NSAIDs	First-line treatment to reduce pain; taken early when premenstrual symptoms are first felt
Oral contraceptives	Suppresses cyclic hormonal response of the endometriosis tissue
Progestogens	Decreases the activity of estrogen receptors, suppressing the effects of estrogen
Antiestrogens	Suppresses a woman's production of estrogen, thus stopping the menstrual cycle and reducing symptoms
Gonadotropin-releasing hormone analogs (GnRH-a)	Suppresses endometriosis symptoms by creating a temporary pseudomenopause

EVIDENCE-BASED PRACTICE 4.1 Oral Contraceptives for Pain Associated with Endometriosis

BACKGROUND

Endometriosis is a common gynecologic condition which affects many women of reproductive age worldwide and is a major cause of pain and infertility. Tissue similar to that of the endometrium grows at sites outside the uterus and responds to monthly hormones that produce the menstrual cycle. Endometriosis is commonly found in women with painful menses, pain with sexual activity, and chronic pelvic pain. Hormonal treatments, including oral contraceptives and gonadotropin-releasing hormone analogs may be used to relieve the painful symptoms associated with endometriosis. However, many of the hormonal treatments have side effects that limit their acceptability and duration of treatment.

STUDY

Five trials involving 612 women met the inclusion criteria for this review. Only three of the five trials involving 404 women were suitable for analysis. The studies took place in Egypt, the United States, Japan, and Italy.

Findings

Based on the limited evidence from the trials and limited data for the specific outcomes for this review, there is insufficient evidence to make a judgment on the effectiveness of the oral contraceptives compared to placebo, and the findings could not be generalized.

Nursing Implications

Although this review was inconclusive in its findings, oral contraceptives continue to be prescribed by many health care professionals to address the monthly pain associated with endometriosis. Nurses can continue to educate women about the rationale behind this therapy and instruct them to report any change in their pain scale levels once this therapy has started. If it is not working for them and their pain levels remain high or if they do not wish to use oral contraceptives, additional treatment modalities might need to be considered.

Brown, J., Crawford, T. J., Datta, S., & Prentice, A. (2018). Oral contraceptives for pain associated with endometriosis. Cochrane Database of Systematic Reviews, 2018(5), CD001019.
https://doi.org/10.1002/14651858.CD001019.pub3

Nursing Assessment

Nurses encounter women with endometriosis in a variety of settings: community health settings, schools, clinics, day surgical centers, and hospitals. Health care professionals must not trivialize or dismiss the concerns of these women, because early recognition is essential to improve long-term quality of life and preserve fertility. The diversity of presenting symptoms and a high rate of misdiagnosis contribute to women with endometriosis falling through the cracks and not being diagnosed promptly.

HEALTH HISTORY

Endometriosis may be difficult to diagnose because its symptoms mimic those of other pelvic and gastrointestinal disorders and the severity of the symptoms does not always reflect the extent of the disease. Obtain a health history and elicit a description of signs and symptoms to determine risk factors. Endometriosis can be asymptomatic, but it can also be a severe and debilitating condition. It is chronic and progressive. Ask specifically about menarche, history of menstrual problems, details of pregnancies, and difficulties

with conception. Assess the client for clinical manifestations, which include:

- Infertility
- Back pain
- Pain before and during menstrual periods
- Pain during or after sexual intercourse
- Painful urination
- Depression
- Fatigue
- Painful bowel movements
- Chronic pelvic pain
- Hypermenorrhea (heavy menses)
- Pelvic adhesions
- Irregular and more frequent menses
- Premenstrual vaginal spotting (DiVasta et al., 2018)

The two most common symptoms are infertility and pelvic pain. Endometriosis occurs in 38% of infertile women and in 71% to 87% of women with chronic pelvic pain. About 30% to 40% of women with this condition experience infertility, making it one of the top three causes of female infertility (Tomassetti & D'Hooghe, 2018).

What are the most common symptoms experienced by women with endometriosis? Is Izzy's profile typical? As a nurse, what would be your role in Izzy's continued workup?

PHYSICAL EXAMINATION AND LABORATORY AND DIAGNOSTIC TESTS

The pelvic examination typically correlates with the extent of the endometriosis growth. The usual finding is nonspecific pelvic tenderness. The hallmark finding is the presence of tender nodular masses on the uterosacral ligaments, the posterior uterus, or the posterior cul-de-sac. A skilled endometriosis specialist may be able to identify suspected adhesions with a pelvic exam, but the only definitive diagnosis is the one made during surgery and with biopsy (Chaplin, 2018).

After a thorough history and a pelvic examination, the health care provider may suspect endometriosis, but the only certain method of diagnosing it is by seeing it. Pelvic or transvaginal ultrasound is used to assess pelvic organ structures and rule out any cysts or fibroids. However, a laparoscopy is needed to diagnose endometriosis. Laparoscopy is the direct visualization of the internal organs with a lighted instrument inserted through an abdominal incision. A tissue biopsy of the suspected implant taken at the same time and examined microscopically confirms the diagnosis. Endometriosis can be treated during laparoscopy by removing the suspected tissue.

Nurses can play a role by offering a thorough explanation of the condition and explaining why tests are needed to diagnose endometriosis. The nurse can set up appointments for imaging studies and laparoscopy.

Nursing Management

In addition to the interventions outlined above, the nurse should encourage the client to adopt healthy lifestyle habits with respect to diet, exercise, sleep, and stress management. Referrals to support groups and internet resources (Box 4.3) can help the woman understand this condition and cope with chronic pain. Dealing with the symptoms and complications of endometriosis can be distressing for a woman. A number of organizations provide information about the diagnosis and treatment of endometriosis and offer support to women and their families. Nurses are uniquely situated to improve client outcomes by assisting women in making informed treatment decisions. A prompt diagnosis ensures the best possible outcomes for this chronic disease.

INFERTILITY

The desire to have children can be powerful and widespread for many women, but for many, that desire can also be unfulfilled. **Infertility** is defined as the inability to conceive a child after 1 year of regular sexual intercourse unprotected by contraception (RESOLVE, 2019). Secondary infertility is the inability to conceive after a previous pregnancy. Many people take the ability to conceive and produce a child for granted, but infertility affects more than 7.4 million Americans, or up to 15% of the reproductive-age population, according to the American Society for Reproductive Medicine (ASRM, 2019). Infertility is a widespread problem that has an emotional, social, and economic impact on couples. Although male infertility contributes to more than half of all causes, infertility typically remains a woman's social burden. It affects relationships, leads to

tension and anger between partners, and can result in severe sexual dysfunction and breakdown of the relationship. Nurses must recognize infertility and understand its causes and treatment options so they can help women and couples understand the possibilities as well as the limitations of current therapies. Nurses have a central role in supporting women and couples through these stressful treatments. Women and couples will frequently confide in a nurse and can gain great benefit from a sympathetic and sensible discussion. Women wish to be treated with respect and dignity and given appropriate information and support. Infertility was once considered a disorder of inconvenience, but it is now classified as a disease in the United States Regulatory Americans with Disabilities Act (Find Law, 2018). Women deserve that their distress be recognized and they deserve to feel cared for and to have confidence in health care providers in situations in which outcomes are uncertain. The caring aspect of professional nursing is an essential component of meeting the special needs of people dealing with infertility (Allan et al., 2018). Prevention of infertility through education should also be incorporated into any client–nurse interaction.

After completing several diagnostic tests, the doctor strongly suspects Izzy has endometriosis. She asks you about her chances of becoming pregnant and becoming pain-free. What treatment options would you explain to Izzy? What information can you give about her future childbearing ability?

Cultural Considerations

Infertility is not only a physiologic problem, but it is one that can initiate a life crisis that is experienced with psychological, familial, social, and cultural consequences. Cross-culturally, the expectation for couples to reproduce is an accepted norm and the inability to conceive may be considered a violation of this cultural norm. In this context, infertility represents a crisis for the woman and/or the couple. The manner in which different cultures, ethnic groups, and religious groups perceive and manage infertility may be very

different. For example, many African Americans believe that assisted reproductive techniques are unnatural and that they remove the spiritual or divine nature of creation from conception. For this reason, they may seek spiritual rather than medical assistance when trying to conceive. Those belonging to Hispanic cultures may believe that children validate the marriage, so families are often large. Like African Americans, Hispanic individuals are often spiritual and may consider infertility a test of faith, leading them to seek spiritual counseling. Disappointing one's spouse can often be of concern to African American women, while avoiding the stigmatization of infertility can be a top concern to Asian American women. African American and Asian American alike may find themselves living with partner tensions, criticism from relatives, and stigmatization from the community (Hess et al., 2018).

Religion often influences cultural factors and for this reason, may also be considered when pursuing treatment for infertility. In the Orthodox Jewish religion, procreation is considered to be a "mitzvah," a religious good deed. However, Orthodox Jews do accept the use of contraceptives to prevent conception when it is not desired. Conservative and Reform Jews put no restrictions on contraception and a lesser demand on procreation. Roman Catholics have a restrictive view of the use of assisted reproductive technologies since in their view, procreation cannot be separated from the relationship between parents. Thus, God wants human life to begin through the "conjugal act" and not artificially. Most religious teachings speak to the significance of procreation, so infertility can impact the self and relational identities of the couple wishing to become parents. Therefore, infertility presents a risk for both a crisis of identity and of faith (Klitzman, 2018). Nurses must be cognizant of the client's cultural and religious background and how it may dictate which, if any, reproductive treatment options are chosen. Nurses need to include this awareness in their counseling of infertile couples.

CONSIDER THIS

We had been married for 3 years and wanted to start a family, but much to our dismay, nothing happened after a year of trying. I had some irregular periods and was finally diagnosed with endometriosis and put on Clomid for three cycles. After that time without achieving a pregnancy, I went to a fertility expert. The doctor lasered the misplaced endometriosis tissue, sent carbon dioxide through my tubes to make sure they were patent, and put me back on Clomid, but still we had no luck. Finally, 2 years later, we considered in vitro fertilization (IVF) and prayed we could find the money for the procedure. By then I felt I was a failure as a woman. We then decided that it was more important for us to be parents than it was for me to be pregnant, so we considered adoption. We tried for another year without any results.

We went to the adoption agency to fill out the paperwork for the process to begin. Our blood was taken and we waited for an hour, wondering the whole time why it was taking so long for the results. The nurse finally appeared and handed a piece of paper to me with the word “positive” written on it. I started to cry tears of joy because I was pregnant and our long journey of infertility was finally ending.

Thoughts: For many women the dream of having a child is not easily realized. Infertility can affect self-esteem, disrupt relationships, and result in depression. This couple experienced many years of frustration in trying to have a family. What help can be offered to couples during this time? What can be said to comfort the woman who feels she is a failure?

Etiology and Risk Factors

Reproduction requires the interaction of the female and the male reproductive tracts, which involves (1) the release of a normal preovulatory oocyte; (2) the production of adequate spermatozoa; (3) the normal transport of the gametes to the ampullary portion of the fallopian tube (where fertilization takes place); and (4) the

subsequent transport of the cleaving embryo into the endometrial cavity for implantation and development (Webster et al., 2018).

Multiple known and unknown factors affect fertility. Female-factor infertility is detected in about 40% of cases and male-factor infertility in about 40% of cases. The remaining 20% fall into a category of combined (both male and female factors) or are considered unexplained. In women, ovarian dysfunction (40%) and tubal/pelvic pathology (40%) are the primary contributing factors to infertility (ASRM, 2019).

Risk factors for infertility in women include:

- Overweight or underweight (can disrupt hormone function)
- Scarred fallopian tubes from infections
- Uterine fibroids
- Tubal blockages
- Anovulation
- Cervical stenosis
- Reduced oocyte quality
- Chromosomal abnormalities
- Congenital anomalies of the uterus
- Immune system disorders
- Chronic illnesses such as diabetes, thyroid disease, asthma
- Sexually transmitted infections (STIs)
- Ectopic pregnancy
- Increased age
- Endometriosis
- Turner syndrome
- Eating disorders
- History of PID
- Smoking and alcohol consumption
- Multiple miscarriages
- Environmental pollutants
- Menstrual abnormalities
- Exposure to chemotherapeutic agents
- Psychological stress (Walker & Tobler, 2020)

Risk factors for infertility in men include:

- Exposure to toxic substances (lead, mercury, x-rays, chemotherapy)
- Cigarette or marijuana smoke
- Diabetes
- Heavy alcohol consumption
- Use of prescription drugs for ulcers or psoriasis
- Exposure of the genitals to high temperatures (hot tubs or saunas)
- Hernia repair
- Cardiovascular disease
- Obesity associated with decreased sperm quality
- Cushing syndrome
- Frequent long-distance cycling or running
- STIs
- Undescended testicles (cryptorchidism)
- Mumps after puberty (Walker & Tobler, 2020)

Therapeutic Management

As noted earlier, the main causes of infertility are female-factor (e.g., anovulation, tubal damage, endometriosis, ovarian failure), male-factor (e.g., low or absent numbers of motile sperm in the ejaculate, erectile dysfunction), or unexplained (Dunne, 2018). The test results are presented to the couple and different treatment options are suggested. The majority of infertility cases are treated with drugs or surgery. Treatment options include lifestyle changes, such as weight loss and smoking cessation; taking clomiphene to promote ovulation; hormone injections to promote ovulation; intrauterine insemination; and IVF. Various ovulation-enhancement drugs and timed intercourse might be used for the woman with ovulation problems. The woman should understand a drug's benefits and side effects before consenting to take it. Depending on the type of drug used and the dosage, some women may experience multiple pregnancies. If the woman's reproductive organs are damaged, surgery can be done to repair them. Still, other couples might opt for the hi-tech approaches of artificial insemination (Fig. 4.2), IVF (Fig. 4.3), and egg donation, or they may contract for a gestational carrier or

surrogate (Taylor et al., 2020). Table 4.3 lists selected treatment options for infertility.

Nursing Assessment

Infertile couples may be under tremendous pressure and often keep the problem a secret, considering it to be personal. Couples and women are often beset by feelings of inadequacy and guilt, and many are subject to pressures from both family and friends. As the problem becomes more chronic, they may begin to blame one another, with consequent marital discord. Seeking help is often a difficult step, and it may take a lot of courage to discuss something about which they feel embarrassed or upset. The nurse working in this specialty setting must be aware of the conflict and problems couples experience and must be sensitive to their needs.

A full medical history should be taken from both partners, along with a physical examination. The data needed for the infertility evaluation are sensitive and of a personal nature, so the nurse must use professional interviewing skills.

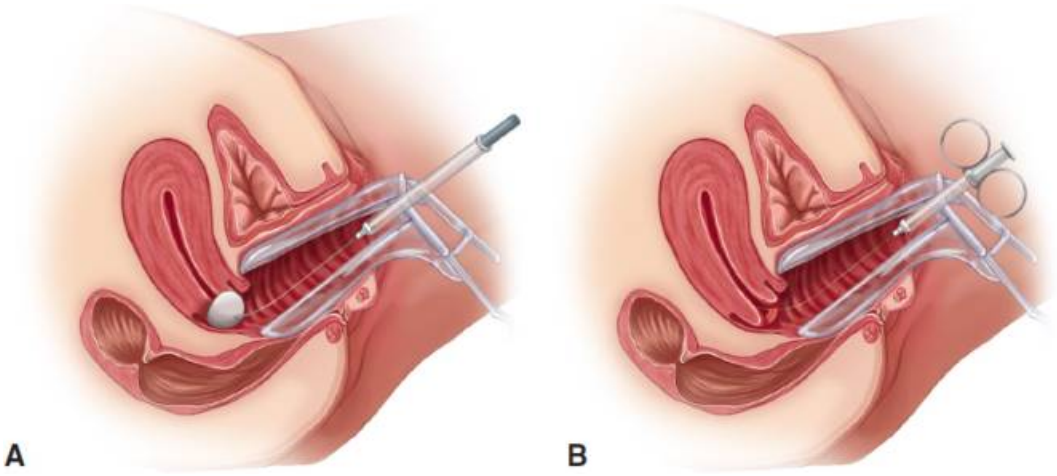

FIGURE 4.2. Artificial insemination. Sperm are deposited next to the cervix (**A**) or injected directly into the uterine cavity (**B**).

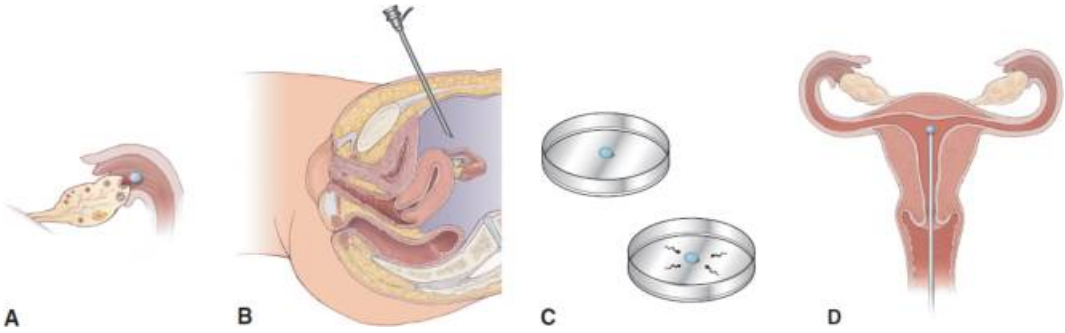

FIGURE 4.3. Steps involved in in vitro fertilization. **A.** Ovulation. **B.** Capture of the ova (done here intra-abdominally). **C.** Fertilization of ova and growth in culture medium. **D.** Insertion of fertilized ova into the uterus.

Infertility has numerous causes and contributing factors, so it is important to use the process of elimination, determining what problems do not exist to better comprehend the problems that may exist. At the first visit, a plan of investigation is outlined and a complete health history is taken. This first visit forces many couples to confront the reality that a desired pregnancy may not occur naturally. At a minimum, women should have evidence of ovulation and tubal patency and the male should have a normal semen analysis for conception to be successful (ACOG, 2019). Alleviate some of the anxiety associated with diagnostic testing by explaining the timing and reasons for each test.

Assessing Male Factors

The initial screening evaluation for the male partner should include a reproductive history and a semen analysis. From the male perspective, three things must happen for conception to take place: the number of sperm must be adequate; those sperm must be healthy and mature; and the sperm must be able to penetrate and fertilize the egg. Normal males have more than 20 million sperm per milliliter with greater than 50% motility (Webster et al., 2018). Semen analysis is the most important indicator of male fertility. The man should abstain from sexual activity for 2 to 5 days before giving the sample. For a semen examination, the man is asked to produce a

specimen by ejaculating into a specimen container and delivering it to the laboratory for analysis within 1 hour. When the specimen is brought to the laboratory, it is analyzed for volume, viscosity, number of sperm, sperm viability, motility, and sperm shape. If semen parameters are normal, no further male evaluation is necessary (Hanson & Hotaling, 2018).

A recent study shows that social strain and stress are highest among couples without a clear etiology for their infertility. These findings highlight the clinically significant negative sexual, personal, and social strains of a perceived infertility diagnosis for men. In men, an investigation of sexual, general, and psychological health status is important to improve reproductive problems and general health (Lotti & Maggi, 2018). Nurses need to be cognizant of this impact on males and address it.

The physical examination routinely includes:

- assessment for appropriate male sexual characteristics, such as body hair distribution, development of the Adam's apple, and muscle development
- examination of the penis, scrotum, testicles, epididymis, and vas deferens for abnormalities (e.g., nodules, irregularities, varicocele)
- assessment for normal development of external genitalia (small testicles)
- performance of a digital internal examination of the prostate to check for tenderness or swelling (Strauss et al., 2019)

Assessing Female Factors

The initial assessment of the woman should include a thorough history of factors associated with ovulation and the pelvic organs. Diagnostic tests to determine female infertility may include:

- Assessment of ovarian function
- Ovulation predictor kits used midcycle
- Urinary LH level
- Clomiphene citrate challenge test
- Assessment of pelvic organs
- Papanicolaou (Pap) smear to rule out cervical cancer or inflammation

- Cervical culture to rule out any STIs
- Ultrasound to assess pelvic structures
- Hysterosalpingography to visualize structural defects
- Laparoscopy to visualize pelvic structures and diagnose and treat endometriosis (Rao, 2018)

TABLE 4.3 Selected Treatment Options for Infertility

Procedure	Comments	Nursing Considerations
Fertility Drugs		
Clomiphene citrate (Clomid)	A nonsteroidal synthetic antiestrogen used to induce ovulation. Clomid is typically discontinued after three cycles of use.	Nurse can advise the couple to have intercourse every other day for 1 wk starting after day 5 of medication.
Human menopausal gonadotropin (HMG) (Pergonal)	Induces ovulation by direct stimulation of ovarian follicle	Same as above
Artificial insemination	The insertion of a prepared semen sample into the cervical os or intrauterine cavity Enables sperm to be deposited closer to improve chances of conception Husband or donor sperm can be used.	Nurse needs to advise couple that the procedure might need to be repeated if not successful the first time.
Assisted Reproductive Technologies[a]		
In vitro fertilization (IVF)	Oocytes are fertilized in the lab and transferred to the uterus. Usually indicated for tubal obstruction, endometriosis, pelvic adhesions, and low sperm counts	Nurse advises woman to take medication to stimulate ovulation so the mature ovum can be retrieved by needle aspiration.
Gamete intrafallopian transfer (GIFT)	Oocytes and sperm are combined and immediately placed in the fallopian tube so fertilization can occur naturally. Requires laparoscopy and general anesthesia,	Nurse needs to inform couple of risks and have consent signed.

	which increases risk	
Intracytoplasmic sperm injection (ICSI)	One sperm is injected into the cytoplasm of the oocyte to fertilize it. Indicated for male factor infertility	Nurse needs to inform the male that sperm will be aspirated by a needle through the skin into the epididymis.
Donor oocytes or sperm	Eggs or sperm are retrieved from a donor, and the eggs are inseminated; resulting embryos are transferred via IVF. Recommended for women older than 40 yrs and those with poor-quality eggs.	Nurse needs to support couple in their ethical/religious discussions prior to deciding.
Preimplantation genetic diagnosis (PGD)	Used to identify genetic defects in embryos created through IVF before pregnancy This is done specifically when one or both genetic parents have a known genetic abnormality and testing is performed on an embryo to see if it also carries a genetic abnormality.	Nurse should inform couple about this option and support them until test results return.
Gestational carrier (surrogacy)	Laboratory fertilization takes place and embryos are transferred to the uterus of another woman, who will carry the pregnancy or intrauterine insemination can be done with the male sperm. Medical legal issues have resulted over the “true ownership” of the resulting infant.	Nurse should encourage an open discussion regarding implications of this method with the couple.

[a] When other options have been exhausted, these are considered.

American Society for Reproductive Medicine (ASRM). (2019). *Quick facts about infertility*. Retrieved June 16, 2020, from https://www.reproductivefacts.org/faqs/quick-facts-about-infertility/; Magowan, B. A., Owen, P., & Thomson, A. (2019). *Clinical obstetrics & gynecology* (4th ed.). Elsevier; Rao, K. A. (2018). *The infertility manual* (4th ed.). Jaypee Brothers Medical Publishers.

Laboratory and Diagnostic Testing

The diagnostic procedures that should be done during an infertility workup should be guided by the couple's history. They generally proceed from less to more invasive tests.

HOME OVULATION PREDICTOR KITS

Home ovulation predictor kits contain monoclonal antibodies specific for LH and use an enzyme-linked immunosorbent assay (ELISA) test to determine the amount of LH present in the urine. A significant color change from baseline indicates the LH surge and presumably the most fertile day of the month for the woman.

CLOMIPHENE CITRATE CHALLENGE TEST

The clomiphene citrate challenge test is used to assess a woman's ovarian reserve (ability of her eggs to become fertilized). FSH levels are drawn on cycle day 3 and on cycle day 10 after the woman has taken 100 mg clomiphene citrate on cycle days 5 through 9. If the FSH level is greater than 15, the result is considered abnormal and the likelihood of conception with her own eggs is low (Knaus et al., 2018).

HYSTEROSALPINGOGRAPHY

Hysterosalpingography (HSG) is the gold standard in assessing patency (being open and unobstructed) of the fallopian tubes. Fallopian tube obstruction is among the most common causes of female factor infertility. Ultrasonography and magnetic resonance imaging (MRI) are used in this assessment. In hysterosalpingography, 3 to 10 mL of an opaque oil-based contrast

medium is slowly injected through a catheter into the endocervical canal so that the uterus and tubes can be visualized during fluoroscopy and radiography. If the fallopian tubes are patent, the dye will ascend upward to distend the uterus and the tubes and will spill out into the peritoneal cavity (Fig. 4.4) (ACOG, 2019).

LAPAROSCOPY

A laparoscopy is usually performed early in the menstrual cycle. It is not part of the routine infertility evaluation. It is used when abnormalities are found on the ultrasound or the hysterosalpingogram or when endometriosis is suspected. Because of the added risks of surgery, the need for anesthesia, and operative costs, it is only used when clearly indicated. During the procedure, an endoscope is inserted through a small incision in the anterior abdominal wall. Visualization of the peritoneal cavity in an infertile woman may reveal endometriosis, pelvic adhesions, tubal occlusion, fibroids, or polycystic ovaries (Sahu & Modi, 2018).

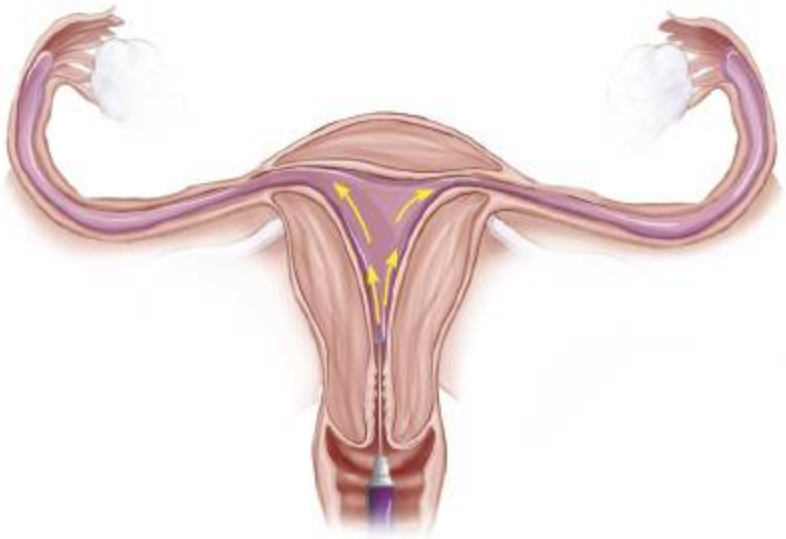

FIGURE 4.4. Insertion of a dye for a hysterosalpingogram. The contrast dye outlines the uterus and fallopian tubes on an x-ray to demonstrate patency.

Nursing Management

Nurses play an important role in the care of infertile couples. They are pivotal educators about preventive health care. A number of potentially modifiable risk factors are associated with the development of impaired fertility in women, and women need to be aware of these risks to institute change. The nurse is most effective when they offer care and treatment in a professional manner and regards the couple as valued and respected individuals. The nurse must be respectful of and mindful that many women may seek spiritual help for their infertility issues in addition to traditional medical modalities. In a recent study, a couple's level of spirituality was positively associated with their own quality of life and helped reduce infertility-related stress (Casu et al., 2018). The nurse's focus must encompass the whole person, not just the results of the various infertility studies. Throughout the entire process, the nurse's role is to provide information, anticipatory guidance, stress management, and counseling. The couple's emotional distress is often high, and the nurse must be able to recognize that anxiety and provide emotional support. The nurse may need to refer couples to a reproductive endocrinologist or surgeon, depending on the problem identified.

There is no absolute way to prevent infertility per se because so many factors are involved in conception. Nurses can be instrumental in educating men and women about the factors that contribute to infertility. The nurse can also outline the risks and benefits of treatments so that the couple can make an informed decision. As couples struggle with infertility, they frequently turn to nurses for empathy, counseling, and support. By understanding the struggles and lived experiences of women and couples experiencing infertility, the nurse can tailor their approach to better meet the couple's needs so that the pregnancy and birth experience of these women are healing, transformative, and positive.

With advances in genetics and reproductive medicine also come a myriad of ethical, social, and cultural issues that will affect the couple's decisions. With this in mind, provide an opportunity for the couple to make informed decisions in a nondirective, nonjudgmental environment. It is important to encourage couples to remain optimistic throughout investigation and treatment. Through the use of

advocacy and anticipatory guidance, assist and support couples through the diagnosis and treatment of infertility (Jordan et al., 2019).

BOX 4.4 Organizations and Web Resources to Assist the Client with Infertility

- RESOLVE: a nationwide network of chapters dedicated to providing education, advocacy, and support for men and women facing infertility. They provide a helpline, medical referral services, and a member-to-member contact system (http://www.resolve.org).
- American Society of Reproductive Medicine (ASRM): provides fact sheets and other resources on infertility, treatments, insurance, and other issues (http://www.asrm.org).
- International Counsel on Infertility (INCIID): provides information about infertility, support forums, and a directory of infertility specialists (http://www.inciid.org).
- American Fertility Association: offers education, referrals, research, support, and advocacy for couples dealing with infertility (http://www.americaninfertility.org).
- Office on Women's Health—Infertility health topic: (https://www.womenshealth.gov/a-z-topics/infertility).
- International Consumer Support for Infertility: an international network engaged in advocacy on behalf of infertile couples via fact sheets and information (http://www.icsi.ws).

Finances and insurance coverage often dictate the choice of treatment. Help couples decipher their insurance coverage and help them weigh the costs of various procedures by explaining what each will provide in terms of their infertility problems. Assisting them in making a priority list of diagnostic tests and potential treatment options will help the couple plan a financial strategy.

Many infertile couples are not prepared for the emotional roller coaster of grief and loss that accompanies infertility treatments. Financial concerns and coping as a couple are two major areas of stress when treatment is undertaken. During the course of what may be months or even years of infertility care, it is essential to develop a holistic approach to nursing care. Stress management and anxiety

reduction need to be addressed, and referral to a peer support group such as RESOLVE might be in order (Box 4.4).

CONTRACEPTION

The terms "**contraception**," "family planning," and "birth control" are used interchangeably when referring to the intentional prevention of pregnancy through the use of various devices, agents, drugs, sexual practices, and surgical procedures. In the United States, there are over 68 million women in their childbearing years (between the ages of 15 and 44), and throughout those years, a variety of contraceptive methods may be used. Studies have shown that 98% of sexually active women in the United States report having used at least one form of contraception; however, despite the widespread use of contraceptives, almost half of all pregnancies in the United States are unintended, accounting for a higher unintended pregnancy rate than any other Western country (Centers for Disease Control and Prevention [CDC], 2019a). As outlined in the United Nations *World Population Prospects* (2019), over 7.7 billion people inhabit the earth now, and over 80 million people are added to the world each year, more than half of whom are unintended (*Healthy People 2030* 4.1).

Objective	Nursing Significance
FP-2030-01 Reduce the proportion of pregnancies that are unintended.	Would reduce number of unplanned pregnancies and girls not finishing their educations. This would in turn reduce the number of single parents on state financial assistance.
FP-2030-07 Increase the proportion of sexually active adolescents aged 15 to 19 years who use any method of contraception at first intercourse.	Awareness of contraceptive methods and accessibility brings about better compliance and prevention of unintended pregnancies.
FP-2030-08 Increase the proportion of female adolescents who receive formal instruction on abstinence, birth control methods, HIV/AIDS prevention, and sexually transmitted diseases before they are 18 years old.	Accessibility of reproductive resources can offer pregnancy prevention and preventive education.
FP-2030-09 Increase the proportion of females in need of publicly supported contraceptive services and supplies who	Would increase accessibility to contraception and prevent unintended pregnancies.

receive those services and supplies.

Adapted from USDHHS. (2020). *Proposed objectives for inclusion in Healthy People 2030*. Retrieved June 16, 2020, from https://www.healthypeople.gov/sites/default/files/ObjectivesPublicComment508.pdf

In addition to unwanted pregnancies, some contraceptives also help prevent transmission of STIs and human immunodeficiency virus (HIV). The UN report also shows that over 40,000 people in the United States become infected with HIV every year. Much of this suffering could be prevented by access to and consistent use of safe, efficient, appropriate, modern contraception for everyone who wants it, as well as proper education regarding benefits and instructions for use (CDC, 2019d). In addition, climate change (extreme temperature changes and rising ocean levels) will interact with population growth in ways that put additional stress on already weak health systems and will exacerbate vulnerability to the adverse health effects of climate change. The damage done to the environment by modern society is perhaps one of the most inequitable health risks of our time. Between 2030 and 2050, climate change is expected to cause approximately 250,000 deaths annually from malnutrition, malaria, diarrhea, and heat stress (WHO, 2018a).

Today, the voluntary control of fertility is of vital importance to modern society. From a global perspective, countries currently face a crisis of rapid population growth that has begun to threaten human survival. At the present rate, the population of the world will double in 40 years; in several of the more socioeconomically disadvantaged countries, populations will double in less than 20 years (UN, 2019).

Types of Contraceptive Methods

Contraceptive methods can be divided into four types: behavioral methods, barrier methods, hormonal methods, and permanent methods. Women must decide which method is appropriate for them to meet their changing contraceptive needs throughout their life cycles. Nurses can educate and assist women during this selection

process. This part of the chapter will outline the most common birth control methods available.

In an era when many women wish to delay pregnancy and avoid STIs, choices can be difficult. An estimated 225 million women in developing countries wish to prevent pregnancy, but they have no access to any method of contraception (WHO, 2018a). Numerous methods of contraception are available today, and many more will be offered in the near future. The ideal contraceptive method for many women would have the following characteristics: ease of use, safety, effectiveness, minimal side effects, "naturalness," be nonhormonal, and be immediately reversible (Kwansa & Stewart-Moore, 2019). Currently, no one contraceptive method offers everything. Box 4.5 outlines the contraceptive methods available today. Table 4.4 provides a detailed summary of each type, including information on failure rates, advantages, disadvantages, STI protection, and danger signs.

Contraceptive methods can be grouped according to their estimated effectiveness in preventing pregnancy as follows:

- Most effective methods: male and female sterilization, intrauterine contraception, and implant
- Very effective methods: Injectable contraceptive, contraceptive patch, ring, and pills
- Less effective methods: Male and female condoms, diaphragm, and fertility awareness (Hatcher et al., 2018)

Sexual Abstinence

Sexual abstinence (not having intercourse) is one of the least expensive forms of contraception and has been used for thousands of years. Pregnancy cannot occur if sperm is kept out of the vagina. It also reduces the risk of contracting HIV/AIDS and other STIs, unless body fluids are exchanged through oral sex; however, some infections, like herpes and human papilloma virus (HPV), can still be passed by skin-to-skin contact. Dental dams can be used to prevent transmission, however. There are many pleasurable options for sex play without intercourse ("outercourse"), such as kissing,

masturbation, erotic massage, sexual fantasy, sex toys such as vibrators, and oral sex.

BOX 4.5 Outline of Contraceptive Methods

Reversible Methods

- Behavioral
  - Abstinence
  - Fertility awareness–based methods (FAMs)
  - Withdrawal (coitus interruptus)
  - Lactational amenorrhea method (LAM)
- Barrier
  - Condom (male and female)
  - Diaphragm
  - Cervical cap
  - Sponge
- Hormonal
  - OC
  - Injectable contraceptive
  - Transdermal patch
  - Vaginal ring
  - Implantable contraceptive
  - Intrauterine contraceptive
  - Emergency contraceptive

Permanent Methods

- Tubal ligation or Essure for women
- Vasectomy for men

Many people have strong feelings about abstinence based on religious and moral beliefs. There are many reasons to choose abstinence. For some, it is a way of life, while for others it is a temporary choice. Some people choose sexual abstinence because they want to:

- wait to have sex until they are older.
- wait to have sex for a long-term relationship.
- avoid pregnancy or STIs.
- relieve feelings of depression or anxiety.
- follow religious or cultural expectations.

Fertility Awareness–Based Methods

Fertility awareness methods are based on identifying fertile days in a woman's cycle and avoiding sexual intercourse during that time. FAMs use physical signs and symptoms that change with hormone fluctuations throughout a woman's menstrual cycle to predict a woman's fertility. Ovulation occurs on one day during each menstrual cycle, and the several days preceding ovulation are when intercourse is most likely to result in pregnancy. Collectively, the potentially fertile days up to and including the day of ovulation are called the "fertile window." Awareness of fertility is a better fertility-producing method than a contraceptive method. Less than 1% of women in the United States who use contraception employ these methods for this purpose (Urrutia et al., 2018). The unifying theme of FAMs is that a woman can reduce her chance of pregnancy by abstaining from coitus or using barrier methods during times of fertility. These methods require couples to take an active role in preventing pregnancy through their sexual behaviors, and women need to have regular menstrual cycles for it to be effective. Couples agree to practice certain techniques, use calculations, and be observant of the fertile and the nonfertile periods in a monthly menstrual cycle. Using these methods for birth control requires a strong commitment from both partners. The normal physiologic changes caused by hormonal fluctuations during the menstrual cycle can be observed and charted. This information can then be used to avoid or promote pregnancy. Many apps are currently available and easily downloaded to mobile devices. Some are geared toward enhancing fertility while others are designed for contraception. Fertility awareness-based methods rely on the following assumptions:

TABLE 4.4 Summary of Contraceptive Methods

Type	Description	Failure Rate	Pros	Cons	STI Protection	Danger Signs	Comments
Nothing/Chance	No birth control method used	85%					
Fertility awareness–based methods	Refrain from sex during fertile period	25%	No side effects; acceptable to most religious groups	High failure rate with incorrect use	None	None	Requires high level of couple commitment
Withdrawal (coitus interruptus)	Man withdraws before ejaculation	22%	Involves no devices and is always available	Requires considerable self-control by the man	None	None	Places woman in trusting and dependent role
Lactational amenorrhea method (LAM)	Uses lactational infertility for protection from pregnancy	1–2% chance of pregnancy in first 6 mo	No cost; not coitus-linked	Temporary method; effective for only 6 mo after giving birth	None	None	Mother must breastfeed infant on demand without supplementation for 6 mo.
Male condom	Thin sheath placed over an erect penis, blocking sperm	18%	Widely available; low cost; physiologically safe	Decreased sensation for man; interferes with sexual spontaneity; breakage risk	Provides protection against STIs	Latex allergy	Couple must be instructed on proper use of condom.
Female condom	Polyurethane sheath inserted vaginally to block sperm	21%	Use controlled by woman; eliminates postcoital drainage of semen	Expensive for frequent use; cumbersome; noisy during sex act; for single use only	Provides protection against STIs	Allergy to polyurethane	Couple must be instructed on proper use of condom.
Diaphragm with spermicide	Shallow latex cup with spring mechanism in its rim to hold it in place in the vagina	12%	Nonhormonal; considered medically safe; provides some protection against cervical cancer	Requires accurate fitting by health care professional; increase in UTIs	None	Allergy to latex, rubber, polyurethane, or spermicide Report symptoms of toxic shock syndrome May become dislodged in female superior position	Woman must be taught to insert and remove diaphragm correctly.
Cervical cap with spermicide	Soft cup-shaped latex device that fits over base of cervix	12%	No use of hormones; provides continuous protection while in place	Requires accurate fitting by health care professional; odor may occur if left in too long	None	Irritation, allergic reaction; abnormal Pap test; risk of toxic shock syndrome	Instructions on insertion and removal must be understood by client.

Sponge with spermicide	Disk-shaped polyurethane device containing a spermicide that is activated by wetting it with water	20%	Offers immediate and continuous protection for 24 hr; OTC	Can fall out of vagina with voiding; is not form-fitting in the vagina	None	Irritation, allergic reactions; toxic shock syndrome can occur if sponge left in too long	Caution woman not to leave sponge in beyond 24 hr.
Oral contraceptives (combination)	A pill that suppresses ovulation by combined action of estrogen and progestin	9%	Easy to use; high rate of effectiveness; protection against ovarian and endometrial cancer	User must remember to take pill daily; possible undesirable side effects; high cost for some women; prescription needed	None	Dizziness, nausea, mood changes, high blood pressure, blood clots, heart attacks, strokes	Each woman must be assessed thoroughly to make sure she is not a smoker and does not have a history of thromboembolic disease.
Oral contraceptives (progestin-only mini-pills)	A pill containing only progestin that thickens cervical mucus to prevent sperm from penetrating	9%	No estrogen-related side effects; may be used by lactating women; may be used by women with history of thrombophlebitis	Must be taken with meticulous accuracy; may cause irregular bleeding; less effective than combination pills	None	Irregular bleeding, weight gain, increased incidence of ectopic pregnancy	Women should be screened for history of functional ovarian cysts, previous ectopic pregnancy, and hyperlipidemia prior to giving prescription.
Patch (Ortho Evra)	Transdermal patch that releases estrogen and progestin into circulation	9%	Easy system to remember; very effective	May cause skin irritation where it is placed; may fall off and not be noticed and thus provide no protection	None	Less effective in women weighing more than 200 lb	Instruct woman to apply patch every week for 3 wks and then not to wear one during week 4.
Ring (NuvaRing)	Vaginal contraceptive ring about 2 in in diameter that is inserted into the vagina; releases estrogen and progestin	9%	Easy system to remember; very effective	May cause a vaginal discharge; can be expelled without noticing and not offer protection	None	Similar to oral contraceptives	Instruct woman to use a backup method if ring is expelled and remains out for more than 3 hr.
Depo-Provera injection	An injectable progestin that inhibits ovulation	6%	Long duration of action (3 mo); highly effective; estrogen-free; may be used by smokers; can be used by lactating women	Menstrual irregularities; return visit needed every 12 wks; weight gain, headaches, depression; return to fertility delayed up to 12 mo	None	If depression is a problem, this method may increase the depression.	Inform woman that fertility is delayed after stopping the injections.

Implant (Nexplanon)	A time-release implant (one rod) of levonorgestrel for 3 yrs	0.05%	Long duration of action; low dose of hormones; reversible; estrogen-free	Irregular bleeding; weight gain; breast tenderness; headaches; difficulty in removal	None	If bleeding is heavy, anemia may occur.	Before insertion, assess woman to make sure she is aware that this method will produce about 3 years of infertility.
Intrauterine contraception system (IUSs)	A T-shaped device inserted into the uterus that releases copper, progesterone, or levonorgestrel	0.2%	It is immediately and highly effective; allows for sexual spontaneity; can be used during lactation; return to fertility not impaired; requires no active compliance by the user after insertion	Insertion requires a skilled professional; menstrual irregularities; prolonged amenorrhea; can be unknowingly expelled; may increase the risk of pelvic infection; user must regularly check string for placement; no protection against STIs; delay of fertility after discontinuing for possibly 6–12 mo	None	Cramps, bleeding, pelvic inflammatory disease; infertility; perforation of the uterus	Instruct woman how to locate string to check monthly for placement.
Postcoital emergency contraceptives (ECs)	Combination of levonorgestrel-only pills; combined estrogen and progestin pills; or the copper IUS inserted within 72 hr after unprotected intercourse	80%	Provides a last chance to prevent a pregnancy	Risk of ectopic pregnancy if EC fails	None	Nausea, vomiting, abdominal pain, fatigue, headache	Inform woman that ECs do not interrupt an established pregnancy, and the sooner they are taken, the more effective they are.
Permanent Sterilization							
Male	Sealing, tying, or cutting the vas deferens	0.15%	One-time decision provides permanent sterility; short recovery time; low long-term risks	Procedures are difficult to reverse; initial cost may be high; chance of regret; some pain/ discomfort after procedures	None for both	Postoperative complications: pain, bleeding, infection	Counsel both as to permanence of procedure and urge them to think it through prior to signing consent.
Female	Fallopian tubes are blocked to prevent conception	0.5%					

Centers for Disease Control and Prevention (CDC). (2019a). *Contraception: How effective are birth control methods?* Retrieved June 16, 2020, from https://www.cdc.gov/reproductivehealth/contraception/index.htm.

- A single ovum is released from the ovary 14 days before the next menstrual period. It lives approximately 24 hours.
- Women using this method must have regular menstrual cycles for it to be effective.
- Sperm can live up to 5 days after intercourse. The fertile period during the menstrual cycle is thus approximately 6 days—3 days before and 3 days after ovulation. Because body changes start to occur before ovulation, the woman can become aware of them and not have intercourse on these days or use another method to prevent pregnancy.
- The exact time of ovulation cannot be determined, so 2 to 3 days are added to the beginning and end to avoid pregnancy.

Techniques used to determine fertility include the cervical mucus ovulation method, the basal body temperature (BBT) method, the symptothermal method, standard days method, and 2-day method (Jordan et al., 2019). Fertility awareness methods are moderately effective but are unforgiving if not carried out as prescribed. Fertility

awareness-based methods can be used in combination with coital abstinence or barrier methods during fertile days if pregnancy is not desired.

CERVICAL MUCUS OVULATION METHOD

Cervical mucus is a jellylike vaginal discharge that comes from the cervix. The **cervical mucus ovulation method** is used to assess the character of the cervical mucus. Cervical mucus changes in consistency during the menstrual cycle and plays a vital role in fertilization of the egg. In the days preceding ovulation, fertile cervical mucus helps draw sperm up and into the fallopian tubes, where fertilization usually takes place. It also helps maintain the survival of sperm. As ovulation approaches, the mucus becomes more abundant, clear, slippery, and smooth; it can be stretched between two fingers without breaking. Under the influence of estrogen, this mucus looks like egg whites. It is called *spinnbarkeit* mucus (Fig. 4.5). After ovulation, the cervical mucus becomes thick and dry under the influence of progesterone.

FIGURE 4.5. Spinnbarkeit mucus is cervical mucus that can stretch a distance before breaking.

The cervical position can also be assessed to confirm changes in the cervical mucus at ovulation. Near ovulation, the cervix feels soft and is high and deep in the vagina, the os is slightly open, and the cervical mucus is copious and slippery (Hatcher et al., 2018). This method works because the woman becomes aware of her body changes that accompany ovulation. When she notices them, she abstains from sexual intercourse or uses another method to prevent pregnancy. Each woman is an individual, so each woman's fertile time of the month is unique and thus must be individually assessed and determined.

BASAL BODY TEMPERATURE METHOD

The **basal body temperature (BBT)** refers to the lowest temperature reached on awakening. The woman takes her temperature orally before rising and records it on a chart. Preovulation temperatures are suppressed by estrogen, while postovulation temperatures are increased under the influence of heat-inducing progesterone. Temperatures typically rise within a day or two after ovulation and remain elevated for approximately 2 weeks (at which point bleeding usually begins). If using this method by itself, the woman should avoid unprotected intercourse until the BBT has been elevated for 3 days. Nurses should instruct women using the BBT method that it is important to keep in mind that illness and any drugs, including alcohol, can raise body temperature and give a false reading. Other FAMs should be used along with BBT for better results (Fig. 4.6).

SYMPTOTHERMAL METHOD

The **symptothermal method** relies on a combination of techniques to recognize ovulation, including BBT, cervical mucus changes, alterations in the position and firmness of the cervix, and other symptoms of ovulation, such as increased libido, *mittelschmerz* (midcycle, lower abdominal pain at ovulation), pelvic fullness or tenderness, and breast tenderness (Clark et al., 2018). Combining all these predictors increases the awareness of when ovulation occurs and increases the effectiveness of this method. A home predictor test for ovulation is also available in most pharmacies. It measures LH levels to pinpoint the day before or the day of ovulation. These tests are widely used for fertility and infertility regimens.

THE STANDARD DAYS METHOD AND THE 2-DAY METHOD

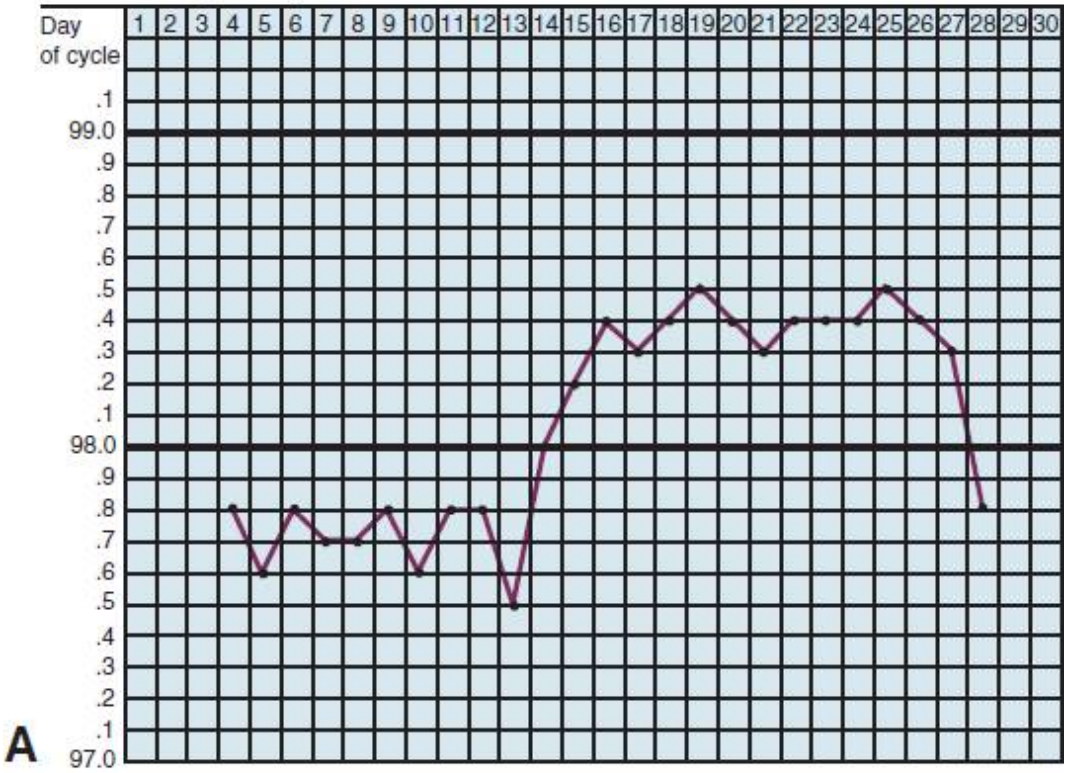
The **standard days method (SDM)** and the 2-day method are both natural methods of contraception developed by Georgetown University Medical Center's Institute for Reproductive Health. Both

methods provide women with simple, clear instructions for identifying fertile days. Women with menstrual cycles between 26 and 32 days long can use the SDM to prevent pregnancy by avoiding unprotected intercourse on days 8 through 19 of their cycles. Most SDM users utilize a visual aid—CycleBeads—to assist their correct use of SDM. SDM identifies the 12-day “fertile window” of a woman’s menstrual cycle. These 12 days take into account the lifespan of the women’s egg (about 24 hours) and the viability of the sperm (about 5 days) as well as the variation in the actual timing of ovulation from one cycle to another.

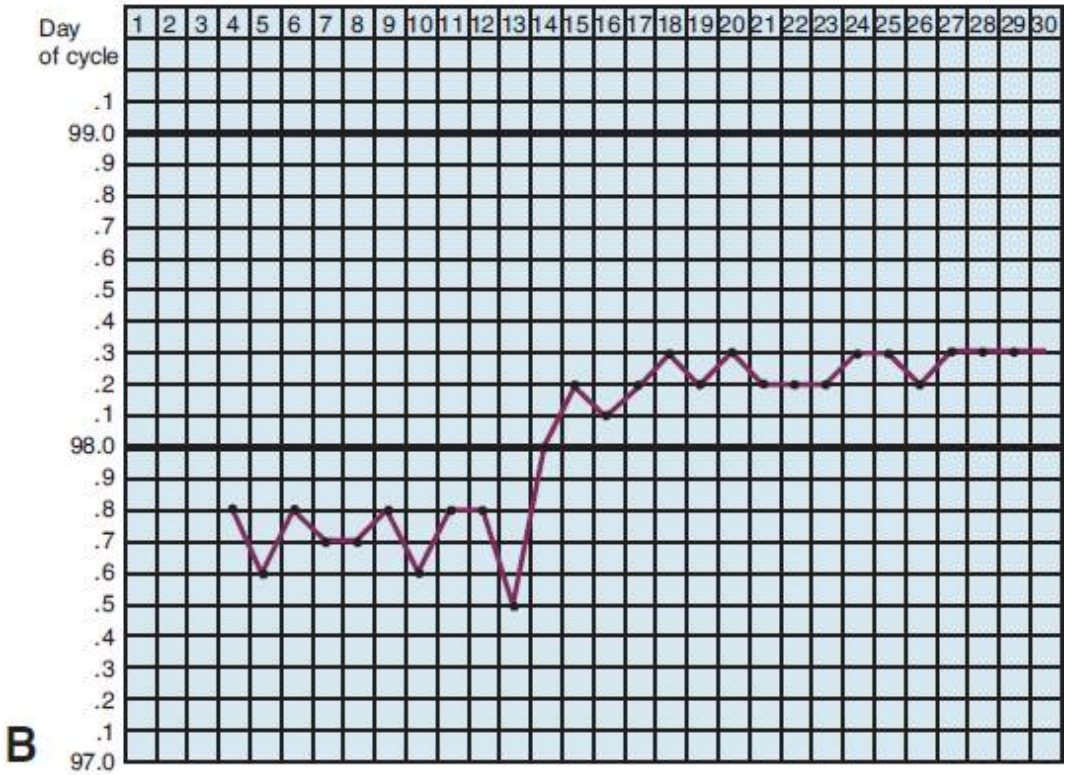
With the 2-day method, women observe the presence or absence of cervical secretions by examining toilet paper or underwear or by monitoring their physical sensations. Every day, the woman asks two simple questions: “Did I note any secretions yesterday?” and “Did I note any secretions today?” If the answer to either question is yes, she considers herself fertile and avoids unprotected intercourse. If the answers are no, she is unlikely to become pregnant from unprotected intercourse on that day (Rodriguez, 2018).

To help women keep track of the days on which they should avoid unprotected intercourse, a string of 32 color-coded beads called CycleBeads can be is used, with each bead representing a day of the menstrual cycle. Starting with the red bead, which represents the first day of her menstrual period, the woman moves a small rubber ring one bead each day. The brown beads are the days when pregnancy is unlikely, and the white beads represent fertile days (Rodriguez, 2018). This method has been used in underdeveloped countries for women with limited educational resources (Fig. 4.7).

Basal body temperature



A



B

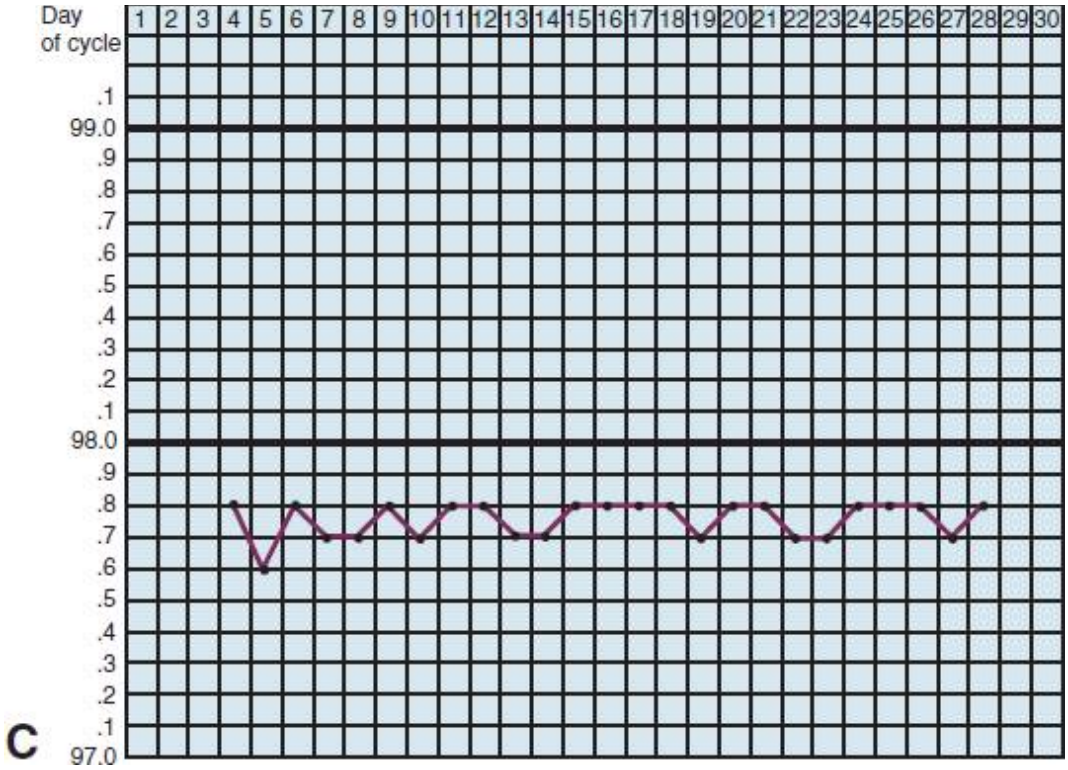


FIGURE 4.6. Basal body temperature graph. **A.** The woman's temperature dips slightly at midpoint in the menstrual cycle, then rises sharply, an indication of ovulation. Toward the end of the cycle (the 24th day), her temperature begins to decline, indicating that progesterone levels are falling and that she did not conceive. **B.** The woman's temperature rises at the midpoint in the cycle and remains at that elevated level past the time of her normal menstrual flow, suggesting that pregnancy has occurred. **C.** There is no preovulatory dip and no rise of temperature anywhere during the cycle. This is the typical pattern of a woman who does not ovulate.

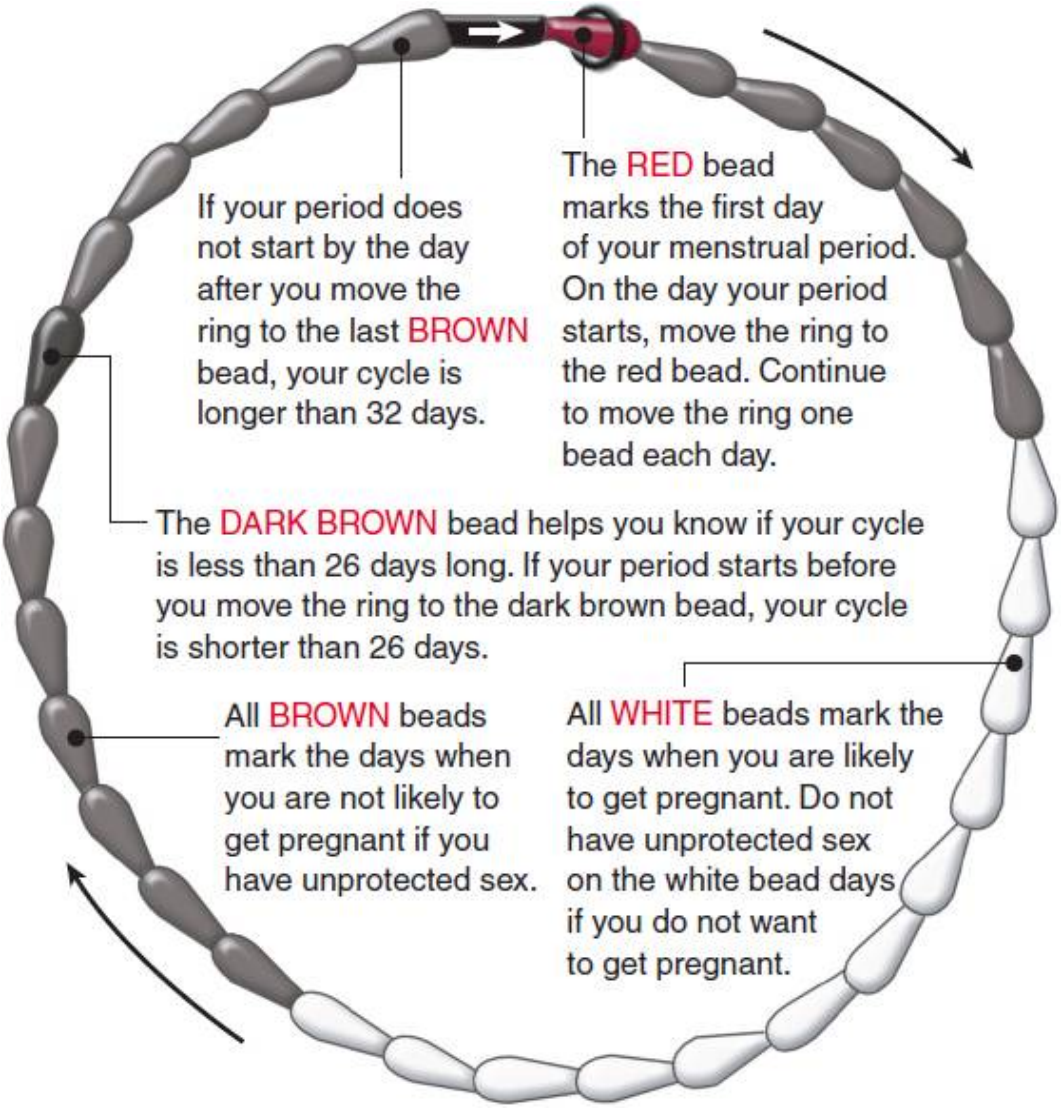

FIGURE 4.7. CycleBeads help women use the standard days method.

Withdrawal (Coitus Interruptus)

In **coitus interruptus**, also known as withdrawal, a man controls his ejaculation during sexual intercourse and ejaculates outside the vagina. It is better known colloquially as “pulling out.” It is one of the oldest and most widely used means of preventing pregnancy in the world and also one of the least effective methods for preventing pregnancy (Hatcher et al., 2018). The problem with this method is that the first few drops of the true ejaculate contain the greatest concentration of sperm, and if some pre-ejaculatory fluid escapes from the urethra before orgasm, conception may result. The typical

failure rate is estimated at 18% to 22% (Jordan et al., 2019). This method requires that the woman rely solely on the cooperation and judgment of the man. Nurses might discuss the use of emergency contraceptives with this couple or use of a more effective method of contraception.

Lactational Amenorrhea Method

The **lactational amenorrhea method (LAM)** is an effective temporary method of contraception used by breastfeeding mothers. It relies on physiologic changes associated with breastfeeding for contraception. Continuous breastfeeding can usually postpone ovulation and thus prevent pregnancy. Breastfeeding stimulates the hormone prolactin, which is necessary for milk production, and it also inhibits the release of another hormone, gonadotropin, which is necessary for ovulation.

Breastfeeding as a contraceptive method can be fairly effective for up to 6 months after giving birth if:

- the woman has not had a menses since she gave birth.
- the infant is younger than 6 months of age.
- the woman breastfeeds her baby at least six times daily on both breasts.
- the woman breastfeeds her baby “on demand” at least every 4 hours.
- the woman does not substitute other foods for a breast-milk meal.
- nighttime feedings are provided at least every 6 hours.

Also, pumping or manual expression of milk may reduce effectiveness. Women should not rely on this method after 6 months (Rivlin & Isley, 2018).

Nurses can help couples make decisions about family planning options available in the postpartum period by discussing the advantages and disadvantages of each, taking into consideration the demands of the postpartum period. The options they may consider include lactational amenorrhea, combined oral contraception, progestin-only pills, implants, intrauterine systems, injectable

methods, barrier methods, emergency contraception, and sterilization (Oyelowo & Johnson, 2018).

Barrier Methods

Barrier contraceptives are physical or chemical devices that prevent pregnancy by preventing the sperm from reaching the ovum. Mechanical barriers include condoms, diaphragms, cervical caps, and sponges. These devices are placed over the penis or cervix to physically obstruct the passage of sperm through the cervix. Chemical barriers called spermicides may be used along with mechanical barrier devices. They come in creams, jellies, foam, suppositories, and vaginal films. They chemically destroy the sperm in the vagina. These contraceptives are called barrier methods because they not only provide a physical barrier for sperm but also protect against STIs. Since the HIV/AIDS epidemic started in the early 1980s, these methods have become extremely popular. Progress has been made in society's reaction to condom use as a disease prevention device now and not just as a contraceptive (Kwansa & Stewart-Moore, 2019).

Many of these barrier methods contain latex. Allergy to latex was first recognized in the late 1970s, and since then, it has become a major health concern, with increasing numbers of people affected. According to the Asthma and Allergy Foundation (AAFA), approximately 6% of the general population and between 8% and 17% of health care workers are sensitive to natural rubber latex (2019b). Teaching Guidelines 4.4 provides tips for individuals with latex allergies.

TEACHING GUIDELINES 4.4

Tips for Individuals Allergic to Latex

- Symptoms of latex allergy include:
  - Skin rash, itching, hives
  - Itching or burning eyes
  - Swollen mucous membranes in the genitals
  - Shortness of breath, difficulty breathing, wheezing
  - Anaphylactic shock
- Use of or contact with latex condoms, cervical caps, and diaphragms is contraindicated for men and women with a latex allergy.
- If the female partner is allergic to latex, have the male partner apply a natural condom over the latex one.
- If the male partner experiences penile irritation after condom use, try different brands or place the latex condom over a natural condom.
- Use polyurethane condoms rather than latex ones.
- Use female condoms; they are made of polyurethane.
- Switch to another birth control method that doesn't involve latex, such as OCs, IUSs, Depo-Provera, fertility awareness, and other nonbarrier methods. However, be aware these methods do not protect against STIs.

Asthma and Allergy Foundation of America (AAFA). (2019b). *Latex allergy*. Retrieved June 16, 2020, from http://www.aafa.org/latex-allergy/; OSHA. (2018). *OSHA medical manuals*. https://www.oshamanual.com/medical-osha.html; and Hatcher, R. A., Nelson, A. L., Trussell, J., Cwaik, C., Cason, P., Policar, M. S., Kowal, D. (2018). *Contraceptive technology* (21st ed.). Ardent Media.

CONDOMS

Condoms are barrier methods of contraceptives made for both males and females. The male condom is made from latex or polyurethane or natural membrane and may be coated with spermicide. Male condoms are available in many colors, textures, sizes, shapes, and thicknesses. When used correctly, the male

condom is put on over an erect penis before it enters the vagina and is worn throughout sexual intercourse (Fig. 4.8). It serves as a barrier to pregnancy by trapping seminal fluid and sperm after orgasm and offers protection against STIs. Condoms are not perfect barriers, however, because breakage and slippage can occur. Emergency postcoital contraception may need to be sought to prevent a pregnancy. Additionally, nonlatex condoms have a higher risk of pregnancy and STIs than do latex condoms (Kwansa & Stewart-Moore, 2019).

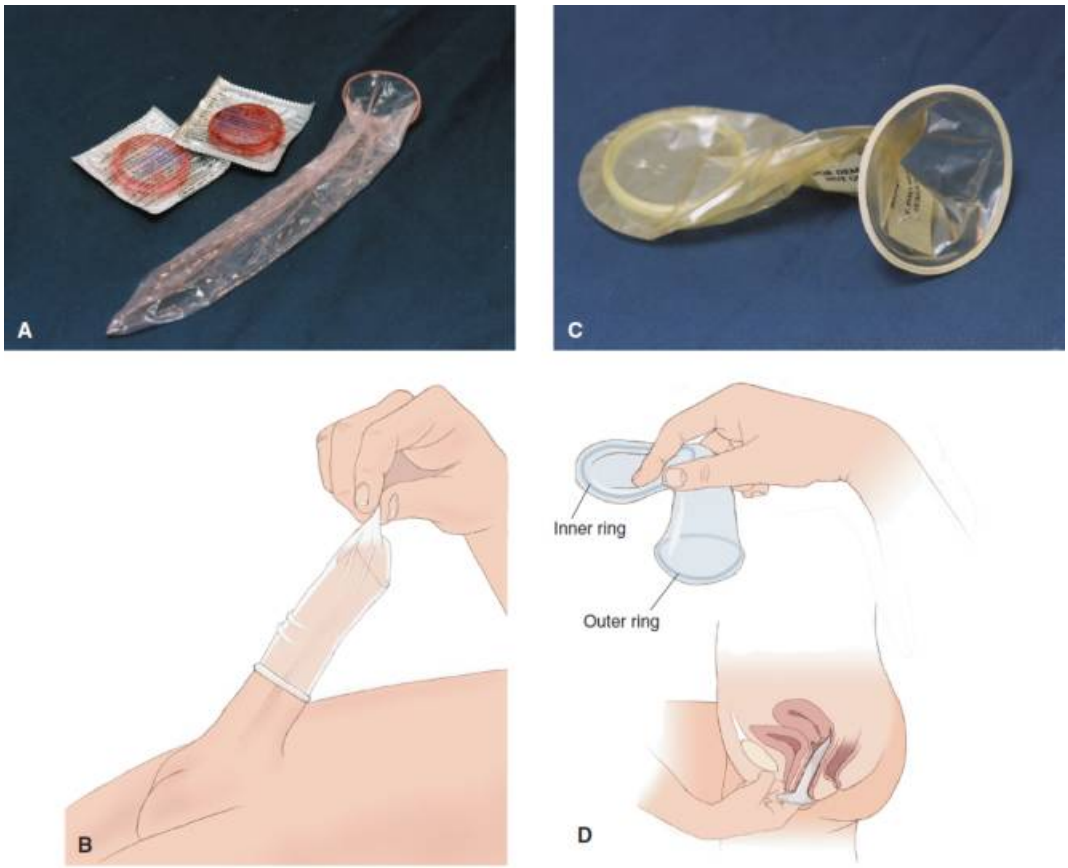

FIGURE 4.8. A. Male condom. **B.** Applying a male condom. Leaving space at the tip helps to ensure the condom will not break with ejaculation. **C.** The female condom. **D.** Insertion technique.

The female or internal condom is a polyurethane or nitrile pouch inserted into the vagina to catch the male ejaculate. It consists of an outer and inner ring that is inserted vaginally and held in place by the

pubic bone. Some women complain that the female condom is cumbersome to use and makes noise during intercourse. Female condoms are readily available, are inexpensive, and can be carried inconspicuously by the woman. The female condom was the first woman-controlled method that offered protection against pregnancy and some STIs. Nurses can play a key role in educating clients on how to initiate and maintain use of the female condom, an underused method for HIV/STI and pregnancy prevention in the United States. Providing a brief education session along with free samples would go a long way to promote increased use of this device to prevent STIs transmission as well as pregnancy (Hatcher et al., 2018).

VAGINAL DIAPHRAGM

The **diaphragm** is a soft latex or silicone dome surrounded by a metal spring. Used in conjunction with a spermicidal jelly or cream, it is inserted into the vagina to cover the cervix (Fig. 4.9). The diaphragm may be inserted up to 2 hours before intercourse and must be left in place for at least 6 hours afterward. Diaphragms are available in a range of sizes and styles. The diaphragm is available only by prescription and must be professionally fitted by a health care provider. Women may need to be refitted with a different-sized diaphragm after pregnancy, abdominal or pelvic surgery, or weight loss or gain of 10 lb or more. As a general rule, diaphragms should be replaced every 1 to 2 years. Recently, a single-size diaphragm used with contraceptive jelly was introduced and studied for its effectiveness.

Diaphragms are user-controlled, nonhormonal methods that are needed only at the time of intercourse, but they are not effective unless used correctly. Women need to receive thorough instruction about diaphragm use and should practice putting one in and taking it out before they leave the health care office (Fig. 4.10).

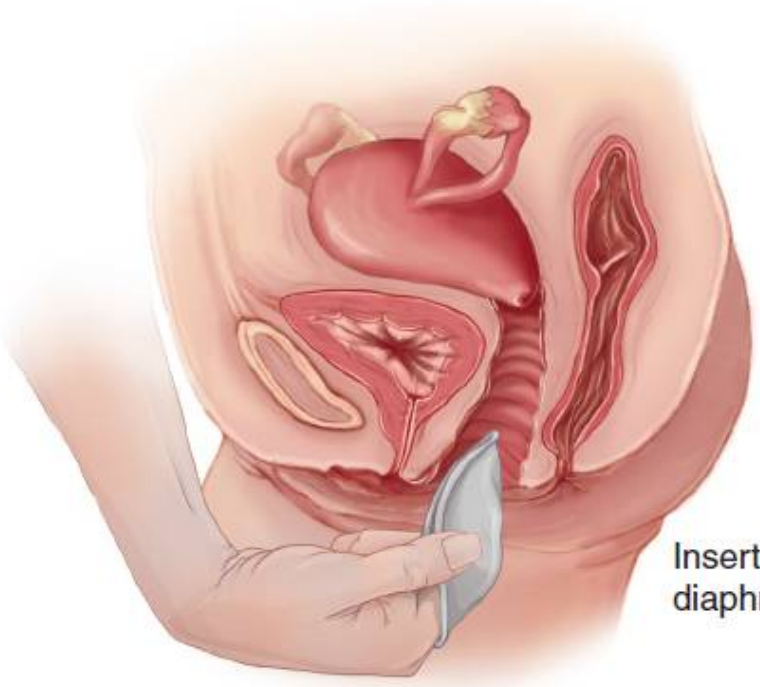
Results of a 2-year multisite study indicate that the effectiveness rates of the SILCS single-size, contoured diaphragm are similar to those of traditional diaphragms, but they also provide a long-term

controlled release of the lead candidate anti-HIV microbicide dapivirine. This would make it a new multipurpose prevention device (Beksinska et al., 2018). The biggest difference with this new device is that since it is a single size, a pelvic exam to assess size is not required, and it also releases an anti-HIV microbicide that is potentially capable of preventing HIV transmission. Most women in the study were able to correctly insert, remove, and check correct position of the device by simply using the instructions (Beksinska et al., 2018).

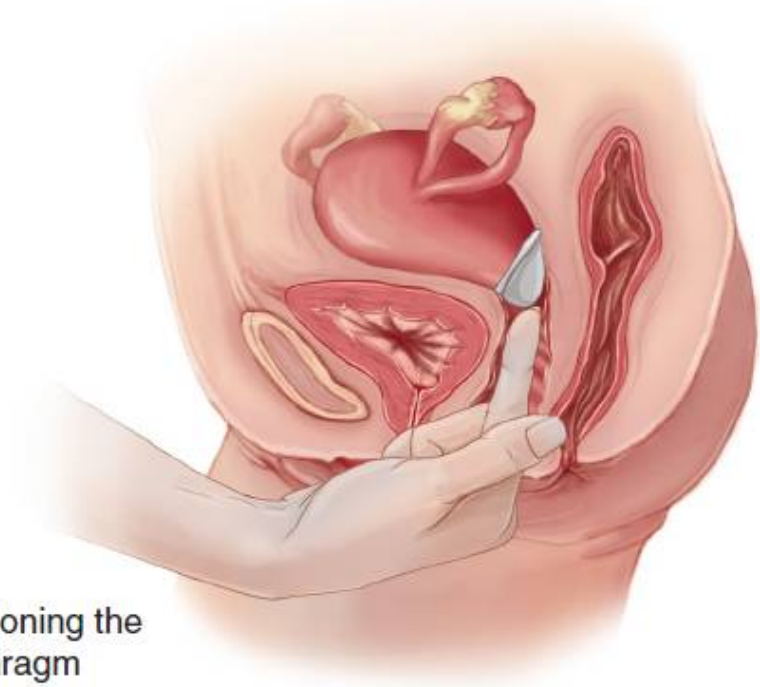
FIGURE 4.9. Sample diaphragm used for measuring.

CERVICAL CAP

The **cervical cap** is smaller than the diaphragm and covers only the cervix; it is held in place by suction. It is shaped like a sailor's hat and prevents sperm from entering the cervix. Caps are made from silicone and are used with spermicide (Fig. 4.11). The FemCap is the only cervical cap device currently available in the United States and comes in three sizes (Planned Parenthood, 2020a). The cap may be inserted up to 36 hours before intercourse and provides protection for 48 hours. The cap must be kept in the vagina for 6 hours after the final act of intercourse and should be replaced every year of use. A refitting may also be necessary when a woman experiences pregnancy, abortion, or weight changes. The dome of the cap is filled about one third full with spermicide. Spermicide should not be applied to the rim because it might interfere with the seal that must form around the cervix. The cap is available only by prescription and must be fitted by a health care provider. Contraindications to use of a cervical cap include cervical cancer, recent urinary tract infection, latex allergy, pelvic organ prolapse, and history of toxic shock syndrome (TSS). Using the cervical cap during menstruation may increase the risk of TSS and therefore should be avoided (Hatcher et al., 2018).



A Inserting the diaphragm



B Positioning the diaphragm

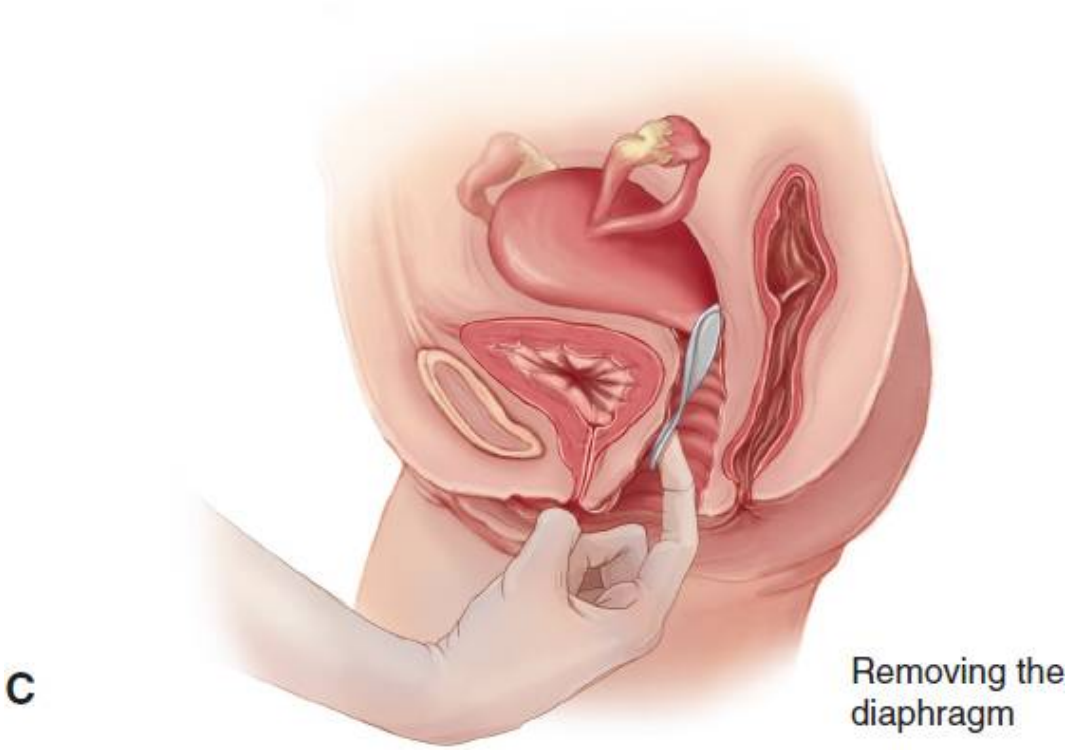


FIGURE 4.10. Application of a diaphragm. **A.** To insert, fold the diaphragm in half, separate the labia with one hand, then insert upward and back into the vagina. **B.** To position, make certain the diaphragm securely covers the cervix. **C.** To remove, hook a finger over the top of the rim and bring the diaphragm down and out.

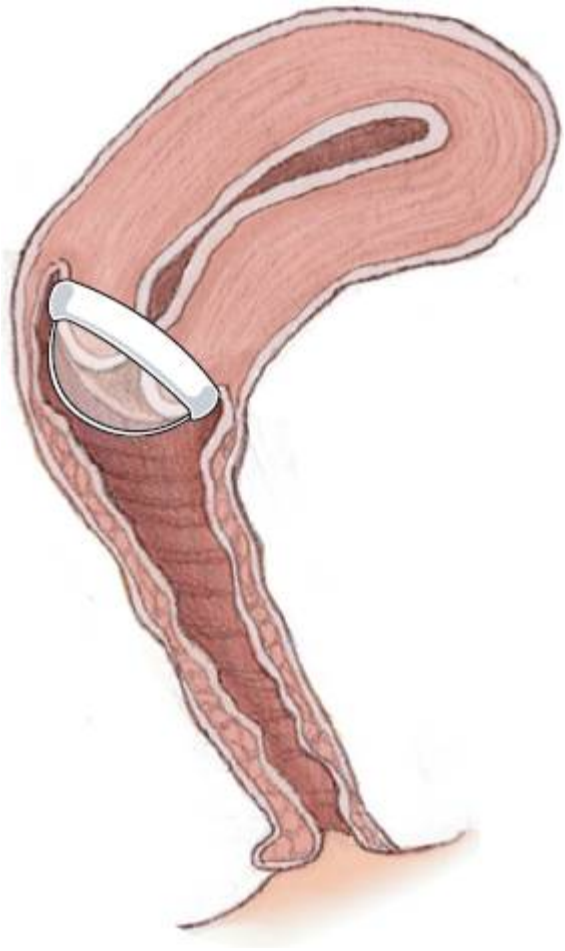

FIGURE 4.11. A cervical cap is placed over the cervix and used with a spermicidal jelly, the same as a diaphragm.

CONTRACEPTIVE SPONGE

The **contraceptive sponge** is a nonhormonal, nonprescription device that includes both a barrier and a spermicide.

It is a soft concave device that prevents pregnancy by covering the cervix and releasing spermicide. The sponge, made of polyurethane saturated with 1 g of nonoxynol-9, releases 125 mg of the spermicide over 24 hours of use. Unlike the diaphragm, the sponge can be used for more than one coital act within 24 hours without the insertion of additional spermicide, and it does not require fitting or a prescription from a health care provider (Kwansa & Stewart-Moore, 2019). While it is less effective than several other methods and does not offer protection against STIs, the sponge achieved a wide

following among women who appreciated the spontaneity with which it could be used and its easy availability.

To use the sponge, the woman first wets it with water, squeezes it until it is thoroughly wet and foamy, and then inserts it into the vagina with a finger, using a cord loop attachment. It can be inserted up to 24 hours before intercourse and should be left in place for at least 6 hours following intercourse. The sponge provides protection for up to 12 hours, but should not be left in for more than 30 hours after insertion to avoid the risk of TSS (Jordan et al., 2019).

Hormonal Methods

Several options are available to women who want long-term but reversible protection against pregnancy. These methods of contraception work by altering the hormones within a woman's body. They rely on estrogen and progestin or progestin alone to prevent ovulation. When used consistently, these methods are a reliable way to prevent pregnancy. Hormonal methods include OCs, injectables, implants, vaginal rings, and transdermal patches.

ORAL CONTRACEPTIVES

As early as 1937, scientists recognized that the injection of progesterone inhibited ovulation in rabbits and provided contraception. The first hormonal pill, called *Enovid*, was approved by the Food and Drug Administration (FDA) in May 1960. It contained high levels of estrogen to prevent ovulation. Since that time, it has evolved through gradual lowering of estrogen and is now combined with many different progestins. Breakthrough bleeding was reported in early clinical trials in women, and the role of estrogen in cycle control was launched. This established the rationale for modern combination OCs that contain both estrogen and progesterone (Martin & Barbieri, 2018).

Development of hormonal contraception marked a revolutionary step in social change that has improved the lives of women and families worldwide. Since the first OC was introduced, hormonal contraception has undergone various stages of advancement. Today,

OC regimens are safer and more tolerable with equal or improved efficacy than that of the early formulations. Incremental decreases in the estrogen dosage helped alleviate some of the unwanted side effects of the pill (Hatcher et al., 2018).

Oral contraception is the most popular method of nonsurgical contraception used by millions of women in the United States (Cooper & Mahdy, 2019) (Fig. 4.12). Unlike the original OCs that women took decades ago, the new low-dose forms carry fewer health risks.

FIGURE 4.12. Oral contraceptive.

Although most commonly prescribed for contraception, OC has long been used in the management of a wide range of conditions and has many health benefits, such as:

- Reduced incidence of ovarian and endometrial cancer
- Treatment of symptoms of endometriosis
- Decreased incidence of acne and hirsutism
- Decreased incidence of ectopic pregnancy

- Decreased incidence of acute PID and possible protection against PID
- Reduced incidence of fibrocystic breast disease
- Decreased perimenopausal symptoms
- Reduced risk of developing uterine fibroids
- Maintenance of bone mineral density
- Improvement in asthmatic symptoms
- Delayed onset of multiple sclerosis and arthritis
- Increased menstrual cycle regularity
- Lower incidence of colorectal cancer
- Decreased number of pregnancy-related deaths by preventing pregnancy
- Reduced iron-deficiency anemia due to heavy menstrual bleeding
- Reduced incidence of dysmenorrhea (Oyelowo & Johnson, 2018)

OCs work primarily by suppressing ovulation by adding estrogen and progesterone to a woman's body, thus mimicking pregnancy. This hormonal level stifles GnRH, which in turn suppresses FSH and LH and thus inhibits ovulation. Cervical mucus also thickens, which hinders sperm transport into the uterus. Implantation is inhibited by suppression of the maturation of the endometrium and alterations of uterine secretions (Webster et al., 2018).

The combination pills are prescribed as monophasic pills, which deliver fixed dosages of estrogen and progestin, or as multiphasic ones. Multiphasic pills (e.g., biphasic and triphasic OCs) alter the amount of progestin and estrogen within each cycle. To maintain adequate hormonal levels for contraception and enhance adherence to the regimen, OCs should be taken at the same time daily.

OCs that contain progestin are sometimes called mini-pills. Progestin-only pills (POPs) have both advantages and disadvantages when compared to combined pills. The pill-taking regimen is simple and fixed; no pill color changes or days without pill-taking occur. These pills are appropriate for women who cannot or should not take estrogen in combined OCs, for example, a woman older than 35 years who smokes cigarettes. These OCs work primarily by thickening the cervical mucus to prevent penetration of the sperm and make the endometrium unfavorable for implantation.

POPs must be taken at a certain time every 24 hours. Breakthrough bleeding and a higher risk of pregnancy have made these OCs less popular than combination OCs (Hatcher et al., 2018).

Extended-cycle OC regimens have been used for the management of menstrual disorders and endometriosis and are attracting wider attention. Surveys asking women about their willingness to reduce their menstrual cycles from 12 to four annually were returned with a resounding “yes.” Research has confirmed that the extended use of active OC pills carries the same safety profile as the conventional 28-day regimens. OCs taken continuously or in long cycles offer benefits with regard to menstrual symptoms, reduced menstrual bleeding, and symptoms related to endometriosis (Nappi et al., 2018). The extended regimen consists of 84 consecutive days of active combination pills followed by 7 days of placebos. The woman has four withdrawal-bleeding episodes a year. Seasonale, Quasense, Introvale, and Seasonique, a combination OC, are a few examples on the market for women who choose to reduce the number of periods that they have.

Lybrel was the first FDA-approved OC with 365-day continuous dosing. It is no longer available, but there is a generic alternative. This provides more hormonal exposure on a yearly basis (13 additional weeks of hormone intake per year) than conventional cyclic OCs that contain the same strength of synthetic estrogens and similar strength of progestins (Hatcher et al., 2018). There is no physiologic requirement for cyclic hormonal withdrawal bleeds while taking these OCs (Skidmore-Roth, 2020).

A growing body of evidence indicates that over-the-counter access to OC pills is safe and effective and that women are interested in obtaining pills this way. With half of all pregnancies unintended—a figure that has remained unchanged for decades—innovation is needed to address this statistic. Although an over-the-counter contraceptive pill may sound revolutionary in the United States, over-the-counter access is already a reality in more than 100 countries and has been for decades. ACOG supports over-the-counter access to contraceptive pills, but numerous social and professional groups oppose it (Grindlay & Grossman, 2018). Even after ACOG’s support,

American women will probably not see an over-the-counter OC product on the local pharmacy shelf any time soon, despite its cost-effectiveness and reduction of unintended pregnancies.

The balance between the benefits and the risks of OCs must be determined for each woman when she is being assessed for this type of contraceptive. It is a highly effective contraceptive when taken properly but can aggravate many medical conditions, especially in women who smoke. Comparison Chart 4.1 lists advantages and disadvantages of OCs. A thorough history and pelvic examination, including a Pap smear, are not required before the medication is prescribed, but a regular medical follow-up is advised. Women should also be counseled that the effectiveness of OCs is decreased when taking antibiotics; thus, an alternative or secondary method should be used during this period to prevent pregnancy.

Nurses need to provide OC users with a great deal of education before they leave the health care facility. They need to be able to identify early signs and symptoms that might indicate a problem.

COMPARISON CHART 4.1 Advantages and Disadvantages of Oral Contraceptives

Advantages	Disadvantages
Regulate and shorten menstrual cycle	Offer no protection against STIs
Decrease severe cramping and bleeding	Pose slightly increased risk of breast cancer
Reduce anemia	Modest risk for venous thrombosis and pulmonary emboli
Reduce ovarian, endometrial, and colorectal cancer risk	Increased risk for migraine headaches
Decrease benign breast disease	Increased risk for myocardial infarction, stroke, and hypertension for women who smoke
Improve acne and reduce incidence of menstrual headaches	May increase risk of depression
Minimize perimenopausal symptoms	User must remember to take pill daily
Decrease incidence of rheumatoid arthritis	High cost for some women
Improve PMS symptoms	
Protect against loss of bone density and reduce risk of osteoporosis

BOX 4.6 Early Signs of Complications for Users of Oral Contraceptives

- A = Abdominal pain may indicate liver or gallbladder problems.
- C = Chest pain or shortness of breath may indicate a pulmonary embolus.
- H = Headaches may indicate hypertension or impending stroke.
- E = Eye problems may indicate hypertension or an attack.
- S = Severe leg pain may indicate a thromboembolic event.

Hatcher, R. A., Nelson, A. L., Trussell, J., Cwaik, C., Cason, P., Policar, M. S., Kowal, D. (2018). *Contraceptive technology* (21st ed.). Ardent Media.

TAKE NOTE!

The mnemonic “ACHES” can help women remember the early warning signs of OC complications that necessitate a return to the health care provider (Box 4.6).

INJECTABLE CONTRACEPTION

Injectable contraception includes progestin-only and combination estrogen and progestin agents that provide safe and highly effective birth control for up to 3 months. Injectable agents are widely available and play an important role in family planning worldwide. They offer a discrete, convenient, reversible, and noncoital-dependent method of birth control. Recent research finds that allowing self-administration of injectable contraceptives can lead to improved contraceptive continuation rates and equivalent pregnancy prevention compared to provider administration (Kronemyer, 2019).

Depo-Provera is the trade name for a 3-month intramuscular injectable of a progesterone-only contraceptive that works at the hypothalamic/pituitary level to stop the hormonal cycle. Depo-Provera works by suppressing ovulation and the production of FSH and LH by the pituitary gland, increasing the viscosity of cervical mucus and causing endometrial atrophy. A single injection of 150 mg into the buttocks acts like other progestin-only products to prevent pregnancy for 3 months at a time (Fig. 4.13). The primary side

effects of Depo-Provera are menstrual cycle disturbances, depression, acne, weight gain, and loss of bone mineral density. It should also be noted that cycles may not be restored fully for up to 9 months following the last Depo-Provera injection.

Recent clinical studies have raised concerns about Depo-Provera's impact on bone mineral density. This evidence has prompted the manufacturer and the FDA to issue a warning about the long-term use (over 2 years) of Depo-Provera and bone loss (Webster et al., 2018). It is not entirely clear if this loss is reversible because there have not been any long-term prospective studies in current and past users.

FIGURE 4.13. Injectable contraceptive.

TRANSDERMAL PATCHES

Transdermal delivery of contraceptive hormones avoids hepatic first-pass metabolism, allowing a lower total hormone dose when compared to that of oral products that are metabolized in the liver. The **transdermal patch** is a 2-in square adhesive that contains ethinyl estradiol and norelgestromin. These substances are

absorbed through the skin when placed on the lower abdomen, upper outer arm, buttocks, or upper torso (avoiding the breasts). The patch is applied weekly for 3 weeks followed by a patch-free week when withdrawal bleeding occurs. The patch delivers continuous levels of progesterone and estrogen. Transdermal absorption allows the drug to enter the bloodstream directly, avoiding rapid inactivation in the liver known as first-pass metabolism. Because estrogen and progesterone are metabolized by liver enzymes, avoiding first-pass metabolism was thought to reduce adverse effects. However, recent evidence suggests that the risk of venous thrombosis and embolism is increased with the patch but still lower than the risk of venous thromboembolism during pregnancy (Peachman, 2018). Additional studies are underway to understand the clinical significance of these findings, but in the interim, nurses need to focus on ongoing risk assessment and should be prepared to discuss current research findings with clients.

Adherence to the regimen of combination contraceptive patch use has been shown to be significantly greater than adherence with OCs. In addition, research suggests that overweight and obese women exceeding 198 lb should be advised of the potentially decreased effectiveness of the patch and increase incidence of venous thromboembolism and weight gain (Patel & Carey, 2018). The patch provides combination hormone therapy with a side effect profile similar to that of OCs (Fig. 4.14).

VAGINAL RINGS

Approved in 2001 by the FDA, the **vaginal ring** contains both estrogen and progesterone. The contraceptive vaginal ring, NuvaRing, is a flexible, soft, transparent ring that is inserted by the user for a 3-week period of continuous use followed by a ring-free week to allow withdrawal bleeding (Fig. 4.15). Ethinyl estradiol and etonogestrel are rapidly absorbed through the vaginal epithelium and result in a steady serum concentration. Because the hormones are released directly into the vagina, a lower daily dose of hormones is required in comparison with OC doses. Studies have demonstrated

that the efficacy and safety of the ring are equivalent to those of OCs. Clients report being highly satisfied with the vaginal ring and report fewer systemic side effects than do OC users. The ring provides effective cycle control as well as symptom relief for women with AUB and polycystic ovary syndrome. Reported problems associated with the use of vaginal rings include erosion of the vaginal wall, ring expulsion, increased vaginal discharge, interference with coitus, unpleasant ring odor, and premature discontinuation due to vaginal discomfort (Kwansa & Stewart-Moore, 2019). The ring can be inserted by the woman and does not have to be fitted. The woman compresses the ring and inserts it into the vagina, behind the pubic bone, as far back as possible, but precise placement is not critical. The hormones are absorbed through the vaginal mucosa. It is left in place for 3 weeks and then removed and discarded. Effectiveness and adverse events are similar to those of combination OCs. Clients need to be counseled regarding timely insertion of the ring and what to do in case of accidental expulsion. Recent studies suggest that a vaginal ring containing etonogestrel and ethinyl estradiol used in an extended regimen is a safe contraceptive method that offers good cycle control and can be an option for women who have gastric intolerance or other side effects when using OCs (Bouchard, 2018).

FIGURE 4.14. Transdermal patch.

FIGURE 4.15. Vaginal ring.

LONG-ACTING REVERSIBLE CONTRACEPTIVES (LARCs)

Long-acting reversible contraceptives (LARCs) include the subdural single rod contraceptive implant Nexplanon and intrauterine systems (IUSs). LARCs are highly effective because they are forgettable methods of contraception. The **implant** is a subdermal time-release method that delivers synthetic progestin that inhibits ovulation. Once in place, it delivers 3 years of continuous, highly effective contraception. Like POPs, implants act by inhibiting ovulation and thickening cervical mucus, so sperm cannot penetrate. Nexplanon is 4 cm long and 2 mm in diameter, and it contains 68 mg of progestin. The implant is radio-opaque and is over 99% effective (Jordan et al., 2019). The side effects are also similar to those of POPs—irregular bleeding, headaches, weight gain, acne, increased appetite, breast tenderness, and depression. Fertility is restored quickly after it is removed. Implants require a minor surgical procedure for both insertion and removal. The implants do not offer any protection against STIs.

Hormonal side effects are not exclusive to implants but tend to be a problem with all hormonal contraceptives. Therefore, with the implant, preinsertion counseling by the nurse is essential to prepare the woman for any such side effects. Expert counseling should cover the one side effect most likely to cause discontinuation—initial irregular bleeding and the possibility of amenorrhea with longer use (DeBoer & Hensley, 2018).

Intrauterine contraceptives are classified as either hormonal or nonhormonal. Both types prevent pregnancy via inhibition of sperm mobility and sperm viability and change the speed of transport of the ovum in the fallopian tube. An **intrauterine contraceptive (IUC)** is a small T-shaped object that is placed inside the uterus to provide contraception (Fig. 4.16). It prevents pregnancy by making the endometrium of the uterus hostile to implantation of a fertilized ovum by causing a nonspecific inflammatory reaction and inhibiting sperm and ovum from meeting (Webster et al., 2018). The hormonal IUC will make monthly periods lighter, shorter, and less painful, making

this a useful method for women with heavy, painful periods. The implants contain either copper or progesterone to enhance their effectiveness. One or two attached strings protrude into the vagina so that the user can check its placement.

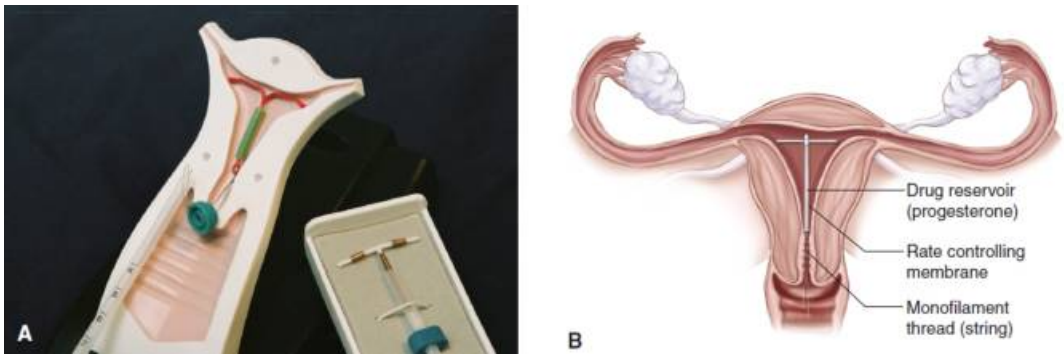

FIGURE 4.16. A. Intrauterine contraceptive. **B.** An IUC in place in the uterus.

Four IUCs are currently available in the United States: the copper ParaGard-TCu-380A, the levonorgestrel-releasing intrauterine systems (LNG-IUSs) marketed as Mirena and Kyleena, and the LNG-IUD marketed as Jaydess. The ParaGard-TCu-380A is approved for 10 years of use and is nonhormonal. Its mechanism of action is based on the release of copper ions, which alone are spermicidal. Additionally, the device causes an inflammatory action leading to a hostile uterine environment. The TCu-380A is also approved for use as emergency contraception. Mirena provides intrauterine conception for 5 years, but has been shown to be effective for as long as 7 years. Jaydess has been approved for 3 years of pregnancy prevention, and Kyleena is effective for 5 years. These three devices release a low dose of progestin causing thinning of the endometrium and thickening of cervical mucus, which inhibits sperm entry into the upper genital tract. Their use results in a major reduction in menstrual flow and dysmenorrhea, suggesting that they are a viable alternative to hysterectomy and endometrial ablation in women with AUB (Smith, 2018). An advantage of these hormonally impregnated IUSs is that they are relatively maintenance-free; users must choose to have them removed to

become pregnant rather than making a daily decision to avoid conception (Goldstuck & Kluge, 2018).

The IUCs provide a safe, highly effective, long-lasting, reversible method of contraception. Expanding access to IUCs is an effective measure to reduce the rate of unintended pregnancy in the United States. Nurses should consider including them in their discussion to appropriate candidates, including women who are nulliparous, adolescent, immediately postpartum, or postabortion; those who desire emergency contraception; and those who want an alternative to permanent sterilization. Limitations and barriers to obtaining intrauterine contraception include requiring cervical cancer (Pap) screening before insertion, routine testing for gonorrhea and chlamydial infection in low-risk women, and/or the fact that scheduling insertion only during menses is necessary. IUC insertion can take place on any day of the menstrual cycle if absence of pregnancy is confirmed (DeBoer & Hensley, 2018). Box 4.7 highlights the warning signs of the potential complications of IUCs.

EMERGENCY CONTRACEPTION

Unplanned pregnancy is a major health, economic, and social issue. Approximately one third of all unplanned pregnancies end in abortion. The unintended pregnancy rate is significantly higher in the United States than in other developed countries (Guttmacher Institute, 2019c). Using an emergency contraceptive provides a woman a second chance to prevent an unintended pregnancy. **Emergency contraception (EC)** reduces the risk of pregnancy after unprotected intercourse or contraceptive failure such as condom breakage (Fig. 4.17). It is used within 72 to 120 hours of unprotected intercourse to prevent pregnancy. The sooner ECs are taken, the more effective they are. They reduce the risk of pregnancy for a single act of unprotected sex by almost 90% (WHO, 2018b). The methods currently available in the United States are (1) ulipristal acetate (UPA), an oral progesterone receptor agonist–antagonist (Ella); (2) levonorgestrel (LNG), an oral progestin (Plan B One-Step);

(3) the copper intrauterine device (Cu-IUD); and (4) off-label use of combined oral contraceptives (Yuzpe method) (Upadhya, 2019).

BOX 4.7 Warnings for Potential Complications for Intrauterine System Users

- P = Period late, pregnancy, abnormal spotting or bleeding
- A = Abdominal pain, pain with intercourse
- I = Infection exposure, abnormal vaginal discharge
- N = Not feeling well, fever, chills
- S = String length shorter or longer or missing

Hatcher, R. A., Nelson, A. L., Trussell, J., Cwaik, C., Cason, P., Policar, M. S., Kowal, D. (2018). *Contraceptive technology* (21st ed.). Ardent Media.

FIGURE 4.17. Emergency contraceptive kit.

Access to ECs has been controversial for minors. Prior to 2013, the pills were available by prescription only, and even when approved for nonprescription status, access was restricted based on age. In 2013, several judicial courts and the FDA ruled in favor of

nonprescription access to EC by all women regardless of age, and it is now sold over the counter. The only contraindication to the use of any of the EC methods is a known pregnancy as defined as implantation.

Although access to EC has increased with nonprescription status and approval of Plan B One-Step without age restrictions, many barriers remain in public awareness and unintended pregnancies continue to rise. Because of the lack of awareness of EC and the politics surrounding it, EC is not used as widely as would be warranted by the incidence of unprotected coitus. Nurses need to educate their clients to bring about increased awareness of this second chance method. Table 4.5 lists recommended oral medication and intrauterine regimens.

Prime points to stress concerning ECs are:

- ECs do not offer any protection against STIs or future pregnancies.
- ECs should not be used in place of a regular birth control method because they are less effective.
- ECs may delay the next menses, so evaluation for pregnancy is needed if menses does not occur within 3 weeks after EC use.
- Report any severe abdominal pain to the health care provider immediately.
- ECs can be regular birth control pills given at a higher dose.
- ECs are contraindicated if pregnant (WHO, 2018b).

TAKE NOTE!

Contrary to popular belief, ECs do not induce abortion and are not related to mifepristone or RU-486, the so-called abortion pill approved by the FDA in 2000. Mifepristone chemically induces abortion by blocking the body's progesterone receptors, which are necessary for pregnancy maintenance. ECs simply prevent embryo creation and uterine implantation from occurring in the first place. There is no evidence that ECs have any effect on an already implanted ovum.

Sterilization

Sterilization is a permanent, safe, and highly effective method of contraception for those who are certain they do not want any or any more children. Vasectomy is the only highly reliable form of male contraception. It is the most widely used method of family planning in the world in both developed and developing countries. **Sterilization** refers to surgical procedures intended to render the person infertile. Laparoscopic, abdominal, and hysteroscopic methods of female sterilization are available in the United States, with most of these procedures performed outside the hospital. Sterilization is relied upon by nearly one in three women ages 35 to 44 years in the United States (Stuart & Ramesh, 2018). More women than men undergo surgical sterilization. According to the Guttmacher Institute (2019a), approximately 22% of women undergo female sterilization in comparison with 7% of men in the United States. Sterilization should be considered a permanent end to fertility because reversal surgery is difficult, expensive, and sometimes unsuccessful. Because these methods are intended to be irreversible, all couples should be appropriately counseled about the permanency of sterilization and the availability of highly effective, long-acting, reversible methods of contraception before this decision is made.

TABLE 4.5 Emergency Postcoital Contraception Options

Product	Dosage (within 72 Hr)	Comments
Combined estrogen and progestin pills (Yuzpe regimen)	OCs are taken in various formulations to prevent conception.	Interfere with the cascade of events that result in ovulation and fertilization
Plan B One-Step; My Way; Next Choice	1.5-mg pill taken	Can cause nausea and vomiting
Ulipristal acetate (Ella or EllaOne)	Single 30-mg tablet	Can cause nausea and vomiting
Copper-bearing IUS (ParaGard-TCu-380A)	Inserted within 5 d after unprotected sexual episode	Can be left in for long-term contraception (10 yrs)

World Health Organization (WHO). (2018b). *Emergency contraception*. Retrieved June 16, 2020, from http://www.who.int/news-room/fact-sheets/detail/emergency-contraception; Turok, D. (2019). Emergency contraception. *UpToDate*. Retrieved December 20, 2019, from https://www.uptodate.com/contents/emergency-contraception.

TUBAL LIGATION

Tubal ligation, the sterilization procedure for women, can be performed postpartum, after an abortion, or as an interval procedure unrelated to pregnancy. Mini-laparotomies and laparoscopies are the two most common techniques. In the laparoscopy procedure, the abdomen is filled with carbon dioxide gas so that the abdominal wall balloons away from the tubes to provide a view of the fallopian tubes. They are grasped and sealed with a cauterizing instrument or with rings, bands, or clips, or cut and tied (Fig. 4.18).

ESSURE

Essure is a nonsurgical, nonhormonal, permanent birth control method that is 99% effective. This method is for women who desire no more children as it is a permanent method of birth control. It

offers several advantages over a conventional tubal ligation; general anesthesia and incisions are not needed, thereby increasing safety, lowering costs, and improving access to sterilization. A tiny coil (Essure) is introduced and released into the fallopian tubes through the cervix. The coil promotes tissue growth in the fallopian tubes, and over a period of 3 months, this growth blocks the tubes. The buildup of tissue creates a barrier that keeps sperm from reaching the ovum, thus preventing conception. This less invasive technique uses a hysteroscopy under local anesthesia in an office setting. Sterilization does not occur immediately after this procedure, so women must be educated to use additional contraception for 3 months until permanent tubal occlusion is verified. Women need to know that this form of sterilization is completely irreversible. The FDA recently has issued a safety warning regarding Essure because of numerous adverse events reported that include persistent pain, migration of the coil, abnormal bleeding, and unintended pregnancies (McCarthy, 2018).

VASECTOMY

Male sterilization is accomplished with a minor surgical procedure known as a **vasectomy**. More than 500,000 men have a vasectomy performed in the United States each year (Ostrowski et al., 2018). It is usually performed under local anesthesia in a urologist's office, and most men can return to work and normal activities in a day or two. The procedure involves making a small incision into the scrotum and cutting the vas deferens, which carries sperm from the testes to the penis (Fig. 4.19). Complications from vasectomy are rare and minor in nature. Immediate risks include infection, hematoma, and pain. After vasectomy, semen no longer contains sperm. This is not immediate, though, and the man must submit semen specimens for analysis 8 to 16 weeks after a vasectomy until two specimens show that no sperm is present. When the specimen shows azoospermia, the man's sterility is confirmed (Kwansa & Stewart-Moore, 2019).

Nursing Management for Choosing a Contraceptive Method

The choice of a contraceptive method is a personal one involving many factors. What makes a woman or couple choose one contraceptive method over another? In making contraceptive choices, women and couples must balance their sexual lives, their reproductive goals, and each partner's health and safety. The search for a choice that satisfies all three objectives is challenging. A method that works for a sexually active teenage girl may not meet her needs later in life. Several considerations influence a person's choice of contraceptives:

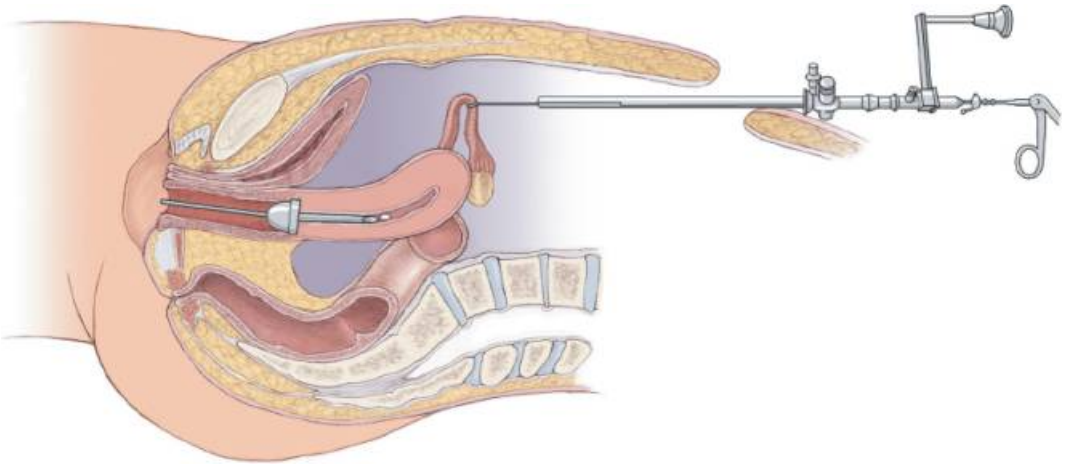

FIGURE 4.18. Laparoscopy for tubal sterilization.

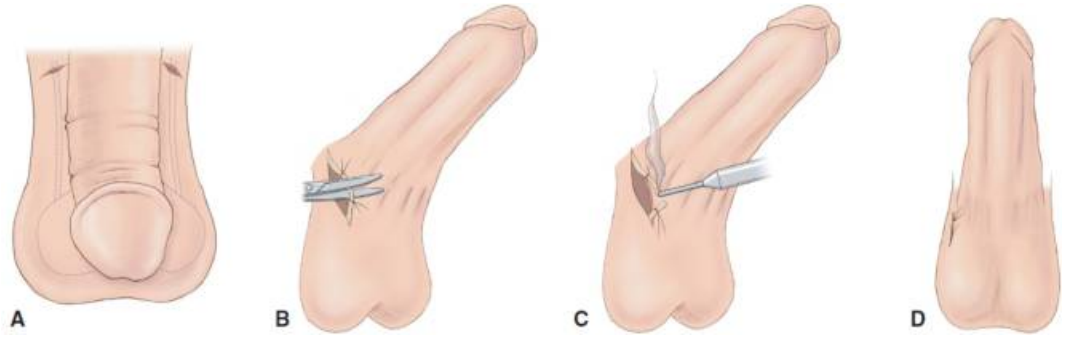

FIGURE 4.19. Vasectomy. **A.** Site of vasectomy incisions. **B.** The vas deferens is cut with surgical scissors. **C.** Cut ends of the vas deferens are cauterized to ensure blockage of the passage of sperm. **D.** Final skin suture.

- Motivation
- Cost
- Cultural and religious beliefs (Box 4.8)
- Convenience
- Effectiveness
- Side effects
- Desire for children in the future
- Safety of the method
- Comfort level with sexuality
- Protection from STIs
- Interference with spontaneity

If a contraceptive is to be effective, the woman must understand how it works, must be able to use it correctly and consistently, and must be comfortable and confident with it. If a client cannot adhere to taking a pill daily, consider a method used once a week (transdermal patches), once every 3 weeks (transvaginal ring), or once every 3 months (Depo-Provera injection). Another option may be a LARC that lasts several years and reduces menstrual flow significantly if hormonal.

Regardless of which method is chosen, the client's needs should be paramount in the discussion. The nurse can educate clients about which methods are available and their advantages and disadvantages, efficacy, costs, and safety. Knowledge of contraceptive effectiveness is crucial to making an informed choice. The couple has to comprehend the pros and cons of the contraceptive methods being considered. Choice may be influenced by understanding the likelihood of pregnancy with each method and factors that influence effectiveness. Counseling can help the woman or couple choose a contraceptive method that is efficacious and fits preferences and lifestyle.

Nursing Assessment

When assessing which contraceptive method might meet the client's needs, the nurse might ask:

- Do your religious beliefs interfere with any methods?

- Will this method interfere with your sexual pleasure?

BOX 4.8 Select Religious Choices for Family Planning and Abortion

- Roman Catholic—Abstinence and natural family planning; no abortion
- Judaism (Orthodox)—Family planning and abortion accepted in first trimester; conservative and Reform Judaism accept both family planning and abortion
- Islam—Family planning accepted; abortion only for serious reasons
- Protestant Christianity—Firmly in favor of family planning; mixed on abortion
- Buddhism—Long experience with family planning and abortion
- Hinduism—Accept both family planning and abortion
- Native American religions—Accept both family planning and abortion
- Chinese religions—Taoism and Confucianism accept both family planning and abortion

---

World Health Organization (WHO). (2018c). *Family planning/contraception*. Retrieved June 16, 2020, from http://www.who.int/news-room/fact-sheets/detail/family-planning-contraception; Stacey, D. (2018). What do religions say about birth control and family planning? Very Well Health. Retrieved June 16, 2020, from https://www.verywellhealth.com/what-are-religious-views-on-birth-control-906618; and Masci, D. (2018). American religion groups vary widely in their views of abortion. Pew Research Center. Retrieved June 16, 2020, from http://www.pewresearch.org/fact-tank/2018/01/22/american-religious-groups-vary-widely-in-their-views-of-abortion/.

- Is cost a major consideration, or does your insurance cover it?
- Does your partner influence which method you choose?
- Are you in a stable, monogamous relationship?
- Have you heard anything that troubles you about any of the methods?
- How comfortable are you touching your own body?
- What are your future plans for having children?

Although deciding on a contraceptive is a personal decision between a woman and her partner, nurses can assist in this process by performing a complete health history and physical examination and by educating the woman and her partner about necessary laboratory and diagnostic testing. Areas of focus during the nursing assessment are:

- Medical history: smoking status, cancer of reproductive tract, diabetes mellitus, migraines, hypertension, thromboembolic

disorder, allergies, risk factors for cardiovascular disease (CVD)
- Family history: cancer, CVD, hypertension, stroke, diabetes
- OB/GYN history: menstrual disorders, current contraceptive, previous STIs, PID, vaginitis, sexual activity
- Personal history: use of tampons and female hygiene products, plans for childbearing, comfort with touching herself, number of sexual partners and their involvement in the decision
- Physical examination: height, weight, blood pressure, breast examination, thyroid palpation, pelvic examination
- Diagnostic testing: urinalysis, complete blood count, Pap smear, wet mount to check for STIs, HIV/AIDS tests, lipid profile, glucose level

Figure 4.20 shows an example of a family planning flow record that can be used during the assessment. After collecting the assessment data, consider the medical factors to help decide if the woman is a candidate for all methods or whether some should be eliminated. For example, if she reports she has multiple sex partners and a history of pelvic infections, she would not be a good candidate for an IUC. Barrier methods (male or female condoms) of contraception might be recommended to this client instead to offer protection against STIs.

Nursing Analyses

A few nursing analyses that might be appropriate based on the nurse's assessment during the decision-making process include:

- Deficient knowledge related to:
  - methods available
  - side effects/safety
  - correct use of method chosen
  - previous myths believed
- Risk for infection related to:
  - unprotected sexual intercourse
  - past history of STIs
  - methods offering protection

Nursing analyses applicable to the contraceptive would be:

- Health-seeking behaviors related to:
  - perceived need for limiting number of children
  - overall health relative to contraceptives
- Risk for ineffective health maintenance related to:
  - not being familiar with the various contraceptive methods
  - being unaware of high-risk sexual behavior leading to STIs
- Fear related to:
  - not understanding the correct procedure to use
  - unintended pregnancy occurring if not used correctly
  - general health concerning the long-term side effects

Nursing Interventions

Contraception is an important issue for all couples, and the method used should be jointly decided by the woman and her partner. Facilitate this process by establishing a trusting relationship with the client and by providing unbiased, accurate information about all methods available. As a nurse, honestly reflect on your feelings about contraceptives while allowing the client's feelings to be paramount. Be aware of the practical issues involved in contraceptive use, and avoid making assumptions, making decisions on the woman's behalf, and making judgments about her and her situation. To do so, it is important to keep up to date on the latest methods available and convey this information to clients. Encourage female clients to take control of their lives by sharing information that allows them to plan their futures.

The following guidelines are helpful in counseling and educating the client or couple about contraceptives:

- Encourage the client or couple to participate in choosing a method.
- Provide client education. The client or couple must become informed users before the method is chosen. Education should be targeted to the client's level so it is understood. Provide step-by-step teaching and an opportunity for practice for certain methods (cervical caps, diaphragms, vaginal rings, and condoms). See Teaching Guidelines 4.5 and Figure 4.21.

- Obtain written informed consents, which are needed for IUCs, implants, abortion, or sterilization. Informed consent implies that the client is making a knowledgeable, voluntary choice; has received complete information about the method, including the risks; and is free to change their mind before using the method or having the procedure (Oyelowo & Johnson, 2018).
- Discuss contraindications for all selected contraceptives.
- Consider the client's cultural and religious beliefs when providing care.
- Address myths and misperceptions about the methods under consideration in your initial discussion of contraceptives.

FIGURE 4.21. The nurse demonstrates insertion of a vaginal ring during client teaching.

TEACHING GUIDELINES 4.5

Tips for the Use of Cervical Caps, Diaphragms, Vaginal Rings, and Condoms

Cervical Cap Insertion/Removal Technique

- It is important to be involved in the fitting process.
- To insert the cap, pinch the sides together, compress the cap dome, insert into the vagina, and place over the cervix.
- Use one finger to feel around the entire circumference to make sure there are no gaps between the cap rim and the cervix.
- After a minute or two, pinch the dome and tug gently to check for evidence of suction. The cap should resist the tug and not slide off easily.
- To remove the cap, press the index finger against the rim and tip the cap slightly to break the suction. Gently pull out the cap.
- The woman should practice inserting and removing the cervical cap three times to validate her proficiency with this device.

Client Teaching and Counseling Regarding the Cervical Cap

- Fill the dome of the cap up about one third full with spermicide cream or jelly. Do not apply spermicide to the rim since it may interfere with the seal.
- Wait approximately 30 minutes after insertion before engaging in sexual intercourse to be sure that a seal has formed between the rim and the cervix.
- Leave the cervical cap in place for a minimum of 6 hours after sexual intercourse. It can be left in place for up to 48 hours without additional spermicide being added.
- Do not use during menses due to the potential for toxic shock syndrome. Use an alternative method such as condoms during this time.
- Replace the cervical cap after each year of use.
- Inspect the cervical cap prior to insertion for cracks, holes, or tears.
- After using the cervical cap, wash it with soap and water, dry thoroughly, and store in its container.

Diaphragm Insertion/Removal Technique

- Always empty the bladder prior to inserting the diaphragm.
- Inspect diaphragm for holes or tears by holding it up to a light source, or fill it with water and check for a leak.
- Place approximately a tablespoon of spermicidal jelly or cream in the dome and around the rim of the diaphragm.
- The diaphragm can be inserted up to 6 hours prior to intercourse.
- Select the position that is most comfortable for insertion:
  - Squatting
  - Leg up, raising the nondominant leg up on a low stool
  - Reclining position, lying on back in bed
  - Sitting forward on the edge of a chair
- Hold the diaphragm between the thumb and fingers and compress it to form a “figure eight” shape.
- Insert the diaphragm into the vagina, directing it downward as far as it will go.
- Tuck the front rim of the diaphragm behind the pubic bone so that the rubber hugs the front wall of the vagina.
- Feel for the cervix through the diaphragm to make sure it is properly placed.
- To remove the diaphragm, insert the finger up and over the top side and move slightly to the side, breaking the suction.
- Pull the diaphragm down and out of the vagina.

Client Teaching and Counseling Regarding the Diaphragm

- Avoid the use of oil-based products, such as baby oil, because they may weaken the rubber.
- Wash the diaphragm with soap and water after use and dry thoroughly.
- Place the diaphragm back into the storage case.
- The diaphragm may need to be refitted after weight loss or gain or childbirth.
- Diaphragms should not be used by women with latex allergies.

Vaginal Ring Insertion/Removal Technique and Counseling

- Each ring is used for one menstrual cycle, which consists of 3 weeks of continuous use followed by a ring-free week to allow for menses.
- No fitting is necessary; one size fits all.
- The ring is compressed and inserted into the vagina, behind the pubic bone, as far back as possible.
- Precision placement is not essential.
- Backup contraception is needed for 7 days if the ring is expelled for more than 3 hours during the 3-week period of continuous use.
- The vaginal ring is left in place for 3 weeks then removed and discarded.
- The vaginal ring is not recommended for women with uterine prolapse or lack of vaginal muscle tone (Oyelowo & Johnson, 2018).

Male Condom Insertion/Removal Technique and Counseling

- Always keep the condom in its original package until ready to use.
- Store in a cool, dry place.
- Spermicidal condoms should be used if available.
- Check expiration date before using.
- Use a new condom for each sexual act.
- Condom is placed over the erect penis prior to insertion.
- Place condom on the head of the penis and unroll it down the shaft.
- Leave a half inch of empty space at the end to collect ejaculate.
- Avoid use of oil-based products, because they may cause breakage.
- After intercourse, remove the condom while the penis is still erect.
- Discard condom after use.

Female Condom Insertion/Removal Technique and Counseling

- Practice wearing and inserting prior to first use with sexual intercourse.
- Condom can be inserted up to 8 hours before intercourse.
- Condom is intended for one-time use.

- It can be purchased over the counter; one size fits all.
- Avoid wearing rings to prevent tears; long fingernails can also cause tears.
- Spermicidal lubricant can be used if desired.
- Insert the inner ring high in the vagina against the cervix.
- Place the outer ring on the outside of the vagina.
- Make sure the erect penis is placed inside the female condom.
- Remove the condom after intercourse. Avoid spilling the ejaculate.

Education and Counseling of Women Using Injectable Contraceptives

- Consume a diet high in calcium and vitamin D to prevent bone mineral loss.
- Know the conditions that need to be reported to the health care provider:
  - Significant headaches
  - Abnormal uterine bleeding
  - Depression
  - Severe abdominal pain
  - Any infection present at injection site

It is also important to clear up common misconceptions about contraception and pregnancy. Resolving misconceptions will permit new learning to take hold and a better client response to whichever methods are explored and ultimately selected. Some common misconceptions include:

- Breastfeeding protects against pregnancy.
- Pregnancy can be avoided if the male partner “pulls out” before he ejaculates.
- Pregnancy cannot occur during menses.
- Douching after sex will prevent pregnancy.
- Pregnancy will not happen during the first sexual experience.
- Taking birth control pills protects against STIs.
- The woman is too old to get pregnant.
- If female orgasm is not reached, conception is not likely.

- Irregular menstruation prevents pregnancy.

When discussing in detail each method of birth control, focus on specific information for each method outlined. Include information such as how this particular method works to prevent pregnancy under normal circumstances of use; the potential noncontraceptive benefits; advantages and disadvantages of all methods; the cost involved for each particular method; danger signs that need to be reported to the health care provider; and the required frequency of office visits needed for the particular method.

In addition, outline factors that place the client at risk for method failure. Contraceptives can fail for any of many reasons. Use Table 4.6 to provide client education concerning a few of the reasons for contraceptive failure. Help clients who have chosen abstinence or fertility awareness methods define the sexual activities in which they do or do not want to participate. This helps them set sexual limits or boundaries. Help them develop communication and negotiation skills that will allow them to be successful. Supporting, encouraging, and respecting a woman's or couple's choice of abstinence is vital for nurses.

After clients have chosen a method of contraception, it is important to complete the following:

- Emphasize that a second method to use as a backup is always needed.
- Provide both oral and written instructions on the method chosen.
- Discuss the need for STI protection if not using a barrier method.
- Inform the client about the availability of ECs.

TABLE 4.6 Contraceptive Problems and Educational Needs

Contraceptive Failure Problem	Client Education Needed
Not following instructions for use of contraceptive correctly	Take pill the same time every day. Use condoms properly and check condition before using. Make sure diaphragm or cervical cap covers cervix completely. Check IUS for placement monthly.
Inconsistent use of contraceptive	Contraceptives must be used regularly to achieve maximum effectiveness. All it takes is one unprotected act of sexual intercourse to become pregnant. During use, 2–5% of condoms will break or tear.
Condom broke during sex	Check expiration date. Store condoms properly. Use only a water-based lubricant. Watch for tears caused by long fingernails. Use spermicides to decrease possibility of pregnancy. Seek emergency postcoital conception.
Use of antibiotics or other herbs taken with OCs	Use alternative methods during the antibiotic therapy, plus seven additional days. Implement on day 1 of taking antibiotics.
Belief that you can't get pregnant during menses or that it is safe "just this one time"	It may be possible to become pregnant on almost any day of the menstrual cycle.

Steady progress in contraception research has been achieved over the past several years. Hormonal and nonhormonal contraceptives have improved women's lives by reducing different

health conditions that contribute to morbidity. However, the contraceptives available today are not suitable to all users, and the need to expand contraceptive choices still exists. It is hoped that the introduction of newer methods in the near future with additional health benefits will continue to help women and couples meet their family planning needs.

There is no “best” method of birth control, and the choice depends on multiple factors including the women’s overall health, age, frequency of sexual activity, number of sexual partners, desire for future fertility, family history of certain diseases, possible side effects, and the woman’s comfort in using the method. A clear understanding of the available contraceptive methods allows the nurse to counsel women about the various methods that are most consistent with their health status, lifestyles, and comfort levels to ensure the highest levels of success.

ABORTION

Abortion sits at the intersection of issues such as public health, human rights, reproductive justice, and bodily autonomy. It has remained controversial for decades. **Abortion** is defined as the expulsion of an embryo or fetus before it is viable (Webster et al., 2018). The practice of abortion is legal in the United States. Abortion can be a medical or surgical procedure. The purpose of abortion is to terminate a pregnancy. One in four women will end a pregnancy by abortion at some time in their reproductive lives. Globally, more than one fifth of all known pregnancies end in abortion (McBride & Keys, 2018). Both medical and surgical abortions are safe and legally protected in the United States; an abortion is considered a woman’s constitutional right based on the fundamental right to privacy. Of abortions, 89% occur in the first 12 weeks of pregnancy (Guttmacher Institute, 2019b).

Since the landmark U.S. Supreme Court decision *Roe v. Wade* protected a woman’s right to abortion in 1973, debate has continued over how and when abortions are provided. Every state has laws

regulating some aspects of abortion, and many have passed restrictions such as parental consent or notification requirements, mandated counseling and waiting periods, and limits on funding for abortion. Each state addresses these matters independently, and the laws that are passed or enforced are legislative decisions and a function of the political system. Although opponents of abortion continue to be a part of the current debates, recently they have refocused their attention on “regulation legislation” among the states to reduce the number of abortions not medically necessary (McBride & Keys, 2018).

Surgical Abortion

Two types of surgical abortion are available: vacuum aspiration or dilation and evacuation (D&C). Method selection is based on gestational age. It is an ambulatory procedure done under local anesthesia. The cervix is dilated prior to surgery and then the products of conception are removed by suction evacuation. The uterus may gently be scraped by curettage to make sure that it is empty. The entire procedure lasts about 10 minutes. The overall risk of complications is less than 1% for surgical termination (Magowan et al., 2019). The major risks and complications in the first trimester are infection, retained tissue or hemorrhage, uterine perforation, retained products of conception, or cervical tear (Webster et al., 2018). For women whose blood is Rh-negative, RhoGAM is indicated prior to the start of either medical or surgical termination.

Medical Abortion

Medical abortions are achieved through administration of medication either vaginally or orally. The administration of medication occurs in the clinic or doctor’s office, may require more than one office visit, and costs between $500 and $800 (Planned Parenthood, 2020b). The most common regimen in the United States involves the use of two different medications, mifepristone and misoprostol. Mifepristone blocks progesterone, which is essential to the development of

pregnancy. Misoprostol, taken 24 to 48 hours later, works to empty the uterus by causing cramping and bleeding. A follow-up visit is scheduled later to confirm the pregnancy was terminated via ultrasound or blood test (Henry J. Kaiser Foundation, 2018).

Complications of medical abortions include incomplete expulsion of uterine contents, uterine infection, and heavy bleeding (McBride & Keys, 2018). A recent Cochrane Systematic Review showed no difference in complication rates between medical and surgical abortions in the first trimester (Webster et al., 2018).

The assessment of the woman with an unintended pregnancy should be performed with cautious sensitivity. It is essential to explore the women's feelings about pregnancy before congratulating or consoling her. The encounter should be guided by the feelings of the client, not by the assumptions and values of the nurse.

Abortion can be an emotional, deeply personal issue. Considerate and sensitive communication is key in dealing with cases of termination of pregnancy. Provide support and accurate information. If you feel unable to actively participate in the care of a woman undergoing an abortion for personal, religious, or ethical reasons, you still have the professional responsibility to ensure that the woman receives the nursing care and help she requires. This may necessitate a transfer to another area or a staffing reassignment. Nurses must keep in mind that all women have the right to have access to unbiased, factual information about available reproductive health choices, whether they seek to end or start a pregnancy, from which they can then make informed decisions about their own reproductive health.

MENOPAUSAL TRANSITION

Midlife is a critical time for women because it encompasses both chronologic aging and menopause. This is a time of pronounced changes in body composition, cardiovascular health, mood, sleep, cognition, and overall functioning (Thurston et al., 2018). Menopause is a natural process that occurs in all women's lives as part of normal

aging. *Meno* is derived from the Greek word for “month,” and *pause* is derived from the Greek word for “pause” or “halt.” Menopause is the technical term for a point in time at which menses and fertility cease (Chelmow et al., 2019). People call it many things: The change of life. The end of fertility. The beginning of freedom. Whatever people call it, menopause is a unique and personal experience for every woman. The term **menopausal transition** refers to the transition from a woman’s reproductive phase of her life to her final menstrual period. This period is also referred to as *perimenopause.* The average age of natural menopause, defined as 1 year without a menstrual period, is 51.4 years old. The average age of natural menopause has remained constant for the last several hundred years despite improvements in nutrition and health care (Woods & Utian, 2018). With current female life expectancy at 84 years, this event comes in roughly the middle of a woman’s adult life. Many women go through the menopausal transition with few or no symptoms, while some have significant or even disabling symptoms.

TAKE NOTE!

Humans are virtually the only species to outlive their reproductive capacities.

Menopause signals the end of an era for many women. It concludes their ability to reproduce, and some women find advancing age, altered roles, and these physiologic changes to be overwhelming events that can precipitate depression and anxiety (Webster et al., 2018). Menopause does not happen in isolation. Midlife is often experienced as a time of change and reflection. Change happens in many arenas; children are leaving or returning home, employment pressures intensify as career moves or decisions are required, older adult parents require more care or the death of a parent may have a major impact, and partners are retrenching or undergoing their own midlife changes. Women must negotiate all these changes in addition to menopause. Managing this stress can be challenging for many women as they make this transition.

A woman is born with approximately 2 million ova, but only about 400 ever mature fully to be released during the menstrual cycle. The absolute number of ova in the ovary is a major determinant of fertility. Over the course of her premenopausal life, there is a steady decline in the number of immature ova (Strauss et al., 2018). No one understands this depletion, but it does not occur in isolation. Maturing ova are surrounded by follicles that produce two major hormones: estrogen, in the form of estradiol, and progesterone. The cyclic maturation of the ovum is directed by the hypothalamus. The hypothalamus triggers a cascade of neurohormones, which act through the pituitary and the ovaries as a pulse generator for reproduction. This hypothalamic–pituitary–ovarian–uterine axis begins to break down long before there is any sign that menopause is imminent. Some scientists believe that the pulse generator in the hypothalamus simply degenerates; others speculate that the ovary becomes more resistant to the pituitary hormone FSH and simply shuts down (Webster et al., 2018). The final act in this well-orchestrated process is amenorrhea.

As menopause approaches, more and more of the menstrual cycles become anovulatory. This period of time, usually 2 to 8 years before cessation of menstruation, is termed *perimenopause* (Gompel, 2018). In perimenopause, the ovaries begin to fail, producing irregular and missed periods and an occasional hot flash. When menopause finally appears, viable ova are gone. Estrogen levels plummet by 90%, and estrone, produced in fat cells, replaces estradiol as the body's main form of estrogen. The major hormone produced by the ovaries during the reproductive years is estradiol; the estrogen found in postmenopausal women is estrone. Estradiol is much more biologically active than estrone (Oyelowo & Johnson, 2018). In addition, testosterone levels decrease with menopause.

With its dramatic decline in estrogen, menopausal transition affects not only the reproductive organs, but also other body systems:

- Brain and central nervous system: hot flashes, disturbed sleep, mood, and memory problems

- Cardiovascular: lower levels of high-density lipoprotein (HDL) and increased risk of CVD
- Skeletal: rapid loss of bone density that increases the risk of osteoporosis
- Breasts: replacement of duct and glandular tissues by fat
- Genitourinary: vaginal dryness, stress incontinence, cystitis
- Gastrointestinal: less absorption of calcium from food, increasing the risk for fractures
- Integumentary: dry, thin skin and decreased collagen levels
- Body shape: more abdominal fat; waist size that swells relative to hips

Therapeutic Management

Menopausal transition should be managed individually. In the past, despite the wide diversity of symptoms and risks, the traditional reaction was to reach for the one-size-fits-all therapy: hormone therapy (HT). Today the medical community is changing its thinking in light of the Women's Health Initiative (WHI, 2020) study and the Heart and Estrogen/Progestin Replacement Study Follow-Up (HERS II) (ongoing), which reported that long-term HT increased the risks of heart attacks, strokes, and breast cancer; in short, the overall health risks of HT exceeded the benefits. Years later, there remains widespread uncertainty as to how to advise menopausal women and when and how to prescribe HT (Davis, 2018). In addition, HT did not protect against the development of coronary artery disease (CAD) nor did it prevent the progression of CAD, as it was previously touted to do.

A recent research finding examined the timing of HT in relation to CAD in women and it found that the earlier initiation of HT was associated with less CAD in women with natural, but not surgical menopause. A current study, however, shows that the incidence of fractures among menopausal transition and postmenopausal women increased significantly in the 3 years after publication of the WHI and HERS II results. This trend followed a decline in the use of HT concurrent with an increase in the use of other bone-modifying

agents. Menopause predisposes women to osteoporosis due to declining estrogen levels. There is considerable evidence that estrogen or HT reduces the risk of postmenopausal osteoporotic fracture of both the spine and hip (Levin et al., 2018).

A number of treatment options are available, but factors in the client's history should be the driving force when determining therapy. Women need to educate themselves about the latest research findings and collaborate with their health care providers on the right menopause therapy. The following factors should be considered when planning management:

- The risk/benefit ratio is highest in younger women who begin HT not long after menopause.
- HT is approved for two indications: relief of vasomotor symptoms and prevention of osteoporosis.
- Research suggests that HT may be beneficial for preventing diabetes, improving mood, or avoiding urinary tract problems.
- Using HT long beyond menopause carries increased risks, which for some women may be outweighed by the benefits (Delamater & Santoro, 2018).

Many women consider nonhormonal therapies such as bisphosphonates and selective estrogen receptor modulators (SERMs). Consider weight-bearing exercises, calcium, vitamin D, smoking cessation, and avoidance of alcohol to treat or prevent osteoporosis. Regular breast examinations and mammograms are essential. Local estrogen creams can be used for vaginal atrophy. Many women consider herbal therapies for symptoms, though none have been validated by rigorous research studies (Brook, 2018).

ACOG has reaffirmed guidelines on treating menopausal symptoms. Their recommendations include: systemic HT with estrogen or estrogen plus progestin as the most effective approach for treating vasomotor symptoms; the lowest effective dose for the shortest duration is the best regimen; thromboembolic disease and breast cancer are risks for combined systemic HT; and local estrogen therapy is advised for isolated atrophic vaginal symptoms (2018c).

BOX 4.9 Common Symptoms of Menopause

- Hot flashes or flushes of the head and neck
- Dryness in the eyes and vagina
- Personality changes
- Anxiety and/or depression
- Loss of libido
- Decreased lubrication
- Weight gain and water retention
- Night sweats
- Atrophic changes—loss of elasticity of vaginal tissues
- Fatigue
- Irritability
- Poor self-esteem
- Insomnia
- Stress incontinence
- Heart palpitations

Adapted from The North American Menopause Society (NAMS). (2020). *Women's health and menopause FAQs*. Retrieved June 16, 2020, from http://www.menopause.org/for-women/expert-answers-to-frequently-asked-questions-about-menopause/women-s-health-and-menopause-faqs; Office on Women's Health (2019). *Menopause symptoms and relief*. Retrieved May 22, 2018, from https://www.womenshealth.gov/menopause/menopause-symptoms-and-relief; and American College of Obstetricians and Gynecologists (ACOG). (2018c). Practice Bulletin No. 141: Management of menopausal symptoms. Obstetrics & Gynecology, 131(3), 604–605.

Although numerous symptoms have been attributed to menopause (Box 4.9), some of them are more closely related to the aging process than to estrogen deficiency. A few of the more common menopausal conditions and their management are discussed next.

Managing Hot Flashes and Night Sweats

Hot flashes during menopause are distressing and result in poor quality of life. The emergence of hot flashes and night sweats (also known as vasomotor symptoms) coincides with a period in life that is also marked by dynamic changes in hormone and reproductive function that interconnect with the aging process, changes in metabolism, lifestyle behaviors, and overall health (Oyelowo &

Johnson, 2018). Hot flashes and night sweats are classic signs of estrogen deficiency and the predominant complaint of perimenopausal women. A hot flash is a transient and sudden sensation of warmth that spreads over the body, particularly the neck, face, and chest. Hot flashes are caused by vasomotor instability. This instability causes inappropriate peripheral vasodilation of superficial blood vessels, which gives the sensation of heat. Nearly 70% of menopausal women experience them. The mean increment in core body and skin temperature is 0.5° and 0.25°C during a hot flash attack (Mallhi et al., 2018). Hot flashes are an early and acute sign of estrogen deficiency. These flashes can be mild or extreme and can last from 2 to 30 minutes and may occur as frequently as every hour to several times per week. On average, women experience hot flashes for a period of 6 months to 2 years, but the symptoms may last up to 10 years or more. Severe vasomotor symptoms can have a significant and detrimental effect on quality of life. Factors that trigger vasomotor symptoms include caffeine and alcohol consumption, intake of hot drinks and spicy foods, hot environment, depression, stress, and anxiety (Santen et al., 2018).

Many options are available for treating hot flashes. Treatment must be based on symptom severity, the client's medical history, and the client's values and concerns. Although the gold standard in the treatment of hot flashes is estrogen, this is not recommended for all women who have high-risk factors in their history.

TRADITIONAL THERAPIES FOR THE MANAGEMENT OF HOT FLASHES

The following are traditional therapies for the management of hot flashes:

- Pharmacologic options
- HT unless contraindicated
- Androgen therapy (potentiates estrogen)
- Estrogen and androgen combinations
- Progestin therapy (Depo-Provera injection every 3 months)

- Clonidine (central alpha-adrenergic agonist) weekly patch
- Neurontin (antiseizure) decreased hot flashes
- Propranolol (beta-adrenergic blocker)
- Brisdelle: FDA-approved nonhormonal medication
- Short-term sleep aids: Ambien, Dalmane
- Gabapentin (Neurontin): antiseizure drug
- SSRIs: venlafaxine (Effexor) and paroxetine (Paxil) have shown promise (Skidmore-Roth, 2020)

COMPLEMENTARY AND ALTERNATIVE THERAPIES FOR MANAGEMENT OF HOT FLASHES

Many women are choosing alternative treatments for managing menopausal symptoms. Bioidentical hormones have the ability to bind to receptors in the human body and function in the same way as a woman's natural hormones. They simulate three estrogens (estradiol, estriol, and estrone), as well as progesterone, testosterone, dehydroepiandrosterone (DHEA), thyroxine, and cortisol. Bioidentical hormones are not, however, natural hormones. The estrogens are derived via a chemical process from soybeans (*Glycine max*) and progesterone from Mexican yam (*dioscorea villosa*). As with conventional hormones, however, bioidentical hormones are available only with a physician's prescription and through a pharmacy. Because of their natural origin, women sometimes believe alternative treatments are safer. The interest in phytoestrogens came about because of the low prevalence of hot flashes in Asian women, which was attributed to their diet being rich in phytoestrogens. Recent studies have found that black cohosh, wild yam, licorice, multibotanical herbs, and increased soy intake do not reduce the frequency or severity of menopausal hot flashes or night sweats.

Other remedies for easing menopausal symptoms might include red clover, motherwort, ginseng, sarsaparilla root, valerian root, L-tryptophan, calcium-magnesium, and kelp tablets (Mallhi et al., 2018). Again, research thus far has been skeptical about efficacy,

but many women report they ease their symptoms, and use has skyrocketed. Although some benefits may accrue from their use, evidence of the efficacy of alternative products in menopause is largely anecdotal. Small, preliminary clinical trials might demonstrate the safety of some of the nonpharmacologic products. Nurses should be aware of the purported action of these agents as well as any adverse effects or drug interactions.

The following are lifestyle changes and CAM therapies for the treatment of hot flashes:

- Lower room temperature; use fans.
- Wear clothing in layers for easy removal.
- Limit caffeine and alcohol intake.
- Drink eight to 10 glasses of water daily.
- Increase fruit and vegetable intake daily.
- Consume seafood and skinless chicken.
- Stop smoking.
- Avoid hot drinks and spicy food.
- Avoid high cholesterol and fast foods.
- Take calcium (1,200 to 1,600 mg) and vitamin D (400 to 600 IU).
- Perform daily aerobic exercise.
- Maintain a healthy weight.
- Identify stressors and ways to manage them.
- Keep a diary to identify triggers of hot flashes.
- Use chamomile as a mild sedative to alleviate insomnia.
- Try relaxation techniques, deep breathing, and meditation.
- Get acupuncture to reduce the frequency of hot flashes.
- Take vitamin E (100 mg daily) (Magowan et al., 2019).

Managing Urogenital Changes

Menopausal transition can be a physically and emotionally challenging time for women. In addition to the psychological burden of leaving behind the reproductive phase of life and the stigma of an aging body, sexual difficulties resulting from urogenital changes plague many women but are frequently not addressed. Sexual desire is affected by endocrine and psychosocial factors. Menopausal hormonal changes are relevant to the causes of sexual dysfunction

during reproductive aging. The frequency of sexual intercourse declines as women enter midlife. While partner availability and function may play a role, menopausal symptoms, such as vaginal dryness, are also present (Bachmann, 2018).

Vaginal atrophy occurs during menopause because of declining estrogen levels. These changes include thinning of the vaginal walls, an increase in pH, irritation, increased susceptibility to infection, **dyspareunia** (difficult or painful sexual intercourse), loss of lubrication with intercourse, vaginal dryness, and a decrease in sexual desire related to these changes. Decreased estrogen levels can also influence a woman's sexual function as well. Delayed clitoral reaction, decreased vaginal lubrication, diminished circulatory response during sexual stimulation, and reduced contractions during orgasm have all been linked to low estrogen levels. Genitourinary tract disorders susceptible to estrogen deficiency are progressive and worsen over time (Casarotti et al., 2018).

Management of these changes might include the use of estrogen vaginal tablets (Vagifem) or Premarin cream; Estring, an estrogen-releasing vaginal ring that lasts for months; testosterone patches; and over-the-counter moisturizers and lubricants (Astroglide) (Skidmore-Roth, 2020). A positive outlook on sexuality and a supportive partner are also needed to make the sexual experience enjoyable and fulfilling. Nurses can improve the sexual health and quality of life in menopausal women by educating them about their symptoms and offering them choices about managing them.

TAKE NOTE!

Sexual health is an important aspect of the human experience. By keeping an open mind, listening to women, and providing evidence-based treatment options, the nurse can help improve quality of life for menopausal women.

Preventing and Managing Osteoporosis

Menopause predisposes women to osteoporosis due to declining estrogen levels. This results in a decrease in bone mineral density

and an increase in fractures. Osteoporosis has been recognized as a significant worldwide public health problem. As the world's population ages, both in the United States and internationally, the prevalence of osteoporosis is expected to increase significantly. **Osteoporosis** is the state of diminished bone density. This disorder is a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue with a consequent increase in bone fragility (National Osteoporosis Foundation [NOF], 2020).

According to recent information from NOF (2020), osteoporosis is a major medical problem that affects 10 million women and 2 million men in the United States. It affects one in four women ages 65 or older. An additional 34 million Americans have low bone mass. Each year, an estimated 1.5 million individuals in the United States experience a fragility fracture secondary to osteoporosis, resulting in an annual cost of $20 billion. By 2025, experts predict that osteoporosis will be responsible for approximately 3 million fractures and $30 billion in costs each year (NOF, 2020). With the rapidly aging population, the problem of osteoporosis is now reaching epidemic proportions. Millions of baby boomers are entering the stage in their lives when they are most at risk for osteoporosis. One half of all women and one third of all men will sustain fragility fractures during their lifetimes. Osteoporosis continues to be underdiagnosed and undertreated because it is often not recognized until the first fracture occurs.

Women are greatly affected by osteoporosis after menopause. Bone mass declines to such an extent that fractures can occur with minimal trauma. Bone loss begins in the third or fourth decade of a woman's life and accelerates rapidly after menopause (Levin et al., 2018). This condition puts many women into long-term care with a resulting loss of independence. Figure 4.22 shows the skeletal changes associated with osteoporosis.

Most women with osteoporosis do not know they have the disease until they sustain a fracture, usually of the wrist or hip. Risk factors for osteoporosis-related fractures include:

- Increasing age

- Postmenopausal status without hormone replacement
- Small, thin-boned frame

FIGURE 4.22. Skeletal changes associated with osteoporosis. (John Radcliffe Hospital/Photo Researcher Inc.)

- Weight less than 127 lb
- Low bone mineral density
- White or Asian with small bone frame
- Impaired eyesight that would increase risk of falling
- Rheumatoid arthritis
- Family history of osteoporosis
- Sedentary lifestyle

- Celiac disease
- Depression
- History of treatment with:
  - Antacids with aluminum
  - Heparin
  - Long-term use of steroids (longer than 3 months)
  - Thyroid replacement drugs
- Smoking and consuming alcohol
- Low calcium and vitamin D intake
- Excessive amounts of caffeine
- Personal history of nontraumatic fracture
- Anorexia nervosa or bulimia (Compston et al., 2019)

Currently, no method exists for directly measuring bone mass. Instead, a bone mass density (BMD) measurement is used. BMD is a two-dimensional measurement of the average content of mineral in a section of bone. BMD evaluations are made at the hip, femoral neck, and spine. There is a significant relationship between BMD and fracture: as BMD is reduced, the risk of fracture increases (Bethel, 2019a). Screening tests to measure bone density are not good predictors for young women who might be at risk for developing this condition. Dual-energy x-ray absorptiometry (DXA or DEXA) is a screening test that calculates the mineral content of the bone at the spine and hip. It is highly accurate, fast, and relatively inexpensive. The DEXA scan is the gold standard radiologic method for identifying osteoporosis through measuring BMD (Bethel, 2019b).

Hip fractures are the most devastating of the fragility fractures secondary to osteoporosis. A number of medical, social, and economic consequences follow a hip fracture. Of women older than 50 years, on average, 24% die within the first year after hip fracture (CDC, 2019e). The concern surrounding osteoporosis is not the rate of fracture alone but also the potential for lifelong disability secondary to fracture. The incidence of hip fracture is estimated to double by the year 2025 and nearly double again by 2050. For women, this is a projected 240% increase (NOF, 2020).

Early identification and intervention is needed to reduce the burden of osteoporotic fractures. The management of a woman with

osteoporosis or osteopenia (bone loss that hasn't reached the extent of that of osteoporosis) includes assessment of fracture risk, evaluation of secondary causes, and selection of the appropriate treatment plan. The best management for this painful, crippling, and potentially fatal disease is prevention.

Women can modify many risk factors by doing the following:

- Engage in daily weight-bearing exercise, such as walking, to increase osteoblast activity.
- Increase calcium and vitamin D intake.
- Remove indoor and outdoor falling hazards.
- Avoid smoking and excessive alcohol (more than two drinks per day).
- Discuss bone health with a health care provider.
- When appropriate, have a bone density test and take medication if needed (Shariati-Sarabi et al., 2018).

Medications that can help prevent and manage osteoporosis include:

- HT (Premarin)
- SERMs (raloxifene [Evista])
- Calcium and vitamin D supplements (Tums)
- Estrogen agonist/antagonist (SERM) (Evista)
- Bisphosphonates (Actonel, Fosamax, Boniva, or Reclast)
- Parathyroid hormone (Forteo)
- Calcitonin (Miacalcin) (Lewiecki, 2018)

Preventing and Managing Cardiovascular Disease

Over the last decade, CVD has become the leading cause of death worldwide. It is largely driven by modifiable risk factors, such as smoking, lack of physical activity, and diets high in fat and sodium (Zipes et al., 2018). Despite the dramatic decrease in annual CVD mortality and total cardiovascular mortality for American women each year since 2000, CVD remains the number-one killer of women, accounting for one in three deaths in the United States. This is likely due to increased rates of obesity, sedentary lifestyle, diabetes, and high cholesterol levels (Sharma & Wood, 2018). More

women die from heart disease and stroke than the next five causes of death combined, including breast cancer. Half a million women die annually in the United States of CVD, with strokes accounting for about 20% of the deaths (Kalman & Wells, 2018). This translates into approximately one death every minute. While men's mortality from CVD has decreased since the 1980s, women's mortality from CVD has climbed. This has resulted in a sex-related CVD mortality gap, with women having higher mortality than men since 1984. Contributing to this female-majority CVD mortality gap is a lack of awareness among women and their physicians of the risk for CVD. Many health care providers still think of CVD as a "man's disease," so they ignore symptoms in women and delay treatment. Awareness campaigns, such as the Heart Truth and the Red Dress symbol, appear to have improved recognition of CVD risk in women. Further, female-specific guidelines have been developed to prevent and reduce CVD in women. Though the current understanding of the role of menopause in CVD is controversial, studies suggest that menopause does not exacerbate CVD independent of aging, and HT is not effective for secondary prevention of CVD (Mehta & McSweeney, 2018).

For the first half of a woman's life, estrogen seems to be a protective substance for the cardiovascular system by smoothing, relaxing, and dilating blood vessels. It even helps boost HDL and lower low-density lipoprotein (LDL) levels, helping keep the arteries clean from plaque accumulation. But when estrogen levels plummet as women age and experience menopause, the incidence of CVD increases dramatically. Women are more likely to have atypical cardiovascular symptoms when compared to men. This may lead to a delayed or misdiagnosis of CAD and suboptimal treatment. These symptoms may include:

- A—Angina (chest pain)
- B—Breathlessness
- C—Chronic fatigue
- D—Dizziness
- E—Edema of hands and feet
- F—Fluttering of the heart

- G—Gastric upset
- H—Heavy pain in back and shoulders

Menopause is not the only factor that increases a woman's risk for CVD. Lifestyle and medical history factors such as the following play a major role:

- Smoking
- Obesity
- High-fat diet
- Sedentary lifestyle
- High cholesterol levels
- Family history of CVD
- Hypertension
- Apple-shaped body
- Diabetes

Two of the major risk factors for coronary heart disease are hypertension and dyslipidemia. Both are modifiable and can be prevented by lifestyle changes and if needed, controlled by medication. This is why prevention is essential. In addition, women who experience early menopause lose the protection afforded by endogenous estrogen to the cardiac system and are at greater risk for more extensive atherosclerosis. Major preventive strategies include a healthy diet, increased activity, exercise, smoking cessation, decreased alcohol intake, and weight reduction.

The nurse is often a woman's first and most consistent point of contact within the health care system. Nurses who work in primary care settings can identify women at risk for CVD, counsel them about their risk factors, and encourage and initiate primary and secondary prevention strategies. Nurses, particularly those caring for women during their reproductive years, are uniquely positioned to provide education and support for women's long-term cardiovascular health. Raising awareness of heart disease in women is an essential role for nurses. The good news is that CVD is largely preventable. Because CVD is a chronic disease that develops over time, primary prevention lifestyle modification interventions are most effective if initiated before the development of overt disease. The gold standard

of treatment and risk reduction for all women, regardless of their risk category, is adhering to a healthy lifestyle, including diet, exercise, adequate sleep, stress reduction, and smoking cessation. Stressing the importance of lifestyle modifications must begin early in life and should be reinforced from the beginning of a young woman's reproductive years through menopause. Nurses are in an ideal position to teach the importance of good nutrition, healthy weight, and daily exercise before CVD becomes clinically evident. Education is the cornerstone to reducing CVD risk and death among women.

Nursing Assessment

Menopausal transition is a universal and irreversible part of the overall aging process involving a woman's reproductive system. Although not a disease state, menopausal transition does place women at greater risk for the development of many conditions of aging. Nurses can help the woman become aware of her risk for postmenopausal diseases as well as strategies to prevent them. The nurse can be instrumental in assessing risk factors and planning interventions in collaboration with the client. These might include:

- Screening for osteoporosis, CVD, and cancer risk
- Assessment of blood pressure to identify hypertension
- Blood cholesterol test to identify hyperlipidemia risk
- Mammogram to find a cancerous lesion
- Pap smear to identify cervical cancer
- Pelvic examination to identify endometrial cancer or masses
- Digital rectal examination to assess for colon cancer
- Bone density testing as a baseline at menopause to identify osteopenia (low bone mass), which might lead to osteoporosis
- Assessing lifestyle to plan strategies to prevent chronic conditions:
  - Dietary intake of fat, cholesterol, and sodium
  - Weight management
  - Calcium intake
  - Use of tobacco, alcohol, and caffeine
  - Amount and type of daily exercise routines

Nursing Management

There is no “magic bullet” in managing menopause. Nurses can counsel women about their risks and help them prevent disease and debilitating conditions with specific health maintenance education. Women should make their own decisions, but the nurse should make sure they are armed with the facts to do so intelligently. Nurses can offer a thorough explanation of the menopausal process, including the latest research findings, to help women understand and make decisions about this inevitable event.

If the woman decides to use HT to control her menopausal symptoms after being thoroughly educated, she will need frequent reassessment. There are no hard-and-fast rules that apply to meeting a woman’s individual needs. The nurse can provide realistic expectations of the therapy to reduce the woman’s anxiety and concerns.

It is also useful to emphasize the value of friends to gain support and share information and resources. Often just talking about emotional difficulties such as the death of a parent or problematic relationships helps solve problems. It also shows the woman that her emotional responses are valid.

Healthy lifestyles and stress management techniques are vital to health and longevity, and it is important to keep these on the client’s agenda when discussing menopause (The North American Menopause Society, 2020). Evidence-based interventions include lifestyle modifications, risk management therapies, and preventive drug interventions, such as:

- Participate actively in maintaining health.
- Stay current on health screenings and vaccinations.
- Exercise regularly to prevent CVD and osteoporosis.
- Take supplemental calcium and eat appropriately to prevent osteoporosis.
- Stop smoking to prevent lung and heart disease.
- Reduce caffeine and alcohol intake to prevent osteoporosis.
- Monitor blood pressure, lipids, and diabetes (drug therapy management).

- Use low-dose aspirin to prevent blood clots.
- Reduce dietary intake of fat, cholesterol, and sodium to prevent CVD.
- Maintain a healthy weight for body frame.
- Perform breast self-examinations for breast awareness.
- Control stress to prevent depression (Office on Women's Health, 2019).

These life approaches may be low-tech, but they can stave off menopause-related complications such as CVD, osteoporosis, and depression. These tips for healthy living work well, and the client needs to be motivated to stick with them.

KEY CONCEPTS

- Establishing good health habits and avoiding risky behaviors early in life will prevent chronic conditions later in life.
- PMS has more than 150 symptoms, and at least two different syndromes are recognized—PMS and PMDD.
- Endometriosis is a condition in which tissue similar to that of the endometrium is located outside the uterine cavity.
- Infertility is a widespread problem that has an emotional, social, and economic impact on couples.
- More than half of all unintended pregnancies occur in women who report using some method of birth control during the month of conception.
- Hormonal methods include OCs, injectables, implants, vaginal rings, and transdermal patches.
- Recent studies have shown that the extension of active extended-cycle OC pills carries the same safety profile as the conventional 28-day regimens.
- The intrauterine contraceptives available in the United States include: the copper ParaGard-TCu-380A; the levonorgestrel-releasing intrauterine system (LNG-IUS) marketed as Mirena; and the LNG-IUD marketed as Jaydess and Kyleena.
- With a dramatic decline in estrogen levels, menopause affects not only the reproductive organs but also other body systems.
- Most women with osteoporosis do not know they have the disease until they sustain a fracture, usually of the wrist or hip (NOF, 2020).
- Half a million women die annually in the United States of CVDs with strokes accounting for about 20% of the deaths (Kalman & Wells, 2018).
- Nurses should aim to have a holistic approach to the sexual health of women from menarche through menopause.

Unfolding Patient Stories: Carla Hernandez • Part 1

Carla Hernandez is a 32-year old gravida 2 para 1. She is at 39 5/7 weeks' gestation when her husband brings her to the hospital. She and her husband tell the nurse that after delivery of the baby, they want to discuss options for preventing a future pregnancy. What information can the nurse prepare to help them make an informed decision? What questions asked by the nurse can help guide the discussion toward methods that correspond with their beliefs and values? (Carla Hernandez's story continues in Chapter 14.)

Care for Carla and other patients in a realistic virtual environment: *vSim for Nursing* (**thepoint.lww.com/vSimMaternity**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. A couple is considered infertile after how many months of trying to conceive?

   a. 6 months
   b. 12 months
   c. 18 months
   d. 24 months

2. A couple reports that the condom broke while they were having sexual intercourse last night. What would you advise to prevent pregnancy?

   a. Inject a spermicidal agent into the woman's vagina immediately.
   b. Obtain emergency contraceptives and take them immediately.
   c. Douche with a solution of vinegar and hot water tonight.
   d. Take a strong laxative now and again at bedtime.

3. Which combination contraceptive has been approved for extended continuous use?

   a. Seasonale
   b. Triphasil
   c. Ortho Evra
   d. Mirena

4. Which measure helps prevent osteoporosis?

   a. Supplementing with iron
   b. Sleeping 8 hours nightly
   c. Eating lean meats only

d. Weight-bearing exercise

5. Which activity will increase a woman's risk of CVD if she is taking oral contraceptives?

a. Eating a high-fiber diet
b. Smoking cigarettes
c. Taking daily multivitamins
d. Drinking alcohol

6. The nurse is preparing to teach a class to a group of middle-aged women regarding the most common vasomotor symptoms experienced during menopause and possible modalities of treatment available. Which is an example of a vasomotor symptom experienced by menopausal women?

a. Weight gain
b. Bone density
c. Hot flashes
d. Heart disease

7. Throughout life, a woman's most proactive activity to promote her health would be to engage in

a. consistent exercise.
b. socialization with friends.
c. quality quiet time with herself.
d. consuming water.

8. Which comment by a woman would indicate that a diaphragm is not the best contraceptive device for her?

a. "My husband says it is my job to keep from getting pregnant."
b. "I have a hard time remembering to take my vitamins daily."
c. "Hormones cause cancer and I don't want to take them."
d. "I am not comfortable touching myself down there."

9. The most common cause of menstrual abnormality in a reproductive-age woman is

   a. ectopic pregnancy.
   b. coagulopathy.
   c. carcinoma.
   d. anovulation.

CRITICAL THINKING EXERCISES

1. Ms. London, age 25, comes to your family planning clinic requesting to have an IUS inserted because “birth control pills give you cancer.” In reviewing her history, you note she has been into the STI clinic three times in the past year with vaginal infections and was hospitalized for PID last month. When you question her about her sexual history, she reports having sex with multiple partners and not always using protection.

   a. Is an IUS the most appropriate method for this client? Why or why not?
   b. What myths/misperceptions will you address in your counseling session?
   c. Outline the safer sex discussion you plan to have with her.

STUDY ACTIVITIES

1. Develop a teaching plan for an adolescent with PMS and dysmenorrhea.
2. Arrange to shadow a nurse working in family planning for the morning. What questions does the nurse ask to ascertain the kind of family planning method that is right for each woman? What teaching goes along with each method? What follow-up care is needed? Share your findings with your classmates during a clinical conference.

3. Access the internet and locate three resources for infertile couples to consult that provide support and resources.
4. Sterilization is the most prevalent method of contraception used by married couples in the United States. Contact a local urologist and gynecologist to learn about the procedure involved and the cost of male and female sterilization. Which procedure poses less risk to the person and costs less?
5. Take a field trip to a local drugstore to check out the variety and costs of male and female condoms. How many different brands did you find? What was the range of costs?
6. Which are noncontraceptive benefits of combined oral contraceptives? Select all that apply.

   a. Protection against ovarian cancer
   b. Protection against endometrial cancer
   c. Protection against breast cancer
   d. Reduction in incidence of ectopic pregnancy
   e. Prevention of functional ovarian cysts
   f. Reduction in the risk of deep venous thrombosis
   g. Reduction in the risk of colorectal cancer

BRINGING IT ALL TOGETHER: A CASE STUDY

L. H. is a 66-year-old White female who presents to the women's health primary care clinic for her annual gynecologic examination. She states that she is fairly healthy with no active medical conditions other than hypertension controlled with medication. She is postmenopausal and feels she is doing well but has a few questions and concerns. Her primary concern is that she is bothered by vaginal dryness and pain with sexual intercourse. Over-the-counter lubricants and moisturizers have not been useful. She never took HT since her hot

flashes were not severe but asks if she should start taking it now to reduce her vaginal dryness.

Go to thePoint to find questions to consider about this case.

5

Sexually Transmitted Infections

WOW

WORDS OF WISDOM

Unconditional self-acceptance in clients is the core to reducing risky behavior and fostering peace of mind.

KEY TERMS

bacterial vaginosis
candidiasis
cervicitis
chlamydia
gonorrhea
pelvic inflammatory disease (PID)
sexually transmitted infection (STI)
syphilis
trichomoniasis
vaginitis

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Evaluate the spread and control of sexually transmitted infections.
2. Identify risk factors and outline appropriate client education needed in common sexually transmitted infections.
3. Describe how contraceptives can play a role in the prevention of sexually transmitted infections.
4. Analyze the physiologic and psychological aspects of sexually transmitted infections.
5. Outline the nursing management needed for women with sexually transmitted infections.

Sandy, a 19-year-old, couldn't imagine what these "things" were that appeared "down there" in her genital area last week. She was too embarrassed to tell anyone, so she stopped by the college health service today to find out what they were.

INTRODUCTION

Sexually transmitted infections (STIs) are a significant global health challenge. More than 30 different bacteria, viruses, and parasites are

known to be transmitted through sexual contact. Eight of these pathogens are linked to the greatest incidence of sexually transmitted disease. Of these eight infections, four are currently curable: syphilis, gonorrhea, chlamydia, and trichomoniasis. The other four are viral infections which are incurable: hepatitis B, herpes simplex virus (HSV or herpes), HIV, and human papillomavirus (HPV). Symptoms or disease due to the incurable viral infections can be reduced or modified through treatment. STIs are bacterial, viral, and parasitic infections of the reproductive tract caused by microorganisms transmitted through vaginal, anal, or oral sexual intercourse. STIs pose a serious threat not only to women's sexual health, but also to the general health and well-being of millions of people worldwide. STIs are responsible for genital tract infections that may lead to later complications in women such as pelvic inflammatory disease (PID) or infertility. They may also cause chronic liver diseases and cancer due to hepatitis B virus (HBV) and hepatitis C virus (HCV) infections: genital cancer associated with HPV, and AIDS caused by HIV. STIs constitute an epidemic of tremendous magnitude globally with an estimated 376 million new cases of curable STIs each year (World Health Organization [WHO], 2019d).

STIs are biologically sexist, presenting greater risk and causing more complications among women than among men. Women are diagnosed with two thirds of the estimated 20 million new cases of STIs annually in the United States. After only a single exposure, women are twice as likely as men to acquire infections from pathogens causing gonorrhea, chlamydia infection, hepatitis B, HPV, and syphilis (American Sexual Health Association [ASHA], 2019). STIs may contribute to cervical cancer, infertility, ectopic pregnancy, chronic pelvic pain, and death. Certain infections can be transmitted in utero to the fetus or during childbirth to the newborn. STIs know no class, racial, ethnic, or social barriers—all individuals are vulnerable if exposed to the infectious organism. Safer-sex practices that include limiting the number of sexual partners and using latex condoms during sexual activity must be recommended to all sexually active individuals. The problem of STIs has still not been tackled

adequately on a global scale, and until this is done, numbers worldwide will continue to increase.

A special section on STIs and adolescents is presented next, followed by discussion of specific STIs categorized according to the CDC framework. The CDC groups STIs according to the major symptom manifested (Box 5.1). The CDC classifies STIs according to their clinical symptoms—see Box 5.1 for the categories. A section on preventing STIs is included at the end of the chapter.

BOX 5.1 CDC Classification of STIs

- Infections characterized by vaginal discharge
  - Vulvovaginal candidiasis
  - Trichomoniasis
  - Bacterial vaginosis
- Infections characterized by cervicitis
  - Chlamydia
  - Gonorrhea
- Infections characterized by genital ulcers
  - Genital herpes simplex
  - Syphilis
- Pelvic inflammatory disease (PID)
- Human immunodeficiency virus (HIV)
- Human papillomavirus infection (HPV)
- Vaccine-preventable STIs
  - Hepatitis A
  - Hepatitis B
- Ectoparasitic infections
- Zika virus
- Pediculosis pubis
- Scabies

SEXUALLY TRANSMITTED INFECTIONS AND ADOLESCENTS

Individuals aged 15 to 24 years represent almost half of all cases of new STIs acquired (CDC, 2018b). Today, two in five sexually active teen girls have an STI that can cause infertility and even death (U.S. Department of Health and Human Services Office of Adolescent Health, 2019). Adolescent males make up approximately 80% of HIV diagnosis among 13- to 19-year-olds (U.S. Department of Health and Human Services Office of Adolescent Health, 2019). In the United States, teens who are sexually active experience high rates of STIs, and some racial or ethnic minority groups are at higher risk due to social conditions, including youths living in poverty and those with limited educational attainment (CDC, 2020).

Biologic, social, and behavioral factors place teenagers at high risk. Female adolescents are more susceptible to STIs due to their anatomy. During adolescence and young adulthood, women's columnar epithelial cells are especially sensitive to invasion by sexually transmitted organisms, such as chlamydia and gonococci, because they extend out over the vaginal surface of the cervix, where they are unprotected by cervical mucus; these cells recede to a more protected location as women age. Social factors such as poverty, lack of education, social inequality, and limited access to health care services impact the prevalence of STIs in this high-risk population (Alexander et al., 2021).

Behaviorally, adolescents and young adults tend to think they are invincible and deny the risks of their behavior. This risky behavior exposes them to STIs and HIV/AIDS. Adolescents frequently have unprotected intercourse, they engage in partnerships of limited duration, and they face many obstacles that prevent them from using the health care system (CDC, 2018c; *Healthy People 2030*).

HEALTHY PEOPLE *2030*

Objective	Nursing Significance
HIV-2030-01 Reduce the number of new HIV infections among adolescents and adults, 13 years and older. **HIV-2030-02** Increase the proportion of persons 13 years and older who know their HIV status. **HIV-2030-04** Increase the percentage of persons 13 years or older with diagnosed HIV infection who are virally suppressed. **STD-2030-01** Increase the proportion of sexually active females aged 16 to 24 years enrolled in Medicaid and commercial health plans who are screened for chlamydial infections. **STD-2030-02** Reduce gonorrhea rates among males aged 15 to 24 years.	Provide confidential care to all adolescents. Assess for sexual behaviors and STI risks during clinic visits; take every opportunity to educate the risks of STIs and risk reduction. Be direct and nonjudgmental and tailor your approach to the adolescent. Encourage adolescents to postpone initiation of sexual intercourse for as long as possible. For teens who have already had sexual intercourse, encourage abstinence at this point. Encourage adolescents to minimize their lifetime number of sexual partners. Educate about the importance of correct and consistent condom use.

STD-2030-03	Reduce the incidence of primary and secondary syphilis in women aged 15 to 44 years.
STD-2030-06	Reduce the proportion of population aged 15 to 24 with herpes simplex virus-2.
STD-2030-04	Reduce congenital syphilis.

Adapted from USDHHS. (2020). *Proposed objectives for inclusion in Healthy People 2030.* https://www.healthypeople.gov/sites/default/files/ObjectivesPublicComment508.pdf

Nursing Assessment

Many health care providers fail to assess adolescent sexual behavior and STI risks, to screen for asymptomatic infection during clinic visits, or to counsel adolescents on STI risk reduction. Nurses need to remember that they play a key role in the detection, prevention, and treatment of STIs in adolescents. All states allow adolescents to give consent to confidential STI testing and treatment. Table 5.1 discusses clinical manifestations of common STIs in adolescents.

Nursing Management

Nurses working with adolescents need to convey their willingness to discuss sexual habits. Provide effective guidance that promotes sexual health so that primary and/or repeat infections can be avoided. Adolescents bear disproportionate burdens when it comes

to STIs, so nurses need to educate them to protect their client's reproductive futures.

Encourage the client to complete the antibiotic prescription (specific management for each type of STI is discussed further in the chapter).

Prevention of STIs among adolescents is critical. Health care providers have a unique opportunity to provide counseling and education to their clients. Adapt the style, content, and message to the adolescent's developmental level. Identify risk factors and risk behaviors and guide the adolescent to develop specific individualized actions of prevention. The nurse's interaction and conversation with the adolescent needs to be direct and nonjudgmental.

Encourage adolescents to postpone initiation of sexual intercourse for as long as possible, but if they choose to have sexual intercourse, explain the necessity of using barrier methods, such as male and female condoms (Teaching Guidelines 5.1). For teens who have already had sexual intercourse, the clinician can encourage abstinence at this point. If adolescents are sexually active, they should be directed to teen clinics where contraceptive options can be explained. In areas where specialized teen clinics are not available, nurses should feel comfortable discussing sexuality, safety, and contraception with teens. Encourage adolescents to minimize their lifetime number of sexual partners, to use barrier methods consistently and correctly, and to be aware of the connection between drug and alcohol use and the incorrect use of barrier methods. Table 5.2 discusses barriers to condom use and means to overcome them.

Think back to Sandy, who was introduced at the beginning of the chapter. How should the nurse handle Sandy's anxious state? What specific questions should the nurse ask Sandy to determine the source of the possible infection in her genital area?

INFECTIONS CHARACTERIZED BY VAGINAL DISCHARGE

Vaginitis is a generic term that means inflammation and infection of the vagina. There can be hundreds of causes for vaginitis, but more often than not the cause is infection by one of three organisms:

TABLE 5.1 Sexually Transmitted Infections Common in Adolescents

Disease	Causative Organism	Transmission Mode	Diagnostic Testing and Recommended Screening for Sexually Active Adolescent	Female Symptoms	Male Symptoms	Recommended Treatment
Chlamydia Curable STI Seen frequently among sexually active adolescents and young adults	*Chlamydia trachomatis* (bacteria)	Vaginal, anal, and oral sex and by childbirth	Culture fluid from urethral swabs in males or endocervical swabs for females Noninvasive, non–culture-based testing is available using nucleic acid amplification and testing (NAAT) from urine—single test can test for chlamydia and gonorrhea Conjunctival secretions in neonates Females: screen annually Males: screen high-risk adolescents	May be asymptomatic Dysuria, urinary frequency, dyspareunia Cervical discharge (mucus or pus) Endocervicitis May lead to pelvic inflammatory disease, ectopic pregnancy, infertility Can cause inflammation of the rectum and conjunctiva Can infect the throat from oral sexual contact with an infected partner	May be asymptomatic Dysuria, urethral itching Penile discharge (mucus or pus) Urethral tingling May lead to epididymitis and sterility Can cause inflammation of the rectum and conjunctiva Can infect the throat from oral sexual contact with an infected partner	Azithromycin (Zithromax) Doxycycline (Vibramycin) Erythromycin (EES) Levofloxacin Ofloxacin (Floxin) Sexual partners need evaluation, testing, and treatment also Abstinence from sexual activity until therapy complete and symptoms no longer present Retesting in 3 months to rule out recurrence
Gonorrhea Curable STI Adolescent often co-infected with *Chlamydia trachomatis*	*Neisseria gonorrhoeae* (bacteria)	Vaginal, anal, and oral sex and by childbirth	Gram stain or culture directly for the bacterium or same noninvasive, non–culture-based test, NAAT, as chlamydia Females: screen annually Male: screen high-risk adolescents	May be asymptomatic or no recognizable symptoms until serious complications such as pelvic inflammatory disease Dysuria Urinary frequency Vaginal discharge (yellow and foul) Dyspareunia Endocervicitis Arthritis May lead to pelvic inflammatory disease, ectopic pregnancy, infertility Symptoms of rectal infection include discharge, anal itching, and occasional painful bowel movements with fresh blood.	Most produce symptoms, but can be asymptomatic Dysuria Penile discharge (pus) Arthritis May lead to epididymitis and sterility Symptoms of rectal infection include discharge, anal itching, and occasional painful bowel movements with fresh blood.	At this time, due to concerns about *N. gonorrhoeae* resistance to certain antimicrobials, the CDC currently recommends only one regimen, dual therapy with ceftriaxone and azithromycin. Sexual partners need evaluation, testing, and treatment also Abstinence from sexual activity until therapy complete and symptoms no longer present Retesting in 3 months to rule out recurrence
Genital Herpes Lifelong recurrent viral disease Most people have not been diagnosed There is no cure.	Herpes simplex virus 1 and 2 (HSV-1 and HSV-2)	HSV-1 is spread through oral secretions; can be spread to genitals through poor handwashing of infected person or oral-genital contact HSV-2 is spread by having sexual contact (vaginal, oral, or anal) with someone who is shedding the herpes virus either during an outbreak or during a period with no symptoms; can be spread to an infant through childbirth.	Visual inspection and symptoms or culture from swabs taken from lesions (success depends stage of lesion—optimum is during vesicular stage) Polymerase chain reaction is more sensitive than culture. Serologic tests, such as antibody-based testing (herpes Western blot assay is the most sensitive) Type specific laboratory testing important Routine screening not recommended	Initial symptoms include itching, tingling, and pain in genital area followed by small pustules and blister-like genital lesions that then crust over and gradually heal. Recurrence episodes are usually milder than the initial episode Dysuria, dyspareunia, and urine retention Fever, headache, malaise, muscle aches	Same as female	Antivirals used to treat first episode, recurrence, and suppression Acyclovir, Valacyclovir, and Famciclovir mainstay in treatment Does not cure; just controls symptoms Counseling important to help adolescent cope and to prevent transmission Sexual partners benefit from evaluation and counseling If symptomatic, need treatment If asymptomatic, offer testing and education
Syphilis	*Treponema pallidum* (spirochete bacteria)	Sexual contact with an infected person.	Serologic testing mainstay for diagnosis Venereal Disease Research Laboratory (VDRL), rapid plasma reagin (RPR), and treponemal tests (e.g., fluorescent treponemal antibody absorbed [FTA-ABS]) can lead to a presumptive diagnosis and are useful for screening. Use of two tests required Darkfield examination and direct fluorescent antibody tests of lesion exudate or tissue provide definitive diagnosis of early syphilis. New tests are in development such as enzyme immunoassay. Screen based on epidemiology and personal risk factors	Course of disease divided into stages **Primary infection:** • Chancre on place of entrance of bacteria (usually vulva or vagina but can develop in other parts of the body) **Secondary infection:** • Maculopapular rash (hands and feet) • Sore throat • Lymphadenopathy • Flu-like symptoms **Latent infection:** • No symptoms • Can be infective during first 1–2 years of latency • Many people if not treated will suffer no further signs and symptoms Some people will go on to develop tertiary or late syphilis. **Tertiary infections:** • Tumors of skin, bones, and liver • Central nervous system symptoms • Cardiovascular symptoms • Usually not reversible at this stage	Course of disease divided into stages **Primary infection:** • Chancre on place of entrance of bacteria (usually on penis but can develop in other parts of the body) **Secondary, latent, and tertiary infections:**All similar to female symptoms	Benzathine penicillin G injection (if penicillin allergy, doxycycline, tetracycline, or erythromycin) Sexual partners need evaluation and testing
Trichomoniasis	*Trichomonas vaginalis* (protozoa)	Vaginal intercourse with an infected partner. May be picked up from direct genital contact with damp or moist objects, such as towels or wet clothing, or	Highly sensitive and specific testing available and recommended, such as NAAT Microscopic evaluation of vaginal secretions or culture still common but less sensitive.	Many women have symptoms but some may be asymptomatic Dysuria Frequency Vaginal discharge (yellow, green, or gray and foul odor) Dyspareunia Irritation or itching of genital area	Most men infected are asymptomatic Dysuria Penile discharge (watery white)	Metronidazole (Flagyl) or tinidazole Sexual partners need evaluation, testing, and treatment also Abstinence recommended until therapy complete
Genital warts (condylomata acuminata) One of the most common STIs in the United States Could lead to cancers of the cervix, vulva, vagina, anus, or penis No cure; warts can be removed but virus remains	Human papillomavirus	Vaginal, anal, or oral sex with an infected partner.	Visual inspection Abnormal pap smear may indicate cervical infection of human papillomavirus (HPV).	Wart-like lesions that are soft, moist, or flesh colored and appear on the vulva and cervix, and inside and surrounding the vagina and anus Sometimes appear in clusters that resemble cauliflower-like bumps, and are either raised or flat, small or large	Wart-like lesions that are soft, moist, or flesh colored and appear on the scrotum or penis. They sometimes appear in clusters that resemble cauliflower-like bumps, and are either raised or flat, small or large	May disappear without treatment Treatment is aimed at removing the lesions rather than HPV itself. No optimal treatment has been identified, but there are several ways to treat depending on size and location. Most methods rely on chemical or physical destruction of the lesion: Imiquimod cream 20% Podophyllin antimitotic solution 0.5% Podofilox solution 5% 5-fluorouracil cream Trichloroacetic acid (TCA) Small warts can be removed by: • Freezing (cryosurgery) • Burning (electrocautery) • Laser treatment • Surgical excision Large warts that have not responded to treatment may be removed surgically. Vaccination recommended starting around age 12 and may lead to decrease in cancer associated with HPV. Abstinence from sexual activity during treatment to promote healing.

TABLE 5.2 Barriers to Condom Use and Means to Overcome Them

Perceived Barrier	Intervention Strategy
Decreases sexual pleasure (sensation) Note: Often perceived by those who have never used a condom	• Encourage client to try. • Put a drop of water-based lubricant or saliva inside the tip of the condom or on the glans of the penis before putting on the condom. • Try a thinner latex condom or a different brand or more lubrication.
Decreases spontaneity of sexual activity	• Incorporate condom use into foreplay. • Remind client that peace of mind may enhance pleasure for self and partner.
Embarrassing, juvenile, “unmanly”	• Remind client that it is “manly” to protect himself and others.
Poor fit (too small or too big, slips off, uncomfortable)	• Smaller and larger condoms are available.
Requires prompt withdrawal after ejaculation	• Reinforce the protective nature of prompt withdrawal and suggest substituting other postcoital sexual activities.
Fear of breakage may lead to less vigorous sexual activity	• With prolonged intercourse, lubricant wears off and the condom begins to rub. Have a water-soluble lubricant available to reapply.
Nonpenetrative sexual activity	• Condoms have been advocated for use during fellatio; unlubricated condoms may prove best for this purpose due to the taste of the lubricant. • Other barriers, such as dental dams or an unlubricated condom, can be cut down the middle to form a barrier; these have been advocated for use during certain forms of nonpenetrative sexual activity (e.g., cunnilingus and anolingual sex).
Allergy to latex	• Polyurethane male and female condoms are available. • A natural skin condom can be used together with a latex condom to protect the man or woman from contact with latex.

Used with permission from the Expert Working Group on the Canadian Guidelines for Sexually Transmitted Infections. (2008). *Canadian guidelines on sexually transmitted infections*. Public Health Agency of Canada.

TEACHING GUIDELINES 5.1

Proper Condom Use

- Use latex condoms.
- Use a new condom with each act of vaginal, anal, or oral sex. Never reuse a condom.
- Handle condoms with care to prevent damage from sharp objects such as fingernails and teeth.
- Ensure condom has been stored in a cool, dry place away from direct sunlight. Do not store condoms in wallet or automobile or anywhere they would be exposed to extreme temperatures.
- Do not use a condom if it appears brittle, sticky, or discolored. These are signs of aging.
- Put condom on before any genital contact.
- Ensure adequate lubrication during intercourse. If external lubricants are used, use only water-based lubricants such as KY Jelly with latex condoms. Oil-based or petroleum-based lubricants, such as body lotion, massage oil, or cooking oil, can weaken latex condoms.

Male Condom Use

- Put condom on when penis is erect with rolled side out. Ensure it is placed so it will readily unroll.
- Hold the tip of the condom while unrolling. Ensure there is a space at the tip for semen to collect (about ½ in), but make sure no air is trapped in the tip (air bubbles can cause breakage).
- If you feel the condom break, stop immediately, withdraw, remove broken condom, and replace.
- Withdraw while penis is still erect, and hold condom firmly against base of penis. Remove carefully to ensure no semen spills out. Dispose of properly.

Female Condom Use

- Do not use a male condom with a female condom.
- The thick inner ring with the closed end goes into the vagina (similar to inserting a tampon) the thin outer ring remains outside the body.

- Ensure condom is not twisted, that penis does not slip between the condom and vaginal wall, and the outer ring does not get pushed into the vagina.

- *Candida*, a fungus
- *Trichomonas*, a protozoa
- *Gardnerella*, a bacterium

The complex balance of microbiologic organisms in the vagina is a key element in the maintenance of health. Subtle shifts in the vaginal environment may allow organisms with pathologic potential to proliferate, causing infectious symptoms.

The nurse's role in managing vaginitis is one of primary prevention and education to limit recurrences of these infections. Primary prevention begins with changing the sexual behaviors that place women at risk for infection. In addition to assessing women for the common signs and symptoms and risk factors, the nurse can help women to avoid vaginitis or to prevent a recurrence by teaching them to take the precautions highlighted in Teaching Guidelines 5.2.

TEACHING GUIDELINES 5.2
The P-LI-SS-IT Model

- **P** – Permission—gives the woman permission to talk about her experience
- **LI** – Limited Information—information given to the woman about STIs
  - Factual information to dispel myths about STIs
  - Specific measures to prevent transmission
  - Ways to reveal information to her partners
  - Physical consequences if the infections are untreated
- **SS** – Specific Suggestions—an attempt to help women change their behavior to prevent recurrence and prevent further transmission of the STI
- **IT** – Intensive Therapy—involves referring the woman or couple for appropriate treatment elsewhere based on their life circumstances

Vaginal Candidiasis (VC)

Candidiasis is one of the most common causes of vaginal discharge. It is also referred to as yeast, monilia, and a fungal infection. It is not considered an STI because Candida is a normal constituent in the vagina and becomes pathologic only when the vaginal environment becomes altered. An estimated 75% of women will have at least one episode of candidiasis, and 40% to 50% will have two or more episodes in their lifetime (CDC, 2019q).

Therapeutic Management

Treatment of candidiasis includes one of the following medications:

- Miconazole cream or suppository
- Clotrimazole tablet or cream
- Terconazole cream or intravaginal suppository
- Fluconazole oral tablet (CDC, 2019q)

Most of these medications are used intravaginally in the form of a cream, tablet, or suppositories for 3 to 7 days. If fluconazole is prescribed, a 150-mg oral tablet is taken as a single dose.

Topical azole preparations are effective in the treatment of VC, relieving symptoms and producing negative cultures in 80% to 90% of women who complete therapy (CDC, 2019q). If VVC is not treated effectively during pregnancy, the newborn can develop an oral infection known as thrush during the birth process; that infection must be treated with a local azole preparation after birth.

Nursing Assessment

Assess the client's health history for predisposing factors for VC, which include:

- Pregnancy
- Use of oral contraceptives with a high estrogen content
- Use of broad-spectrum antibiotics
- Diabetes mellitus
- Obesity
- Use of steroid and immunosuppressive drugs
- HIV infection
- Wearing tight, restrictive clothes and nylon underpants
- Trauma to vaginal mucosa from chemical irritants or douching

Assess the client for clinical manifestations of VC. Typical symptoms, which can worsen just before menses, include:

- Pruritus
- Vaginal discharge (thick, white, curd-like)
- Vaginal soreness
- Vulvar burning
- Erythema in the vulvovaginal area
- Dyspareunia
- External dysuria

Figure 5.1 shows the typical appearance of VC.

Speculum examination will reveal white plaques on the vaginal walls. The vaginal pH remains within normal range. Definitive

diagnosis is made by a wet smear, which reveals the filamentous hyphae and spores characteristic of a fungus when viewed under a microscope.

Nursing Management

Teach preventive measures to women with frequent VVC infections, including:

- Reduce dietary intake of simple sugars and soda.
- Wear white, 100% cotton underpants.
- Avoid wearing tight pants or exercise clothes with spandex.
- Shower rather than taking tub baths.
- Wash with a mild, unscented soap and dry the genitals gently.

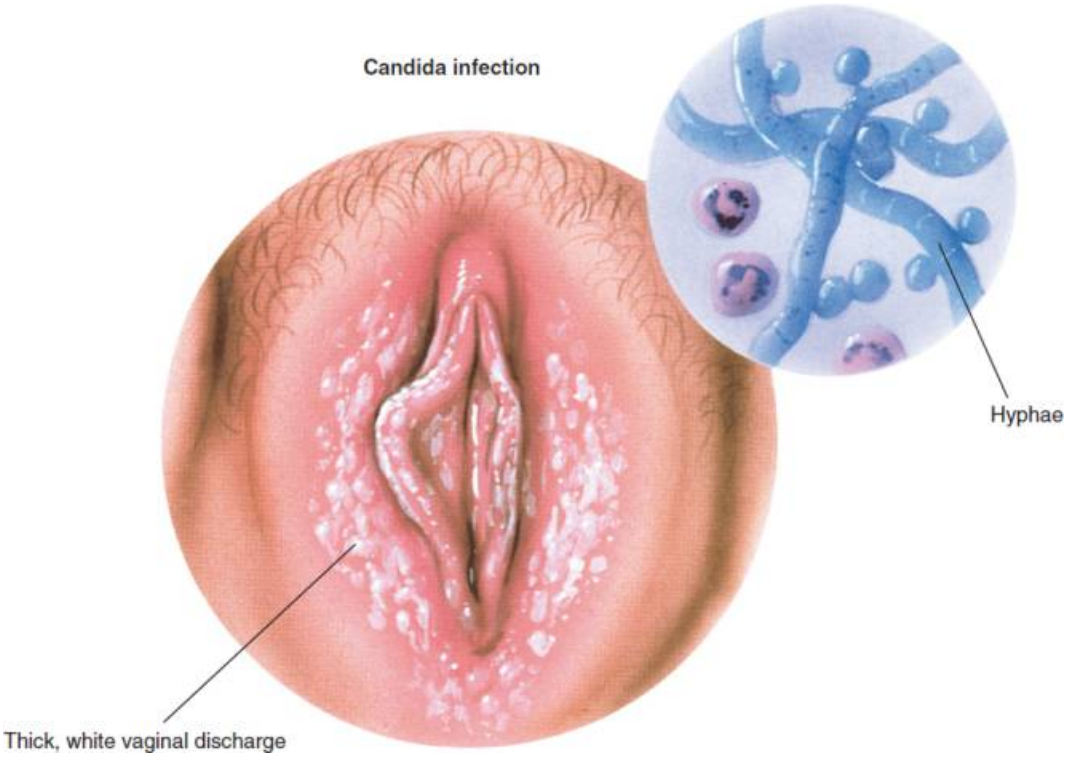

FIGURE 5.1. Vulvovaginal candidiasis. (Asset provided by Anatomical Chart Co.)

- Avoid the use of bubble baths or scented bath products.
- Wash underwear in unscented laundry detergent and hot water.

- Dry underwear in a hot dryer to kill the yeast that clings to the fabric.
- Remove wet bathing suits promptly.
- Practice good body hygiene.
- Avoid vaginal sprays/deodorants.
- Avoid wearing pantyhose (or cut out the crotch to allow air circulation).
- Use white, unscented toilet paper and wipe from front to back.
- Avoid douching (which washes away protective vaginal mucus).
- Avoid the use of super-absorbent tampons (use pads instead).

Trichomoniasis

Trichomoniasis is another common vaginal infection that causes a discharge, but is not always sexually transmitted. It is the most prevalent nonviral STI in the United States, affecting 3.7 million individuals. The organism can live on damp/wet surfaces and poorly cleaned/maintained hot tubs and drains. The woman may be markedly symptomatic or asymptomatic. When symptoms are present, they include vulvar itching and a malodorous foamy vaginal discharge. Men are asymptomatic carriers. Although this infection is localized, there is increasing evidence of preterm birth and postpartum endometritis in women with this vaginitis (CDC, 2019p). The high prevalence of this infection globally and frequency of coinfection with other STIs make trichomoniasis a public health concern. Notably, research finds that an infection with trichomoniasis increases the risk of HIV transmission in both men and women (Office of Population Affairs, 2019b). *Trichomonas vaginalis* is an ovoid, single-cell protozoan parasite that can be observed under the microscope making a jerky swaying motion. It is transferred when the parasite passes from an infected person to an uninfected person during sex.

Therapeutic Management

A single 2-g dose of oral metronidazole or tinidazole for both partners is a common treatment for this infection. Sex partners of women with trichomoniasis should be treated to avoid recurrence of infection.

Nursing Assessment

Assess the client for clinical manifestations of trichomoniasis, which include:

- A heavy yellow/green or gray frothy or bubbly discharge
- Vaginal pruritus and vulvar soreness
- Dyspareunia
- Cervix may bleed on contact

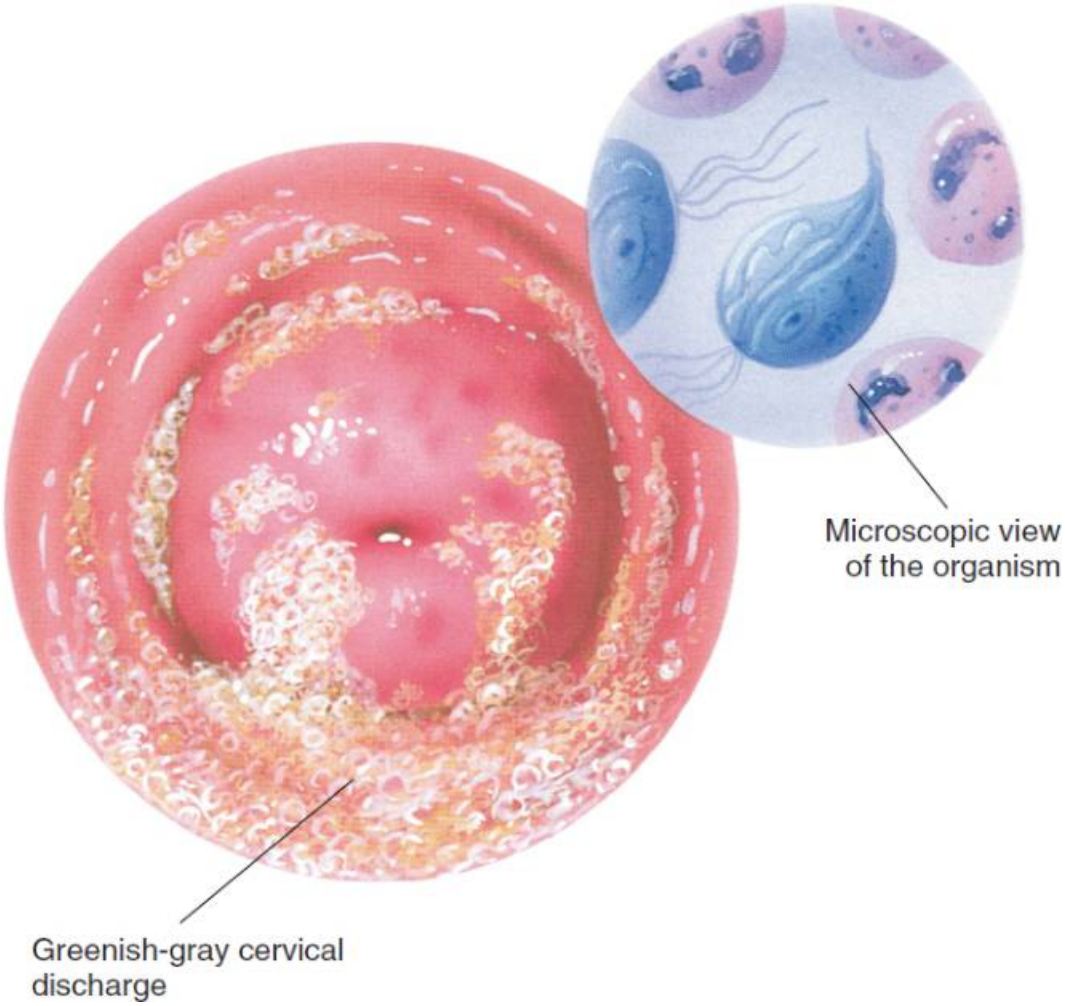

FIGURE 5.2. Trichomoniasis. (Asset provided by Anatomical Chart Co.)

- Dysuria
  - Vaginal odor, described as foul
  - Vaginal or vulvar erythema
- Petechiae on the cervix

Figure 5.2 shows the typical appearance of trichomoniasis.

The diagnosis is confirmed when a motile flagellated trichomonad is visualized under the microscope. In addition, a vaginal pH of greater than 4.5 is a typical finding. FDA-cleared tests for trichomoniasis in women include OSOM Trichomonas Rapid Test (Genzyme Diagnostics, Cambridge, Massachusetts), an immunochromatographic capillary flow dipstick technology, and the Affirm VP III (Becton Dickenson, San Jose, California), a nucleic acid

probe test that evaluates for *T. vaginalis, Gardnerella vaginalis,* and *Candida albicans.* Each of these tests, which are performed on vaginal secretions, have a sensitivity of 83% and a specificity of 97%. Both tests are considered point-of-care diagnostics (CDC, 2019p).

Nursing Management

Instruct clients to avoid sexual activity until they and their sex partners are cured (i.e., when therapy has been completed and both partners are symptom-free) and also to avoid consuming alcohol during treatment because mixing the medications and alcohol causes severe nausea and vomiting (CDC, 2019p). In addition, it is important to provide information regarding infection cause and transmission, effects on reproductive organs and future fertility, and the need for partner notification and treatment. Follow-up testing is not indicated if symptoms resolve with treatment. See Evidence-Based Practice 5.1 for a global intervention to reduce specific STIs in women.

Bacterial Vaginosis (BV)

A third common infection of the vagina is bacterial vaginosis caused by the gram-negative bacillus *G. vaginalis.* It is the most prevalent cause of vaginal discharge or malodor, but up to 50% to 75% of women are asymptomatic. While some women with BV can present with a vaginal discharge, BV is not typically associated with redness, swelling, or pain seen with “overt” inflammation, which is why it is referred to as “vaginosis” rather than “vaginitis.” Bacterial vaginosis is a sexually associated infection characterized by alterations in vaginal flora in which lactobacilli in the vagina are replaced with high concentrations of anaerobic bacteria. The cause of the microbial alteration is not fully understood, but is associated with having multiple sex partners, douching, and lack of vaginal lactobacilli. Bacterial vaginosis can increase a woman’s susceptibility to other STIs such as HIV, herpes, chlamydia, and gonorrhea (CDC, 2019b).

Research suggests that bacterial vaginosis is associated with preterm labor, premature rupture of membranes (PROM), chorioamnionitis, postpartum endometritis, and PID (CDC, 2019b).

EVIDENCE-BASED PRACTICE 5.1 Does Male Circumcision Reduce Women's Risk of Sexually Transmitted Infections, Cervical Cancer, and Associated Conditions?

STUDY

Sexually transmitted infections are an increasing threat to global health. STIs in women often have no symptoms, can cause adverse birth outcomes, can increase their susceptibility to HIV infections, can have long-term morbidity, and can cause infertility. Scientific evidence consistently points to the vulnerability of the male prepuce (foreskin) to infection. Male circumcision has been reported to reduce the transmission of sexually transmitted infections to female partners. A detailed systematic review of 68 scientific literature articles were included to determine the relationship between MC and risk of STIs and associated conditions in women.

Findings

Evaluation of the data from the 68 studies concluded that male circumcision reduced the risk in women of being infected with HPV, trichomoniasis, bacterial vaginosis, and genital ulcer disease. The reduction in risk of these STIs adds to the data supporting global efforts to employ male circumcision as a health promotion and life-saving public health measure.

Nursing Implications

This systematic review of the scientific evidence to date identifies male circumcision as a potentially powerful tool to reduce the global burden of STIs on women. Based on the highest-quality evidence from RCTs, it can be concluded that male circumcision reduces the risk of oncogenic HPV genotypes, cervical cancer,

Trichomoniasis vaginalis, bacterial vaginosis, and genital ulcer disease in women. This information can be shared with new parents deciding to have their male offspring to be circumcised or not. Although the decision to circumcise or not is fully up to the parents, nurses can present facts to them in their decision-making process.

Adapted from Morris, B. J., Hankins, C. J., Banerjee, J., Lumbers, E. R., Mindel, A., Klausner, J. D., & Krieger, J. N. (2019). Does male circumcision reduce women's risk of sexually transmitted infections, cervical cancer, and associated conditions? *Frontiers in Public Health*, *7*, 4. https://doi.org/10.3389/fpubh.2019.00004

Therapeutic Management

Treatment for bacterial vaginosis includes metronidazole (oral or gel) or clindamycin cream. Treatment of the male partner has not been beneficial in preventing recurrence because sexual transmission of bacterial vaginosis has not been proven (CDC, 2019b).

Nursing Assessment

Assess the client for clinical manifestations of bacterial vaginosis. Primary symptoms are a thin, white homogeneous vaginal discharge and a characteristic "stale fish" odor. Figure 5.3 shows the typical appearance of bacterial vaginosis.

To diagnose bacterial vaginosis, three of the four criteria must be met:

- Thin, white homogeneous vaginal discharge
- Vaginal pH 4.5
- Positive "whiff test" (secretion is mixed with a drop of 10% potassium hydroxide on a slide, producing a characteristic stale fishy odor)
- The presence of clue cells on wet-mount examination (CDC, 2019b)

Nursing Management

The nurse's role is one of primary prevention and education to limit recurrences of these infections. Primary prevention begins with changing the sexual behaviors that place women at risk for infection. In addition to assessing women for common signs, symptoms, and risk factors, the nurse can help women to avoid vaginitis or to prevent a recurrence by teaching them to take the precautions highlighted in Teaching Guidelines 5.2.

INFECTIONS CHARACTERIZED BY CERVICITIS

Cervicitis is a catchall term that implies the presence of inflammation or infection of the cervix. It is used to describe everything from symptomless erosions to an inflamed cervix that bleeds on contact and produces quantities of purulent discharge containing organisms not ordinarily found in the vagina. Cervicitis is usually caused by gonorrhea or chlamydia, as well as almost any pathogenic bacterial agent and a number of viruses. The treatment of cervicitis involves the appropriate therapy for the specific organism that has caused it.

Chlamydia

Chlamydia is the most commonly reported bacterial STI in the United States. It not only infects humans, but animals as well. The CDC (2019d) estimates that there are about 3 million cases in the United States annually; the highest predictor for this infection is age. The highest rates of infection are among those aged 15 to 19 years, mainly because their sexual relations are often unplanned and are sometimes the result of pressure or force, and typically happen before they have the experience and skills to protect themselves. The rates are highest among this group regardless of demographics or location. It is estimated that one in 20 sexually active young women aged 14 to 24 years has chlamydia (CDC, 2019d). The young have the most to lose from acquiring STIs, since they will suffer the consequences the longest and might not reach their full reproductive potential. The most common risk factors associated with chlamydia are age less than 25 years, recent change in sexual partner or multiple sexual partners, poor socioeconomic conditions, exchange of sex for money, nonwhite race, single status, and lack of use of barrier contraception. Worldwide, it is likely the most common infectious cause of infertility in women. An estimated 127 million cases of chlamydia occur globally among both men and women each year, so the global burden is substantial (WHO, 2019d).

Asymptomatic infection is common among both men and women. Men primarily develop urethritis. In women, chlamydia is linked with cervicitis, acute urethral syndrome, salpingitis, ectopic pregnancy, PID, and infertility (Qureshi, 2019). Chlamydia causes half of the 1

million recognized cases of PID in the United States each year, and treatment costs run over $701 million yearly. The CDC (2019d) recommends yearly chlamydia testing of all sexually active women aged 25 years or younger, older women with risk factors for chlamydial infections (those who have a new sex partner or multiple sex partners), and all pregnant women.

Chlamydia trachomatis is the bacterium that causes chlamydia. It is an intracellular parasite that cannot produce its own energy and depends on the host for survival. It is often difficult to detect, and this can pose problems for women due to the long-term consequences of untreated infection. Moreover, lack of treatment provides more opportunity for the infection to be transmitted to sexual partners. Newborns delivered to infected mothers may develop conjunctivitis which occurs in 25% to 50% of all newborns. Ophthalmia neonatorum is an acute mucopurulent conjunctivitis occurring in the first month of birth. It is essentially an infection acquired during vaginal delivery. The most frequent infectious agents involved in are *Chlamydia trachomatis* and *Neisseria gonorrhea* (ACOG, 2019).

Therapeutic Management

Antibiotics are the only treatment currently available, however, with high rates of reinfection, there is mounting pressure to develop *Chlamydia* vaccines. Antibiotics are usually used in treating this STI. The CDC treatment options for chlamydia include doxycycline 100 mg orally twice a day for 7 days or azithromycin 1 g orally in a single dose. Because of the common coinfection of chlamydia and gonorrhea, a combination regimen of ceftriaxone with doxycycline or azithromycin is prescribed frequently (CDC, 2019d). Additional CDC guidelines for client management include annual screening of all sexually active women; screening of all high-risk people; and treatment with antibiotics effective against both gonorrhea and chlamydia for anyone diagnosed with a gonococcal infection (CDC, 2019d). Except in pregnant women, test-of-cure (repeat testing 3 to 4 weeks after completing therapy) is not recommended for women treated with the recommended or alterative regimens, unless

therapeutic compliance is in question, symptoms persist, or reinfection is suspected (CDC, 2019d).

Nursing Assessment

Assess the health history for significant risk factors for chlamydia, which may include:

- Being an adolescent
- Having multiple sex partners
- Having a new sex partner
- Engaging in sex without using a barrier contraceptive (condom)
- Using oral contraceptives
- Being pregnant
- Having a history of another STI (King et al., 2019)

Assess the client for clinical manifestations of chlamydia. The majority of women (70% to 80%) are asymptomatic (CDC, 2019d). If the client is symptomatic, clinical manifestations include:

- Mucopurulent vaginal discharge
- Urethritis
- Bartholinitis
- Endometritis
- Salpingitis
- Dysfunctional uterine bleeding

The diagnosis can be made by urine testing or swab specimens collected from the endocervix or vagina. Culture, direct immunofluorescence, enzyme immunoassay (EIA), or nucleic acid amplification methods such as GenProbe or Pace2 are highly sensitive and specific when used on urethral and cervicovaginal swabs. They can also be used with good sensitivity and specificity on first-void urine specimens (Qureshi, 2019). The chain reaction tests are the most sensitive and cost-effective. The CDC (2019d) strongly recommends screening of asymptomatic women at high risk in whom infection would otherwise go undetected.

Chlamydia is an important preventable cause of infertility and other adverse reproductive health outcomes. Effective prevention

interventions are available to reduce the burden of chlamydia and its sequelae, but they are underutilized. Although many prevention programs are available, improvements can be made in raising awareness about chlamydia, increasing screening coverage, and enhancing partner services. In addition, nurses can focus their efforts on reaching disproportionately affected racial/ethnic groups. To break the cycle of chlamydia transmission in the United States, health care providers should encourage annual chlamydia screening for all sexually active females aged >25 years, maximize use of effective partner treatment services, and rescreen infected females and males 3 months after treatment (CDC, 2019d).

Gonorrhea

Gonorrhea is a serious, and potentially very severe, bacterial infection. It is the second most commonly reported infection in the United States, and is an urgent problem globally because it is now capable of developing resistance to multiple antibiotic classes. Gonorrhea is highly contagious and is a reportable infection to the health department authorities. Gonorrhea increases the risk for PID, infertility, ectopic pregnancy, and HIV acquisition and transmission (CDC, 2019h). It is rapidly becoming more and more resistant to cure. In the United States, an estimated 820,000,000 new gonorrhea infections occur annually (CDC, 2019h). In common with all other STIs, it is an equal-opportunity infection—no one is immune to it, regardless of race, creed, gender, age, or sexual preference.

The cause of gonorrhea is an aerobic gram-negative intracellular diplococcus, *Neisseria gonorrhoeae* that infects mucosal surfaces. The site of infection is the columnar epithelium of the endocervix. Gonorrhea is almost exclusively transmitted by sexual activity. In pregnant women, gonorrhea is associated with chorioamnionitis, premature labor, PROM, and postpartum endometritis (Ryan et al., 2020). It can also be transmitted to the newborn in the form of ophthalmia neonatorum during birth by direct contact with gonococcal organisms in the cervix. Ophthalmia neonatorum is

highly contagious and if untreated leads to blindness, joint infection, or a life-threatening blood infection in the newborn.

Therapeutic Management

Gonorrhea can be cured with the right treatment. CDC now recommends dual therapy (i.e., using two drugs as the treatment for gonorrhea). Dual therapy is recommended to prevent drug resistance and is also effective against chlamydia. The treatment of choice for uncomplicated gonococcal infections is azithromycin 1 g orally in a single dose and ceftriaxone 250 mg intramuscular (IM) in a single dose. A new drug underdevelopment, zoliflodacin, shows promise in GC treatment (CDC, 2019i).

Azithromycin orally or doxycycline should accompany all gonococcal treatment regimens if chlamydial infection is not ruled out (CDC, 2019i). Pregnant women with gonorrhea should not be treated with quinolones or tetracyclines. Pregnant women with a positive test for gonorrhea should be treated with the same recommended dual therapy of ceftriaxone with either azithromycin or amoxicillin (CDC, 2019i). To prevent gonococcal ophthalmia neonatorum, a prophylactic agent should be instilled into the eyes of all newborns; this procedure is required by law in most states. Erythromycin or tetracycline ophthalmic ointment in a single application is recommended (King et al., 2019). With use of recommended treatment, follow-up testing to document eradication of gonorrhea is no longer recommended. Instead, rescreening in 2 to 3 months to identify reinfection is suggested (CDC, 2019i).

Nursing Assessment

Assess the client's health history for risk factors, which may include low socioeconomic status, living in an urban area, single status, inconsistent use of barrier contraceptives, age under 20 years old, and multiple sex partners. Assess the client for clinical manifestations of gonorrhea, keeping in mind that between 50% and 90% of women infected with gonorrhea are totally symptom-free

(Fyle-Thorpe, 2019). Because women are so frequently asymptomatic, they are regarded as a major factor in the spread of gonorrhea. If symptoms are present, they might include:

- Abnormal vaginal discharge
- Dysuria
- Cervicitis
- Enlarged lymph glands locally
- Abnormal vaginal bleeding
- Bartholin abscess
- PID
- Neonatal conjunctivitis in newborns
- Mild sore throat (for pharyngeal gonorrhea)
- Rectal infection (itching, soreness, bleeding, discharge)
- Perihepatitis (King et al., 2019)

Sometimes, a local gonorrhea infection is self-limiting (there is no further spread), but usually the organism ascends upward through the endocervical canal to the endometrium of the uterus, further on to the fallopian tubes, and out into the peritoneal cavity. When the peritoneum and the ovaries become involved, the condition is known as PID. The scarring to the fallopian tubes is permanent. This damage is a major cause of infertility and a contributing factor in ectopic pregnancy (Reekie et al., 2019).

If gonorrhea remains untreated, it can enter the bloodstream and produce a disseminated gonococcal infection. This severe form of infection can invade the joints (arthritis), the heart (endocarditis), the brain (meningitis), and the liver (toxic hepatitis). Figure 5.4 shows the typical appearance of gonorrhea.

The CDC recommends screening for all women at risk for gonorrhea. Pregnant women should be screened at the first prenatal visit and again at 36 weeks' gestation. Nucleic acid hybridization tests (GenProbe) are used for diagnosis. Any woman suspected of having gonorrhea should be tested for chlamydia also because coinfection (45%) is extremely common (CDC, 2019i).

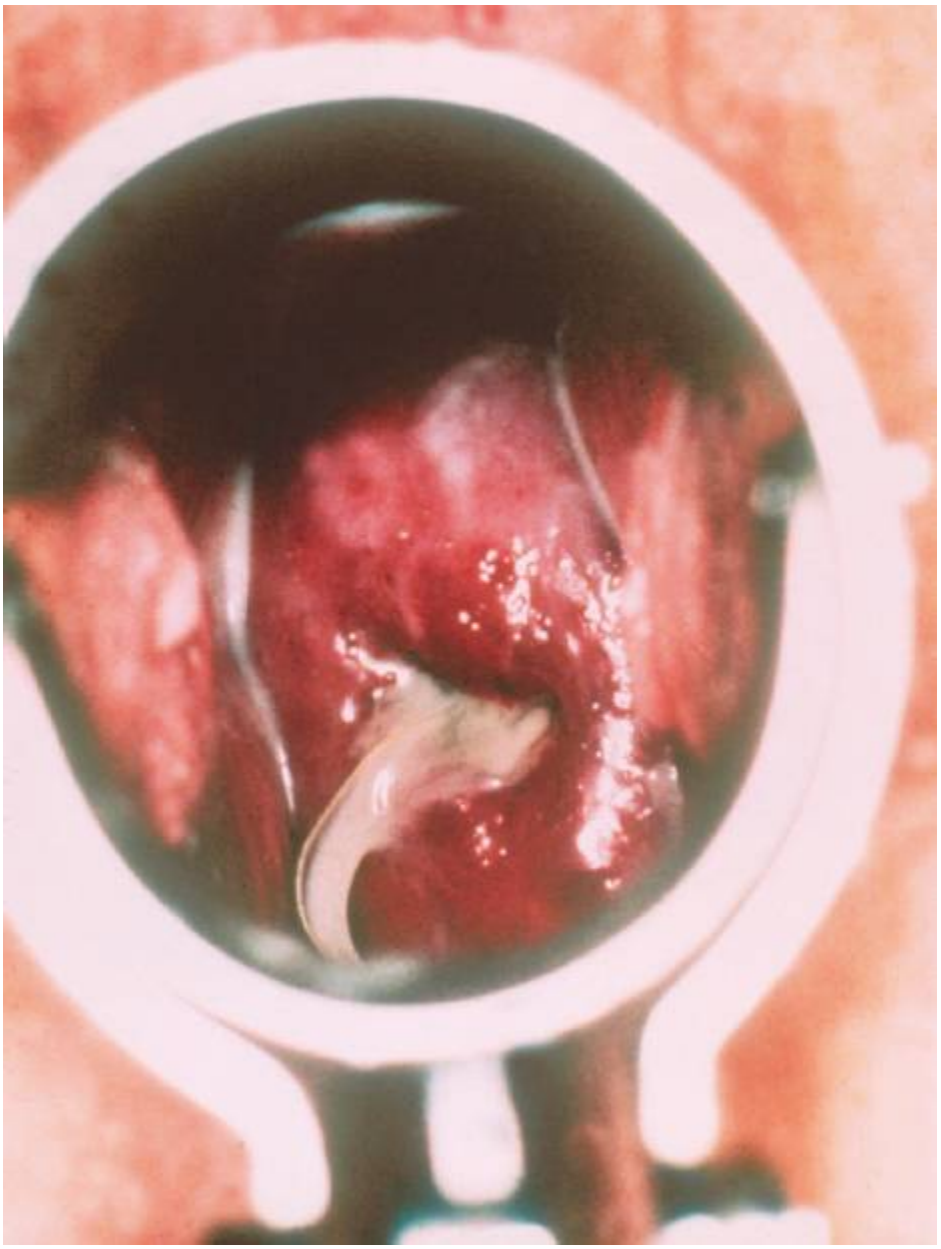

FIGURE 5.4. Gonorrhea. (From Jensen, S. [2015]. *Nursing health assessment: A best practice approach* [2nd ed.]. Wolters Kluwer.)

Nursing Management of Chlamydia and Gonorrhea

The prevalence of chlamydia and gonorrhea is increasing dramatically, and these infections can have long-term effects on people's lives. Sexual health is an important part of a person's

physical and mental health, and nurses have a professional obligation to address it. Be particularly sensitive when addressing STIs because women are often embarrassed or feel guilty. There is still a social stigma attached to STIs, so women need to be reassured about confidentiality.

The nurse's knowledge about chlamydia and gonorrhea should include treatment strategies, referral sources, and preventive measures. It is important to be skilled at client education and counseling and to be comfortable talking with, and advising, women diagnosed with these infections. Provide education about risk factors for these infections. High-risk groups include single women, women younger than 25 years, African American women, women with a history of STIs, those with new or multiple sex partners, those with inconsistent use of barrier contraception, HIV+ status, pregnant women, illicit drug use, and women living in communities with high infection rates (Wong, 2019). Assessment involves taking a health history that includes a comprehensive sexual history. Ask about the number of sex partners and the use of safer-sex techniques. Review previous and current symptoms. Emphasize the importance of seeking treatment and informing sex partners. The four-level P-LI-SS-IT model (Box 5.2) can be used to determine interventions for various women because it can be adapted to the nurse's level of knowledge, skill, and experience. Of utmost importance is the willingness to listen and show interest and respect in a nonjudgmental manner.

In addition to meeting the health needs of women with chlamydia and gonorrhea, the nurse is responsible for educating the public about the increasing incidence of these infections. This information should include high-risk behaviors associated with these infections, signs and symptoms, and the treatment modalities available. Stress that both of these STIs can lead to infertility and long-term sequelae. Teach safer-sex practices to people in nonmonogamous relationships. Know the physical and psychosocial responses to these STIs to prevent transmission and the disabling consequences. Nurses must also inform their pregnant clients that they should avoid quinolones or tetracyclines to prevent risks associated with

malformation of teeth, bones, and joints in the fetus and possible hepatotoxicity and pancreatitis in the mother (King et al., 2019). Nurses should focus on STI prevention efforts which include regular screening, rapid diagnosis, provision of effective therapy, partner notification, condom promotion, and health promotion activities.

BOX 5.2 Preventing Vaginitis

- Avoid douching to prevent altering the vaginal environment.
- Use condoms to avoid spreading the organism.
- Avoid tights, nylon underpants, and tight clothes.
- Wipe from front to back after using the toilet.
- Avoid powders, bubble baths, and perfumed vaginal sprays.
- Wear clean cotton underpants.
- Change out of wet bathing suits as soon as possible.
- Become familiar with the signs and symptoms of vaginitis.
- Choose to lead a healthy lifestyle.

TAKE NOTE!

If the epidemic of chlamydia and gonorrhea is to be halted, nurses must take a major front-line role now.

INFECTIONS CHARACTERIZED BY GENITAL ULCERS

In the United States, the majority of young, sexually active clients who have genital ulcers have genital herpes, syphilis, or chancroid. The frequency of each condition differs by geographic area and client population; however, genital herpes is the most prevalent of these diseases. More than one of these diseases can be present in a client who has genital ulcers. All three of these diseases have been associated with an increased risk for HIV infection. Not all genital ulcers are caused by STIs.

Genital Herpes Simplex

Genital herpes is a recurrent, lifelong viral infection that has the potential for transmission throughout the lifespan. The CDC estimates that one out of six people 14 to 49 years old have genital herpes simplex (HSV) infection, with at least 50 million people infected in the United States, and over 500 million worldwide new cases annually. It is more common in women versus men (CDC, 2019f). Two serotypes of HSV have been identified: HSV-1 and HSV-2. Today, a smaller portion of genital herpes infections are thought to be caused by HSV-1 and the bulk of them by HSV-2. HSV-1 mostly causes the familiar fever blisters or cold sores on the lips, eyes, and face. HSV-2 typically invades the mucous membranes of the genital tract and is known as herpes genitalis. Most people infected with HSV-2 have not been diagnosed.

The herpes simplex virus is transmitted by contact of mucous membranes or breaks in the skin with visible or nonvisible lesions. Most genital herpes infections are transmitted by individuals unaware that they have an infection. Many have mild or unrecognized infections but still shed the herpes virus intermittently. HSV is transmitted primarily by direct contact with an infected individual who is shedding the virus. Kissing, sexual contact, including oral sex, and vaginal birth are means of transmission. The virus replicates at the site of infection, then travels to the dorsal root ganglia and remains latent until stimuli such as fever, stress, ultraviolet radiation, or immunosuppression occurs and reactivates it (Albrecht, 2019).

Having sex with an infected partner places the individual at risk for contracting HSV. After the primary outbreak, the virus remains dormant in the nerve cells for life, resulting in periodic recurrent outbreaks. Recurrent genital herpes outbreaks are triggered by precipitating factors such as emotional stress, menses, and sexual intercourse, but more than half of recurrences occur without a precipitating cause. Immunocompromised women have more frequent and more severe recurrent outbreaks than normal hosts (Office of Population Affairs, 2019a).

Living with genital herpes can be difficult due to the erratic, recurrent nature of the infection, the location of the lesions, the unknown causes of the recurrences, and the lack of a cure. Further, the stigma associated with this infection may affect the individual's feelings about herself and her interaction with partners. Potential psychosocial consequences may include emotional distress, isolation, fear of rejection by a partner, fear of transmission of the disease, loss of confidence, and altered interpersonal relationships (Boskey, 2019).

Along with the increase in the incidence of genital herpes has been an increase in neonatal herpes simplex viral infections, which are associated with a high incidence of mortality and morbidity. The risk of neonatal infection with a primary maternal outbreak is between 30% and 50%; it is less than 1% with a recurrent maternal infection (CDC, 2019f).

Therapeutic Management

No cure exists, but antiviral drug therapy helps to reduce or suppress symptoms, shedding, and recurrent episodes. Advances in treatment with acyclovir 400 mg orally three times daily for 7 to 10 days, famciclovir 250 mg orally three times daily for 7 to 10 days, and valacyclovir 1 g orally twice daily for 7 to 10 days have resulted in an improved quality of life for those infected with HSV. However, these drugs neither eradicate latent virus nor affect the risk, frequency, or severity of recurrences after the drug is discontinued (CDC, 2019f). Suppressive therapy is recommended for individuals with six or more recurrences per year. The natural course of the disease is for recurrences to be less frequent over time.

The management of genital herpes includes antiviral therapy. The safety of antiviral therapy has not been established during pregnancy. Disclosure of this lifelong viral infection is often a challenge for individuals living with genital herpes. Therapeutic management also includes counseling regarding the natural history of the disease, the risk of sexual and perinatal transmission, and the use of methods to prevent further spread. The following are a few

guidelines to delivering information in a time-limited environment: (a) use all available client reading materials; (b) have another knowledgeable staff member in the office who can spend extra time with women who need it; (c) refer clients to good and accurate websites such as the ASHA (http://www.ashasexualhealth.org/); (d) know the phone numbers of herpes support groups in your area; (e) educate the client to abstain from all sexual activity until HSV lesions resolve; (f) use good hand washing technique to prevent spread; (g) educate that there is no cure, and that practicing safe sex (using condoms) with every sex act is essential to prevent transmission; and (h) encourage all clients to inform their current sex partners that they have genital herpes and to inform future partners before initiating a sexual relationship. Finally, many experts recommend a sympathetic, nonjudgmental approach. The nurse can state in clear terms that having herpes does not change the core of the person or make them less worthwhile (Luthi, 2019).

Nursing Assessment

Assess the client for clinical manifestations of HSV. Clinical manifestations can be divided into the primary episode and recurrent infections. The first or primary episode is usually the most severe, with a prolonged period of viral shedding. Primary HSV is a systemic disease characterized by multiple painful vesicular lesions, mucopurulent discharge, superinfection with candida, fever, chills, malaise, dysuria, headache, genital irritation, inguinal tenderness, and lymphadenopathy. The lesions in the primary herpes episode are frequently located on the vulva, vagina, and perineal areas. The vesicles will open and weep and finally crust over, dry, and disappear without scar formation (Fig. 5.5). This viral shedding process usually takes up to 2 weeks to complete.

Recurrent infection episodes are usually much milder and shorter in duration than the primary one. Tingling, itching, pain, unilateral genital lesions, and a more rapid resolution of lesions are characteristics of recurrent infections. Recurrent herpes is a localized disease characterized by typical HSV lesions at the site of

initial viral entry. Recurrent herpes lesions are fewer in number and less painful and resolve more rapidly (King et al., 2019).

Diagnosis of HSV is often based on clinical signs and symptoms and is confirmed by viral culture of fluid from the vesicle. Papanicolaou (Pap) smears are an insensitive and nonspecific diagnostic test for HSV and should not be relied on for diagnosis. The woman should be tested for all common STIs, especially if she has a new sexual partner. Hopefully, the woman would initiate an open conversation with her sexual partner about the risk of transmission and the need for safer-sexual practices.

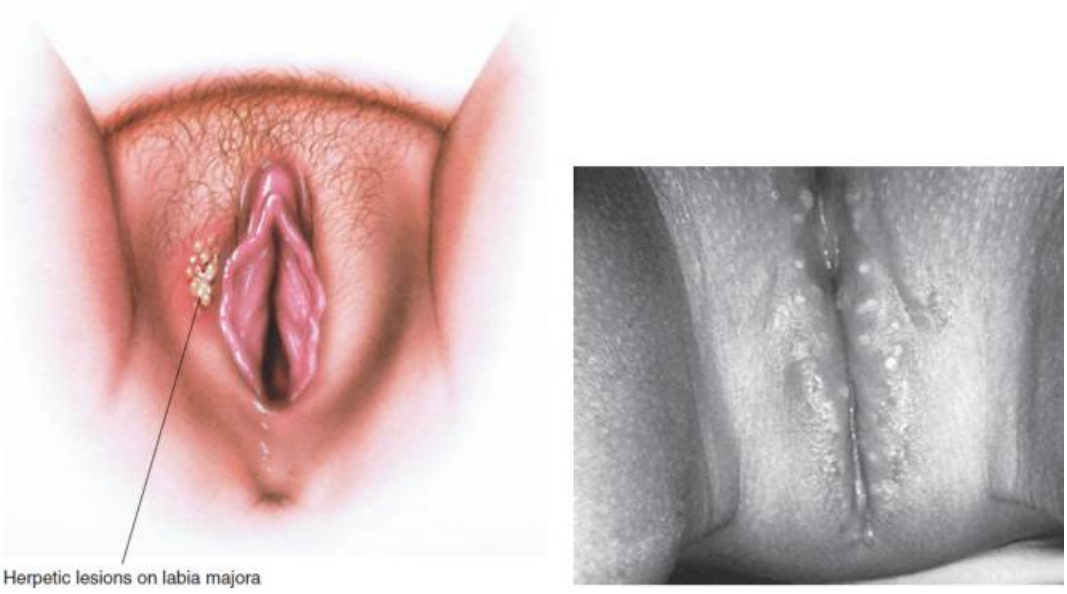

FIGURE 5.5. Genital herpes simplex. (Illustration provided by Anatomical Chart Co. Photograph courtesy of Stephen Ludwig, MD.)

Syphilis

Syphilis is a chronic, multistage, curable bacterial infection caused by the spirochete *Treponema pallidum* that is typically transmitted sexually with an infected partner or congenitally from an infected mother to her fetus. It is a serious systemic disease that can lead to disability and death if untreated. Rates of syphilis in the United States are increasing. Of primary and secondary syphilis cases, 75% occur in men who have sex with men (CDC, 2019o). It continues to

be one of the most important STIs both because of its biologic effect on HIV acquisition and transmission and because of its impact on infant health. Because there is no vaccine to prevent syphilis, control is mainly dependent on the identification and treatment of infected individuals and their contacts with benzathine penicillin given intramuscularly, the first-line drug for all stages of syphilis (Carter et al., 2018).

The spirochete rapidly penetrates intact mucous membranes or microscopic lesions in the skin and within hours enters the lymphatic system and bloodstream to produce a systemic infection long before the appearance of a primary lesion. The site of entry may be vaginal, rectal, or oral (Hussain & Vaidya, 2019). The syphilis spirochete can cross the placenta at any time during pregnancy. One out of every 10,000 infants born in the United States and one out of every million pregnancies worldwide have a child born with congenital syphilis (CDC, 2019o). Maternal infection consequences include spontaneous abortion, low birth weight, fetal growth restriction, prematurity, stillbirth, and multisystem failure of the heart, lungs, spleen, liver, and pancreas, as well as structural bone damage and nervous system involvement and mental retardation (Cunningham et al., 2018). Most newborns born with congenital syphilis are exposed in utero after the fourth month of pregnancy, although syphilis acquired late in the third trimester can also be transmitted to an infant through exposure to an active genital lesion at the time of birth. If untreated, syphilis is a lifelong infection progressing in orderly staging. The five stages of syphilis infection are: (1) primary, (2) secondary, (3) early latent, (4) late latent, and (5) tertiary. The primary, secondary, and early latent stages are considered the most infectious: the estimated risk of per person transmission is 60% (Ryan et al., 2020).

Therapeutic Management

Fortunately, there is effective treatment for syphilis. Benzathine penicillin G, administered by either the IM or intravenous route, is the preferred drug for all stages of syphilis. For pregnant or nonpregnant

women with syphilis of less than 1 year's duration, the CDC recommends 2.4 million units of benzathine penicillin G intramuscularly in a single dose. If the syphilis is of longer duration (more than 1 year) or of unknown duration, 2.4 million units of benzathine penicillin G is given intramuscularly once a week for 3 weeks. The preparations used, the dosage, and the length of treatment depend on the stage and clinical manifestations of disease (CDC, 2019o). Other medications, such as doxycycline, are available if the client is allergic to penicillin.

Women should be re-evaluated at 6 and 12 months after treatment for primary or secondary syphilis with additional serologic testing. Women with latent syphilis should be followed clinically and serologically at 6, 12, and 24 months and also tested for HIV (Sukhija-Cohen et al., 2019).

Nursing Assessment

Assess the client for clinical manifestations of syphilis. Syphilis is divided into four stages: primary, secondary, latency, and tertiary. Primary syphilis is characterized by a chancre (painless ulcer) at the site of bacterial entry that will disappear within 1 to 6 weeks without intervention (Fig. 5.6). Motile spirochetes are present on dark-field examination of ulcer exudate. In addition, painless bilateral adenopathy is present during this highly infectious period. If left untreated, the infection progresses to the secondary stage. Secondary syphilis appears 2 to 6 months after the initial exposure and is manifested by flu-like symptoms and a maculopapular rash of the trunk, palms, and soles. Alopecia and adenopathy are both common during this stage. In addition to rashes, secondary syphilis may present with symptoms of fever, pharyngitis, weight loss, and fatigue (Ryan et al., 2020). The secondary stage of syphilis lasts about 2 years. Once the secondary stage subsides, the latency period begins. This stage is characterized by the absence of any clinical manifestations of disease, although the serology is positive. This stage can last as long as 20 years. If not treated, tertiary or late syphilis occurs, with life-threatening heart disease and neurologic

disease that slowly destroys the heart, eyes, brain, central nervous system, and skin.

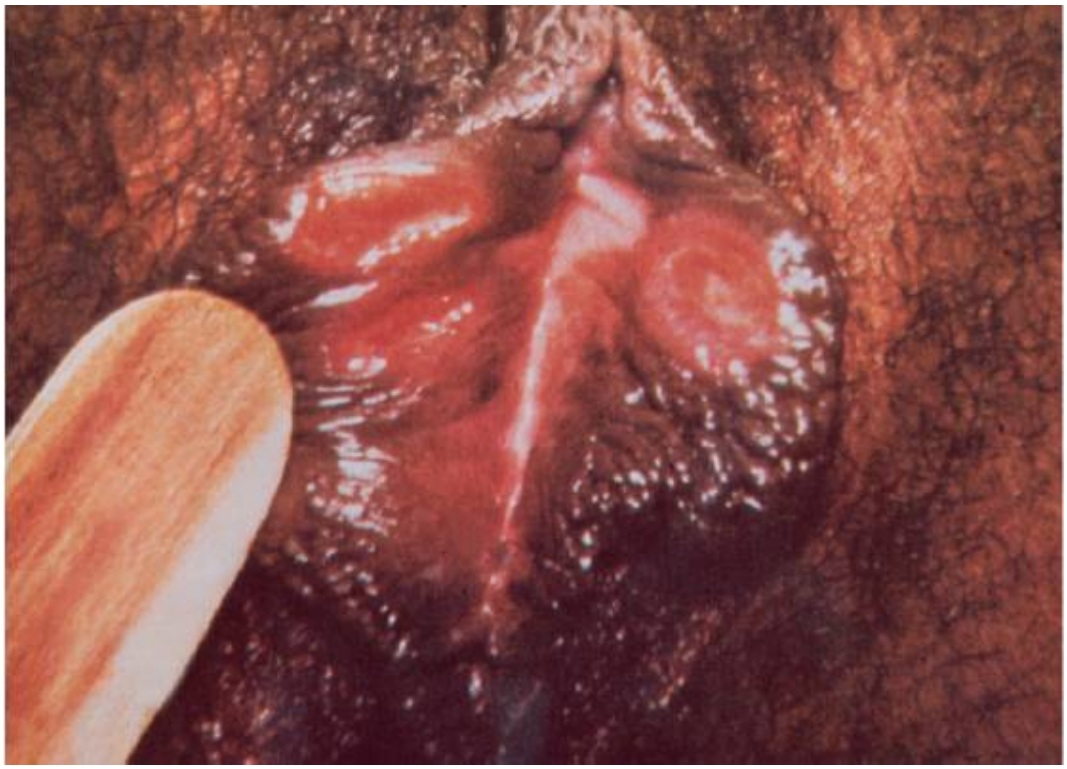

FIGURE 5.6. Chancre of primary syphilis. (From Sweet, R. L., Gibbs, R. S. [2005]. *Atlas of infectious diseases of the female genital tract*. Lippincott Williams & Wilkins.)

Clients with a diagnosis of HIV or another STI should be screened for syphilis, and all pregnant women should be screened at their first prenatal visit. Dark-field microscopic examinations and direct fluorescent antibody tests of lesion exudate or tissue are the definitive methods for diagnosing early syphilis. A presumptive diagnosis can be made by using two serologic tests:

- Nontreponemal tests (Venereal Disease Research Laboratory [VDRL] and rapid plasma reagin [RPR])
- Treponemal tests (fluorescent treponemal antibody absorbed [FTA-ABS] and *T. pallidum* particle agglutination [TP-PA]). Dark-field microscopic examinations and direct fluorescent antibody tests of lesion exudate or tissue are the definitive methods for diagnosing early syphilis (CDC, 2019o)

Nursing Management of Herpes and Syphilis

Genital ulcers from either herpes or syphilis can be devastating to women, and the nurse can be instrumental in helping her through this difficult time. Referral to a support group may be helpful. Address the psychosocial aspects of these STIs with women by discussing appropriate coping skills, acceptance of the lifelong nature of the condition (herpes), and options for treatment and rehabilitation. Teaching Guidelines 5.3 highlights appropriate teaching points for the client with genital ulcers.

TEACHING GUIDELINES 5.3
Caring for Genital Ulcers

- Abstain from intercourse during the prodromal period and when lesions are present.
- Wash hands with soap and water after touching lesions to avoid autoinoculation.
- Use comfort measures such as wearing nonconstricting clothes, wearing cotton underwear, urinating in water if urination is painful, taking lukewarm sitz baths, and air-drying lesions with a hair dryer on low heat.
- Avoid extremes of temperature such as ice packs or hot pads to the genital area as well as application of steroid creams, sprays, or gels.
- Use condoms with all new or noninfected partners.
- Inform health care professionals of your condition.

PELVIC INFLAMMATORY DISEASE (PID)

PID is an infection-induced inflammation of the female upper reproductive tract. PID rates remain unacceptably high. PID may involve the uterine lining (endometritis), the connective tissue adjacent to the uterus (parametritis), the Fallopian tubes (salpingitis), or the serous membrane that lines part of the abdominal cavity and viscera (peritonitis), or it may manifest as tubo-ovarian abscess

(Wiesenfeld, 2019). PID results from an ascending polymicrobial infection of the upper female reproductive tract, frequently caused by untreated chlamydia or gonorrhea (Fig. 5.7). Over a million women experience an episode of PID annually, resulting in over100,000 becoming infertile. One in eight women with a history of PID experiences difficulty getting pregnant (CDC, 2019m). Complications include ectopic pregnancy, pelvic abscess, subfertility, recurrent or chronic episodes of the disease, chronic abdominal pain, pelvic adhesions, and depression (Tough DeSapri & Christmas, 2019). Because most PID cases are secondary to STIs, especially chlamydia, the most effective approach to control it is prevention. Because of the seriousness of the complications of PID, an accurate diagnosis is critical (*Healthy People 2030*).

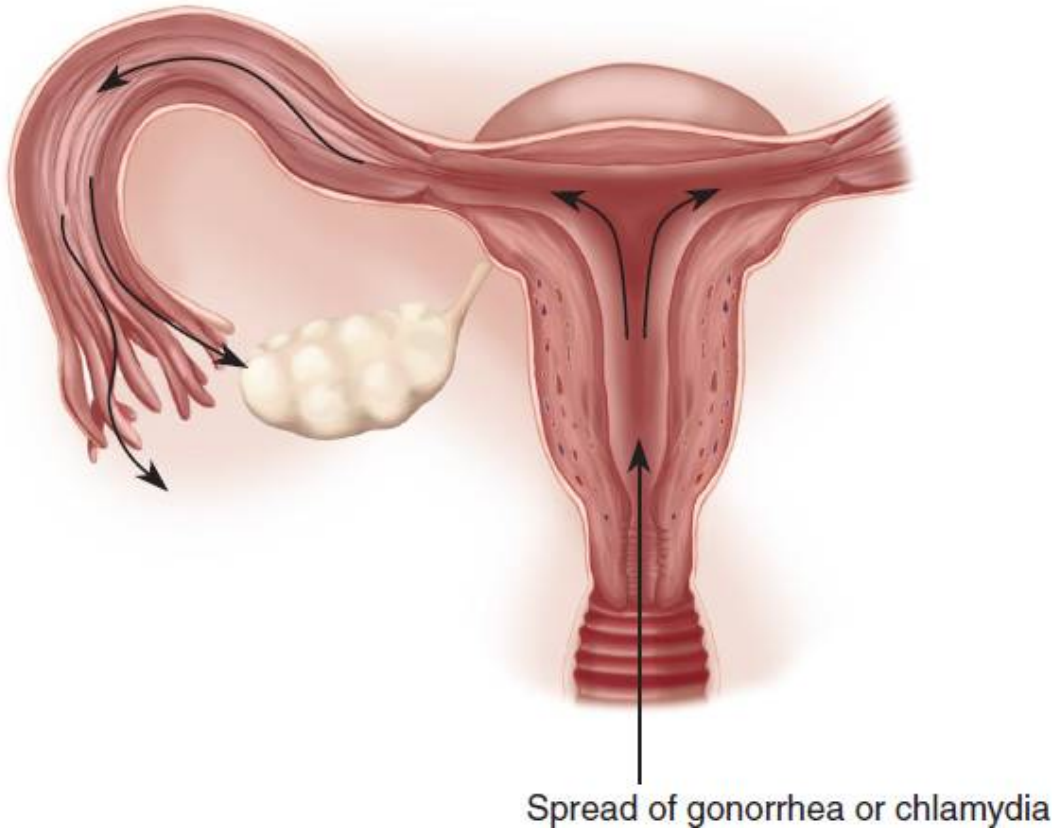

FIGURE 5.7. Pelvic inflammatory disease. Chlamydia or gonorrhea spreads up the vagina into the uterus and then to the fallopian tubes and ovaries.

HEALTHY PEOPLE *2030*

Objective	Significance
STD-2030-05 Reduce pelvic inflammatory disease in women aged 15 to 24 years.	Educate women that abstinence is the only way to completely avoid contracting sexually transmitted infections. Encourage women always to use condoms if participating in any sexual act. Provide an open and confidential environment so women will report symptoms and seek treatment earlier.

Adapted from USDHHS. (2020). *Proposed objectives for inclusion in Healthy People 2030.* https://www.healthypeople.gov/sites/default/files/ObjectivesPublicComment508.pdf

Therapeutic Management

Broad-spectrum antibiotic therapy is generally required to cover chlamydia, gonorrhea, and/or any anaerobic infection. A parenteral cephalosporin in a single injection with doxycycline 100 mg twice a day for 14 days is the current CDC recommendation (CDC, 2019m). PID in pregnancy is uncommon, but a combination of cefotaxime, azithromycin, and metronidazole for 14 days may be used. The client is treated on an ambulatory basis with a single-dose injectable antibiotic or is hospitalized and given antibiotics intravenously. The decision to hospitalize a woman is based on clinical judgment and the severity of her symptoms (e.g., severely ill with high fever, a tubo-ovarian abscess is suspected, woman is immunocompromised or presents with protracted vomiting). Treatment then includes intravenous antibiotics, increased oral fluids to improve hydration, bed rest, and pain management. Follow-up is needed to validate that the infectious process is gone to prevent the development of chronic pelvic pain.

Nursing Assessment

Nursing assessment of the woman with PID involves a complete health history and assessment of clinical manifestations, physical

examination, and laboratory and diagnostic testing. It is imperative that a woman's sexual health be assessed at each visit, specifically among those of reproductive age—15 to 44 years. An appropriate sexual history (e.g., the five Ps: partners, practices, prevention of pregnancy, protection from STIs, and past history of STIs) should be obtained. The answers to these questions will help to guide education on sexual health.

Health History and Clinical Manifestations

Explore the client's current and past medical health history for risk factors for PID, which may include:

- Adolescence or young adulthood
- Non-White female
- Having multiple sex partners
- Early onset of sexual activity
- History of PID or STI
- Sexual intercourse at an early age
- Alcohol or drug use
- Having intercourse with a partner who has untreated urethritis
- Recent insertion of an intrauterine contraceptive (IUC)
- Nulliparity
- Cigarette smoking
- Recent termination of pregnancy
- Lack of consistent condom use
- Lack of contraceptive use
- Douching
- Prostitution (Reekie et al., 2019)

Assess the client for clinical manifestations of PID, keeping in mind that because of the wide variety of clinical manifestations of PID, clinical diagnosis can be challenging. To reduce the risk of missed diagnosis, the CDC has established criteria to establish the diagnosis of PID. Minimal criteria (all must be present) are lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness. Additional supportive criteria that support a diagnosis of PID are:

- Abnormal cervical or vaginal mucopurulent discharge
- Oral temperature above 101° F
- Cervical motion tenderness
- Elevated erythrocyte sedimentation rate (inflammatory process)
- Elevated C-reactive protein level (inflammatory process)
- *N. gonorrhoeae* or *C. trachomatis* infection documented (causative bacterial organism)
- White blood cells on saline vaginal smear
- Prolonged or increased menstrual bleeding
- Dysmenorrhea
- Dysuria
- Painful sexual intercourse
- Nausea
- Vomiting (CDC, 2019m)

Physical Examination and Laboratory and Diagnostic Tests

Inspect the client for presence of fever (usually over 101° F) or vaginal discharge. Palpate the abdomen, noting tenderness over the uterus or ovaries. However, the only way to diagnose PID definitively is through an endometrial biopsy, transvaginal ultrasound, or laparoscopic examination.

Nursing Management

If the woman with PID is hospitalized, maintain hydration via intravenous fluids, if necessary and administer analgesics as needed for pain. Semi-Fowler positioning facilitates pelvic drainage. A key element to treatment of PID is education to prevent recurrence. Depending on the clinical setting (hospital or community clinic) where the nurse encounters the woman diagnosed with PID, a risk assessment should be done to ascertain what interventions are appropriate to prevent a recurrence. To gain the woman's cooperation, explain the various diagnostic tests needed. Discuss the implications of PID and the risk factors for the infection; her sexual partner should be included if possible. Sexual counseling

should include practicing safer sex, limiting the number of sexual partners, using barrier contraceptives consistently, avoiding vaginal douching, considering another contraceptive method if she has an intrauterine system (IUS) and has multiple sexual partners, and completing the course of antibiotics prescribed. Nurses who provide reproductive health care to women serve an important role in safeguarding their health and curbing the increasing incidence of STIs in the United States. This can be achieved by protecting them from STI-related morbidity with appropriate screening and treatment of STIs using all currently available options, including expedited partner therapy to prevent reinfection (Jamison et al., 2019). Review the serious sequelae that may occur if the condition is not treated or if the woman does not comply with the treatment plan. Ask the woman to have her partner go for evaluation and treatment to prevent a repeat infection. Provide nonjudgmental support while stressing the importance of barrier contraceptive methods and follow-up care. Teaching Guidelines 5.4 gives further information related to PID prevention.

TEACHING GUIDELINES 5.4
Preventing Pelvic Inflammatory Disease

- Advise sexually active girls and women to insist their partners use condoms.
- Discourage routine vaginal douching, as this may lead to bacterial overgrowth.
- Encourage regular STI screening.
- Emphasize the importance of having each sexual partner receive antibiotic treatment.

VACCINE-PREVENTABLE STIS

Some STIs can be effectively prevented through pre-exposure vaccination. Vaccines are under development or are undergoing clinical trials for certain STIs, including HIV and HSV. However, the

only vaccines currently available are for prevention of HAV, HBV, and HPV infection. Vaccination efforts focus largely on integrating the use of these available vaccines into STI prevention and treatment activities (CDC, 2019n). The National Institutes of Health (NIH) recently provided $50 million in grant monies over 5 years to four cooperative research centers to focus on developing vaccines to prevent bacteria that cause syphilis, gonorrhea, and chlamydia infections (NIH, 2019).

Human Papillomavirus

HPV is the most common viral infection in the United States, with an estimated 80% of sexually active people contracting it at some point in their lives (CDC, 2019g). Genital warts or condylomata (Greek for "warts") are caused by HPV. Conservative estimates suggest that in the United States, approximately 80 million people have productive HPV infection, and 14 million Americans acquire it annually (CDC, 2019g). Research has confirmed that HPV is the cause of essentially all cases of cervical, vulvar, vaginal, penile, anal, and oropharyngeal cancers (American Cancer Society [ACS], 2017). HPV-mediated oncogenesis is responsible for up to 99% of cervical squamous cell carcinomas and nearly all preinvasive cervical neoplasms (National Cancer Institute [NCI], 2019a). More than 40 types of HPV can infect the genital tract. HPV is most prevalent in young women between the ages of 20 and 24 years, followed closely by the 15- to 19-year-old age group (WHO, 2019c).

TAKE NOTE!

Most sexually active men and women will get HPV at some point in their lives. This means everyone is at risk (CDC, 2019g).

Nursing Assessment

Nursing assessment of the woman with HPV involves a complete health history and assessment of clinical manifestations, physical examination, and laboratory and diagnostic testing.

Health History and Clinical Manifestations

Assess the client's health history for risk factors for HPV, which include having multiple sex partners, ages 15 to 25 years, sex with a male who has had multiple sexual partners, and first intercourse at 16 years or younger (NCI, 2019b). Risk factors contributing to the development of cervical cancer include smoking, few or no screenings for cervical cancer, multiple sex partners, weakened immune system, nulliparity, long-term contraceptive use (more than 2 years), coinfection with another STI, pregnancy, nutritional deficiencies, and early onset of sexual activity (WHO, 2019c).

Assess the client for clinical manifestations of HPV. Most HPV infections are asymptomatic, unrecognized, or subclinical. Visible genital warts are usually caused by HPV types 6 or 11. In addition to the external genitalia, genital warts can occur on the cervix and in the vagina, urethra, anus, and mouth. Depending on the size and location, genital warts can be painful, friable, and pruritic, although most are typically asymptomatic (Fig. 5.8). The strains of HPV associated with genital warts are considered low risk for development of cervical cancer, but other HPV types (16, 18, 31, 33, 45, 52, and 58) have been strongly associated with cervical cancer (CDC, 2019g).

Physical Examination and Laboratory and Diagnostic Tests

Clinically, visible warts are diagnosed by inspection. The warts are fleshy papules with a warty, granular surface. Lesions can grow very large during pregnancy, affecting urination, defecation, mobility, and descent of the fetus (CDC, 2019g). Large lesions, which may resemble cauliflowers, exist in coalesced clusters and bleed easily.

FIGURE 5.8. Genital warts. (Illustration provided by Anatomical Chart Co. Photograph from Gorbach, S. L., Bartlett, J. G., & Blacklow, N. R. [2004]. *Infectious diseases*. Lippincott Williams & Wilkins.)

Serial Pap smears are performed for low-risk women. These regular Pap smears will detect the cellular changes associated with HPV. The FDA has approved an HPV test as a follow-up for women who have an ambiguous Pap test. In addition, this HPV test may be a helpful addition to the Pap test for general screening of women aged 30 years and above. The HPV test is a diagnostic test that can determine the specific HPV strain, which is useful in discriminating between low-risk and high-risk HPV types. A specimen for testing can be obtained with a fluid-phase collection system such as Thin Prep. The HPV test can identify several of the high-risk types of HPV associated with the development of cervical cancer and can detect high-risk types of HPV even before there are any conclusive visible changes to the cervical cells. If the test is positive for the high-risk types of HPV, the woman should be referred for colposcopy.

Upon physical examination, it is determined that Sandy has genital warts. The nurse finds out that Sandy engaged in high-risk behavior with a stranger she "hooked up" with recently at college. She couldn't imagine that he would give her an STI because "he looked so clean-cut." She wonders how she could possibly have genital warts. What information should be given to Sandy about STIs in general? What specific information about HPV should be stressed?

Therapeutic Management

There is currently no medical treatment or cure for HPV. Instead, therapeutic management focuses heavily on prevention through the use of the HPV vaccine and education and on the treatment of lesions and warts caused by HPV. The CDC recommends that children start receiving two doses of the HPV vaccine around 11 or 12 years old. Two doses are needed for those vaccinated before 15; while three are recommended for older people. It also recommends adults ages 27 through 45 who had not been adequately vaccinated make shared decisions with their doctors about getting vaccinated. In the United States, only the 9-valent vaccine, which covers 90% of the cancers attributed to HPV in U.S. registries, is available. Because higher titers are found at younger ages, two rather than three doses are needed if the first dose is given prior to age 15 years. Gardasil 9 is effective against HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58 (Braverman, 2019). Prophylactic HPV vaccines are safe, well tolerated, and highly efficacious in preventing persistent infections and cervical/penile and oropharyngeal diseases associated with vaccine-HPV types among young males and females.

The vaccine is administered intramuscularly in two or three separate doses. The first dose may be given to any individual 9 to 14 years old prior to infection with HPV. The second dose is administered within 6 to 12 months later. For persons 15 through 45 years of age, Gardasil 9 is given using a 3-dose schedule; the second dose should be given 2 months after the first dose and the third dose should be given 6 months after the first injection (Merck & Company, 2019). The deltoid region of the upper arm or anterolateral area of the thigh may be used. The most common vaccine side effects include pain, fainting, redness, and swelling at the injection site; fatigue; headache; muscle and joint aches; and gastrointestinal distress. The vaccine is given in a series of two or three injections depending on the age of the individuals (CDC, 2019g).

If the woman doesn't receive primary prevention with the vaccine, then secondary prevention would focus on education about the

importance of receiving regular Pap smears including an HPV test to determine whether the woman has a latent high-risk virus that could lead to precancerous cervical changes. No definitive evidence suggests that any one recommended treatment is superior to another, and no single treatment is ideal for all patients or all warts. Finally, treatment options for precancerous cervical lesions or genital warts caused by HPV are numerous and may include:

- Topical trichloroacetic acid 80% to 90%
- Liquid nitrogen cryotherapy
- Topical imiquimod 5% cream
- Topical podophyllin 10% to 25%
- Sinecatechins 15% ointment
- Laser carbon dioxide vaporization
- Client-applied podofilox 0.5% solution or gel
- Simple surgical excision
- Loop electrosurgical excisional procedure (LEEP)
- Intralesional interferon therapy (CDC, 2019a)

The goal of treating genital warts is to remove the warts and induce wart-free periods for the client. Treatment of genital warts should be guided by the preference of the client and available resources. No single treatment has been found to be ideal for all clients, and most treatment modalities appear to have comparable efficacy. Because genital warts can proliferate and become friable during pregnancy, they should be removed using a local agent. A cesarean birth is not indicated solely to prevent transmission of HPV infection to the newborn, unless the pelvic outlet is obstructed by warts (Morris, 2019).

Nursing Management

An HPV infection has many implications for the woman's health, but most women are unaware of HPV and its role in cervical cancer. The average age of sexual debut is in early adolescence; therefore, it is important to target this population for use of the HPV/cervical cancer vaccine.

Key nursing roles are teaching about prevention of HPV infection and client education and promotion of vaccines and screening tests to reduce the morbidity and mortality associated with cervical cancer caused by HPV infection. Teach all women that the only way to prevent HPV is to refrain from any genital contact with another person. Although the effect of condoms in preventing HPV infection is unknown, latex condom use has been associated with a lower rate of cervical cancer. Teach women about the link between HPV and cervical cancer. Explain that, in most cases, there are no signs or symptoms of infection with HPV. Strongly encourage all young women to consider getting Gardasil 9 vaccine to prevent HPV. For all women, promote the importance of obtaining regular Pap smears and, for women over 30 years, suggest an HPV test to rule out the presence of a latent high-risk strain of HPV.

Education and counseling are important aspects of managing women with genital warts. Teach the woman that:

- even after genital warts are removed, HPV remains, and viral shedding will continue.
- the likelihood of transmission to future partners and the duration of infectivity after treatment for genital warts are unknown.
- the recurrence of genital warts within the first few months after treatment is common and usually indicates recurrence rather than reinfection (CDC, 2019g).

Hepatitis A and B

Hepatitis is an acute, systemic, viral infection that can be transmitted sexually. The viruses associated with hepatitis or inflammation of the liver are hepatitis A, B, C, D, E, and G. Hepatitis A virus (HAV) is primarily transmitted fecal–orally after close contact with an infected person; it is the most common cause of viral hepatitis worldwide. It can be acquired by drinking polluted water, by eating uncooked shellfish from sewage-contaminated waters or food handled by a hepatitis carrier with poor hygiene, and from oral/anal sexual contact, by men having sex with men (MSM). Approximately 33% of the U.S. population has serologic evidence of prior hepatitis A infection; the

rate increases directly with age. Increasing vaccination among groups at risk for hepatitis A infection might halt ongoing outbreaks and prevent future outbreaks (Foster et al., 2019).

Hepatitis B (HBV) is transmitted through saliva, blood serum, semen, menstrual blood, and vaginal secretions. The incubation period from the time of exposure to onset of symptoms is 6 weeks to 6 months. The virus can survive outside the body for at least 7 days (CDC, 2019j). The highest transmission rate is among heterosexual partners among men who have sex with men. The WHO estimates that the prevalence of hepatitis B worldwide is over 2 billion people, with about 257 million chronically infected with it. Worldwide, hepatitis B has the highest death rate of any STI except HIV (WHO, 2019a). Risk factors for infection include having multiple sex partners, engaging in unprotected receptive anal intercourse, and having a history of other STIs (CDC, 2019j). The most effective means to prevent the transmission of hepatitis A or B is pre-exposure immunization. Vaccines are available for the prevention of HAV and HBV, both of which can be transmitted sexually. Every person seeking treatment for an STI should be considered a candidate for hepatitis B vaccination, and some individuals (e.g., men who have sex with men, and injection-drug users) should be considered for hepatitis A vaccination (CDC, 2019j).

Therapeutic Management

Unlike other STIs, HBV and HAV are preventable through immunization. HAV is usually self-limiting and does not result in chronic infection. HBV can result in serious, permanent liver damage. Treatment is generally supportive. No specific treatment for acute HBV infection exists.

Nursing Assessment

Assess the client for clinical manifestations of hepatitis A and B. Hepatitis A produces flu-like symptoms with malaise, skin rashes, fatigue, anorexia, nausea, pruritus, fever, and upper right quadrant

pain. Symptoms of hepatitis B are like those of hepatitis A, but with less fever and skin involvement. The diagnosis of hepatitis A cannot be made based on clinical manifestations alone and requires serologic testing. The presence of IgM antibody to HAV is diagnostic of acute HAV infection. Hepatitis B is detected by a blood test that looks for antibodies and proteins produced by the virus and is positively diagnosed by the presence of hepatitis B surface antibody (HBsAb) (Pyrsopoulos & Reddy, 2019).

Nursing Management

Nurses should encourage all women to be screened for hepatitis when they have their annual Pap smear, or sooner if high-risk behavior is identified. Nurses should also encourage women to undergo HBV screening at their first prenatal visit and repeat screening in the last trimester for women with high-risk behaviors (Wilkins et al., 2019). Nurses can also explain that hepatitis B vaccine is given to all infants after birth in most hospitals. The vaccination consists of a series of three injections given within 6 months. The vaccine has been shown to be safe and well tolerated by most recipients (CDC, 2019j). Hepatitis A vaccine is strongly encouraged for children between 12 and 23 months; persons 1 year of age and older traveling to countries with a high prevalence of hepatitis A, such as Central or South America, Mexico, Asia, Africa, and eastern Europe; men who have sex with men; persons who use street drugs; and persons with chronic liver disease (CDC, 2019j). For others, hepatitis A vaccine series (two doses 6 months apart) may be started whenever a person is at risk of infection.

Hepatitis C

Although HCV is not transmitted sexually, it deserves a brief mention here because injection-drug use by women places them at risk for it. It infects humans only and primarily targets liver cells. Women at high risk include those with a history of injecting-drug use, nonsterile tattooing, HIV+ status, STIs, multiple sexual partners, and those with

a history of blood transfusion or organ transplant before 1992 (CDC, 2019k). The prevalence of HCV infection in pregnant women is approximately 1%. Most infected women are not aware they have HCV because they are not clinically ill. Perinatal transmission of HCV is relatively rare, except in women who are immunocompromised (HIV/AIDS) (Cunningham et al., 2018).

Zika Virus

Zika virus has been identified as being transmitted in humans by sexual activity, by perinatal transmission, and by blood transfusion. The primary method of transmission is by a mosquito bite from the *Aedes aegypti* mosquito which lives in tropical climates. Most Zika virus cases are found in southeastern states, Southeast Asia and South America. Eighty percent of clients who acquire infection are completely asymptomatic (Resnik et al., 2019).

Having a Zika infection during pregnancy can cause devastating damage to the fetus's central nervous system. It is associated with microcephaly, ventriculomegaly, calcifications, placentomegaly, motor abnormalities, epilepsy, hearing loss, neurologic impairments, ophthalmologic abnormalities, intrauterine growth restriction, and stillbirth (Pomar et al., 2019).

There is no vaccine or antiviral prophylaxis therapy that prevents Zika virus currently, although vaccine development is being researched. The key preventive measures include avoid traveling to areas where Zika virus is endemic; use preventive measures to avoid mosquito bites; use effective mosquito repellants, and use condoms during sexual activity. Treatment of a Zika virus infection is supportive at this time.

ECTOPARASITIC INFECTIONS

Ectoparasites are a common cause of skin rash and pruritus throughout the world, affecting people of all ages, races, and socioeconomic groups. Bedbugs, mites and scabies are

ectoparasites that commonly affect humans. Bedbugs (Cimex species) were once rare in the United States, but are now very common. They cause intensely pruritic lesions on exposed skin. Management of bedbugs includes symptomatic relief of itching and elimination of infestations. Overcrowding, delayed diagnosis and treatment, and poor public education contribute to the prevalence of ectoparasites in both industrial and nonindustrial nations. Approximately 300 million cases of ectoparasitic cases are reported worldwide each year (CDC, 2019e). These infections include infestations of scabies and pubic lice. Since these parasites are easily passed from one person to another during sexual intimacy, clients should be assessed for them when receiving care for other STIs. Scabies is an intensely pruritic dermatitis caused by a mite. Scabies affects 5% of the world's population. The female mite burrows under the skin and deposits eggs, which hatch. The lesions start as a small papule that reddens, erodes, and sometimes crusts. Diagnosis is based on history and appearance of burrows in the webs of the fingers and the genitalia. Management of scabies involves use of permethrin cream, oral ivermectin, or benzyl benzoate (Huntington et al., 2019).

Clients with pediculosis pubis (pubic lice), also known as "crabs," usually seek treatment because of the pruritus, because of a rash brought on by skin irritation from scratching, or because they notice lice or nits in their pubic hair, axillary hair, abdominal and thigh hair, and sometimes in the eyebrows, eyelashes, and beards. Infestation is usually asymptomatic until after a week or so, when bites cause pruritus and secondary infections from scratching (Fig. 5.9). Diagnosis is based on history and the presence of nits (small, shiny, yellow, oval, dewdrop-like eggs) affixed to hair shafts or lice (a yellowish, oval, wingless insect) (Bragg, 2019).

Treatment is directed at the infested area, using permethrin 1% cream rinse and pyrethrin with piperonyl butoxide, which are FDA approved for treating head lice. Both are available as over-the-counter (OTC) preparations. Repeat treatment in 1 week is advised to eradicate eggs that may have hatched after treatment started (King et al., 2019). Bedding and clothing should be washed in hot

water to decontaminate it. Sexual partners should be treated also, as well as family members who live in close contact with the infected person.

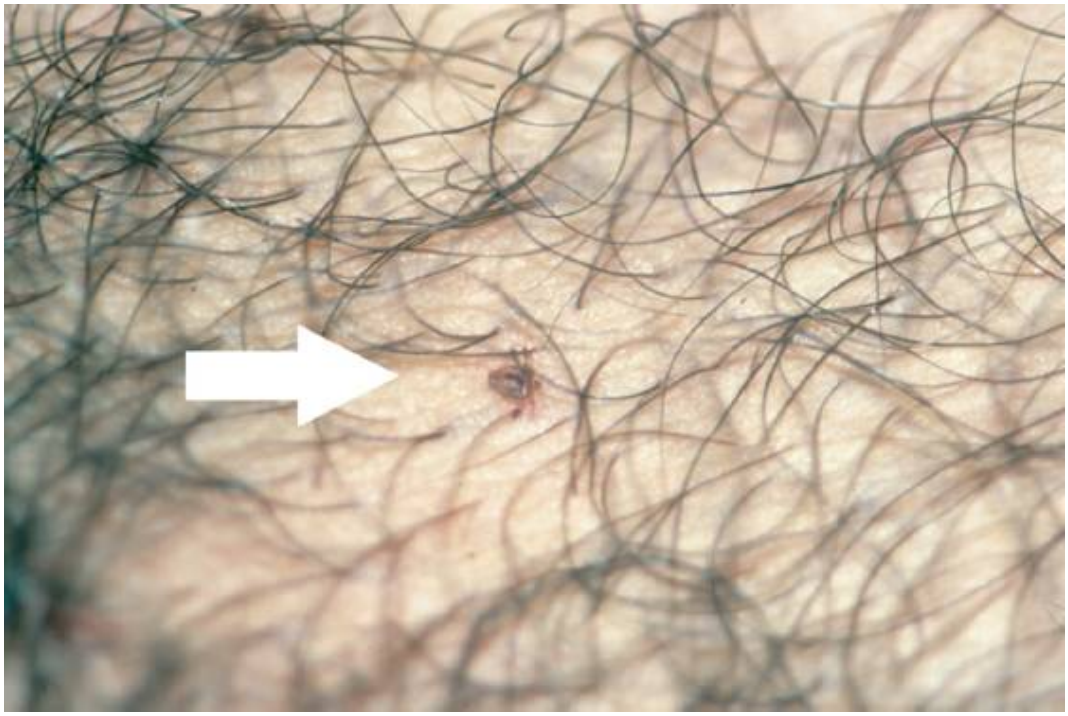

FIGURE 5.9. Pubic lice. A small brown living crab louse is seen at the base of hairs (*arrow*). (From Goodheart, H. [2009]. *Goodheart's photoguide of common skin disorders*. Lippincott Williams & Wilkins.)

Nursing care of a woman infested with lice or scabies involves a three-tiered approach: eradicating the infestation with medication, removing nits, and preventing spread or recurrence by managing the environment. All women should also be screened for other STIs. OTC products are safe for use and kill the active lice or mites. Nurses should provide education about these products (Teaching Guidelines 5.5). The nurse can follow these same guidelines to prevent the health care facility from becoming infested.

TEACHING GUIDELINES 5.5

Treating and Minimizing the Spread of Scabies and Pubic Lice

- Use the medication according to the manufacturer's instructions.
- Remove nits with a fine-toothed nit comb.
- Do not share any personal items with others or accept items from others.
- Treat objects, clothing, and bedding and wash them in hot water.
- Meticulously vacuum carpets to prevent a recurrence of infestation.

HUMAN IMMUNODEFICIENCY VIRUS (HIV)

HIV is the virus that causes AIDS and can be transmitted during sexual intercourse; when sharing needles; and from mother to child during pregnancy, childbirth or breastfeeding. Acquired immunodeficiency syndrome (AIDS) is a term which applies to the most advanced stages of HIV infection. It is defined by the occurrence of any of more than 20 opportunistic infections or HIV-related cancers. HIV is the cause of one of humanity's deadliest and most persistent epidemics and remains a major public health concern on every continent today.

An estimated 1.1 million people in the United States and 38 million globally currently live with HIV and new cases of HIV infection in the United States have remained stable at about 40,000 annually. One in seven are unaware they are infected (Kaiser Family Foundation, 2019). In terms of epidemiology, fatality rate, and its social, legal, ethical, and political aspects, HIV infection became a global public health crisis over 40 years ago and has generated more concern than any other infectious disease in modern medical history. More than 35 million people with AIDS have died since the beginning of the epidemic globally (CDC, 2019l). To date, there is no cure for this fatal viral infection.

The transmission patterns have shifted over time. Currently, most newly diagnosed cases of HIV occur through male-to-male sexual

contact. Transmission through heterosexual sex has declined. The District of Columbia has the highest rate of HIV in the nation. The top states are located in the south. New HIV diagnosis are concentrated primarily in large metropolitan areas, with Miami, Orlando, and Atlanta topping the list of the area's most heavily burdened. Approximately one in four people living with HIV infection in the United States are women (CDC, 2019l). HIV infection disproportionately affects African American and Hispanic women. Together they represent less than 25% of all U.S. women, yet they account for the majority of HIV infection cases. More than 250,000 women are living with HIV in the United States (CDC, 2019l).

Women are particularly vulnerable to heterosexual transmission of HIV due to substantial mucosal exposure to seminal fluids. This biologic fact amplifies the risk of HIV transmission when coupled with the high prevalence of nonconsensual sex, sex without condoms, and the unknown and/or high-risk behaviors of their partners (NIAID, 2019). Therefore, the face of HIV/AIDS is becoming the face of young women. That shift will ultimately exacerbate the incidence of HIV because women spread it not only through sex, but also through nursing and childbirth.

AIDS is a breakdown in the immune function caused by HIV, a retrovirus. The infected person develops opportunistic infections or malignancies that become fatal. Progression from HIV infection to AIDS varies within individuals. HIV affects CD4 cells in two ways: by depleting them and by impairing the remaining ones. This invasion of CD4 cells results in a gradual loss of immune function. If nothing is done to stop this invasion of CD4 cells, HIV can destroy as many as 1 billion CD4 cells daily (King et al., 2019).

TAKE NOTE!

Once the HIV infection has progressed to AIDS, the survival period is usually less than 5 years in untreated clients (WHO, 2019b).

The fetal and neonatal effects of acquiring HIV through perinatal transmission can be devastating. If the HIV-infected infant goes untreated, progression to AIDS and eventual fatality will occur. An infected mother can transmit HIV infection to her newborn before or during birth and through breastfeeding. Current incidence of perinatal transmission is less than 2% if HIV+ mother is taking antiretroviral medication during pregnancy. In the absence of any intervention, the risk of perinatal transmission of HIV infection is approximately 25% (Resnik et al., 2019).

HIV and Adolescents

As a typical function of development adolescents may view themselves as invincible, and thus delay seeking health care. They may be embarrassed or lack access to health care or may delay or refuse treatment if a diagnosis of HIV infection is made. Though the rates of HIV infection among adolescents have remained stable over time, the effects of HIV infection in this population continue to be of concern (CDC, 2019c). On average, the development of AIDS occurs about 2 to 15 years after infection, so most young adults with AIDS were infected during adolescence (WHO, 2019b).

Most HIV-infected adolescents are exposed to the virus through heterosexual or homosexual contact. The majority of HIV-infected adolescent males are infected through sex with other males, while female teenagers are mostly exposed through heterosexual contact. Injected drug use accounts for a small percentage of HIV infection among male and female adolescents. Similar to HIV infection in women, African American and Hispanic adolescents represent a disproportionate percentage of HIV infection among teenagers (USDHHS, 2019a). Millions of adolescents between the ages of 13 and 19 are living with HIV, and many do not receive the care and support they need to stay in good health or alive.

Clinical Manifestations

HIV infection undergoes three distinct phases—acute seroconversion, asymptomatic infection, and then progresses to AIDS. When a person is initially infected with HIV, he or she goes through an acute primary infection period for about 3 weeks. The HIV viral load drops rapidly because the host's immune system works well to fight this initial infection. The onset of the acute primary infection occurs 2 to 6 weeks after exposure. Symptoms include fever, pharyngitis, rash, and myalgia. Most people do not associate this flu-like condition with HIV infection. After initial exposure, there is a period of 3 to 12 months before seroconversion. The person is considered infectious during this time.

After the acute phase, the infected person becomes asymptomatic, but the HIV virus begins to replicate. Even though there are no symptoms, the immune system runs down. A normal person has a CD4 T-cell count of 450 to 1,200 cells/μL. When the CD4 T-cell count reaches 200 or less, the person has reached the stage of AIDS. The immune system begins a constant battle to fight this viral invasion, but over time it falls behind. A viral reservoir occurs in T cells that can store various stages of the virus. The onset and severity of the disease correlate directly with the viral load: the more HIV virus that is present, the worse the person will feel.

As profound immunosuppression begins to occur, opportunistic infections will occur, qualifying the person for the diagnosis of AIDS. The diagnosis is finally confirmed when the CD4 count is below 200. As of now, AIDS will eventually develop in everyone who is HIV-positive.

The WHO (2019b) recommends early initiation of ART for adults and adolescents, the delivery of more client-friendly antiretroviral (ARV) drugs, and prolonged use of ARVs to reduce the risk of mother-to-child transmission of HIV. ART should be started immediately after a positive HIV diagnosis. Also, WHO (2019b) recommends that HIV-positive mothers or their infants take ARVs while breastfeeding to prevent HIV transmission for up to 12 months after birth. Early and consistent antiretroviral treatment is essential in prolonging lives.

Diagnosis

HIV testing is regarded as the gateway to prevention and treatment. Several types of tests are approved to detect antigens, antibodies, or RNA. Screening for HIV infection is paramount, since infected individuals may remain asymptomatic for years while the infection progresses. Currently, there are three types of tests available: nucleic acid tests (NAT), antigen/antibody tests, and antibody tests. The initial screening test for HIV infection should be the HIV01/2 Antigen and Antibodies, Fourth Generation, with Reflexes. If this test is positive, the lab should automatically perform the Multispot test (Bio-Rad, Hercules, CA) an antibody differentiation immunoassay. If this second test is positive, the diagnosis of HIV infection is confirmed (Resnik et al., 2019).

People who are infected with HIV, but not aware of it are not able to take advantage of the therapies that can keep them healthy and extend their lives, nor do they have the knowledge to protect their sex or drug-use partners from becoming infected. Knowing whether one is positive or negative for HIV confers great benefits in healthy decision-making.

Therapeutic Management

Treatment of HIV depends on the stage of the disease and any concomitant opportunistic infection.

The goals of HIV drug therapy are to:

- decrease the HIV viral load below the level of detection.
- restore the body's ability to fight off pathogens.
- improve the client's quality of life.
- reduce HIV morbidity and mortality (King et al., 2019).

Antiretroviral therapy (ART) has dramatically improved the prognosis of HIV/AIDS. Treatment with ART should begin for any person with an AIDS-defining illness or as soon as possible after diagnosis. Long-acting injectable medication and oral medications are available to suppress the viral load.

Current therapy to prevent the transmission of HIV to the newborn includes having the mother take ART agents continually throughout pregnancy. During labor, an ART agent is administered intravenously until birth. An ART medication is administered to the infant within 6 to 12 hours after birth and continued for 6 weeks.

Dramatic new treatment advances with ART medications have turned a disease that used to be a death sentence into a chronic, manageable one for individuals who live in countries where ART is available. Despite these advances in treatment, however, only a minority of HIV-positive people in the United States who take ART medications are receiving the full benefits because they are not adhering to the prescribed regimen. Successful ART requires nearly perfect adherence to a complex medication regimen; less-than-perfect adherence leads to drug resistance (King et al., 2019).

Adherence is difficult because of the complexity of the regimen and the lifelong duration of treatment. Adherence is made even more difficult because of the unpleasant side effects, such as nausea and diarrhea. Women in early pregnancy already experience these, and the ART medication only exacerbates them.

Nursing Management

HIV treatment and prevention begins with knowing one's HIV status. If women are found to be living with HIV, effective treatments are available to help them live long, healthy lives and prevent HIV transmission to sexual partners. If HIV-negative, prevention tools are available—PrEP and PEP. A safe and effective vaccine is needed to ensure a durable end to this global epidemic (NIAID, 2019). Nurses can play a major role in caring for the HIV-positive woman by helping her accept the possibility of a shortened life span, cope with others' reactions to a stigmatizing illness, and develop strategies to maintain her physical and emotional health. Educate the woman about changes she can make in her behavior and taking prevention medications to prevent spreading HIV to others, and refer her to appropriate community resources such as HIV medical care services, substance abuse, mental health services, and social

services. See Nursing Care Plan 5.1: Overview for the Woman with HIV (at the end of the chapter).

Providing Education about Drug Therapy

The goal of ART is to suppress viral replication so that the viral load becomes undetectable by diagnostic tests. This is done to preserve immune function and delay disease progression but is a challenge because of the side effects of nausea and vomiting, diarrhea, altered taste, anorexia, flatulence, constipation, headaches, anemia, and fatigue. Although not everyone experiences all of the side effects, the majority do have some of them.

Help to reduce the development of drug resistance and thus treatment failure by identifying the barriers to adherence; identifying these barriers can help the woman to overcome them. Some of the common barriers exist because the woman:

- does not understand the link between drug resistance and nonadherence.
- fears revealing her HIV status by being seen taking medication.
- hasn't adjusted emotionally to the HIV diagnosis.
- doesn't understand the dosing regimen or schedule.
- experiences unpleasant side effects frequently.
- feels anxious or depressed (Bennett & Gilroy, 2019).

Educate the woman about the prescribed drug therapy and stress that it is very important to take the regimen as prescribed. Offer suggestions about how to cope with anorexia, nausea, and vomiting by:

- separating the intake of food and fluids.
- eating dry crackers upon arising.
- eating six small meals daily.
- using high-protein supplements (Boost, Ensure) to provide quick and easy protein and calories.
- eating "comfort foods," which may appeal to them when other foods don't.

Promoting Compliance

Remaining compliant with drug therapy is a huge challenge for many HIV-infected people. Compliance becomes difficult when the same pills that are supposed to thwart the disease are making the person sick. Nausea and diarrhea are just two of the possible side effects. It is often difficult to increase the client's quality of life when so much oral medication is required. The combination medication therapy is challenging for many people, and staying compliant over a period of years is extremely difficult. Stress the importance of taking the prescribed ART drug therapies by explaining that they help prevent replication of the retroviruses and subsequent progression of the disease, as well as decreasing the risk of perinatal transmission of HIV. In addition, provide written materials describing diet, exercise, medications, and signs and symptoms of complications and opportunistic infections. Reinforce this information at each visit.

Preventing HIV Infection

The lack of information about HIV infection and AIDS causes great anxiety and fear of the unknown. It is vital to take a leadership role in educating the public about risky behaviors in the fight to control this disease. The core of HIV prevention is to abstain from sex until marriage, to be faithful, and to use condoms. This is all good advice for many women, but some simply do not have the economic and social power or choices or control over their lives to put that advice into practice. Recognize that fact, and address the factors that will give women more control over their lives by providing anticipatory guidance, giving ample opportunities to practice negotiation techniques and refusal skills in a safe environment, and encouraging the use of female condoms to protect against this deadly virus. Prevention is the key to reversing the current infection trends.

In addition, taking PrEP (pre-exposure prophylaxis) medication daily will help reduce the chances of contracting an HIV infection for those at high risk of getting HIV. If the individual is exposed to HIV, having the PrEP medicine in the bloodstream can stop HIV from taking hold and spreading. PEP (post-exposure prophylaxis) prevents or controls the spread of HIV. PEP is intended for

emergency situations and must be started within 72 hours after a possible exposure of HIV to prevent it. PEP will be taken for 28 days after the HIV exposure (USDHHS, 2019b).

Providing Care During Pregnancy and Childbirth

Voluntary counseling and HIV testing should be offered to all pregnant women as early in the pregnancy as possible to identify HIV-infected women so that treatment can be initiated early. Once a pregnant woman is identified as being HIV-positive, she should be informed about the risk for perinatal infection. The risk of perinatal transmission of HIV from an infected mother to her newborn is about 25%. This risk falls to less than 2% if the mother receives ART during pregnancy (Resnik et al., 2019). HIV can be spread to the infant through breastfeeding so that when acceptable alternative infant formulas are readily available, HIV-infected mothers should be counseled to avoid breastfeeding and use formula instead.

In addition, the woman needs instructions on ways to enhance her immune system by following these guidelines during pregnancy:

- Getting adequate sleep each night (7 to 9 hours)
- Avoiding infections (e.g., staying away from crowds, handwashing)
- Decreasing stress in her life
- Consuming adequate protein and vitamins
- Increasing her fluid intake to 2 L daily to stay hydrated
- Planning rest periods throughout the day to prevent fatigue

Despite the dramatic reduction in perinatal transmission, hundreds of infants will be born infected with HIV. The birth of each infected infant is a missed prevention opportunity. To minimize perinatal HIV transmission, identify HIV infection in women, preferably before pregnancy; provide information about disease prevention; and encourage HIV-infected women to follow the prescribed drug therapy.

TABLE 5.3 Maternal and Fetal Effects from STIs

STI	Maternal Effects	Fetal Effects
Candidiasis	Resistant to treatment during pregnancy Uncomfortable localized genital itching and discharge	Can acquire thrush in the mouth during birthing process if mother infected
Trichomoniasis	Has been implicated to cause PROM and preterm births	Risk of prematurity
Bacterial vaginosis	Increases risk for spontaneous abortion, PROM, chorioamnionitis, postpartum endometritis, and preterm labor	Risk of neonatal sepsis
Chlamydia	Postpartum endometritis, PROM, and preterm birth	Newborn can be infected during childbirth Eye infections (neonatal conjunctivitis), pneumonia, low birth weight, increased risk of premature rupture of the membranes (PROM), and preterm birth
Gonorrhea	Chorioamnionitis, preterm birth, PROM, fetal growth restriction, postpartum sepsis	Newborn can be infected during childbirth. Eye infection *gonococcal ophthalmia* neonatorum can lead to blindness and sepsis (including arthritis and meningitis)
Genital herpes	Spontaneous abortion, intrauterine infection, preterm labor, PROM, fetal growth restriction	Contamination can occur during birth. Birth anomalies; transplacental infection. Newborn may develop skin or mouth sores. Intellectual disability, premature birth, low birth weight, blindness, death
Syphilis	Spontaneous abortion, preterm birth, stillbirth	Can be passed in utero. Can result in fetal or infant death.

		Congenital syphilis leads to multisystem organ failure, structural damage including teeth and bones, can lead to blindness, hearing loss, and mental retardation
Human papillomavirus (HPV)	May cause dystocia if large lesions	None known
Hepatitis B	May cause preterm birth; can be transmitted to fetus if active in last trimester	Can become chronic carrier of hepatitis B which may lead to liver cancer or cirrhosis
HIV	Fatigue, nausea, weight loss	Transmission can occur transplacentally, during childbirth or through breast milk

Providing Appropriate Referrals

The HIV-infected woman may have difficulty coping with the normal activities of daily living because she has less energy and decreased physical endurance. She may be overwhelmed by the financial burdens of medical and drug therapies and the emotional responses to a life-threatening condition, as well as concern about her infant's future, if she is pregnant. A case management approach is needed to deal with the complexity of her needs during this time. Be an empathetic listener and make appropriate referrals for nutritional

services, counseling, homemaker services, spiritual care, and local support groups. Many community-based organizations have developed programs to address the numerous issues regarding HIV/AIDS. The national AIDS hotline (1–800–342-AIDS) is a good resource. Table 5.3 provides a summary of perinatal effects of STIs during pregnancy.

PREVENTING SEXUALLY TRANSMITTED INFECTIONS

Education about safer-sex practices—and the resulting increase in the use of condoms—can play a vital role in reducing STI rates all over the world. Clearly, knowledge and prevention are the best defenses against STIs. The prevention and control of STIs is based on the following concepts (Rietmeijer, 2019).

1. Education and counseling of people at risk about safer-sexual behavior
2. Identification of asymptomatic and symptomatic people unlikely to seek diagnosis and treatment for STIs
3. Effective diagnosis and treatment of infected people
4. Evaluation, treatment, and counseling of sex partners of people who are infected with an STI
5. Pre-exposure vaccination of people at risk for vaccine-preventable STIs
6. Use latex condoms every time for sexual activity
7. Become mutually sexually exclusive with your partner
8. Avoid alcohol or drugs prior to sexual activity, so as not be impaired
9. STI prevention education and counseling tailored to the needs of adolescents

Nurses play an integral role in identifying and preventing STIs. They have a unique opportunity to educate the public about this serious public health issue by communicating the methods of transmission and symptoms associated with each condition, tracking

the updated CDC treatment guidelines, and offering clients strategic preventive measures to reduce the spread of STIs.

It is not easy to discuss STI prevention when globally we are failing at it. Knowledge exists on how to prevent every single route of transmission, but the incidence continues to climb. Challenges to prevention of STIs include lack of resources and difficulty in changing the behaviors that contribute to their spread. Regardless of the challenging factors involved, nurses must continue to educate and meet the needs of all women to promote their sexual health. Successful treatment and prevention of STIs is impossible without education. Successful teaching approaches include giving clear, accurate messages that are age-appropriate and culturally sensitive.

Primary prevention strategies include education of all women, especially adolescents, regarding the risk of early sexual activity, the number of sexual partners, and STIs. Sexual abstinence is ideal, but often not practiced; therefore, the use of barrier contraception (condoms) should be encouraged (see Teaching Guidelines 5.1).

Secondary prevention involves the need for annual pelvic examinations with Pap smears for all sexually active women, regardless of age. Many women with STIs are asymptomatic, so regular screening examinations are paramount for early detection. Understanding the relationship between poor socioeconomic conditions and poor patterns of sexual and reproductive self-care is significant in disease prevention and health promotion strategies.

Every successful form of prevention requires a change in behavior. The nursing role in teaching and rendering quality health care is invaluable evidence that the key to reducing the spread of STIs is through behavioral change. Nurses working in these specialty areas have a responsibility to educate themselves, their clients, their families, and the community about STIs, and to provide compassionate and supportive care to clients. Some strategies nurses can use to prevent the spread of STIs are detailed in Box 5.3.

BOX 5.3 Selected Nursing Strategies to Prevent the Spread of STIs

- Provide basic information about STI transmission.
- Outline safer-sexual behaviors for people at risk for STIs.
- Refer clients to appropriate community resources to reduce risk.
- Screen asymptomatic persons with STIs.
- Identify barriers to STI testing and remove them.
- Offer pre-exposure immunizations for vaccine-preventable STIs.
- Respond honestly about testing results and options available.
- Counsel and treat sexual partners of persons with STIs.
- Educate school administrators, parents, and teens about STIs.
- Support youth development activities to reduce sexual risk-taking.
- Promote the use of barrier methods (condoms, diaphragms) to prevent the spread of STIs.
- Assist clients to gain skills in negotiating safer sex.
- Discuss reducing the number of sexual partners to reduce risk.

CONSIDER THIS

I was thinking of my carefree college days, when the most important thing was having an active sorority life and meeting guys. I had been raised by very strict parents and was never allowed to date under their watch. Since I attended an out-of-state college, I figured that my parents' outdated advice and rules no longer applied. Abruptly, my thoughts of the past were interrupted by the HIV counselor asking about my feelings concerning my positive diagnosis. What was there to say at this point? I had a lot of fun, but never dreamed it would haunt me for the rest of my life, which was going to be shortened considerably now. I only wish I could turn back the hands of time and listen to my parents' advice, which somehow doesn't seem so outdated now.

Thoughts: All of us have thought back on our lives to better times and wondered how our lives would have changed if we had made better choices or gone down another path. It is a pity that we have only one chance to make good, sound decisions at times. What would you have changed in your life if given a second chance? Can you still make a change for the better now?

Behavior Modification

Research validates that changing behaviors does result in a decrease in new STIs, but it must encompass all levels—governments, community organizations, schools, churches, parents, and individuals. Nurses can advocate for the development and implementation of educational initiatives to increase awareness of STIs. As the STI epidemic rages in the United States, it is the health care providers who see clients on a daily basis who will be key to address it, not federal or state health agencies (Bortz, 2019). Education must address ways to prevent becoming infected, ways to prevent transmitting infection, symptoms of STIs, and treatment. At this point in the STI epidemic, nurses do not have time to debate the relative merits of prevention versus treatment: both are underused and underfunded, and one leads to the other. But being serious

about prevention and focusing on the strategies outlined above will bring about a positive change on everyone's part.

Contraception

The spread of STIs could be prevented by access to safe, efficient, appropriate, modern contraception for everyone who wants it. Nurses can play an important role in helping women to identify their risk of STIs and to adopt preventive measures through the dual protection that contraceptives offer. Traditionally, family planning and STI services have been separate entities. Family planning services have addressed a woman's need for contraception without considering her or her partner's risk of STI; meanwhile, STI services have been heavily slanted toward men, ignoring the contraceptive needs of men and their partners.

NURSING CARE PLAN 5.1 Overview of the Woman Who Is HIV-Positive

Annie, a 28-year-old African American woman, is HIV-positive. She acquired HIV through unprotected sexual contact. She has been inconsistent in taking her antiretroviral medications and presents today stating she is tired and doesn't feel well.

NURSING ANALYSIS: Ineffective protection related to risk of infection secondary to inadequate immune system as manifested by client stating she has been inconsistent in taking her antiretroviral therapy medications.

OUTCOME IDENTIFICATION AND EVALUATION

Client will remain free of opportunistic infections as evidenced by temperature within acceptable parameters and absence of signs and symptoms of opportunistic infections.

INTERVENTIONS: *Minimizing the Risk of Opportunistic Infections*

- Assess CD4 count and viral loads *to determine disease progression* (CD4 counts 500/L and viral loads >10,000 copies/L = increased risk for opportunistic infections).
- Assess complete blood count *to identify presence of infection* (>10,000 cells/mm^3 may indicate infection).
- Assess oral cavity and mucous membranes for painful white patches in mouth *to evaluate for possible fungal infection.*
- Teach client to monitor for general signs and symptoms of infections, such as fever, weakness, and fatigue, *to ensure early identification.*
- Provide information explaining the importance of avoiding people with infections when possible *to minimize risk of exposure to infections.*
- Teach importance of keeping appointments so her CD4 count and viral load can be monitored *to alert the health care provider about her immune system status.*
- Instruct her *to reduce her exposure to infections* via:
  - Meticulous handwashing
  - Thorough cooking of meats, eggs, and vegetables
  - Wearing shoes at all times, especially when outdoors
- Encourage a balance of rest with activity throughout the day *to prevent overexertion.*
- Stress importance of maintaining prescribed antiretroviral drug therapies *to prevent disease progression and resistance.*

- If necessary, refer Annie to a nutritionist to help her understand what constitutes a well-balanced diet with supplements *to promote health and ward off infection.*

NURSING ANALYSIS: Knowledge deficit related to HIV infection and possible complications.

OUTCOME IDENTIFICATION AND EVALUATION

Client will demonstrate increased understanding of HIV infection as evidenced by verbalizing appropriate health care practices and adhering to measures to comply with therapy and reduce her risk of further exposure and reduce risk of disease progression.

INTERVENTIONS: ***Providing Client Education***

- Assess her understanding of HIV and its treatment *to provide a baseline for teaching.*
- Establish trust and be honest with Annie; encourage her to talk about her fears and the impact of the disease *to provide an outlet for her concerns.* Encourage her to discuss reasons for her noncompliance.
- Provide a nonjudgmental, accessible, confidential, and culturally sensitive approach *to promote Annie's self-esteem and allow her to feel that she is a priority.*
- Explain measures, including safer-sex practices and birth control options, to prevent disease transmission; determine her willingness to practice safer sex to protect others *to determine further teaching needs.*
- Discuss the signs and symptoms of disease progression and potential opportunistic infections *to promote early detection for prompt intervention.*
- Outline with the client the availability of community resources and make appropriate referrals as needed *to provide additional education and support.*
- Encourage Annie to keep scheduled appointments *to ensure follow-up and allow early detection of potential problems.*

Many women are at significant risk for unintended pregnancy and STIs, yet with this separation of services, there is limited evaluation of whether they need dual protection—that is, concurrent protection from STIs and unintended pregnancy. This lack of integration of services represents a missed opportunity to identify many at-risk women and to offer them counseling on dual protection (Ryan et al., 2020).

Nurses can expand their scopes in either setting by discussing dual protection by use of a male or female condom alone or by use of a condom along with a nonbarrier contraceptive. Because barrier methods are not the most effective means of fertility control, they have not been typically recommended as a method alone for dual protection. Unfortunately, the most effective pregnancy prevention methods—sterilization, hormonal methods, and intrauterine devices—do not protect against STIs. Dual-method use protects against STIs and pregnancy.

KEY CONCEPTS

- Avoiding risky sexual behaviors may preserve fertility and prevent chronic conditions later in life.
- An estimated 65 million people live with an incurable STI, and another 20 million are infected each year.
- The most reliable way to avoid transmission of STIs is to abstain from sexual intercourse (i.e., oral, vaginal, or anal sex) or to be in a long-term, mutually monogamous relationship with an uninfected partner.
- Barrier methods of contraception are recommended because they increase protection from contact with urethral discharge, mucosal secretions, and lesions of the cervix or penis.
- The high rate of asymptomatic transmission of STIs calls for teaching high-risk women the nature of transmission and how to recognize infections.
- The CDC and ACOG recommend that all women be offered group B streptococcal screening by rectovaginal culture at 35 to 37 weeks' gestation, and that colonized women be treated with intravenous antibiotics at the time of labor or ruptured membranes.
- Nurses should practice good handwashing techniques and follow standard precautions to protect themselves and their clients from STIs.
- Nurses are in an important position to promote the sexual health of all women. Nurses should make their clients and the community aware of the perinatal implications and lifelong sequelae of STIs.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. Which of the following contraceptive methods offers protection against sexually transmitted infections (STIs)?

   a. Oral contraceptives
   b. Withdrawal
   c. Latex condom
   d. Intrauterine system

2. When teaching about HIV transmission, which of the following does the nurse explain that the virus cannot be transmitted by?

   a. Shaking hands
   b. Sharing drug needles
   c. Sexual intercourse
   d. Breastfeeding

3. A woman with HPV is likely to present with which nursing assessment finding?

   a. Profuse, pus-filled vaginal discharge
   b. Clusters of genital warts
   c. Single painless ulcer
   d. Multiple vesicles on genitalia

4. The nurse's discharge teaching plan for the woman hospitalized with PID should reinforce which of the following potentially life-threatening complications?

   a. Involuntary infertility
   b. Chronic pelvic pain
   c. Depression

d. Ectopic pregnancy

5. To confirm a finding of primary syphilis, the nurse would observe which of the following on the external genitalia?

a. A highly variable skin rash
b. A yellow-green vaginal discharge
c. A nontender, indurated ulcer
d. A localized gumma formation

6. A sexually active 19-year-old presents to the clinic with postcoital bleeding, dysuria, and a yellow discharge. Her cervix upon exam is red and friable. What might the nurse suspect?

a. Cervical cancer
b. A tampon injury
c. Primary syphilis
d. Chlamydia

CRITICAL THINKING EXERCISES

1. Sally, age 17, comes to the teen clinic saying that she is in pain and has some “crud” between her legs. The nurse takes her into the examining room and questions her about her symptoms. Sally states she had numerous genital bumps that had been filled with fluid, then ruptured and turned into ulcers with crusts. In addition, she has pain on urination and overall body pain. Sally says she had unprotected sex with several men when she was drunk at a party a few weeks back, but she thought they were “clean.”

a. Which STI would the nurse suspect?
b. The nurse should give immediate consideration to which of Sally’s complaints?
c. What should be the goal of the nurse in teaching Sally about STIs?

STUDY ACTIVITIES

1. Select a website at the end of the chapter to explore. Educate yourself about one specific STI thoroughly and share your expertise with your clinical group.
2. Contact your local health department and request current statistics regarding three STIs. Ask them to compare the current number of cases reported to last year's. Are they less or more? What may be some of the reasons for the change in the number of cases reported?
3. Request permission to attend a local STI clinic to shadow a nurse for a few hours. Describe the nurse's counseling role with clients and what specific information is emphasized to clients.
4. Two common STIs that appear together and commonly are treated together regardless of identification of the secondary one are _____ and _____.
5. Genital warts can be treated with which of the following? Select all that apply.

   a. Penicillin
   b. Podophyllin
   c. Imiquimod
   d. Cryotherapy
   e. Antiretroviral therapy
   f. Acyclovir

BRINGING IT ALL TOGETHER: A CASE STUDY

Charlotte, a 22-year-old, has presented at the local clinic with concerns of having contracted a sexually transmitted infection (STI). During the nursing interview Charlotte identifies that she has been sexually active since the age of 15 and has had "at least a dozen different sex partners." The health assessment confirms that Charlotte has been

infected with pediculosis pubis (pubic lice) and treatment has been prescribed.

Go to thePoint to find questions to consider about this case.

6

Disorders of the Breasts

WOW

WORDS OF WISDOM

Focus on reducing fear, anxiety, pain, and loneliness in all women diagnosed with a breast disorder.

KEY TERMS

benign breast disorder

breast augmentation (awg´men-tā´shŭn)

breast cancer

breast-conserving surgery

breast implants

breast self-examination (BSE)

carcinoma

chemotherapy

duct ectasia (dŭkt ek-tā´zē-ă)

endocrine therapy

fibroadenomas (fī´brō-ad-ĕ-nō´măz)

fibrocystic breast changes

mammography

mastitis

modified radical mastectomy

simple mastectomy

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Identify the incidence, risk factors, screening methods, and treatment modalities for benign breast conditions.
2. Analyze the incidence, risk factors, treatment modalities, and nursing considerations related to breast cancer.
3. Appraise reasons behind breast augmentation including the potential benefits and risks.
4. Outline preventive strategies for breast cancer through lifestyle changes and health screening.
5. Develop an educational plan to teach BSE to a group of high-risk women.

Nancy hasn't been able to sleep well since she felt the lump in her left breast over a month ago, just after her 60th birthday. She knows she is at high risk because her mother died of breast cancer, but she can't bring herself to have it checked out.

INTRODUCTION

The breasts, or mammary glands, are modified sweat glands lying over the pectoralis major muscles of the anterior chest wall. Physiologically, the breast is an organ specialized for milk formation to nourish the woman's offspring. Each breast extends approximately from the second to the seventh rib. The female breasts are closely linked to womanhood in American culture. Women's breasts act as physical markers for transitions from one stage of life to another, and although the primary function of the breasts is lactation, they are perceived as a symbol of beauty and sexuality.

This chapter discusses assessments, screening procedures, and management of specific benign and malignant breast disorders. Nurses play a key role in helping women maintain breast health by providing education and screening. A good working knowledge of early detection techniques, diagnosis, and treatment options is essential.

BENIGN BREAST DISORDERS

Benign breast disorders are a common complaint among women from puberty to menopause. A **benign breast disorder** is any noncancerous breast abnormality. Though not life threatening, benign disorders can cause pain and discomfort, and they account for a large number of visits to primary care providers. As the breasts are constantly undergoing changes due to hormonal influences, there is a lot of confusion in differentiating between normal and pathologic findings. Fully understanding benign breast disorders should enable the nurse to appropriately evaluate symptoms,

determine which breast findings require treatment, and identify women who are at increased risk for breast cancer.

Depending on the type of benign breast disorder, treatment may or may not be necessary. Although these disorders are benign, the emotional trauma women experience can be severe. Fear, anxiety, disbelief, helplessness, and depression are just a few of the feelings a woman may have when she discovers a lump in her breast. Many women believe that all lumps are cancerous, but in reality more than 80% of the lumps discovered are benign and need no treatment (Santen, 2018). Patience, support, and education are essential components of nursing care.

The most commonly encountered benign breast disorders in women include fibrocystic changes of the breasts, fibroadenomas, and mastitis. Although these breast disorders are considered benign, fibrocystic changes of the breasts may carry a cancer risk depending on the type of atypical cells found, with prolific masses and hyperplastic changes occurring within the breasts. Generally speaking, fibroadenomas and mastitis carry little risk for cancer (Sabel, 2019). Table 6.1 summarizes benign breast conditions.

Fibrocystic Breast Changes

Fibrocystic breast changes, also classified as a nonproliferative lesions, represent a variety of changes in the glandular and structural tissues of the breast. Because this condition affects 50% of all women at some point, it is more accurately defined as a “change” rather than a “disease.” Fibrocystic changes are caused by an overgrowth of fibrous tissues in the connective tissues supporting the breasts. This is frequently accompanied by the presence of fluid-filled cysts, which contribute to the lumpy feeling women notice. In contrast to malignant breast lesions, the cysts that develop move freely when palpated, and symptoms decline after menopause when levels of estrogen and progesterone drop (Sabel, 2019). Fibrocystic changes do not increase the risk of breast cancer for most women except when the breast biopsy shows “atypia” or abnormal breast cells. The cause for concern for many women with fibrocystic

changes is that breast examinations and mammography become more difficult to interpret with multiple cysts present, and early cancerous lesions may be overlooked (American Cancer Society [ACS], 2020a).

TABLE 6.1 Summary of Benign Breast Disorders

Breast Condition	Nipple Discharge	Site	Characteristics/ Age of Client	Tenderness	Diagnosis and Treatment
Fibrocystic breast changes	+ or –	Bilateral; upper outer quadrant	Round, smooth Several lesions Cyclic, palpable 30–50 years old	+	Aspiration and biopsy Limit caffeine Ibuprofen Supportive bra
Fibroadenomas	–	Unilateral; nipple area or upper outer quadrant	Round, firm, movable Palpable, rubbery Well delineated Single lesion 15–30 years old	–	Mammogram "Watchful waiting" Aspiration and biopsy Surgical excision
Mastitis	–	Unilateral; outer quadrant	Wedge-shaped Warmth, redness Swelling Nipple cracked Breast engorged	+	Antibiotics Warm shower Supportive bra Breastfeeding Increase fluids

(2018). *Atypical breast proliferation lesions and benign breast disease.* Springer International Publishers; and Kirby, I., Bland, M. D., Copeland, E. M., Klimberg, S., & Gradishar, W. J. (2018). *The breast: Comprehensive management of benign and malignant diseases* (5th ed.). Elsevier.

Fibrocystic breast changes are most common in women between the ages of 30 and 50. The condition is rare in postmenopausal women not taking hormone replacement therapy (HRT). According to the ACS (2020a), fibrocystic breast changes affect at least half of all women at some point in their lives.

Therapeutic Management

Management of the symptoms of fibrocystic breast changes begins with self-care. For some women, diet and lifestyle changes help reduce discomfort. Other options include wearing a supportive bra, taking over-the-counter pain relievers, and limiting salt consumption which can cause fluid retention (Knaus et al., 2018). In severe cases, drugs, including bromocriptine, tamoxifen, or danazol, can be used to reduce the influence of estrogen on breast tissue. However, several undesirable side effects, including masculinization, have

been documented. Aspiration or surgical removal of breast lumps will reduce pain and swelling by removing space-occupying masses.

Nursing Assessment

Nursing assessment consists of a health history, which should include issues having to do with the onset; frequency; quality and quantity of any pain, discharge, or masses; medications taken; physical activity; family history; reproductive history; any associated symptoms; physical examination of the breasts; and laboratory and diagnostic tests.

HEALTH HISTORY

Ask the woman about common clinical manifestations, which include lumpy, tender breasts and a feeling of fullness, particularly during the week before menses. Changes in breast tissue produce pain by nerve irritation from edema in connective tissue and by fibrosis from nerve pinching. The pain is cyclic and frequently dissipates after the onset of menses. The pain is described as a dull, aching feeling of fullness. Masses or nodularity usually appear in both breasts and are often found in the upper outer quadrants. Some women also experience spontaneous clear to yellow nipple discharge when the breast is squeezed or manipulated.

PHYSICAL EXAMINATION

It is best to examine a woman's breast a week after menses, when swelling has subsided. The breast exam is performed using the "triple touch method" in which the health care provider uses the pads of the middle three fingers and makes dime-sized overlapping circles to feel the breast tissue with three levels of pressure: light, medium, and firm (Jarvis, 2019). Observe the breasts for fibrosis, or thickening of the normal breast tissues, which occurs in the early stages. Cysts form in the later stages and feel like multiple, smooth, well-delineated tiny pebbles or bumpy oatmeal under the skin (Fig. 6.1). On physical examination of the breasts, a few characteristics

might be helpful in differentiating a cyst from a cancerous lesion. Cancerous lesions are typically fixed and painless and may cause skin retraction (pulling). Cysts tend to be mobile and tender and do not cause skin retraction in the surrounding tissue.

LABORATORY AND DIAGNOSTIC TESTS

Mammography can be helpful in distinguishing fibrocystic changes from breast cancer. Ultrasound is a useful adjunct to mammography for breast evaluation because it helps differentiate a cystic mass from a solid one (Miller, 2019). Ultrasound produces images of the breasts by sending sound waves through a gel applied to the breasts. Fine-needle aspiration biopsy can also be done to differentiate a solid tumor, cyst, or malignancy. A fine-needle aspiration biopsy uses a thin needle guided by ultrasound to the mass. In a method called stereotactic needle biopsy, a computer maps the exact location of the mass using mammograms taken from two angles, and the map is used to guide the needle.

Nursing Management

A nurse caring for a woman with fibrocystic breast changes can teach her about the condition, provide tips for self-care (Teaching Guidelines 6.1), suggest lifestyle changes, and demonstrate how to perform a monthly breast self-examination (BSE) after her menses to monitor the changes. Nursing Care Plan 6.1 presents a plan of care for a woman with fibrocystic breast changes.

TEACHING GUIDELINES 6.1

Relieving Symptoms of Fibrocystic Breast Changes

- Wear an extra supportive, well-made bra to prevent undue strain on the ligaments of the breasts to reduce discomfort.
- Take oral contraceptives as recommended by a health care practitioner to stabilize the monthly hormonal levels.
- Eat a low-fat diet rich in fruits, vegetables, and grains to maintain a healthy nutritional lifestyle and ideal weight.
- Apply heat or cool packs to the breasts to help reduce pain.
- Take diuretics as recommended by a health care practitioner to counteract fluid retention and swelling of the breasts.
- Reduce salt intake to reduce fluid retention and swelling in the breasts.
- Take over-the-counter medications, such as acetylsalicylic acid (Aspirin) or ibuprofen (Motrin, Advil, Nuprin), to reduce inflammation and discomfort.
- Use thiamine and vitamin E therapy. This has been found helpful for some women, but research has failed to demonstrate a direct benefit from either therapy.
- Take medications as prescribed (e.g., bromocriptine, tamoxifen, or danazol).
- Discuss the possibility of aspiration or surgical removal of breast lumps with a health care practitioner.
- Restrict use of alcohol.
- Avoid caffeinated drinks (coffee, tea, soda), which tend to trigger breast discomfort.

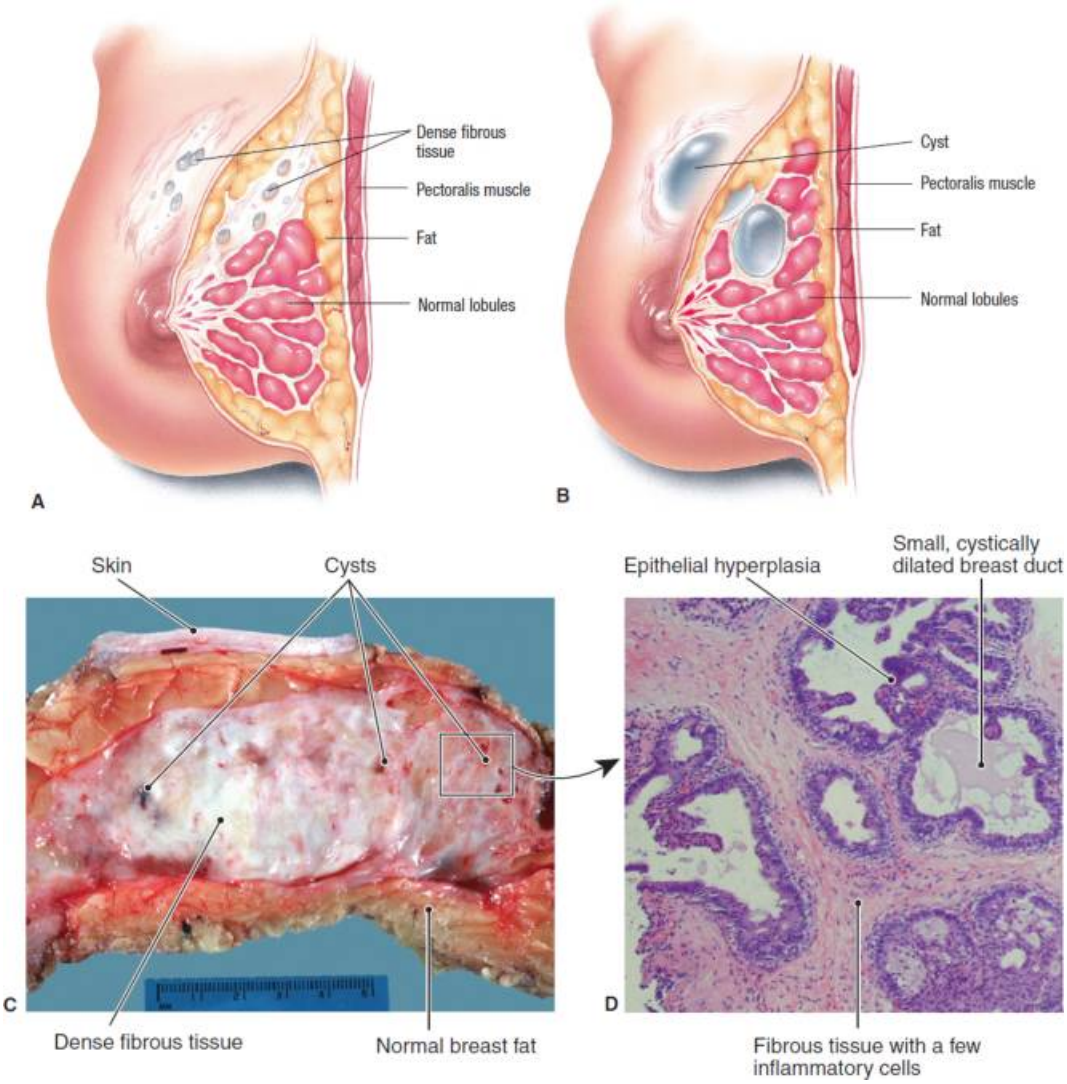

FIGURE 6.1. **A.** Fibrocystic breast changes. **B.** Breast cysts. **C.** This gross study shows that most of the abnormal tissue is fibrous. Cysts are relatively inconspicuous in this example. **D.** The microscopic study shows dense fibrous tissue containing dilated ducts lined by hyperplastic epithelium. [2014]. *The nature of disease pathology for the health professions* (2nd ed.). Lippincott Williams & Wilkins.)

NURSING CARE PLAN 6.1 Overview of the Woman with Fibrocystic Breast Changes

Sheree Rollins is a 37-year-old woman who comes to the clinic for her routine check-up. During the examination, she says, “Sometimes my breasts feel so heavy, and they ache a lot. I noticed a couple of lumpy areas in my breast last week just before I got my period. Is this normal? Now they feel like they’re almost gone. Should I be worried?” The clinical breast examination reveals two small (pea-sized), mobile, slightly tender nodules in each breast bilaterally. No skin retraction noted. Previous mammogram revealed fibrocystic breast changes.

NURSING ANALYSIS: Pain related to changes in breast tissue

OUTCOME IDENTIFICATION AND EVALUATION

The client will demonstrate a decrease in breast pain as evidenced by a pain rating of 1 or 2 on a pain rating scale of 0 to 10 and statements that pain is lessened.

INTERVENTIONS: *Relieving Pain*

- Ask client to rate her pain using a numeric pain rating scale *to establish a baseline*.
- Discuss with client any measures used to relieve pain *to determine effectiveness of the measures*.
- Encourage use of a supportive bra *to aid in reducing discomfort*.
- Instruct client in use of over-the-counter analgesics *to promote pain relief*.
- Advise the client to apply warm compresses or allow warm water from the shower to flow over her breasts *to promote vasodilation and subsequent pain relief*.
- Tell client to reduce her intake of salt *to reduce risk of fluid retention and swelling leading to increased pain*.

NURSING ANALYSIS: Lack of knowledge related to fibrocystic breast changes and appropriate care measures

OUTCOME IDENTIFICATION AND EVALUATION

The client will verbalize understanding of condition as evidenced by statements about the cause of breast changes and appropriate choices for lifestyle changes, and demonstration of self-care measures.

INTERVENTIONS: *Providing Client Education*

- Assess client's knowledge of fibrocystic breast changes *to establish a baseline for teaching*.
- Explain the role of monthly hormonal level changes, and describe the signs and symptoms *to promote understanding of this condition*.
- Teach the client how to perform breast self-examination after her menstrual period *to monitor for changes*.
- Encourage client to report any changes promptly *to ensure early detection of problems*.
- Suggest client speak with her primary care provider about the use of oral contraceptives *to help stabilize monthly hormonal levels*.
- Review lifestyle choices, such as eating a low-fat diet rich in fruits, vegetables, and grains, and adhering to screening recommendations *to promote health*.
- Discuss measures for pain relief *to minimize discomfort associated with breast changes*.

Fibroadenomas

Fibroadenomas, also classified as proliferative lesions without atypia (cell abnormalities), are common slow-growing, benign solid breast tumors that occur in about 25% of all women and account for up to half of all breast biopsies. They are the most common mass in women ages 15 to 30 years (Oyelowo & Johnson, 2018). They are considered hyperplastic lesions associated with an aberration of normal development and involution rather than a neoplasm. Fibroadenomas can be stimulated by external estrogen, progesterone, lactation, and pregnancy (Amersi & Calhoun, 2018). They are composed of both fibrous and glandular tissue that feels round or oval, firm, rubbery, and smooth, and they are mobile and may be tender. They are usually unilateral, but may present in both breasts (Jarvis, 2019). Giant fibroadenomas account for approximately 4% of cases. These masses are frequently larger than 5 cm and occur most often in pregnant or lactating women. These large lesions may reduce in size once hormonal stimulation subsides (Kirby et al., 2018). Fibroadenomas are rarely associated with cancer.

Therapeutic Management

Treatment may include a period of “watchful waiting” because many fibroadenomas stop growing or shrink on their own without any treatment. Other growths may need to be surgically removed if they do not regress or if they remain unchanged. Cryoablation (cryotherapy), an alternative to surgery, can also be used to remove a tumor. In this procedure, extremely cold gas is piped into the tumor using ultrasound guidance. The tumor freezes and dies. The current trend is toward a more conservative approach to treatment after careful evaluation and continued monitoring.

Nursing Assessment

Ask the woman about clinical manifestations of fibroadenomas. These lumps are felt as firm, rubbery, round, well-circumscribed, freely mobile nodules that might or might not be tender when palpated.

Breast fibroadenomas are usually detected incidentally during clinical or self-examinations and are usually located in the upper outer quadrant of the breast; more than one may be present (Fig. 6.2). Several other breast lesions have similar characteristics, so every woman with a breast mass should be evaluated to exclude cancer. A clinical breast examination by a health care provider is critical. In addition, diagnostic studies include imaging studies (mammography, ultrasound, or both) and some form of biopsy, most often a fine-needle aspiration, core needle biopsy, or stereotactic needle biopsy. The core needle biopsy removes a small cylinder of tissue from the breast mass, more than the fine-needle aspiration biopsy. If additional tissue needs to be evaluated, the advanced breast biopsy instrument (ABBI) is used. This instrument removes a larger cylinder of tissue for examination by using a rotating circular knife. The ABBI procedure removes more tissue than any of the other methods except a surgical biopsy (ACS, 2020a).

Nursing Management

The nurse should urge the client to return for reevaluation in 6 months, perform monthly BSEs, and return annually for a clinical breast examination. Recent studies suggest that women with high breast density and proliferative benign breast disease are at a high risk for future breast cancer. Women with low breast density are at a low risk, regardless of their benign pathologic diagnosis (Miller, 2019). This is all the more reason for women to have close monitoring over time.

Mastitis

Mastitis is an infection or inflammation of the connective tissue in the breast that occurs primarily in lactating or engorged women. The prevalence may be as high as 33% of all breastfeeding women (Jordan et al., 2019). Mastitis is divided into lactational or nonlactational types. The usual causative organisms for lactational mastitis are *Staphylococcus aureus*, *Hemophilus influenzae*, and hemophilus and streptococcus species, the source of which is the baby's flora. Lactating mastitis typically occurs in the first 2 to 3 weeks of lactation, but can occur at any stage of lactation. One or more of the ducts drain poorly or become blocked, resulting in milk stasis and bacterial growth in the retained milk (Angelopoulous et al., 2018). The only evidence-based predisposing factor that may lead to mastitis is the development of milk stasis. However, other associated factors include damaged or cracked nipples, especially those colonized with *Staphylococcus aureus*; irregular or missed feedings; failing to allow the infant to empty one breast completely before moving on to the next breast; poor latch and transfer of milk; illness of mother or infant; oversupply; a tight bra; blocked nipple pore or duct; being a primiparous women; and maternal stress and fatigue (Miller, 2019).

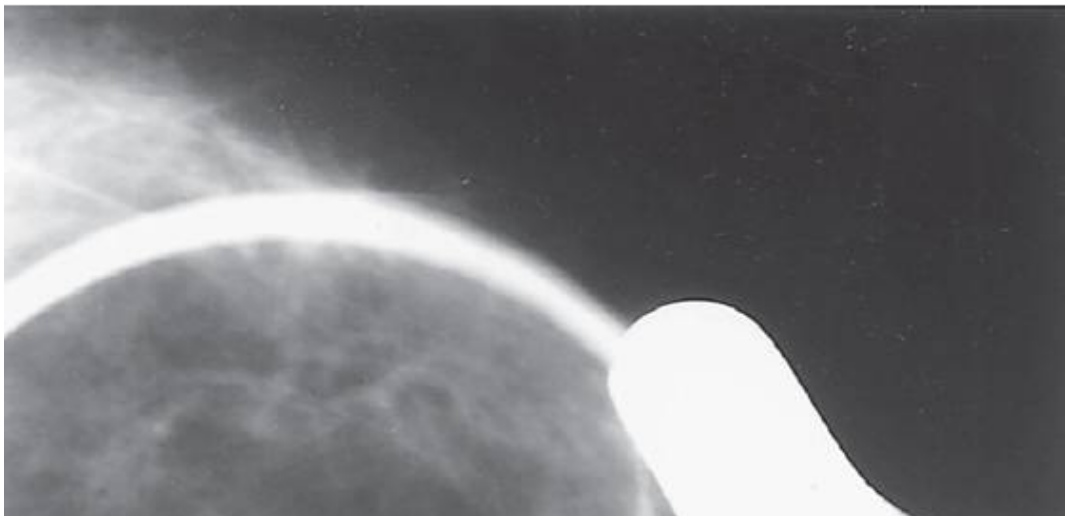
A



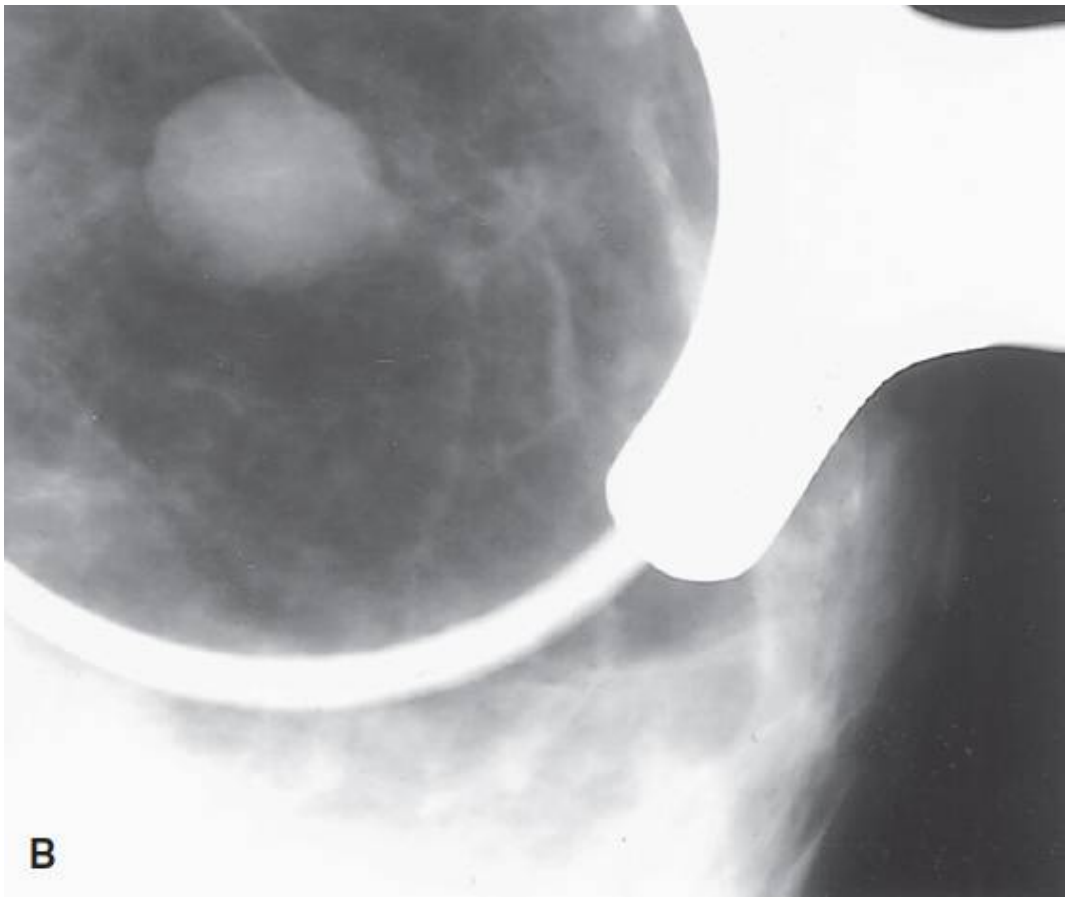


FIGURE 6.2. A. Fibroadenoma. (Asset provided by Anatomical Chart Co.) **B.** Spot compression view of a smoothly marinated mass proven to represent a fibroadenoma. Ultrasonography demonstrated a solid mass.

Nonlactational mastitis can be caused by **duct ectasia**, which occurs when the milk ducts become congested with secretions and debris, resulting in periductal inflammation. It may be divided into central (periareolar) and peripheral breast lesions. Periareolar infections consist of active inflammation around nondilated subareolar breast ducts—a condition termed periductal mastitis. Peripheral nonlactating breast abscesses are less common than periareolar abscesses and are often associated with an underlying condition such as diabetes, rheumatoid arthritis, steroid treatment, granulomatous lobular mastitis, and trauma (Amersi & Calhoun, 2018). Women with these types of abscesses present with greenish nipple discharge, nipple retraction, and noncyclical pain.

Therapeutic Management

Effective milk removal, pain medication, and antibiotic therapy have been the mainstays of treatment. Management of both types of mastitis involves the use of oral antibiotics (usually a penicillinase-resistant penicillin or cephalosporin), warm compresses to the inflamed area of the breast, continued breastfeeding, and acetaminophen (Tylenol) for pain and fever (Jordan et al., 2019).

Nursing Assessment

Assess the client's health history for risk factors for mastitis, which include poor hand hygiene ductal abnormalities, nipple cracks and fissures, lowered maternal defenses due to fatigue, tight clothing, poor support of pendulous breasts, failure to empty the breasts properly while breastfeeding, or missing feedings.

The diagnosis of mastitis is made clinically on the basis of a localized, unilateral area of erythema with associated fever. Assess the client for clinical manifestations of mastitis, which include flu-like symptoms of malaise, nausea, headache, leukocytosis, fever, fatigue, and chills. Physical examination of the breasts reveals increased warmth, swollen area of one breast, redness, tenderness, and swelling. The nipple is usually cracked or abraded and the breast is distended with milk (Fig. 6.3). In a lactating woman, severe engorgement can be differentiated from mastitis because engorgement is bilateral with general involvement of the whole breast. Ultrasound scans can be undertaken to differentiate between the types of mastitis or abscesses, but typically the diagnosis is made based on history and examination.

FIGURE 6.3. Mastitis. (From Sweet, R. L., & Gibbs, R. S. [2009]. *Infectious diseases of the female genital tract.* Philadelphia, PA: Lippincott Williams & Wilkins.)

Nursing Management

Teach the woman about the etiology of mastitis and encourage her to continue to breast-feed, emphasizing that it is safe for her infant to do so. Stress to all breastfeeding mothers to check for medication safety before taking it. Drugs administered to mothers can accumulate in the bodies of their infants and can alter the infant's bowel flora, causing diarrhea. Mothers should be warned about this to reduce anxiety. Once it has been declared safe to do so, the nurse should urge the mother to take the medication as prescribed until completed. Continued emptying of the breast or pumping improves the outcome, decreases the duration of symptoms, and decreases the incidence of breast abscess. Thus, continued breastfeeding is recommended in the presence of mastitis (Hale, 2019).

Although 80% of breast biopsy results prove to be benign, increased surveillance is necessary because of the risk of cancer development. The recommended follow-up schedule is imaging

(mammography or ultrasound) and a clinical breast exam by a surgeon at 6, 12, and 24 months after a benign breast biopsy finding (Kirby et al., 2018). Instructions for the woman with mastitis are detailed in Teaching Guidelines 6.2.

TEACHING GUIDELINES 6.2

Caring for Mastitis

- Take medications as prescribed to reduce inflammation and infection.
- Continue breastfeeding as tolerated to keep the milk flowing.
- Begin feeding on most affected breast to allow it to be emptied first.
- Massage the breasts before and during breastfeeding to encourage milk extraction.
- Wear a supportive bra 24 hours a day to support the breasts for comfort.
- Increase fluid intake to stay hydrated.
- Gently massage toward nipple several times daily.
- Vary the infant's breastfeeding position: cradle, side-lying, football, and belly to belly.
- Make sure infant is positioned correctly on the nipple to prevent discomfort.
- Practice good hand hygiene techniques to reduce risk of bacterial transfer.
- Apply warm compresses to the affected breast or take a warm shower before breastfeeding.
- Frequently change positions while nursing to improve milk flow.
- Get adequate rest and nutrition to support or improve the immune system.
- Instruct the client to contact her health care provider if she experiences fever, chills, or worsening symptoms.

(2018). *The breast: Comprehensive management of benign and malignant diseases* (5th ed.). Elsevier.

MALIGNANT BREAST DISORDER

Breast cancer is a neoplastic disease in which normal body cells are transformed into malignant ones (National Cancer Institute ([NCI], 2019a). It is the most common cancer in women and the second leading cause of cancer deaths (lung cancer is first) among American women. Breast cancer accounts for one of every three cancers diagnosed in the United States (ACS, 2020b). A new case is discovered every 2 minutes. It is estimated that one out of every eight women will develop the disease at some time during their lives, and the mortality rate of those with breast cancer is one in 36 (NCI, 2019a).

Over 200,000 cases of invasive breast cancer are diagnosed in the United States each year (CDC, 2019a). Breast cancer can also affect men, but only 1% of all individuals diagnosed with breast cancer annually are men. About 2,550 men are diagnosed with breast cancer annually, with about a 1-in-4 mortality rate (ACS, 2020c). Because men are not routinely screened for breast cancer, the diagnosis is often delayed. The most common clinical manifestation of male breast cancer is a painless, firm, subareolar breast mass. Any suspicious breast mass in a male should undergo diagnostic biopsy. If a malignancy is diagnosed, typical treatment is mastectomy with assessment of the axillary nodes.

The cause of breast cancer, while not well understood, is thought to be a complex interaction between environmental, genetic, and hormonal factors. Breast cancer is a progressive rather than a systemic disease, meaning that most cancers grow from a small size with low metastatic potential to a larger size and greater metastatic potential. Tumor stage, size, and lymph node involvement are major predictors of metastatic potential (Oyelowo & Johnson, 2018).

CONSIDER THIS

It was pouring down rain and I was driving alone along dark wet streets to my 8 a.m. appointment for a breast ultrasound. I recently had my annual mammogram and the radiologist thought he saw something suspicious on my right breast. I was on my way to find out if his suspicions were right, and I couldn't keep focused on the road ahead. For the past few days, I had been so anxious, fearing the worst. I was playing it out in my mind, what I would do if…? What changes would I make in my life, and how would I react when told? I have been through such personal turmoil since that doctor announced he wanted "more tests."

Thoughts: This woman is worrying and is emotionally devastated before she even has a conclusive diagnosis. Is this a typical reaction to a breast disorder? Why do women fear the worst? Many women use denial to mask their feelings and hope the doctor made a mistake or misread the mammogram. How would you react if you or your sister, significant other, or mother were confronted with a breast disorder?

Pathophysiology

Cancer is not just one disease but rather a group of diseases that result from unregulated cell growth. Without regulation, cells divide and grow uncontrollably until they eventually form a tumor. Extensive research has determined that all cancer is the result of changes in DNA or chromosome structure that cause the mutation of specific genes. Most genetic mutations that cause cancer are acquired sporadically, which means they occur by chance and are not necessarily due to inherited mutations (Banasik & Copstead, 2019). Cancer development is thought to be clonal in nature, which means that each cell is derived from another cell. If one cell develops a mutation, any daughter cell derived from that cell will have that same mutation, and this process continues until a malignant tumor forms.

Breast cancer starts in the epithelial cells that line the mammary ducts within the breast. The growth rate depends on hormonal

influences, mainly that of estrogen and progesterone. The two major categories of breast cancer are noninvasive and invasive. Noninvasive (in situ) breast cancers are those that have not extended beyond the duct, lobule, or other point of origin into the surrounding breast tissue. Conversely, invasive (infiltrating) breast cancers have extended into the surrounding breast tissue with the potential to metastasize. Many researchers believe that most invasive cancers probably originate as noninvasive cancers (McCance & Huether, 2019).

Breast cancer metastasizes widely and to almost all organs of the body, but primarily to the bone, lungs, lymph nodes, liver, and brain. The first sites of metastases are usually local or regional, involving the chest wall or axillary supraclavicular lymph nodes or bone (Breast Cancer Organization, 2020a).

Invasive Ductal Carcinoma

By far the most common breast cancer is invasive ductal carcinoma, which represents 80% of all cases (ACS, 2020b). **Carcinoma** is a malignant tumor that occurs in epithelial tissue; it tends to infiltrate and give rise to metastases. The incidence of this cancer peaks in the sixth decade of life. It spreads rapidly to axillary and other lymph nodes, even while small. Infiltrating ductal carcinoma may take various histologic forms—well differentiated and slow-growing, poorly differentiated and infiltrating, or highly malignant and undifferentiated with numerous metastases. This common type of breast cancer starts in the ducts, breaks through the duct wall, and invades the fatty breast tissue (Aydiner et al., 2019).

Invasive Lobular Carcinoma

Invasive or infiltrating lobular carcinomas originate in the terminal lobular units of breast ducts and account for 10% of all cases of breast cancer. The peak incidence is in women in their early 60s. It presents as an area of ill-defined thickening rather than a palpable mass. The tumor is frequently located in the upper outer quadrant of

the breast, and by the time it is discovered, the prognosis is usually poor (Breast Cancer Organization, 2020b).

Other Invasive Carcinomas

Another invasive type of breast cancer is tubular carcinoma (29%), which typically occurs in women aged 55 and older. Colloid carcinoma (2% to 4%) occurs in women 60 to 70 years of age and is characterized by the presence of large pools of mucus interspersed with small islands of tumor cells. Medullary carcinoma accounts for 5% to 7% of malignant breast tumors; it occurs frequently in younger women (under 50 years of age) and grows into large tumor masses. Inflammatory breast cancer (more than 4%) often presents with skin edema, redness, and warmth and is associated with a poor prognosis. Paget disease (2% to 4%) originates in the nipple and typically occurs with invasive ductal carcinoma (Aydiner et al., 2019).

Staging of Breast Cancer

The American Joint Committee on Cancer (AJCC) recently updated the staging classifications for breast tumors, now taking into account biology and behavior. The new staging incorporates grade, estrogen receptor status, progesterone receptor status, and HER2 (human epidermal growth factor receptor 2, a gene that can be a factor in developing breast cancer) status, along with tumor size, lymph node involvement, and evidence of metastasis (AJCC, 2019).

Tumor staging helps determine the probability that the tumor has metastasized to decide on an appropriate course of therapy and assess the client's prognosis. Table 6.2 gives details and characteristics of each stage (see also Fig. 6.4). The overall 10-year survival rate for a woman with stage I breast cancer is 80% to 90%; for a woman with stage II, it is about 50%. The outlook is significantly decreased for women with stage III or IV disease (National Cancer Institute, 2019b).

There is no completely accurate way to know whether the cancer has micrometastasized to distant organs, but certain tests can help

determine if the cancer has spread. A bone scan can be performed to assess the bones, and magnetic resonance imaging (MRI) can be used to detect metastases to the liver, abdominal cavity, lungs, or brain.

TABLE 6.2 Staging of Breast Cancer

Stage	Characteristics
0	In situ, early type of breast cancer
I	Localized tumor <1 in in diameter
II	Tumor 1–2 in in diameter; spread to axillary lymph nodes
III	Tumor 2 in or larger; spread to other lymph nodes and tissues
IV	Cancer has metastasized to other body organs

American Joint Committee on Cancer (AJCC). (2019). *Cancer staging manual.* Retrieved March 13, 2018, from https://cancerstaging.org/references-tools/deskreferences/Pages/Breast-Cancer-Staging.aspx

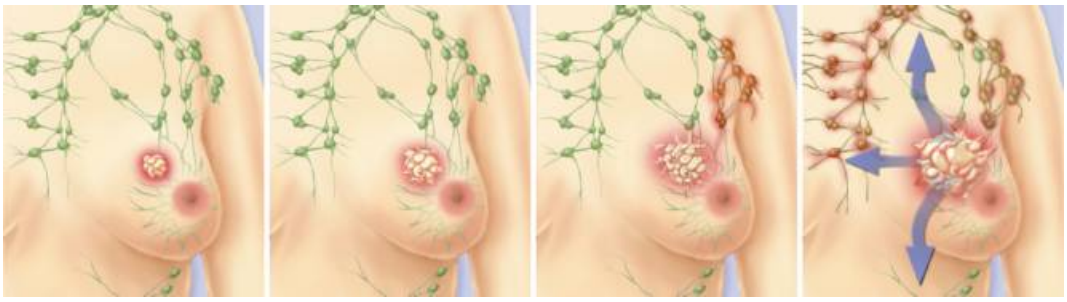

FIGURE 6.4. Stages I to IV of breast cancer.

Risk Factors

Breast cancer is thought to develop in response to a number of related factors: aging; gender (99% of cases occur in women); delayed childbearing or nulliparity; genetic influences; BRCA1 and BRCA2 genetic mutations; history of receiving ionizing radiation; high breast density on a mammogram; postmenopausal obesity; family history of cancer; hormonal factors such as early menarche

younger than 12 years, late menopause older than 50 years, first term pregnancy older than 30 to 35 years of age; HRT with estrogen plus progestin; obesity; lifelong physical inactivity; White race; and ingestion of two drinks or more alcohol each day (NCI, 2019c). Other factors might contribute to breast cancer but have not yet been scientifically proven.

In 1970, the lifetime risk for developing breast cancer was one in 10; since then, the risk has gradually risen (NCI, 2019b). This slight increase in incidence might be explained in a variety of ways. Better detection and screening tools are available, which have identified more cases; women are living to older ages when their risk increases; and lifestyle changes in American women (such as having their first pregnancy at an older age, having fewer children, and using HRT to treat the symptoms of menopause) might have produced the higher numbers. Age is a significant risk factor. Because rates of breast cancer increase with age, estimates of risk at specific ages are more meaningful than estimates of lifetime risk. The estimated chances of a woman being diagnosed with breast cancer between the ages of 30 and 70 are detailed in Table 6.3.

Risk factors for breast cancer can be divided into those that cannot be changed (nonmodifiable risk factors) and those that can be changed (modifiable risk factors). Nonmodifiable risk factors (NCI, 2019c) include:

- Gender (female)
- Aging (older than 50 years old)
- Genetic mutations (BRCA1 and BRCA2 genes)
- Personal history of ovarian or colon cancer
- Increased breast density increases the risk three- to fivefold
- Family history of breast cancer
- Personal history of breast cancer (three- to fourfold increase in risk for recurrence)
- Race/ethnicity (higher in White women, though African American women are more likely to die of breast cancer)
- Previous abnormal breast biopsy (atypical hyperplasia)
- Exposure to chest radiation (radiation damages DNA)
- Previous breast radiation (12 times normal risk)

- Early menarche (younger than 12 years old) or late onset of menopause (older than 55 years old), which represents increased estrogen exposure over the lifetime

Modifiable risk factors related to lifestyle choices (ACS, 2020d) include:

- Not having children at all or not having children until after age 30; this increases the risk of breast cancer by not reducing the number of menstrual cycles
- Postmenopausal use of estrogens and progestins; the Women's Health Initiative study reported increased risks with long-term (longer than 5 years) use of HRT
- Failing to breast-feed for up to a year after pregnancy; increases the risk of breast cancer because it does not reduce the total number of lifetime menstrual cycles
- Alcohol consumption; boosts the level of estrogen in the bloodstream
- Smoking; exposure to carcinogenic agents found in cigarettes
- Obesity and consumption of high-fat diet; fat cells produce and store estrogen, so more fat cells create higher estrogen levels
- Sedentary lifestyle and lack of physical exercise; increases body fat, which houses estrogen

TABLE 6.3 Estimated Risk of Breast Cancer at Specific Ages

Ages 30–39	1 out of 228
Ages 40–49	1 out of 69
Ages 50–59	1 out of 43
Ages 60–69	1 out of 29

Breast Cancer Organization. (2020g). *Risk of developing breast cancer*. Retrieved December 20, 2018, from https://www.breastcancer.org/symptoms/understand_bc/risk/understanding

Breast cancer incidence rates are higher in non-Hispanic White women compared with African American women for most age groups. However, African American women have a higher incidence

rate before 40 years of age and are more likely to die from breast cancer at every age (ACS, 2020d). Some of that gap is because of social factors such as poverty and restricted access to health care. Some studies have also found genetic differences in the type of breast cancer that develops in African American and White women. Little is known, however, about whether other risk factors have a different impact in women of different races. A new study's findings suggest that the risk factors are similar in both races (ACS, 2020d).

The presence of risk factors, especially several of them, calls for careful ongoing monitoring and evaluation to promote early detection. Even though risk factors are important considerations, many women with newly diagnosed breast cancer have no known risk factors. Although routine mammography and self-examination are prudent for high-risk women, these precautions may become lifesavers for early detection of cancerous lesions.

Consuming a low-fat diet with plenty of fruits, vegetables, legumes, and whole grains can provide all the vitamins and nutrients our bodies need and has been shown to significantly reduce the risk of developing many types of cancer. A plant-based diet can also reduce cancer recurrence; this includes high-fiber, low-fat diets rich in fruits and vegetables and avoiding sugared beverages, calorie-dense foods, and processed meats (ACS, 2020e). Researchers studied the effectiveness of a high-vegetable, low-fat diet aimed at markedly raising circulating carotenoid concentrations from food sources in reducing additional breast cancer events and early death in women with early-stage invasive breast cancer. This diet proved to be a prescription for cancer prevention that has only positive side effects, including lower cholesterol, weight loss, and a lower risk of heart disease. Adherence to a plant-based diet that limits red meat intake may be associated with reduced risk of breast cancer, particularly in postmenopausal women (ACS, 2020e).

Screening for breast cancer begins with a routine history and physical exam. Nurses should take every opportunity to educate and emphasize the goal of breast cancer screening: early detection reduces mortality. Screening also includes a BSE, clinical breast exam, and mammography.

Diagnosis

Many studies can be performed to make an accurate diagnosis of a malignant breast lump. Diagnostic tests include:

- Diagnostic mammography or digital mammography
- Magnetic resonance mammography (MRM)
- Fine-needle aspiration
- Stereotactic needle-guided biopsy
- Sentinel lymph node biopsy
- Hormone receptor status
- Infrared thermal imaging
- DNA ploidy status
- Cell proliferative indices
- HER2/neu genetic marker (Oyelowo & Johnson, 2018)

Mammography

Mammography has become an accepted screening procedure that is sanctioned by most cancer organizations and is paid for annually by most health insurance agencies. Mammography can provide a diagnosis while screening for preclinical disease to prevent adverse outcomes, improve survival, and avoid intensive treatment. Mammography involves taking x-ray pictures of a bare breast while it is compressed between two plastic plates. This can identify and characterize a breast mass and detect an early malignancy. It remains the gold standard screening method for women at average risk for breast cancer. It is relatively inexpensive, requires only a low dose of radiation, and reliably identifies malignant tumors, including those that are too small to feel. It can also be used to investigate breast lumps and other symptoms. A screening mammogram typically consists of four views, two per breast (Fig. 6.5). It can detect lesions as small as 0.5 cm; the average size of a tumor detected by a woman practicing occasional BSE is approximately 2.5 cm (CDC, 2019b).

A diagnostic mammogram is performed when a woman has suspicious clinical findings on a breast examination or an abnormality has been found on a screening mammogram. A

diagnostic mammogram uses additional views of the affected breast as well as magnification views. Diagnostic mammography provides the radiologist with additional detail to render a more specific diagnosis. Currently, digital mammography is being used to diagnose breast lesions.

Most women find the 10-minute mammography procedure uncomfortable but not painful. Teaching Guidelines 6.3 offers tips for a client to follow before she undergoes this procedure.

FIGURE 6.5. Mammography. **A.** A top-to-bottom view of the breast. **B.** A side view of the breast.

TEACHING GUIDELINES 6.3

Preparing for a Screening Mammogram

- Schedule the procedure just after menses when breasts are less tender.
- Do not use deodorant or powder on the day of the procedure, because they can appear on the x-ray film as calcium spots.
- Acetaminophen (Tylenol) or acetylsalicylic acid (aspirin) can relieve any discomfort after the procedure.
- Remove all jewelry from around the neck because the metal can cause distortions on the film image.
- Select a facility that is accredited by the American College of Radiology to ensure appropriate credentialed staff.

The U.S. Preventive Services Task Force (USPSTF) changed its recommendations for breast cancer screening in 2018, resulting in considerable controversy. The USPSTF now recommends biennial screening mammography for women ages 50 to 74 years. Previously, women 40 years and older were advised to start screening mammography. The organization stated that the decision to start regular, biennial screening mammography before the age of 50 years should be an individual one and take client context into account, including the client's values regarding specific benefits and harms. In addition, the USPSTF concluded that the current evidence is insufficient to assess the additional benefits and harms of screening mammography in women 75 years or older. Finally, the USPSTF recommended against teaching BSE because scientific evidence does not support this practice as a valid screening method for women since its sensitivity ranges from 12% to 41%, lower than that of the clinical breast exam (CBE) done by a health care provider and mammography; it is also age-dependent.

The ACS has different guidelines for women with no symptoms or family histories of breast cancer than does the USPSTF. The ACS still recommends annual mammograms and clinical breast exams for women starting at ages 40 to 54 and then biennially, starting at age

55. The ACS also recommends a clinical breast exam about every 3 years for women in their 20s and 30s and every year for women older than 40. Per the ACS, BSE is an option for women starting in their 20s (AFP, 2018).

The American College of Obstetricians and Gynecologists (ACOG) recommends that mammography screening be offered annually or biennially to women beginning at ages 40 to 75. ACOG continues to recommend annual CBEs for women ages 40 and older and every 1 to 3 years for women ages 20 to 39. Additionally, it encourages breast self-awareness for women ages 20 and older (ACOG, 2018).

This conflicting information can be confusing to women trying to make decisions about breast cancer screening. Nurses can present the latest evidence-based research to help women make informed decisions based on their age, overall health status, and family history of cancer. (See Table 6.4 for a helpful outline.) Because they contradict one another, there isn't any clear direction from the authoritative organizations; each woman and her health care provider should make the best choice for her. The associated risk is delay in detecting a breast lesion early when it could be treated earlier.

Magnetic Resonance Mammography

MRM of the breast uses a powerful magnetic field, radio waves, and a computer to produce detailed pictures of the breast structures. It allows for earlier detection because it can detect smaller lesions and provide finer detail. MRM is a highly accurate (higher than 90% sensitivity for invasive carcinoma) but costly tool. Contrast infusion is used to evaluate the rate at which the dye initially enters the breast tissue. The basis of the high sensitivity of MRM is the tumor angiogenesis (vessel growth) that accompanies a majority of breast cancers, even early ones. Currently, MRM is used as a complement to mammography and CBE because it is expensive, but recent research findings report that it is more accurate than mammography for size assessment of breast lesions (Radiology Information Organization, 2018).

TABLE 6.4 Screening Recommendations from USPSTF, ACS, and ACOG

U.S. Preventive Services Task Force (USPSTF)	Updated recommendations include biennial screening mammography for women aged 50–74 years and no BSE since scientific evidence does not support this practice as a valid screening method for women because its sensitivity ranges from 12–41%, which is lower than that of the CBE done by a health professional and mammography, and it is age-dependent (2018). The USPSTF states a woman's decision to start regular, biennial screening mammography before the age of 50 years should be an individual one and take client context into account, including the client's values regarding specific benefits and harms. The USPSTF also reports that current evidence is insufficient to assess the additional benefits and harmful aspects of screening mammography in women 75 years or older (2018).
American Cancer Society (ACS)	The ACS still recommends annual mammograms and CBEs for women starting at age 45–54. At age 55 and older, women should have them every 2 years or continue annually. ACS suggests BSEs can be optional for women from age 20 onward (2020i).
American College of Obstetricians and Gynecologists (ACOG)	ACOG recommends screening mammograms be offered annually to women beginning at age 40. Previous guidelines recommended a mammogram every 1–2 years starting at age 40 and annually beginning at age 50. CBEs are still recommended every year, but BSEs are optional and not strongly recommended (2018).

Fine-Needle Aspiration Biopsy or Core Biopsy

Fine-needle aspiration biopsy is done to identify a solid tumor, cyst, or malignancy. It is a simple office procedure that can be performed with or without anesthesia. A small (23- to 27-gauge) needle connected to a 10-mL or larger syringe is inserted into the breast mass, and suction is applied to withdraw the contents. The aspirate is then sent to the cytology laboratory to be evaluated for abnormal cells.

A core needle biopsy is much like a fine-needle biopsy except that a larger needle is used to withdraw small cylinders or cores of tissue

from the abnormal area of the breast. It takes longer than the fine-needle biopsy, but more tissue is sampled to be tested.

Stereotactic Needle-Guided Biopsy

Stereotactic needle-guided biopsy is used to target and identify mammographically detected nonpalpable lesions in the breast. This procedure is less expensive than an excisional biopsy. The procedure takes place in a specially equipped room and generally takes about an hour. Women are required to lie prone and must be able to remain still for approximately 20 minutes while the biopsy is taken. When proper placement of the breast mass is confirmed by digital mammograms, the breast is locally anesthetized and a spring-loaded biopsy gun is used to obtain two or three core biopsy tissue samples. After the procedure is finished, the biopsy area is cleaned and a sterile dressing is applied.

Sentinel Lymph Node Biopsy

The status of the axillary lymph nodes is an important prognostic indicator in early-stage breast cancer. The presence or absence of malignant cells in lymph nodes is highly significant; the more lymph nodes involved and the more aggressive the cancer, the more powerful chemotherapy will have to be, both in terms of the toxicity of drugs and the duration of treatment (Breast Cancer Organization, 2020c). With a sentinel lymph node biopsy, the clinician can determine whether breast cancer has spread to the axillary lymph nodes without having to do a traditional axillary lymph node dissection. Experience has shown that the lymph ducts of the breast typically drain to one lymph node first before draining through the rest of the lymph nodes under the arm. The first lymph node is called the sentinel lymph node.

This procedure can be performed under local anesthesia. A radioactive blue dye is injected 2 hours before the biopsy to identify the afferent sentinel lymph node. The surgeon usually removes one to three nodes and sends them to the pathologist to determine whether cancer cells are present. The sentinel lymph node biopsy is

usually performed before a lumpectomy to make sure the cancer has not spread. Removing only the sentinel lymph node can allow women with breast cancer to avoid many of the side effects (lymphedema) associated with a traditional axillary lymph node dissection. This procedure is associated with less morbidity compared to the axillary lymph node dissection, which results in more accurate staging, better axillary tumor control and improved survival.

Hormone Receptor Status

Normal breast epithelium has hormone receptors and responds specifically to the stimulatory effects of estrogen and progesterone. Most breast cancers retain estrogen receptors, and for those tumors, estrogen will retain proliferative control over the malignant cells. It is therefore useful to know the hormone receptor status of the cancer to predict which women will respond to hormone manipulation. Hormone receptor status reveals whether the tumor is stimulated to grow by estrogen and progesterone. Postmenopausal women tend to be ER-positive (have cancer cells that grow in response to estrogen); premenopausal women tend to be ER-negative (have fewer hormone receptors and thus don't respond to hormones) (Breast Cancer Organization, 2020d). To determine hormone receptor status, a sample of breast cancer tissue obtained during a biopsy or a tumor removed surgically during a lumpectomy or mastectomy is examined by a cytologist.

Therapeutic Management

Women diagnosed with breast cancer have many treatments available to them. Generally, treatments fall into two categories: local and systemic. Local treatments are surgery and radiation therapy. Effective systemic treatments include chemotherapy, hormonal therapy, and immunotherapy.

Treatment plans are based on multiple factors, with the primary factors being whether the cancer is invasive or noninvasive, the

tumor's size and grade, the number of cancerous axillary lymph nodes, the hormone receptor status, the woman's overall health, and the ability to obtain clear surgical margins (ACS, 2020f). A combination of surgical options and adjunctive therapy is often recommended.

Another consideration in making decisions about a treatment plan is genetic testing for BRCA1 and BRCA2 genetic mutations. This genetic testing became available in 1995 and can identify women who have a significantly increased risk for breast, ovarian cancer, and contralateral breast cancer; individuals with BRCA1 and BRCA2 mutations have a 75% lifetime risk of breast cancer and a 30% lifetime risk of ovarian cancer. Most cases of breast and ovarian cancers are sporadic in nature, but approximately 10% of breast and ovarian cancers are thought to result from genetic inheritance (Morgan et al., 2018). DNA (from a blood or saliva sample) is needed for mutation testing. The sample is sent to a laboratory for analysis. Testing positive for a BRCA1 or BRCA2 mutation can significantly alter health care decisions. In some cases, before genetic testing was available, lumpectomy with radiation, or mastectomy was the treatment most often recommended. The risk posed by a BRCA mutation can help women and their teams determine the prognosis and ultimately treatment (Fasching, 2018). Some women may choose to have a preventative mastectomy (Evidence-Based Practice 6.1). Based on Mendelian genetics, women with BRCA1 and BRCA2 mutations are five to 20 times more likely to develop breast and ovarian cancers (Caruso et al., 2018).

However, severe psychological distress can occur as a result of genetic testing. Distress is related to family cancer history, relationships, coping strategies, communication patterns, and mutation status (Bredart et al., 2018). Nurses might find it useful to explore these issues in order to prepare clients before BRCA testing and to support them through shifts in family dynamics after disclosure of results. Many women perceive their breasts as intrinsic to their femininity, self-esteem, and sexuality, and the possibility of losing a breast can provoke extreme anxiety (O'Neill et al., 2018). Nurses need to address the physical, emotional, and spiritual needs

of the women they care for as well as those of their families. Nurses should identify the woman's personal coping style which has an impact on how she experiences and copes with distress after a diagnosis. Women who are emotionally expressive and/or have a "fighting spirit" usually experience lower levels of emotional distress.

EVIDENCE-BASED PRACTICE 6.1 Risk-Reducing Mastectomy for the Prevention of Primary Breast Cancer

BACKGROUND

Recent progress in understanding the genetic basis of breast cancer and widely publicized reports of celebrities undergoing risk-reducing mastectomy (RRM) have increased interest in RRM as a method of preventing breast cancer.

STUDY

The objective of this study was to determine whether risk-reducing mastectomy reduced death rates from any cause in women who have never had cancer and in women who have a history of breast cancer in one breast. The data included 61 observational studies on 15,077 women who had a wide range of risk factors for breast cancer and who underwent RRM. RRM could include either surgically removing both breasts to prevent breast cancer or removing the disease-free breast in women who have had breast cancer to reduce the incidence of breast cancer in the other breast.

Findings

The studies reported that BRRM (bilateral risk-reducing mastectomy) reduced the incidence of breast cancer or the number of deaths or both, but many of the studies had methodologic limitations. After BRRM, most women were satisfied with the decision. One of the complications of RRM was the need for additional unplanned surgeries in women undergoing reconstruction of the surgical area. However, most women expressed reduced worry of developing and dying from breast cancer. While published observational studies demonstrated

BRRM was effective in both reducing the incidence of and death of breast cancer, more rigorous prospective studies are suggested.

Nursing Implications

Nurses need to advise women that BRRM is a surgical procedure to be considered only by those women at high risk, as it is not a procedure that should routinely be considered by women with an average risk of breast cancer. BRRM clearly reduces the incidence of breast cancer, but women also need to understand and be advised of the psychological risks and physical harms. Nurses should advise genetic counseling for women to determine their actual risk profiles. Nurses should offer understandable and complete information about all options to women who are making their decision about whether to have RRM. The nurse should ensure psychosocial support for all women throughout the process; this is always a highly personal decision.

Carbine, N. E., Lostumbo, L., Wallace, J., & Ko, H. (2018). Risk-reducing mastectomy for the prevention of primary breast cancer. Cochrane Database of Systematic Reviews. Issue 4.
https://doi.org/10.1002/14651858.CD002748.pub4

Surgical Options

The primary goal of breast cancer surgery is to successfully remove the breast cancer from the woman. A secondary and important goal is to reconstruct the removed tissue so as to allow the woman to feel whole from a psychological perspective. Both these goals are central to the surgical decision-making of breast cancer treatment (Chatterjee, 2018). Women with tumors larger than 5 cm or inflammatory breast cancer may undergo neoadjuvant chemotherapy or radiotherapy to shrink the tumor before surgical removal is attempted (Warburton et al., 2018). The surgical options depend on the type and extent of cancer. The choices are typically either breast-conserving surgery (lumpectomy with radiation) or mastectomy with

or without reconstruction. The overall survival rate with lumpectomy and radiation is about the same as that with modified radical mastectomy (Kirby et al., 2018). Research has shown that the survival rates in women who have had mastectomies versus those who have undergone breast-conserving surgery followed by radiation are the same. However, lumpectomy may not be an option for some women, including those:

- who have two or more cancer sites that cannot be removed through one incision.
- whose surgery will not result in a clean margin of tissue.
- who have active connective tissue conditions (lupus or scleroderma) that make body tissues especially sensitive to the side effects of radiation.
- who have had previous radiation to the affected breast.
- whose tumors are larger than 5 cm (2 in) (National Comprehensive Cancer Network [NCCN], 2019).

These decisions are made jointly between the woman and her surgeon. If mastectomy is chosen, because of either tumor characteristics or client preference, then discussion needs to include breast reconstruction and regional lymph node biopsy versus sentinel lymph node biopsy. The mastectomy techniques are a simple mastectomy with sentinel node biopsy or a radical mastectomy with regional node biopsy. Removal of numerous lymph nodes places the client at high risk for lymphedema.

BREAST-CONSERVING SURGERY

Breast-conserving surgery, the least invasive procedure, is the wide local excision (or lumpectomy) of the tumor along with a 1-cm margin of normal tissue. A lumpectomy is often used for early-stage localized tumors. The goal of breast-conserving surgery is to remove the suspicious mass along with tissue free of malignant cells to prevent recurrence. The results are less drastic and emotionally less scarring than having a mastectomy to the woman. Women undergoing breast-conserving therapy may receive radiation after lumpectomy with the goal of eradicating residual microscopic cancer

cells to limit locoregional recurrence. In women who do not require adjuvant chemotherapy, radiation therapy typically begins 2 to 4 weeks after surgery to allow healing of the lumpectomy incision site. Radiation is administered to the entire breast at daily doses over a period of several weeks and has been found to increase survival rates over mastectomy without radiation (de Boniface et al., 2018).

A sentinel lymph node biopsy may also be performed since the lymph nodes draining the breast are located primarily in the axilla. Theoretically, if breast cancer is to metastasize to other parts of the body, it will probably do so via the lymphatic system. If malignant cells are found in the nodes, more aggressive systemic treatment may be needed.

MASTECTOMY

A **simple mastectomy** is the removal of all breast tissue, the nipple, and the areola. The axillary nodes and pectoral muscles are spared. This procedure would be used for a large tumor or multiple tumors that have not metastasized to adjacent structures or the lymph system.

A **modified radical mastectomy** is another surgical option conducive to breast reconstruction and resulting in greater mobility and less lymphedema (Kirby et al., 2018). This procedure involves removal of breast tissue, and a few positive axillary nodes. Breast-conserving surgeries do not increase the future risk of death from recurrent disease when compared to mastectomy (Lagendijk et al., 2018).

In conjunction with the mastectomy, lymph node surgery (removal of underarm nodes) may need to be done to reduce the risk of distant metastasis and improve a woman's chance of long-term survival. For women with a positive sentinel node biopsy, 10 to 20 underarm lymph nodes may need to be removed. Complications associated with axillary lymph node surgery include nerve damage during surgery, causing temporary numbness down the upper aspect of the arm; seroma formation (fluid buildup) followed by wound infection; restrictions in arm mobility (some women need

physiotherapy); and lymphedema (swelling related to the lymph glands). In many women, lymphedema can be avoided by:

- avoiding using the affected arm for drawing blood, inserting intravenous lines, or measuring blood pressure (can cause trauma and possible infection).
- seeking medical care immediately if the affected arm swells.
- wearing gloves when engaging in activities such as gardening that might cause injury.
- wearing a well-fitted compression sleeve to promote drainage return.

Women having mastectomies must decide whether to have further surgery to reconstruct the breast. If the woman decides to have reconstructive surgery, it is ideally performed immediately after the mastectomy. The woman must also determine whether she wants the surgeon to use saline implants or natural tissue from her abdomen (TRAM flap method) or back (LAT flap method).

If reconstructive surgery is desired, the ultimate decision regarding the method will be determined by the woman's anatomy (e.g., sufficient fat and muscle to permit natural reconstruction) and her overall health status. Both procedures require a prolonged recovery period.

Some women opt for no reconstruction, and many of them choose to wear breast prostheses. Some prostheses are worn in the bra cup and others fit against the skin or into special pockets created into clothing.

Whether to have reconstructive surgery is an individual and complex decision. Each woman must be presented with all of the options and then allowed to decide. The nurse can play an important role here by presenting the facts to the woman so that she can make an intelligent decision to meet her unique situation. Breast reconstruction surgery can help restore the look and feel of the breast after a mastectomy. Performed by a plastic surgeon, breast reconstruction can be done immediately after the mastectomy or at a later date. Breast reconstruction can be done with **breast implants** (filled with saline or silicone); natural tissue flaps (using skin fat and

muscle from the woman's own body); or a combination of both. Side effects or complications include risk of rupture, hardening of the tissues around the implant, infection, and pain. Nurses need to educate the woman about these potential problems and make sure she understands before consenting to breast reconstruction. See Figure 6.6 for examples of postmastectomy and reconstruction.

BREAST AUGMENTATION

Breast augmentation is a surgical procedure by which the breast size is enhanced. It is a common surgical procedure with women undergoing it with implants for a variety of reasons ranging from aesthetic to reconstructive surgery following a mastectomy. Saline-filled or silicone-filled implants are used in cosmetic enhancement and reconstructive surgeries, but both have an outer silicone shell. The exact anatomic placement of breast implants can vary, but the location is typically subglandular (over the pectoral muscle) or subpectoral (under the muscle). Breast implants are not lifetime devices, but most are guaranteed for approximately 10 years in case of rupture. Breast augmentation with implants is not without risks. Potential complications include capsular contracture, rippling, implant rupture, asymmetry, breast pain, infection, or hematoma. Capsular contraction occurs when scar tissue forms, contracts, and hardens around the implant. Rippling most often occurs when wrinkles form in the implant or as a complication of contracture (Fardo & Pensler, 2019).

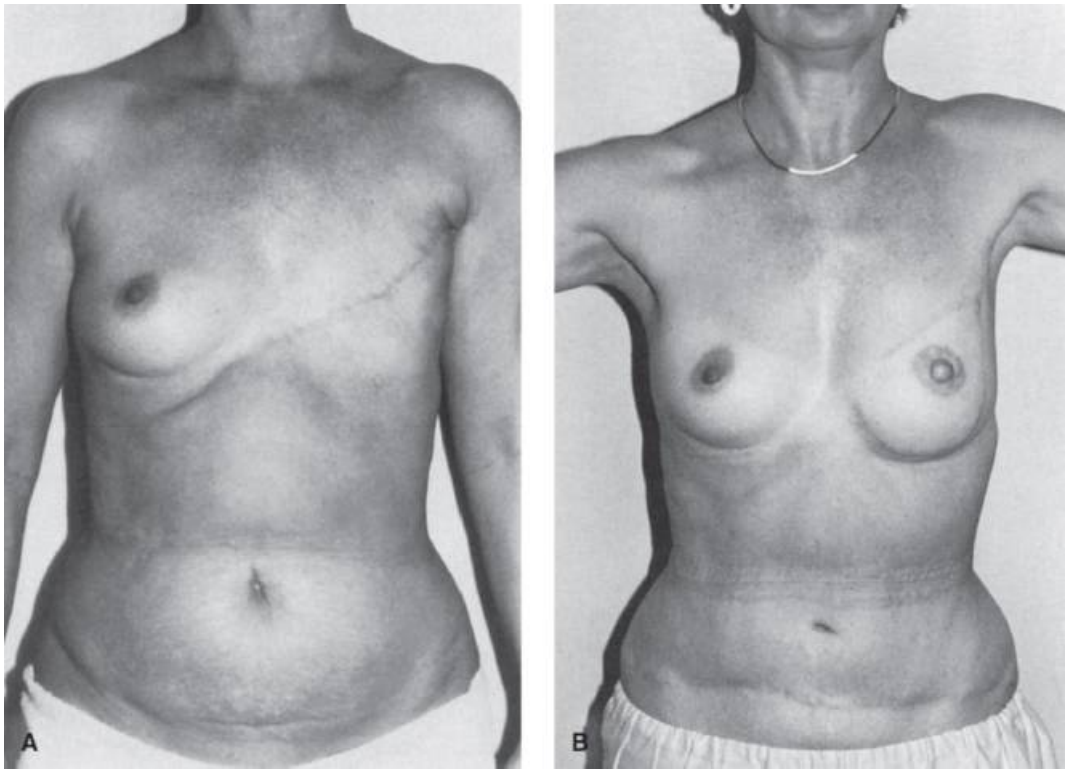

FIGURE 6.6. Before and after photos of postmastectomy and reconstruction.

Breast examination in women with reconstructive surgery is done exactly the same way as for natural breasts. Breasts with implants in place usually feel firmer than normal breast tissue on palpation due to the formation of a fibrotic band or capsule around the implant. If implants are used, press firmly inward at the edges of the implant to feel the ribs beneath it.

Adjunctive Therapy

Adjunctive therapy is supportive or additional therapy that is recommended after surgery. Adjunctive therapies include local therapy such as radiation therapy and systemic therapies using chemotherapy, hormonal therapy, and immunotherapy.

RADIATION THERAPY

Radiation therapy (also called radiotherapy) uses high-energy rays to destroy cancer cells that might have been left behind in the breast, chest wall, or underarm area after a tumor has been removed surgically. Usually serial radiation doses are given 5 days a week to the tumor site for 6 to 8 weeks postoperatively. Each treatment takes only a few minutes, but the dose is cumulative. Women undergoing breast-conserving therapy receive radiation to the entire breast after lumpectomy with the goal of eradicating residual microscopic cancer cells to reduce the chance of recurrence (Oyelowo & Johnson, 2018).

Side effects of traditional radiation therapy include inflammation, local edema, anorexia, swelling, and heaviness in the breast; sunburn-like skin changes in the treated area; and fatigue. Changes to the breast tissue and skin usually resolve in about a year in most women. Radiation induces systemic alterations in a number of innate and adaptive immune cells (Lewin, 2018). This type of therapy can be given several ways: external beam radiation, which delivers a carefully focused dose of radiation from a machine outside the body, or internal radiation, in which tiny pellets that contain radioactive material are placed into the tumor.

Several advances have taken place in the field of radiation oncology for the treatment of women with early-stage breast cancer that assist in reducing the side effects. The treatment position for external radiation has changed from supine to prone with the arm on the affected side raised above the head so that the treated breast hangs dependently through the opening of the treatment board. Treatment in the prone position improves dose distribution within the breast and allows for a decrease in the dose delivered to the heart, lung, chest wall, and other breast (NCCN, 2019).

High-dose brachytherapy is another advance that is an alternative to traditional radiation treatment. A balloon catheter is used to insert radioactive seeds into the breast after the tumor has been removed surgically. The seeds deliver a concentrated dose directly to the operative site; this is important because most cancer recurrences in the breast occur at or near the lumpectomy site (Kauer-Dorner & Berger, 2018). This allows a high dose of radiation to be delivered to

a small target volume with a minimal dose to the surrounding normal tissue. This procedure takes 4 to 5 days as opposed to the 4 to 6 weeks that traditional radiation therapy takes; it also eliminates the need to delay radiation therapy to allow for wound healing. Brachytherapy is now used frequently after breast-conserving surgery in selected women as an alternative to whole breast irradiation (NCI, 2019d). Side effects of brachytherapy include redness or discharge around catheters, fever, and infection. Daily cleansing of the catheter insertion site with a mild soap and application of an antibiotic ointment will minimize the risk of infection.

Intensity-modulated radiation therapy (IMRT) offers another approach to the delivery of treatment to reduce the dose within the target area while sparing surrounding normal structures. A computed tomography scan is used to create a three-dimensional model of the breast. Based on this model, a series of intensity-modulated beams is produced to the desired dose distribution to reduce radiation exposure to underlying structures. Acute toxicity is thus minimized (Cho, 2018). Research is ongoing to evaluate the impact of all of these advances in radiation therapy.

CHEMOTHERAPY

Chemotherapy refers to the use of drugs that are toxic to all cells and interfere with a cell's ability to reproduce. They are particularly effective against malignant cells but affect all rapidly dividing cells, especially those of the skin, the hair follicles, the mouth, the gastrointestinal tract, and the bone marrow. Breast cancer is a systemic disease in which micrometastases are already present in other organs by the time the breast cancer is diagnosed. Chemotherapeutic agents perform a systemic "sweep" of the body to reduce the chances that distant tumors will start growing.

Chemotherapy may be indicated for women with tumors larger than 1 cm, positive lymph nodes, or cancer of an aggressive type. Chemotherapy is prescribed in cycles, with each period of treatment followed by a rest period. Treatment typically lasts 3 to 6 months, depending on the dose used and the woman's health status. Recent

research indicates many women with early-stage breast cancer don't need adjuvant chemotherapy to prevent recurrence of cancer. Chemotherapy may be avoided in about 70% of women with HR-positive, HER2-negative, node-negative breast cancer (Sparano et al., 2018).

Different classes of drugs affect different aspects of cell division and are used in combinations or "cocktails." The most active and commonly used chemotherapeutic agents for breast cancer include alkylating agents, anthracyclines, antimetabolites, and vinca alkaloids. There are more than 50 chemotherapeutic agents that can be used to treat breast cancer; however, a combination drug approach appears to be more effective than a single-drug treatment (ACS, 2020g).

Side effects of chemotherapy depend on the agents used, the intensity of dosage, the dosage schedule, the type and extent of cancer, and the client's physical and emotional status. Nurses need to remain updated in order to accommodate new treatments and the side-effect profiles. This knowledge is vital in providing evidence-based care for women receiving these treatments (Breast Cancer Organization, 2020e). However, typical side effects include nausea and vomiting, diarrhea or constipation, hair loss, weight loss, stomatitis, fatigue, and immunosuppression. The most serious is bone marrow suppression (myelosuppression). This causes an increased risk of infection, bleeding, and a reduced red blood cell count, which can lead to anemia. Treatment of the side effects can generally be addressed through appropriate support medications such as antinausea drugs. In addition, growth-stimulating factors, such as epoetin alfa (Procrit) and filgrastim (Neupogen), help keep blood counts from dropping too low. Counts that are too low can stop or delay the use of chemotherapy.

An aggressive systemic option, when other treatments have failed or when there is a strong possibility of relapse or metastatic disease, is high-dose chemotherapy with bone marrow and/or stem cell transplant. This therapy involves the withdrawal of bone marrow before the administration of toxic levels of chemotherapeutic agents. The marrow is frozen and then returned to the client after the high-

dose chemotherapy is finished. Due to the limited efficacy of chemotherapy alone against metastatic breast cancer, autologous hematopoietic stem cell transplantation has been used to avoid the myelotoxic effects of high-dose chemotherapy (Karadurmus et al., 2018).

HORMONAL THERAPY

One of estrogen's normal functions is to stimulate the growth and division of healthy cells in the breasts. However, in some women with breast cancer, this normal function contributes to the growth and division of cancer cells.

The objective of **endocrine therapy** is to block or counter the effect of estrogen. Estrogen plays a central role in the pathogenesis of cancer, and treatment with estrogen deprivation has proven to be effective. Approximately two thirds of women diagnosed with early-stage breast cancer have hormone-sensitive disease (estrogen receptor-positive and/or progesterone receptor-positive), and adjuvant hormone therapy plays an essential role in reducing the risk of recurrence and improving survival. Hormone therapy acts in one of three ways: blocks estrogen, prevents the body from producing estrogen, and eliminates the hormone receptors on cells, making it impossible for estrogen to properly attached itself to breast cell tissue to grow (Vachani, 2020). Several different drug classes are used to interfere or block estrogen receptors. They include selective estrogen receptor modulators (SERMs), estrogen receptor downregulators, aromatase inhibitors, luteinizing hormone-releasing hormone, progestin, and biologic response modifiers (Skidmore-Roth, 2021). Current recommendations for most women with ER-positive breast cancer are to take a hormone-like medication—known as a SERM antiestrogenic agent—daily for up to 5 years after initial treatment. Certain areas in the female body (breasts, uterus, ovaries, skin, vagina, and brain) contain specialized hormone receptors that allow estrogen to enter the cell and stimulate it to divide. SERMs enter these same receptors and act like keys, turning off the signal for growth inside the cell (Skidmore-Roth, 2021). The

best-known SERM is tamoxifen (Nolvadex, 20 mg daily for 5 years). Although it works well in preventing the further spread of cancer, it is also associated with an increased incidence of endometrial cancer, pulmonary embolus, deep vein thrombosis, hot flashes, vaginal discharge and bleeding, stroke, and cataract formation (Breast Cancer Organization, 2020f).

Another class of endocrine agents, aromatase inhibitors, works by inhibiting the conversion of androgens to estrogens. Aromatase inhibitors include letrozole (Femara, 2.5 mg daily), exemestane (Aromasin, 25 mg daily), and anastrozole (Arimidex, 1 mg daily for 5 years), all of which are taken orally. These are usually given to women with advanced breast cancer. In recent clinical studies in postmenopausal women with breast cancer, third-generation aromatase inhibitors were shown to be superior to tamoxifen for the treatment of metastatic disease (Vachani, 2018).

The side effects associated with these endocrine therapies include hot flashes, bone pain, bone thinning, insomnia, weight gain, depression, fatigue, mood swings, constipation, nausea, cough, dyspnea, and headache (Breast Cancer Organization, 2020f). Women with hormone-sensitive cancers can live for long periods without any intervention other than hormonal manipulation, but quality-of-life issues need to be addressed in the balance between treatment and side effects.

IMMUNOTHERAPY

Immunotherapy, used as an adjunct to surgery, represents an attempt to stimulate the body's natural defenses to recognize and attack cancer cells. It uses the immune system to identify and attack cancer cells. Trastuzumab emtansine (Kadcyla), trastuzumab (Herceptin), and pertuzumab (Perjeta) are immunotherapy options that target the HER2 pathway (Cancer Research Institute, 2019). Immunotherapy treatment has the potential to improve outcomes for clients with breast cancer, and it has several advantages over more conventional chemotherapy-based treatments that directly target the tumor itself. The benefits of immunotherapy include: bolstering other

therapies, such as chemotherapy; it is effective when other treatments aren't; it targets only the client's immune system, so side effects are minimal; and cancer is less likely to return after the client's immune system has learned to target any future cancer cells (NCI, 2019f).

Concept Mastery Alert

Tamoxifen Versus Trastuzumab in Breast Cancer Treatment

Tamoxifen is a SERM used to prevent the further spread of breast cancer in women with ER-positive breast cancer. Trastuzumab is a monoclonal antibody used in the treatment of breast cancer and is considered immunotherapy.

Adverse effects of trastuzumab include cardiac toxicity, vascular thrombosis, hepatic failure, fever, chills, nausea, vomiting, and pain with the first infusion (Skidmore-Roth, 2021).

Nursing Process for the Client with Breast Cancer

When a woman is diagnosed with breast cancer, she faces treatment that may alter her body shape, may make her feel unwell, and may not carry a certainty of cure. Nurses can support women from the time of diagnosis, through the treatments, and through follow-up after the surgical and adjunctive treatments have been completed. Allowing clients the time to ask questions and to discuss any necessary preparations for treatment is critical. As our understanding of breast disorders keeps improving, treatments continue to change.

Although the goal of treatment remains improved survival, increasing emphasis is being focused on prevention. Breast cancer prevention measures focus on evaluating and reducing risk factors. Approaches for reducing breast cancer risk include lifestyle modifications (diet and physical exercise), chemoprevention (SERMs and aromatase inhibitors), and prophylactic surgery (bilateral salpingo-oophorectomy and bilateral prophylactic mastectomy) (National Cancer Institute, 2019e). Nurses can have an impact on early detection of breast disorders, treatment, and symptom management. Women with cancer diagnoses often experience negative emotions and nurses' empathic response can help alleviate this distress (Mahon, 2019). A nurse who is involved in the woman's treatment plan from the beginning can effectively offer support throughout the whole experience.

Teamwork is important in breast screening and caring for women with breast disorders. Treatment is often fragmented between the hospital and community treatment centers, and this can be emotionally traumatic for the woman and her family. The advances being made in the diagnosis and treatment of breast disorders mean that guidelines are constantly changing, requiring all health care providers to keep up to date. Informed nurses can provide

support, information, and most importantly, continuity of care for the woman undergoing treatment for a breast problem.

The nurse plays a particularly important role in providing psychological support and self-care teaching to clients with breast cancer. Nurses can influence both physical and emotional recovery, which are both important aspects of care that help in improving the woman's quality of life and the ability to survive. The nurse's role should extend beyond helping clients; spreading the word in the community about screening and prevention is a big part of the ongoing fight against cancer. The community should see nurses as both educators and valued sources of credible information. This role will help improve clinical outcomes while achieving high levels of client satisfaction.

Despite the new guidelines issued by various governmental agencies regarding BSEs, regular CBEs done by professional health care providers are essential for good breast health for all women. See Box 6.1 for additional information.

Remember Nancy from the chapter opener. Is her response typical of many women upon discovering a lump in the breast? Nancy confides her discovery of the lump and her worries to you. What advice would you give her?

Assessment

Early breast cancer has no symptoms. The earliest sign of breast cancer is often an abnormality seen on a screening mammogram before the woman or the health care provider feels it. A healthy, asymptomatic presentation is typical. However, symptoms may include a lump in the breast that is usually nontender, fixed, and hard with irregular borders. In the woman presenting with a breast disorder, take a thorough history of the problem and explore the woman's risk factors for breast cancer. Assess the woman for clinical manifestations of breast cancer, such as changes in breast appearance and contour, which become apparent with advancing breast cancer (ACS, 2020h). These changes include:

BOX 6.1 Clinical Breast Examination by a Health Care Provider

If the woman is deemed high risk, the nurse would also teach the woman to perform a BSE to enhance breast awareness.

Purpose: To Assess Breasts for Abnormal Findings

- Inspect the breast for size, symmetry, and skin texture and color. It is common for the left breast to be slightly larger than the right. Inspect the nipples and areola. Ask the client to sit at the edge of the examination table with her arms resting at her sides.

- Inspect the breast for masses, retraction, dimpling, or ecchymosis.
- The client places her hands on her hips.

• She then raises her arms over her head so the axillae can also be inspected.

• The client then stands, places her hands on her hips, and leans forward.

- Palpate the breasts using the pads of your first three fingers and make a rotary motion on the breast. Assist the client into a supine position with her arms above her head. Place a pillow or towel under the client's head to help spread the breasts. Three patterns might be used to palpate the breasts:

1. Spiral

2. Pie-shaped wedges

3. Vertical strip

- Compress the nipple gently between the thumb and index finger to evaluate for masses and squeeze to check for any discharge.

- Palpate the axillary area for any tenderness or lymph node enlargement. Have the client sit up and move to the edge of the examination table. While supporting the client's arm, palpate downward from the armpit, palpating toward the ribs just below the breast.

Jarvis, C. (2019). *Physical examination and health assessment* (8th ed.). St. Louis, MO: Saunders Elsevier.

- Continued and persistent changes in the breast
- A lump or thickening in one breast
- Persistent nipple irritation
- Unusual breast swelling or asymmetry
- A lump or swelling in the axilla
- Changes in skin color or texture
- Nipple retraction, tenderness, or discharge

Complete a breast examination to validate the clinical manifestations and findings of the health history and risk factor assessment. The CBE involves both inspection and palpation (see Box 6.1). Helpful characteristics in evaluating palpable breast masses are described in Table 6.5. If a lump can be palpated, the cancer has been there for quite some time.

Be cognizant of the impact that breast cancer has on a woman's emotional state, coping ability, and quality of life. Women may experience sadness, vulnerability, loss of control, alteration of body image and integrity, anger, the illness's impact on relationships, fear of mortality, the need to reprioritize her life, and guilt as a result of having breast cancer. However, despite potential negative outcomes, many women have positive outlooks for their futures and adapt to treatment modalities with good quality of life (Mahon, 2019). Closely monitor clients for their psychosocial adjustment to diagnosis and treatment and be able to identify those who need further psychological intervention. By giving practical advice, the nurse can help the woman adjust to her altered body image and accept the changes in her life.

Because family members play a significant role in supporting women through breast cancer diagnosis and treatment, assess the emotional distress of family members during the course of treatment, and if needed, make a referral for psychological counseling. By identifying interpersonal strain, negative psychosocial side effects of cancer treatment can be minimized.

TABLE 6.5 Characteristics of Benign Versus Malignant Breast Masses

Benign Breast Masses Are Described As	Malignant Breast Masses Are Described As
• Frequently painful	• Hard on palpation
• Firm, rubbery mass	• Painless
• Bilateral masses	• Irregularly shaped (poorly delineated)
• Induced nipple discharge	• Immobile, fixed to the chest wall
• Regular margins (clearly delineated)	• Skin dimpling
• No skin dimpling	• Nipple retraction
• No nipple retraction	• Unilateral mass
• Mobile, not affixed to the chest wall	• Bloody, serosanguineous, or serous nipple discharge
• No bloody discharge	• Spontaneous nipple discharge

Nursing Analyses

Appropriate nursing analyses for a woman with a diagnosis of breast cancer might include:

- Disturbed body image related to:
  - Loss of body part (breast)
  - Loss of femininity
  - Loss of hair due to chemotherapy
- Fear related to:
  - Diagnosis of cancer
  - Prognosis of disease
- Deficient knowledge related to:
  - Cancer treatment options
  - Reconstructive surgery decisions
  - Breast self-examination

Nursing Interventions

Offer information, support, and perioperative care to women diagnosed with breast cancer who are undergoing treatment. Implement health promotion and disease prevention strategies to minimize the risk for developing breast cancer and to promote optimal outcomes.

Remember Nancy, who discovered a breast lump? You offer to go with her to the doctor. After a full examination and several diagnostic tests, the results come back positive for breast cancer. What treatment options does Nancy have, and what factors need to be considered in selecting those options?

Providing Client Education

Help the woman and her partner and/or family members prioritize the voluminous amount of information given to them so that they can make informed decisions. Explain all treatment options in detail so the client and her family understand them. By preparing an individualized packet of information and reviewing it with the woman and her family, the nurse can help the woman understand her specific type of cancer, the diagnostic studies and treatment options she may choose, and the goals of treatment. For example, nurses play an important role in educating women about the use of endocrine therapies, observing women's experiences with treatment, and communicating those observations to their primary health care providers to make dosage adjustments, in addition to contributing to the knowledge base of endocrine therapy in the treatment of breast cancer.

Providing information is a central role of the nurse in caring for the woman with a diagnosis of breast cancer. This information can be given via telephone counseling, one-to-one contact, and pamphlets. Telephone counseling with women and their partners and families may be an effective method to improve symptom management and quality of life. Educate women on living with risk, maintaining quality of life, and participating in support groups (Oyelowo & Johnson, 2018).

Providing Emotional Support

The diagnosis of cancer affects all aspects of life for a woman and her family. The threatening nature of the disease and feelings of uncertainty about the future can lead to anxiety and stress. Address the woman's need for:

- Information about diagnosis and treatment
- Physical care while undergoing treatments
- Contact with supportive people
- Education about disease, options, and prevention measures
- Discussion and support by a caring, competent nurse

Reassure the client and her family that the diagnosis of breast cancer does not necessarily mean imminent death, a decrease in attractiveness, or diminished sexuality. Encourage the woman to express her fears and worries. Be available to listen and address the woman's concerns in an open manner to help her recovery. All aspects of care must include sensitivity to the client's personal efforts to cope and heal. Some women will become involved in organizations or charities that support cancer research; they may participate in breast cancer walks to raise awareness or become a volunteer to help others. Each woman copes in her own personal manner, and all of these efforts can be positive motivators for her own healing.

To help women cope with the diagnosis of breast cancer, the ACS launched Reach to Recovery more than 30 years ago. Specially trained breast cancer survivors give women and their families' opportunities to express their feelings, verbalize their fears, and get answers. When appropriate, recovery volunteers can also provide temporary breast forms and give information on types of permanent prostheses as well as lists of where those items are available in the community. Most importantly, Reach to Recovery volunteers offer understanding, support, and hope through face-to-face visits or by telephone; they are proof that people can survive breast cancer and live productive lives. National contact information is 1-800-ACS-2345.

Providing Postoperative Care

For the woman who has had surgery to remove a malignant breast lump or an entire breast, excellent postoperative nursing care is crucial. Tell the woman what to expect in terms of symptoms and when they usually occur during treatment and after surgery. This allows women to anticipate these symptoms and proactively employ management strategies to improve the experience. Postoperative care includes immediate postoperative care, pain management, care of the affected arm, wound care, mobility care, respiratory care, emotional care, referrals, and educational needs.

IMMEDIATE POSTOPERATIVE CARE

Assess the client's respiratory status by auscultating the lungs and observing the breathing pattern. Assess circulation; note vital signs, skin color, and skin temperature. Observe the client's neurologic status by evaluating the level of alertness and orientation. Monitor the wound for amount and color of drainage. Monitor the intravenous lines for patency, correct fluid, and rate. Assess the drainage tube for amount, color, and consistency of drainage.

PAIN MANAGEMENT

Provide analgesics as needed. Reassure the woman that her pain will be controlled. Teach the woman how to communicate her pain intensity on a scale of 0 to 10, with 10 being the worst pain imaginable. Assess the client's pain level frequently and anticipate pain before assisting the woman in ambulating.

AFFECTED ARM CARE

Elevate the affected arm on a pillow to promote lymph drainage. Make sure no treatments are performed on the affected arm, including laboratory draws, intravenous lines, blood pressures, and so on. Place a sign above the bed to warn others not to touch the affected arm.

WOUND CARE

Observe the wound often and empty drainage reservoirs as needed. Tell the client to report any evidence of infection early, such as fever, chills, or any area of redness or inflammation along the incision line. Also tell the client to report any increase in drainage, foul odor, or separation at the incision site.

MOBILITY CARE

Perform active range-of-motion and arm exercises as ordered. Encourage self-care activities for successful rehabilitation. Perform

dressing and drainage care; explain the care during the procedure.

RESPIRATORY CARE

Assist with turning, coughing, and deep breathing every 2 hours. Explain that this helps to expand collapsed alveoli in the lungs, promotes faster clearance of inhalation agents from the body, and prevents postoperative pneumonia and atelectasis.

EMOTIONAL CARE AND REFERRALS

Encourage the client to participate in her care. Assess her coping strategies preoperatively. Explain possible body image concerns after discharge. Promote the ACS websites, which provide the latest cancer therapy news. Encourage the client to attend local support groups for breast cancer survivors, such as Reach to Recovery.

EDUCATIONAL NEEDS

Provide follow-up information about adjunctive therapy. Explain that radiation therapy may start postoperatively within weeks. Discuss chemotherapy, its side effects and cycles, home care during treatment, and future monitoring strategies. Explain hormonal therapy, including antiestrogens or aromatase inhibitors. Teach progressive arm exercises to minimize lymphedema. Explain that ongoing surveillance is needed to detect recurrence of cancer or a new primary site and that the client will typically see the health care provider every 6 months.

Nancy underwent a mastectomy with radiation and chemotherapy. What follow-up care is needed? How can the nurse assist Nancy in coping with her uncertain future? What community resources might help her?

IMPLEMENTING HEALTH PROMOTION AND DISEASE PREVENTION STRATEGIES

Combining extensive clinical knowledge of breast cancer with an understanding of the support needs of women, nurses play an essential role in making positive impacts on women's lives. Many advances in treating breast cancer have been made, and nurses can serve as the first line of communication for questions throughout the entire journey from diagnosis through treatment.

Prior to any diagnosis of breast cancer, nurses can help guide women toward breast cancer prevention through screenings, lifestyle changes, and health care practices to decrease their risks. In the fight against cancer, nurses often assume a variety of roles, such as educator, counselor, advocate, and role model. Nurses can offer education about:

- Prevention
- Early detection
- Screening
- Dispelling myths and fears
- Self-examination techniques
- Individual risk status and strategies for risk reduction

It is important to be knowledgeable about the most current evidence-based practices and cognizant of how the media presents this information. Offer prevention strategies within the context of a woman's life. Factors such as lifestyle choices, economic status, and multiple roles need to be taken into consideration when counseling women. Advocate for healthy lifestyles and making sound choices to prevent cancer. Nurses, like all health care providers, should offer guidance from a comprehensive perspective that acknowledges the unique needs of each individual. Provide women with information about detection and risk factors, inform them about the new ACS screening guidelines, instruct them on BSEs, and outline dietary changes that might reduce the risk of breast cancer.

Awareness is the first step toward a change in habits. Raising the level of awareness about breast cancer is of paramount importance, and nurses can play an important role in health promotion, disease prevention, and education.

Breast Cancer Screening

The three components of early detection are BSE, CBE, and mammography. The ACS (2020e) has issued breast cancer screening guidelines that offer specific guidance for the women and greater clarification of the role of breast examinations (see Table 6.4). ACS screening guidelines are revised about every 5 years to include new scientific findings and developments.

Women are exposed to multiple sources of cancer prevention information, and much of it may not be sound. Discuss the benefits, risks, and potential limitations of BSE, CBE, and mammography with each woman and tailor the information to her specific risk factors (ACS, 2020e). Based on the new guidelines, make clinical judgments as to the appropriateness of recommending BSE, and reevaluate the need to teach the procedure to all women; the focus might instead be on encouraging regular mammograms (depending, of course, on the woman's individual risk factors).

Breast Self-Examination

Breast self-examination (BSE) is a technique that enables a woman to detect changes in her breasts. BSEs, once thought essential for early breast cancer detection, are now considered optional. Instead, breast awareness is stressed. Breast awareness refers to a woman being familiar with the normal consistency of both breasts and the underlying tissue. This emphasis is now on awareness of breast changes, not just discovery of cancer. Research has shown that BSE plays a small role in detecting breast cancer compared with self-awareness. However, doing BSE is one way for a woman to know how her breasts normally feel so that she can notice any changes that do occur (CDC, 2019c).

If appropriate, there are two steps in conducting a BSE: visual inspection and tactile palpation. The visual part should be done in three separate positions: with the arms up behind the head, with the arms down at the sides, and bending forward. Instruct the woman to look for:

- changes in shape, size, contour, or symmetry.

- skin discoloration or dimpling, bumps/lumps.
- sores or scaly skin.
- discharge or puckering of the nipple.

In the second part, the tactile examination, the woman should feel the breasts in one of three specific patterns: spiral, pie-shaped wedges, or a vertical strip (up and down). When using any of the three patterns, the woman should use a circular rubbing motion (in dime-sized circles) without lifting the fingers. She should check not only the breasts but also between the breast and the axilla, the axilla itself, and the area above the breast up to the clavicle and across the shoulder. The pads of the three middle fingers on the right hand are used to assess the left breast; the pads of the three middle fingers on the left hand are used to assess the right breast. Instruct the woman to use three different degrees of pressure:

- Light (move the skin without moving the tissue underneath)
- Medium (midway into the tissue)
- Hard (down to the ribs)

Nutrition

As discussed previously, nutrition plays a critical role in all health promotion and disease prevention. Cancer is considered to be a chronic disease that may be influenced at many stages by nutrition. These factors may affect prevention, progression, and treatment of the disease. Research suggests that approximately one third of breast cancer diagnoses could be prevented by reducing alcohol intake, increasing the fruit and vegetable intake in the diet, and increasing levels of physical activity (Taha & Eltom, 2018). Being overweight or obese is a risk factor for breast cancer in postmenopausal women. Excess body weight has been linked to an increased risk of postmenopausal breast cancer, and growing evidence also suggests that obesity is associated with poorer prognoses in women diagnosed with early-stage breast cancer. Dozens of studies demonstrate that women who are overweight or obese at the time of breast cancer diagnosis are at an increased risk

of cancer recurrence and death compared with leaner women, and some evidence suggests that women who gain weight after a breast cancer diagnosis may also be at increased risk of poor outcomes (Bandera & John, 2018). *Healthy People 2030* identified being overweight or obese as one of the 10 leading health indicators and a major health concern (U.S. Department of Health and Human Services [USDHHS], 2020). A Mediterranean diet high in fruits, vegetables, and high-fiber carbohydrates and low in animal fat seems to offer some protection against breast cancer while facilitating weight control. Women who follow these dietary guidelines decrease their risk of breast cancer. In addition, substantial evidence has shown that obesity as measured by body mass index (BMI) is linked to breast cancer outcomes and greater mortality risks because of increased receptor site activity, which synthesizes more estrogen subsequently promoting carcinogenesis (Chen & Hsieh, 2018).

The American Institute for Cancer Research (2018) made the following recommendations to reduce a woman's risk for developing breast cancer:

- Engaging in daily moderate exercise and weekly vigorous physical activity
- Consuming at least five servings of fruits and vegetables daily
- Not smoking or using any tobacco products
- Keeping a maximum BMI of 25 and limiting weight gain to no more than 11 lb since age 18
- Consuming seven or more daily portions of complex carbohydrates, such as whole grains and cereals
- Limiting intake of processed foods and refined sugar
- Limiting consumption of energy-dense foods and sugary drinks
- Avoiding use of dietary supplements which are unlikely to improve prognosis
- Restricting red meat intake to approximately 3 oz daily
- Limiting intake of fatty foods, particularly those of animal origin
- Restricting intake of salted foods and use of salt in cooking

The medical community is also starting to study the role of phytochemicals in health. The unique geographic variability of breast

cancer around the world and the low rate of breast cancer in Asia compared with Western countries prompted this interest. This area of research provides hope for women seeking to prevent breast cancer as well as those recovering from it. Although the mechanism is not clear, certain foods demonstrate anticancer properties and boost the immune system. Phytochemical-rich foods include:

- Green tea and herbal teas
- Garlic
- Whole grains and legumes
- Onions and leeks
- Soybeans and soy products
- Tomato products (cooked tomatoes)
- Fruits (citrus, apricots, pumpkin, berries)
- Green leafy vegetables (spinach, collards, romaine)
- Colorful vegetables (carrots, squash, tomatoes)
- Cruciferous vegetables (broccoli, cabbage, cauliflower)
- Flax seeds (Forman, 2020)

Adopt a holistic approach when addressing the nutritional needs of women with breast cancer. Incorporate nutritional assessment into the general overall assessment of all women. Culturally sensitive nutritional assessment tools need to be developed and used to enhance this process. Providing examples of appropriate foods associated with the woman's current dietary habits, relating current health status to nutritional intake, and placing proposed modifications within a realistic personal framework may increase a woman's willingness to incorporate needed changes in her nutritional behavior. Be able to interpret research results and stay up to date on nutritional influences so that you can transmit this key information to the public.

KEY CONCEPTS

- Many women believe that all lumps are cancerous, but actually more than 80% of lumps discovered are benign and need no treatment.
- The most commonly encountered benign breast disorders in women include fibrocystic breasts, fibroadenomas, and mastitis.
- Current research suggests that women with fibrocystic breast disease or other benign breast conditions are more likely to develop breast cancer later only if a breast biopsy shows “atypia” or abnormal breast cells.
- Fibroadenomas are common benign solid breast tumors that can be stimulated by external estrogen, progesterone, lactation, and pregnancy.
- Mastitis is an infection of the connective tissue in the breast that occurs primarily in lactating or engorged women; it is divided into lactational and nonlactational types.
- Management of both types of mastitis involves the use of oral antibiotics (usually a penicillinase-resistant penicillin or cephalosporin) and acetaminophen (Tylenol) for pain and fever.
- Breast cancer is the most common cancer in women and the second leading cause of cancer deaths (lung cancer is first) among American women.
- Breast cancer metastasizes widely and to almost all organs of the body but primarily to the bone, lungs, lymph nodes, liver, and brain.
- The etiology of breast cancer is unknown, but the disease is thought to develop in response to a number of related factors: aging, delayed childbearing or nulliparity, high breast density, family history of cancer, late menopause, obesity, and hormonal factors.
- Breast cancer treatments fall into two categories: local and systemic. Local treatments are surgery and radiation therapy. Effective systemic treatments include chemotherapy, hormonal therapy, and immunotherapy.
- Women commonly perceive their breasts as intrinsic to their femininity, self-esteem, and sexuality, and the risk of losing a breast can provoke extreme anxiety.

- Nurses can influence both physical and emotional recovery, which are both important aspects of care that help in improving the woman's quality of life and the ability to survive.
- Health promotion measures that will reduce the risk of breast cancer include breastfeeding, daily exercise, avoiding alcohol, and maintaining a normal weight range.
- The common ways to screen for breast cancer include mammography, clinical breast exams by a health care provider, and performing monthly self-breast exams to get to know one's own breasts to be better able to identify any abnormal lesions.
- Providing up-to-date information and emotional support are central roles of the nurse in caring for the woman with a diagnosis of breast cancer.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. Breast self-examinations involve both palpation of breast tissue and

   a. palpation of cervical lymph nodes.
   b. firm squeezing of both nipples.
   c. visualizing both breasts for any change.
   d. a mammogram to evaluate breast tissue.

2. Which of the following is the strongest risk factor for breast cancer?

   a. Advancing age and being female
   b. High number of children
   c. Genetic mutations in BRCA1 and BRCA2 genes
   d. Family history of colon cancer

3. A biopsy procedure that traces radioisotopes and blue dye from the tumor site through the lymphatic system into the axillary nodes is

   a. stereotactic biopsy.
   b. sentinel node biopsy.
   c. axillary dissection biopsy.
   d. advanced breast biopsy.

4. The most serious potential adverse reaction from chemotherapy is

   a. thrombocytopenia.
   b. deep vein thrombosis.
   c. alopecia.
   d. myelosuppression.

5. What suggestion would be helpful for the client experiencing painful fibrocystic breast changes?

   a. Increase her caffeine intake.
   b. Take a mild analgesic when needed.
   c. Reduce her intake of leafy vegetables.
   d. Wear a loose-fitting bra without support.

6. A postoperative mastectomy client should be referred to which organization for assistance upon discharge from the hospital?

   a. National Organization for Women (NOW)
   b. Food and Drug Administration (FDA)
   c. March of Dimes Foundation (MDF)
   d. Reach to Recovery (RTR)

7. Breast cancer that is localized is referred to as

   a. primary.
   b. in situ.
   c. metastasized.
   d. localized.

8. A 25-year-old woman presents with an asymptomatic breast mass. Which statement is true concerning her diagnosis and treatment?

   a. All breast masses should be considered premalignant.
   b. The breast mass should be surgically removed immediately.
   c. Ultrasound is typically used to determine the diagnosis.
   d. Since it is asymptomatic, only reassurance is needed now.

CRITICAL THINKING EXERCISES

1. Mrs. Gordon, 48, presents to the women's community clinic where you work as a nurse. She is upset and

crying. She tells you that she found lumps in her breast: “I know that it’s cancer and I will die.” When you ask her about her problem, she says she does not check her breasts monthly and hasn’t had a mammogram for years because “they’re too expensive.” She also describes the intermittent pain she experiences.

   a. What specific questions would you ask this client to get a clearer picture?
   b. What education is needed for this client regarding breast health?
   c. What community referrals are needed to meet this client’s future needs?

2. Ms. Davis, 51, stops in at the urgent care facility with an anxious look on her face. She tells the nurse practitioner that she has green discharge coming from her right breast and discomfort intermittently. She can’t understand how this would happen since she hasn’t previously had any nipple discharge or pain.

   a. What benign breast condition might the nurse practitioner suspect based on her description?
   b. What specific information should the nurse practitioner give Ms. Davis about duct ectasia?
   c. The typical treatment of this benign breast condition would include what?

STUDY ACTIVITIES

1. Discuss with a group of women what their breasts symbolize to them and to society. Do they symbolize something different to each one?
2. When a woman experiences a breast disorder, what feelings might she be experiencing and how can a nurse help her sort them out?
3. Interview a woman who has fibrocystic breast changes and find out how she manages this condition. Which

interventions work and which don't seem to help?

4. An infection of the breast connective tissue that frequently occurs in the lactating woman is _____.

BRINGING IT ALL TOGETHER: A CASE STUDY

A 67-year-old obese woman presents to her internist after several years without a routine exam. A right breast mass that she felt 4 weeks ago seems to be getting larger. She has also recently noticed a 10-lb weight loss over the past 6 months and occasional right upper quadrant discomfort. She states she has been feeling tired over the last several months, but rationalized it as "old age catching up with her."

ASSESSMENT

The client has a family history of breast and colon cancer in her immediate family and both of her parents died from these (mother from breast cancer and father from colon cancer). Her aunt also had breast cancer but is in remission now after treatment. She can't remember when the last time she had a Pap smear or mammogram. She admits that she does not keep up with her health check-ups, since she babysits for her grandchildren and has difficulty scheduling them. She confesses that her diet hasn't been what it should be since her grandchildren prefer fast food and sodas for meals rather than home-cooked ones. Thus, she gives into them and eats what they eat.

Go to thePoint to find questions to consider about this case.

Benign Disorders of the Female Reproductive Tract

WOW

WORDS OF WISDOM

Women can influence the aging process by making wise lifestyle choices early on.

KEY TERMS

Bartholin cysts

cystocele (sis´tō-sēl)

enterocele (en´tĕr-o-sēl)

genital fistulas

ovarian cyst

pelvic floor muscle exercises (Kegel exercises)

pelvic organ prolapse (POP)

pessary

polycystic ovary syndrome (PCOS)

polyps

rectocele (rek´tō-sēl)

urinary incontinence (UI)

uterine fibroids

uterine prolapse

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Characterize the major pelvic relaxation disorders in terms of etiology, management, and nursing interventions.
2. Evaluate urinary incontinence in terms of pathology, clinical manifestations, treatment options, and effect on quality of life.
3. Compare the various benign growths in terms of their symptoms and management.
4. Analyze the emotional impact of polycystic ovary syndrome and the nurse's role as a counselor, educator, and advocate.

Liz, a 26-year-old overweight woman, presented to the clinic with hirsutism and facial acne and told the nurse that she was concerned about her irregular menstrual periods. She also said that recently the hair on top of her head seemed to be falling out. What diagnostic tests might the nurse anticipate with this client? How can the nurse prepare Liz for them?

INTRODUCTION

The incidence of several benign pelvic disorders increases as women age. For instance, women may experience pelvic floor disorders related to pelvic relaxation or urinary incontinence. These disorders generally develop after years of wear and tear on the muscles and tissues that support the pelvic floor. This can result from childbearing, chronic coughing, straining, surgery, or simply aging. In addition to pelvic floor disorders, woman may also experience various benign neoplasms of the reproductive tract, such as cervical polyps, uterine leiomyomas (fibroids), ovarian cysts, genital fistulas, and Bartholin cysts. This chapter provides an overview of various pelvic floor disorders and benign neoplasms, discussing the assessment, treatment, and prevention strategies for each. It also addresses female genital cutting as a harmful practice that affects girls' and women's health.

PELVIC FLOOR DISORDERS

Pelvic floor disorders include urinary incontinence, pelvic organ prolapse, fecal incontinence, and other sensory and emptying abnormalities. These are widely prevalent and largely undertreated.

Researchers report that more than one third of women in the United States have a pelvic floor disorder, and nearly one quarter of women in the United States have one or more pelvic floor disorders that cause symptoms. According to the study, the frequency of pelvic floor disorders increases with age, affecting more than 40% of

women from 60 to 79 years of age and about 50% of women 80 years and older (Hartigan & Smith, 2018).

Pelvic floor disorders cause significant physical and psychological morbidity and can diminish women's social interactions, emotional well-being, and overall quality of life. Because these disorders increase with age, the problem grows worse as our population ages.

The term "pelvic floor" refers to the group of muscles that form a sling or hammock across the pelvis. Together with their surrounding tissues, these muscles hold the pelvic organs (uterus, bladder, and bowel) in place so they can function correctly. These disorders occur as a result of weakness of the connective tissue and muscular support of pelvic organs due to factors including pregnancy, vaginal childbirth, obesity, lifting, chronic cough from smoking, straining at defecation secondary to constipation, radiation to the pelvis for cancer, and estrogen deficiency (American College of Obstetricians and Gynecologists [ACOG], 2019). The female anatomy is susceptible to the development of pelvic floor disorders because of its vertical structure placement. The bony pelvis has an exaggerated lumbar spinal curve and downward tilt to it. The bladder rests on the symphysis and the posterior organs rest on the sacrum and coccyx. The pelvis holds the organs, but a woman's erect posture causes a funneling effect and constant downward pressure.

Pelvic Organ Prolapse

Pelvic organ prolapse (POP) (from the Latin *prolapsus*, "a slipping forth") refers to the abnormal descent or herniation of the pelvic organs from their original attachment sites or their normal position in the pelvis. POP occurs when structures of the pelvis shift and protrude into or outside the vaginal canal. This disorder affects a woman's micturition, defecation, and sexual activity. The Egyptians were the first to describe prolapse of the genital organs. In 400 bc, Hippocrates made reference to placing a pomegranate half into the vagina to treat organ prolapse. A disorder exclusive to women, POP rarely results in severe morbidity or mortality but can affect a woman's daily activities and quality of life (Rogers & Fashokun,

2019). It is difficult to determine the incidence of POP because the disorder is often asymptomatic and many women do not seek treatment. It has been estimated, however, that up to 75% of all women who have had a vaginal birth have POP (ACOG, 2019). Each year, over 250,000 women undergo surgery to repair the prolapse at a cost of over $1.5 billion for hospitalization and physician fees alone (Milsom & Gyhagen, 2018). As the older adult population is expected to double in number by 2030, POP and its associated symptoms will continue to become more prevalent (Bradley, 2018).

Obesity is associated with a high prevalence of pelvic floor disorders. Obesity can also aggravate symptoms of POP, fecal incontinence, sexual dysfunction, and stress urinary incontinence and increase the risk of endometrial polyps and symptomatic fibroids. Weight reduction enhances reproductive outcomes, diminishes symptoms of urinary incontinence, improves sexual dysfunction, and reduces morbidity following gynecologic surgery. Sustained and substantial weight loss, however, is difficult to achieve for many women with common current lifestyle and dietary choices (Young et al., 2018).

The treatment and diagnosis of POP is challenging and problematic.

Types of Pelvic Organ Prolapse

The four most common types of pelvic or genital prolapse are cystocele, rectocele, enterocele, and uterine prolapse (Fig. 7.1):

- Cystocele occurs when the bladder drops into the vagina.
- Rectocele occurs when the rectum sags and bulges into the vagina.
- Enterocele occurs when the small intestine bulges into the vagina.
- Uterine prolapse occurs when the uterus drops into the vagina. Multiparous women are at particular risk for uterine prolapse. The extent of uterine prolapse is classified in terms of stages:
  - *Stage 0:* No descent of pelvic structure during straining.

- *Stage I:* The prolapsed descending organ is more than 1 cm above the hymenal ring.
- *Stage II:* The prolapsed organ extends approximately 1 cm below the hymenal ring.
- *Stage III:* The prolapsed organ extends 2 to 3 cm below the hymenal ring.
- *Stage IV:* The vagina is completely everted or the prolapsed organ is more than 3 cm below the hymenal ring (ACOG, 2019).

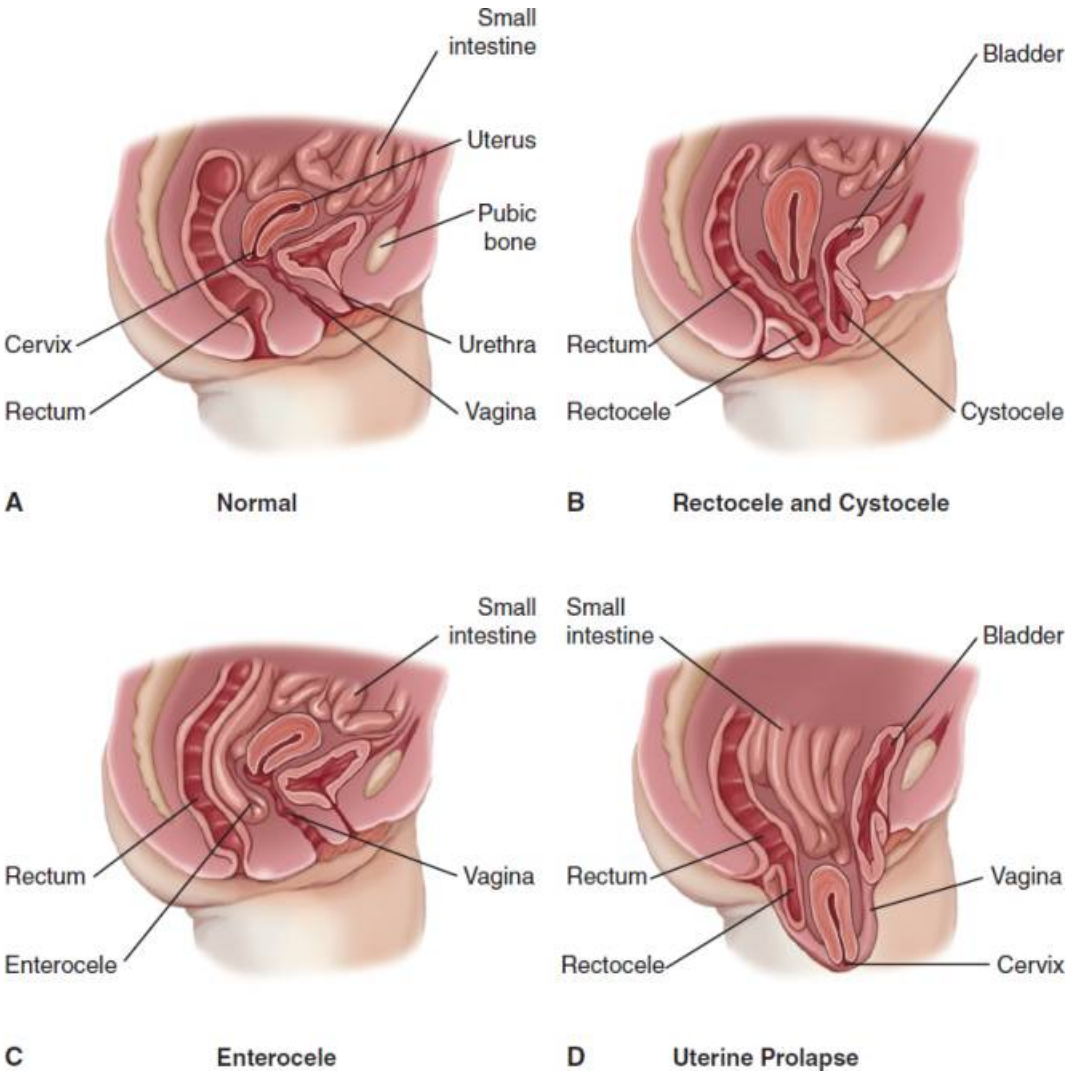

FIGURE 7.1. Types of pelvic prolapses. **A.** Normal. **B.** Rectocele and cystocele. **C.** Enterocele. **D.** Uterine prolapse.

Etiology

Anatomic support of the pelvic organs is mainly provided by the levator ani muscle complex and the connective tissue attachments of the pelvic organ fascia. Dysfunction of one or both of these components can lead to loss of support and eventually POP. Weakened pelvic floor muscles also prevent complete closure of the urethra, resulting in urine leakage during physical stress. This problem is not limited to older women; urinary incontinence has been documented in women of varying ages, including young women younger than 25 (Lazarou, 2019).

Many risk factors for POP have been suggested, but the true cause is likely multifactorial. Causes might include:

- Constant downward gravity because of erect human posture
- Atrophy of supporting tissues with aging and decline of estrogen levels
- Weakening of pelvic support related to childbirth trauma
- Reproductive surgery, including hysterectomy
- Instrumental childbirth
- Multiparity
- Uncontrolled rapid birth
- Family history of POP
- Young age at first birth
- Connective tissue disorders
- Infant birth weight of more than 4,500 g
- Pelvic radiation
- Increased abdominal pressure secondary to:
  - lifting of children or heavy objects.
  - straining due to chronic constipation.
  - respiratory problems or chronic coughing.
  - obesity (Jelovsek, 2020).

Therapeutic Management

Treatment options for POP depend on the symptoms and their effect on the woman's quality of life. Important considerations when deciding on nonsurgical or surgical options include the severity of symptoms; the woman's preferences, health status, age, and suitability for surgery; and the presence of other pelvic conditions

(urinary or fecal incontinence). Conservative measures such as pelvic floor muscle exercises (PFMEs) or formally termed Kegel exercises supplemented by lifestyle interventions such as weight loss, avoidance of straining (reducing lifting heavy weights, treatment of chronic cough and constipation) are recommended as first-line management.

When surgery is being considered, the nature of the procedure and the likely outcome must be fully explained and discussed with the woman and her partner. In addition to PFMEs and surgery, treatment options for POP may include estrogen replacement therapy, dietary and lifestyle modifications, use of a pessary (a removable device placed into the vagina to support pelvic organs), and surgery.

PELVIC FLOOR MUSCLE EXERCISES

Pelvic floor muscle exercises (Kegel exercises) strengthen the pelvic floor muscles to support the inner organs and prevent further prolapse. They are generally accepted as first-line treatment for stress and urge urinary incontinence and are also widely used for anal incontinence. Over the past 30 years, a wealth of research has supported the benefits of pelvic floor muscle exercises in treating both urinary incontinence and POP (Radziminska et al., 2018). The purpose of pelvic floor exercises is to increase the muscle volume, which will result in a stronger muscular contraction. Pelvic floor muscle exercises might limit the progression of mild prolapse and alleviate mild prolapse symptoms, including low back pain and pelvic pressure (Evidence-Based Practice 7.1). They will not, however, help severe uterine prolapse.

HORMONE REPLACEMENT THERAPY

Hormone replacement therapy, or HRT (orally, transdermally, low-dose vaginal ring or vaginal cream) may improve the tone, natural thickness, and vascularity of the supporting tissue in perimenopausal and menopausal women by increasing blood perfusion and the

elasticity of the vaginal wall. HRT has many benefits as well as risks. It is essential that the benefits are weighed against the risks with the client before this therapy is initiated.

EVIDENCE-BASED PRACTICE 7.1 Pelvic Floor Muscle Training Versus No Treatment, or Inactive Control Treatments, for Urinary Incontinence in Women

STUDY

Involuntary leakage of urine (urinary incontinence) affects women of all ages, particularly older women who live in residential care such as nursing homes. Some women leak urine during exercise or when they cough or sneeze (stress urinary incontinence), and this may occur as a result of weakness of the pelvic floor muscles such as damage during childbirth. Other women leak urine before going to the toilet when there is a sudden and compelling need to pass urine (urgency urinary incontinence). This may be caused by involuntary contraction of the bladder muscle. Mixed urinary incontinence is the combination of both stress and urgency urinary incontinence. Pelvic floor muscle training (PFMT) is a supervised physical therapy treatment and it involves muscle-clenching exercises to strengthen the pelvic floor muscles. It is a common treatment used by women to stop urine leakage. Other treatments are also available which can either be used alone or in combination with PFMT.

PFMT is a conservative treatment for urinary incontinence in women. This systematic review evaluated the effects of PFMT when compared to no treatment, placebo, or other inactive control treatments for urinary incontinence in women.

This study was done to compare the effects PFMT to no treatment, placebo, or other inactive control treatments in the management of women with urinary incontinence.

Findings

Randomized or quasi-randomized trials were used. There were 31 trials involving 1,817 women that met the eligibility criteria for inclusion, comprising women with stress urinary incontinence, urgency urinary incontinence or mixed urinary incontinence, and they compared PFMT added to no treatment, placebo, or other inactive control treatments.

This systematic review found support for the widespread recommendation that PFMT should be included in first-line conservative management programs for women with stress and any type of urinary incontinence. In women with stress incontinence, there was high-quality evidence that PFMT is associated with improvement or cure.

Nursing Implications

Overall, according to this study, there is sufficient evidence to support the widespread recommendation that PFMT should be included in a first-line conservative management program for women with stress, urge, or mixed urinary incontinence. Previous studies have validated that pelvic floor exercises do help in bringing tone to the muscles that control micturition. Nurses can continue to instruct women with urinary incontinence to perform PFMT daily to improve their urinary control and their quality of life.

Adapted from Dumoulin, C., Cacciari, L. P., & Hay-Smith, E. J. C. (2018). Pelvic floor muscle training verses no treatment, or inactive control treatments, for urinary incontinence in women. *Cochrane Database of Systematic Reviews 2018*, Issue 10. Art No: CD005654. https://doi.org/10.1002/14651858.CD005654.pub4.

TAKE NOTE!

Before hormone therapy is considered, a thorough medical history must be taken to assess a woman's risk for complications (e.g., endometrial cancer, myocardial infarction, stroke, breast cancer, pulmonary emboli, deep vein thrombosis). Because of these risks, estrogens, with or without progestins, should be given at the lowest effective dose and for the shortest duration consistent with the treatment goals and risks for the individual woman (ACOG, 2018).

DIETARY AND LIFESTYLE MODIFICATIONS

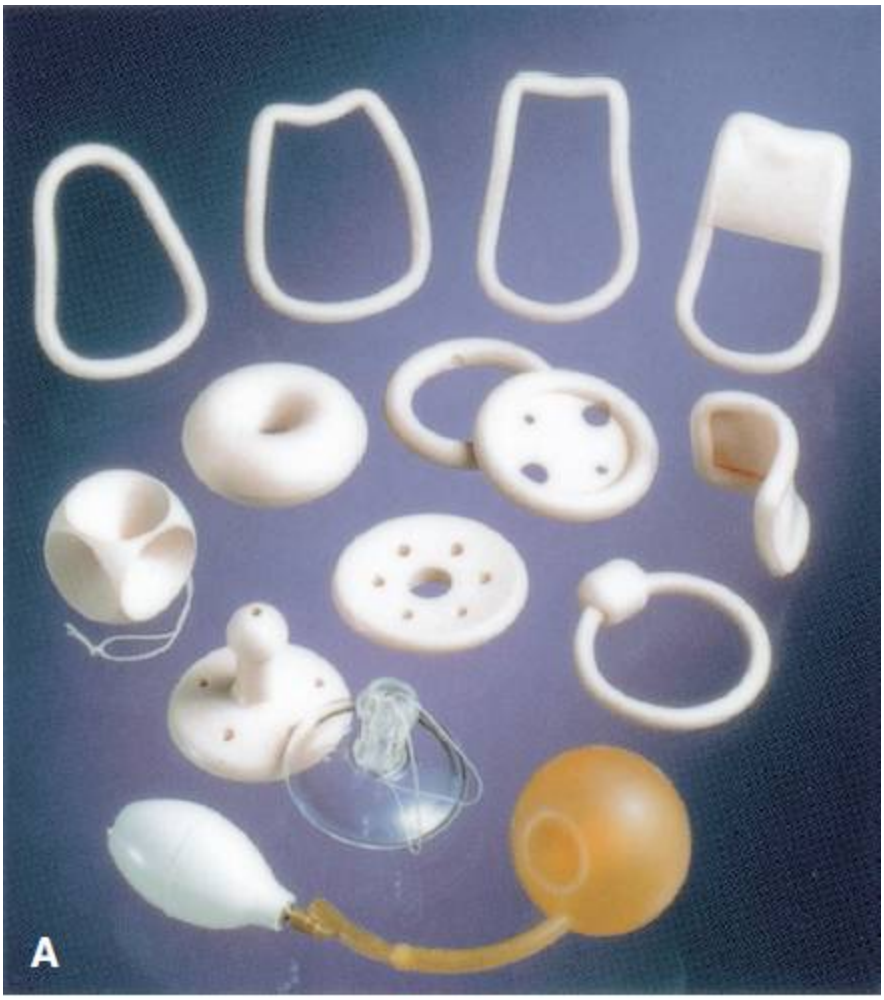
Dietary and lifestyle modifications may help prevent pelvic relaxation and chronic problems later in life. Specific lifestyle changes would include avoiding constipation, bladder irritants, heavy lifting, high impact exercise, weight loss, and smoking cessation. Dietary habits can exacerbate the prolapse by causing constipation and consequently chronic straining. The stools of a constipated woman are hard and dry, and typically she must strain while bearing down to defecate. This straining to pass a hard stool increases intra-abdominal pressure, which over time causes the pelvic organs to prolapse. Dietary modifications can help establish regular bowel movements without discomfort and eliminate flatus and bloating. A weight loss regimen might also need to be instituted if the woman is overweight.

PESSARIES

A vaginal pessary is a synthetic support device inserted in the vagina to provide support to the bladder and other pelvic organs as a corrective measure for urinary incontinence and/or POP (Fig. 7.2). Today, almost all pessaries are made of medical-grade silicone, which provides many advantages. Silicone pessaries are pliable and have a long shelf life; lack odor and secretion absorption; are biologically inert, nonallergenic, and noncarcinogenic; and they can be boiled or autoclaved for sterilization. Because most pessaries are made of silicone, pessary style and size, rather than material, are the

main considerations when selecting a pessary (Clements, 2019). Although many types and shapes are available, the most commonly used pessary is a firm ring that presses against the wall of the vagina and urethra to help decrease leakage and support a prolapsed vagina or uterus. Pessaries are a low-risk treatment option with the advantage of being cost-effective and minimally invasive. They also provide immediate relief of symptoms.

Indications for pessary use include uterine prolapse or cystocele, especially among elderly clients for whom surgery is contraindicated; younger women with prolapse who plan to have additional children; and women with marked prolapse who prefer to use a pessary rather than undergo surgery (Bodner-Adler et al., 2019). Many women use pessaries for only a short period of time and become free of symptoms. Long-term use can lead to pressure necrosis and the development of fistulas in some women; in this situation, other methods of support should be explored. Pessaries are fitted by trial and error; the woman often needs to try several sizes or styles. The largest pessary that the woman can wear comfortably is generally the most effective. The woman should be instructed to report any discomfort or difficulty with urination or defecation while wearing the pessary and also to attend follow-up care appointments to check positioning.



A

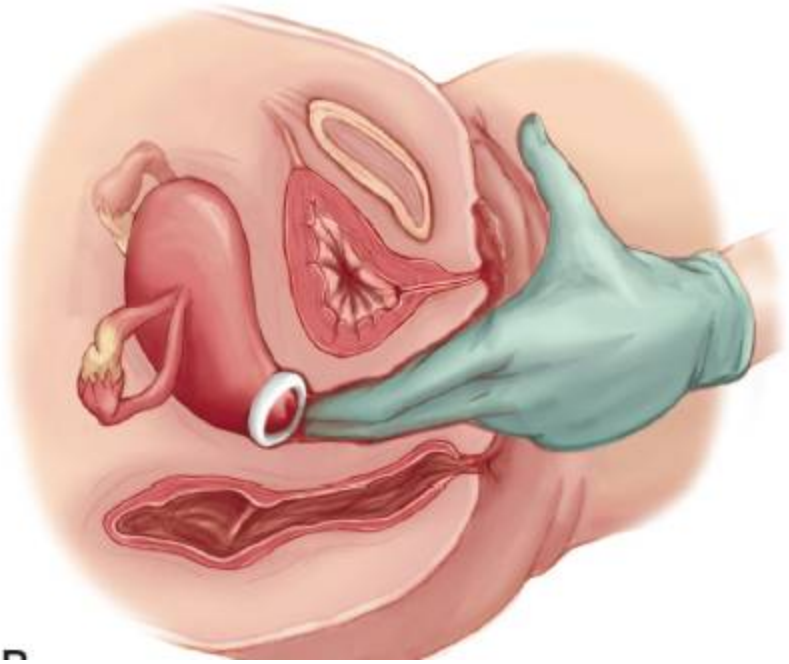


FIGURE 7.2. Examples of pessaries. **A.** Various shapes and sizes of pessaries available. **B.** Insertion of one type of pessary.

Nurses need to be aware of the personal isolation and embarrassment and social and cultural implications that urinary incontinence may cause as well as the subjective experiences of using a pessary. With appropriate support, vaginal pessaries can provide women with the freedom to lead active, engaged social lives.

SURGICAL INTERVENTIONS

Surgical interventions for pelvic or genital organ prolapse are designed to correct specific defects, with the goals being to restore normal anatomy and to preserve function. Approximately 200,000 stress incontinence surgical procedures are performed annually in the United States (Nager & Tan-Kim, 2019). However, surgery is not an option for all women. Women who are at high risk of suffering recurrent prolapse after a surgical repair or who have morbid obesity, chronic obstructive pulmonary disease, or medical conditions in which general anesthesia would be risky are not good candidates for surgical repair (Aube & Tu, 2018), and noninvasive treatment strategies should be discussed with them.

Surgical interventions might include anterior or posterior colporrhaphy (to repair a cystocele or rectocele) and vaginal hysterectomy (for uterine prolapse). This can be done laparoscopically, removing the uterus through the vagina. An anterior and posterior colporrhaphy may be effective for a first-degree prolapse. This surgical procedure tightens the anterior and posterior vaginal wall, thus repairing a cystocele or rectocele. The pubocervical fascia (supportive tissue between the vagina and bladder) is folded and sutured to bring the bladder and urethra in proper position (ACOG, 2018).

A vaginal hysterectomy is the treatment of choice for uterine prolapse because it removes the prolapsed organ that is bringing

down the bladder and rectum with it. It can be combined with an anterior and posterior repair if a cystocele or rectocele is present.

Nursing Assessment

Nursing assessment for women with POP includes a thorough health history, a physical examination, and several laboratory and diagnostic tests.

HEALTH HISTORY AND CLINICAL MANIFESTATIONS

A history and general assessment of the client is important to exclude pathology and evaluate various factors that may influence choice and success of management. Evaluation of systems such as bowel, urinary and sexual function, coexistent morbidities, medical and surgical history, any physical or mental impairment, and lifestyle are important, particularly in older women. The client's social circumstances and support systems, desire for treatment, and expectations will have implications on the management options.

The cause of prolapse is multifactorial, with vaginal childbirth, advancing age, heavy manual work, poor nutrition, large fibroids or tumors, vaginal surgery, menopause, chronic coughing, constipation, or straining, and increasing body mass index being the most common risk factors (Rogers & Fashokun, 2019). Assessment of risk factors in the woman's history will assist the health care provider in the diagnosis and treatment of POP. The history should include questions about:

- The woman's obstetrical history (number of pregnancies, weight of newborns, pregnancy spacing)
- Chronic respiratory condition (chronic coughing)
- Menopausal status
- Weight history (loss or gain)
- Constipation (frequency and chronicity)
- Age
- Work history (e.g., physical labor or light office work)
- Nutritional assessment

- Family history (family member with POP)
- Urinary incontinence
- Previous pelvic surgeries

Assess for clinical manifestations of POP. POP is often asymptomatic, but when symptoms do occur, they are often related to the site and type of prolapse. Symptoms common to all types of prolapse are a feeling of dragging, a lump in the vagina, or something “coming down.” Women with POP can present either with one symptom, such as vaginal bulging or pelvic pressure, or with several complaints, including multiple bladder, bowel, and pelvic symptoms. Symptoms associated with POP are summarized in Box 7.1.

BOX 7.1 Symptoms Associated with Pelvic Organ Prolapse

- Urinary symptoms
  - Stress incontinence
  - Frequency (diurnal and nocturnal)
  - Urgency and urge incontinence
  - Hesitancy
  - Feeling of pelvic pressure
  - Poor or prolonged stream
  - Feeling of incomplete emptying
- Bowel symptoms
  - Difficulty with defecation
  - Incontinence of flatus or liquid or solid stool
  - Urgency of defecation
  - Feeling of incomplete evacuation
  - Rectal protrusion or prolapse after defecation
- Sexual symptoms
  - Inability to have frequent intercourse
  - Dyspareunia
  - Lack of satisfaction or orgasm
  - Incontinence during sexual activity
- Other local symptoms
  - Pressure or heaviness in the vagina
  - Pain in the vagina or perineum
  - Low back pain after long periods of standing
  - Palpable bulge in the vaginal vault
  - Difficulty in walking due to a protrusion from the vagina
  - Difficulty inserting or keeping a tampon in place
  - Vaginal–cervical mucosa hypertrophy, excoriation, ulceration, and bleeding
- Abdominal pressure or pain

Adapted from American College of Obstetricians and Gynecologists (ACOG). (2018). *Surgery for pelvic organ prolapse*. Retrieved June 16, 2020, from https://www.acog.org/Patients/FAQs/Surgery-for-Pelvic-Organ-Prolapse#are

Women present with varying degrees of uterine descent. Uterine prolapse is the most troubling type of pelvic relaxation because it is often associated with concomitant defects of the vagina in the anterior, posterior, and lateral compartments (Schillo, 2019).

PHYSICAL EXAMINATION

The pelvic examination performed by the health care provider includes an external genital inspection to visualize any obvious protrusion of the uterus, bladder, urethra, or vaginal wall occurring at the vaginal opening. Usually the woman is asked to perform the Valsalva maneuver (bearing down) while the examiner notes which organ prolapses first and the degree to which it occurs. Any urine leakage during the examination is important to note. The woman is asked to contract the pubococcygeal muscles (pelvic floor muscle exercise); the health care provider inserts two fingers into the vagina to assess the strength and symmetry of the contraction. Because pelvic or genital organ prolapse can cause urinary symptoms such as incontinence, bladder function should be assessed by determining postvoid residual with a catheter. If the woman has more than 100 mL of retained urine, she should be referred for further urodynamic evaluation and testing.

LABORATORY AND DIAGNOSTIC TESTS

Common laboratory tests that may be ordered to determine the cause of POP include a urinalysis to rule out a bacterial infection, urine culture to identify the specific organism if present, visualization of urine loss during the pelvic examination, and measurement of postvoid urine volume.

Nursing Management

Help the woman understand the nature of the condition, the treatment options, and the likely outcomes. Nursing considerations might include:

- Describe normal anatomy and causes of pelvic prolapse.
- Assess how this condition has affected the woman’s life.
- Outline the options with the advantages and disadvantages of each.
- Allow the client to make the decision that is right for her.
- Provide education.
- Schedule preoperative activities needed for surgery.
- Reassure the client that there is a solution for her symptoms.

- Provide community education about genital prolapse.

Nursing Care Plan 7.1 provides an overview of care for a woman with POP.

PROMOTE PREVENTION STRATEGIES

Researchers are studying ways to prevent POP, but a nurse needs to first understand its incidence, risk factors, prevalence, clinical implications, and treatment options to be an effective caregiver for the woman. The nurse's understanding will not only improve his or her ability to treat this growing client population but will also help in developing preventive strategies to address a woman's suffering from this condition.

Approaches include lifestyle changes that reduce modifiable risk factors, such as losing weight, avoiding heavy lifting, stopping smoking to prevent chronic coughing, and choosing foods with high fiber to prevent constipation. Explore with the woman what factors in her lifestyle might be modified to reduce her risk of developing POP (primary prevention) or to improve her quality of life after receiving treatment (secondary prevention).

ENCOURAGE PELVIC FLOOR MUSCLE TRAINING

Encourage the woman to perform pelvic floor muscle exercises daily (Teaching Guidelines 7.1). Discuss current research findings and educate the woman about estrogen therapy, allowing the woman to make her own decision about whether to use hormones. Controversy still exists regarding the benefits and risks of taking hormones, so the woman must weigh her options carefully (ACOG, 2019).

TEACHING GUIDELINES 7.1
Performing Pelvic Floor Exercises

- Squeeze the muscles in your rectum as if you are trying to prevent passing flatus.
- Stop and start urinary flow to help identify the pubococcygeus muscle.
- Tighten the pubococcygeus muscle for a count of three, and then relax it.
- Contract and relax the pubococcygeus muscle rapidly 10 times.
- Try to bring up the entire pelvic floor and bear down 10 times.
- Repeat pelvic floor muscle exercises at least five times daily.

ENCOURAGE DIETARY AND LIFESTYLE MODIFICATIONS

Instruct clients to increase dietary fiber and fluids to prevent constipation. A high-fiber diet with an increase in fluid intake alleviates constipation by increasing stool bulk and stimulating peristalsis. It is accomplished by replacing refined, low-fiber foods with high-fiber foods. The recommended daily intake of fiber for women is 25 g (Office on Women's Health, 2019). In addition to increasing the amount of fiber in her diet, also encourage the woman to drink eight 8-oz glasses of fluid daily and to engage in regular low-impact aerobic exercise, which promotes muscle tone and stimulates peristalsis.

NURSING CARE PLAN 7.1 Overview of a Woman with Pelvic Organ Prolapse

Katherine, a 62-year-old multiparous woman, came to her gynecologist with complaints of a chronic dragging or heavy painful feeling in her pelvis, lower backache, constipation, and urine leakage. Her symptoms increase when she stands for long periods. She has not had menstrual cycles for at least a decade. She tells you, "I'm not taking any of those menopausal hormones." She also states that she is self-conscious and embarrassed about her urine leakage and restricts her outside activities.

NURSING ANALYSIS: Body image changes related to relaxation of pelvic support and elimination difficulties

OUTCOME IDENTIFICATION AND EVALUATION

The client will report improved body image after management of pelvic organ prolapse and improved urinary control.

INTERVENTIONS: *Providing Pain Management*

- Obtain a thorough history including ongoing embarrassing experiences, methods of urine control used, what worked, what didn't, any changes in sexual practices related to this, and the effect of this condition on her activities of daily living *to provide a baseline and enable a systematic approach to address it.*
- Assess the frequency, severity, precipitating factors, and aggravating/alleviating factors *to identify characteristics of the client's abnormal urinary patterns to plan appropriate interventions.*
- Educate client about any medications prescribed (correct dosage, route, side effects, and precautions) *to increase the client's understanding of the therapy and promote compliance.*
- Assess problematic elimination patterns *to identify underlying factors from which to plan appropriate prevention strategies.*
- Encourage client to increase fluids and fiber in diet and increase physical activity daily *to promote peristalsis.*
- Assist client with establishing regular toileting patterns by setting aside time daily for bowel elimination *to promote regular bowel function and evacuation.*
- Urge client to avoid routine use of laxatives *to reduce risk of compounding constipation.*

NURSING ANALYSIS: Lack of knowledge related to causes of structural disorders and treatment options

OUTCOME IDENTIFICATION AND EVALUATION

The client will demonstrate an understanding of current condition and treatments as evidenced by identifying treatment options, making health-promoting lifestyle choices, verbalizing appropriate health care practices, and adhering to treatment plan.

INTERVENTIONS: *Providing Client Education*

- Assess client's understanding of pelvic organ prolapse and its treatment options *to provide a baseline for teaching.*
- Review information provided about surgical procedures and recommendations for healthy lifestyle, obtaining feedback frequently, *to validate client's understanding of instructions.*
- Discuss association between uterine, bladder, and rectal prolapse and symptoms *to help client understand the etiology of her symptoms and pain.*
- Have client verbalize and discuss information related to diagnosis, surgical procedure, preoperative routine, and postoperative regimen *to ensure adequate understanding and provide time for correcting or clarifying any misinformation or misconceptions.*
- Provide written material with pictures *to promote learning and help client visualize what has occurred to her body secondary to aging, weight gain, childbirth, and gravity.*
- Discuss pros and cons of hormone replacement therapy, osteoporosis prevention, and cardiovascular events common in postmenopausal women *to promote informed decision-making by the client about available menopausal therapies.*
- Inform client about the availability of community resources and make appropriate referrals as needed *to provide additional education and support.*
- Document details of teaching and learning *to allow for continuity of care and further education if needed.*

Educate the client about other lifestyle changes that will assist with prolapse, such as:

- Achieve an ideal weight to reduce intra-abdominal pressure and strain on pelvic organs, including pressure on the bladder.
- Wear a girdle or abdominal support to support the muscles surrounding the pelvic organs.

- Avoid lifting heavy objects to reduce the risk of increasing intra-abdominal pressure, which can push the pelvic organs downward.
- Avoid high-impact aerobics, jogging, or jumping repeatedly to minimize the risk of increasing intra-abdominal pressure, which places downward pressure on the organs.
- Give up smoking to minimize the risk for a chronic “smoker’s cough,” which increases intra-abdominal pressure and forces the pelvic organs downward.

PROVIDE TEACHING FOR PESSARY USE

Educate the woman about pessary use. Discuss complications as part of the instruction. Although the pessary is a safe device, it is still a foreign body in the vagina. Because of this, the most common side effects of the pessary are increased vaginal discharge, urinary tract infections, vaginitis, and odor. Odors can be reduced by douching with dilute vinegar or hydrogen peroxide. Postmenopausal women with thin vaginal mucosa are susceptible to vaginal ulceration with the use of a pessary. Advise the woman to use estrogen cream to make the vaginal mucosa more resistant to erosion and to strengthen the vaginal walls.

The woman must be capable of managing use of the pessary, either alone or with the help of a caregiver. The most common recommendations for pessary care include removing the pessary twice weekly and cleaning it with soap and water; using a lubricant for insertion; and having regular follow-up examinations every 6 to 12 months after an initial period of adjustment.

Besides cleaning, clients must properly reinsert the device into their vaginal cavity, and the woman must also be willing to participate in all aspects of care of the pessary for this treatment option to be successful. Any woman who chooses this option must be instructed in the care of her pessary so that she feels comfortable with all aspects of it before leaving the health care facility. Health care visits should allow adequate time for women to share their concerns, anxieties, and fears surrounding the transition to life with a pessary.

PROVIDE PERIOPERATIVE CARE

Prepare the woman for surgery by reinforcing the risks and benefits of surgery and describing the postoperative course. Explain that a Foley catheter will be in place for up to 1 week, and that she might not be able to urinate due to the swelling after the catheter has been removed. Provide home care instructions for the Foley catheter. She should cleanse the perineal area daily with mild soap and water, especially around where the catheter enters the urinary meatus. If the woman is provided with a leg bag to be worn during waking hours, instruct her to empty it frequently and keep it below the level of the bladder to prevent backflow. The same principles are applied to the primary Foley bag when emptying it.

During the recovery period for several weeks, instruct the client to avoid activities that cause an increase in abdominal pressure, such as straining, sneezing, and coughing. In addition, advise her to avoid lifting anything heavy or straining to push anything. Explain to the woman that stool softeners and gentle laxatives might be prescribed to prevent constipation and straining with bowel movements. Avoiding vaginal intercourse will be recommended until the operative area is healed in 6 weeks.

Urinary Incontinence

Urinary incontinence (UI) is defined by the International Continence Society (2020) as the involuntary loss of urine that represents a hygienic or social problem to the individual. This disorder affects over 15 million women in the United States (Tso & Lee, 2018) but is underreported. It has been estimated that 50% of all women experience UI at some time in their life, varying in severity from mild to severe (Office on Women's Health, 2019). The psychosocial costs and morbidities are even more difficult to quantify. Embarrassment and depression are common. The affected individual may experience a decrease in social interactions, economic burden, decreased quality of life, excursions out of the home, and sexual activity (Hu & Pierre, 2019). It is more common than diabetes and

Alzheimer disease, both of which receive a great deal of press attention. Despite the considerable impact of incontinence on quality of life, many women are unlikely to bring up the subject of their lack of bladder control and few women seek help or treatment for incontinence concerns. There are several possible explanations for why clients do not talk about their bladder control issues. The client may:

- believe UI is inevitable and not amenable to treatment.
- feel UI is a “normal” part of aging.
- believe UI is part of being “female.” Women tend to accept urinary symptoms such as UI more than men do.
- feel embarrassment and try to deny that it is a real problem.
- think that the only treatment option is surgical.
- consider UI a hygiene problem and not a medical condition.

TAKE NOTE!

Incontinence is preventable, treatable, and often curable. However, many women believe that loss of bladder function is a normal and expected part of aging.

Incontinence can have far-reaching effects. Some women experience anxiety, depression, social isolation, embarrassment, insomnia, fear, feelings of uncleanliness, worry, vulnerability, shame, limits in the ability to travel far from home or have social engagements, and disruptions in self-esteem and dignity. UI can cause the woman to stop working, traveling, socializing, and enjoying sexual relationships. In addition, incontinence can create a tremendous burden for caregivers and is a common reason for admission to a long-term care facility. Depression, anxiety, and high levels of stress are typical in women who experience UI (Siddiqui et al., 2018).

Women often try to cope with UI through lifestyle modifications such as wearing protective pads, avoiding certain activities, emptying the bladder frequently, and modifying diet and fluid intake. Women who experience UI are generally most distressed by the

social implications and many go to great efforts to hide their symptoms. In some cultures, UI is abhorred to the point at which women are shunned by their communities. A sense of control, normality, and self-esteem are central issues in living with UI. Generally, with time and a worsening of symptoms, women pursue medical evaluation and treatment (Lukacz, 2019).

COMPARISON CHART 7.1 Urge Incontinence Versus Stress Incontinence

	Urge Incontinence	Stress Incontinence
Description	Precipitous loss of urine, preceded by a strong urge to void, with increased bladder pressure and detrusor contraction	Accidental leakage of urine that occurs with increased pressure on the bladder from coughing, sneezing, laughing, or physical exertion
Etiology	Causes might be neurologic, idiopathic, or infectious	Develops commonly in women in their 40s and 50s, usually as the result of weakened muscles and ligaments in the pelvis following childbirth
Signs and Symptoms	Urgency, frequency, nocturia, and a large amount of urine loss	Involuntary loss of a small amount of urine in response to physical activity that raises intra-abdominal pressure

The types of urinary incontinence are defined based on their presenting symptoms and signs. The three most common types of incontinence are urgency urinary incontinence (overactive bladder caused by detrusor muscle contractions); stress incontinence (inadequate urinary sphincter function); and mixed incontinence (involves both stress and urge incontinence) (Hu & Pierre, 2019). Comparison Chart 7.1 details these types of UI.

Pathophysiology and Etiology

Urinary continence requires several factors, including effective functioning of the bladder, adequate pelvic floor muscles, neural control from the brain, and integrity of the neural connections that facilitate voluntary control. The bladder neck and proximal urethra function as a sphincter. During urination, the sphincter relaxes and the bladder empties. The ability to control urination requires the integrated function of numerous components of the lower urinary tract, which must be structurally sound and functioning normally.

Incontinence can develop if the bladder muscles become overactive due to weakened sphincter muscles, if the bladder muscles become too weak to contract properly, or if signals from the nervous system to the urinary structures are interrupted. A major factor in women that contributes to urinary continence is the estrogen level, because this hormone helps maintain bladder sphincter tone. In perimenopausal or menopausal women, incontinence can be a problem as estrogen levels begin to decline and genitourinary changes occur. In simple terms, the bladder is the reservoir, the urethra is the seal, and the levator ani muscle is the gate that holds pressure against the outflow of urine by supporting the urethra and bladder from below. When any of these three structures is not functioning normally, incontinence occurs.

Contributing factors in urinary incontinence include:

- Fluid intake, especially alcohol, carbonated drinks, and caffeinated beverages
- Constipation: alters the position of the pelvic organs and puts pressure on the bladder
- Habitual “preventive” emptying: may result in training the bladder to hold only small amounts of urine
- Menopause and depletion of estrogen
- Chronic disease such as stroke, multiple sclerosis, or diabetes
- Smoking: nicotine increases detrusor muscle contractions
- Advancing age: age-related anatomic changes result in less pelvic support
- Pregnancy and childbirth: damage to pelvic structures during childbirth

- Obesity: increases abdominal pressure (International Urogynecological Association [IUGA], 2019)

Therapeutic Management

Treatment options depend on the type of UI. In general, the least invasive procedure with the fewest risks is the first choice for treatment. Surgery is used only if other methods have failed. There is a widespread belief that UI is an inevitable problem of getting older and that little or nothing can be done to relieve symptoms or reverse it. However, nothing is further from the truth, and attitudes must change so that women will feel comfortable seeking help for what can be an embarrassing condition.

For many women with urge incontinence, simple reassurance and lifestyle interventions might help. The promotion of a healthy weight can help reduce incontinence related to obesity. However, if more than simple lifestyle measures are needed, effective treatments might include:

- Bladder training to establish normal voiding intervals (every 3 to 5 hours)
- Pelvic floor muscle exercises to strengthen the pelvic floor musculature
- A pessary to support pelvic structures that have weakened
- Pharmacotherapy to reduce the urge to void. Anticholinergic agents such as oxybutynin (Ditropan) or tolterodine (Detrol) or oxybutynin (Oxytrol) might be prescribed. The most common side effects of anticholinergic agents are dry mouth, blurred vision, constipation, nausea, dizziness, and headaches (Skidmore-Roth, 2021).

For women with stress incontinence, treatment is not always a cure, but it can minimize the impact of this condition on the woman's quality of life. Some treatment options for stress incontinence might include:

- Weight loss if needed
- Avoidance of constipation
- Smoking cessation

- Pelvic floor muscle exercises to strengthen the pelvic floor
- Pessaries
- Weighted vaginal cones to improve the tone of pelvic floor muscles
- Periurethral injection (injecting a bulking agent [collagen] to form a bulge that brings the urethral walls closer together to achieve a better closure)
- Medications such as duloxetine (Cymbalta, Yentreve) to increase urethral sphincter contractions during the storage phase of the urination cycle
- Estrogen replacement therapy to improve bladder sphincter tone
- Surgery to correct genital prolapse and improve urethral and bladder tone

CONSIDER THIS

Life can be complicated and embarrassing at times when we least expect it. I met a man in church who seemed interested in me, and he asked me out for coffee after Sunday services. I have been alone for 10 years and this prospect seemed exciting to me. We talked for hours over coffee and seemed to have a great deal in common, especially since both of us had lost our spouses to cancer. He asked me to go square dancing with him, since that was an activity we both had enjoyed in the past with our spouses. I hadn't been out or physically active for ages and didn't realize how my body had changed with age.

It was during the first dance that I noticed a wet sensation between my legs, which I was unable to control. I managed to continue on and pretend that all was fine, but then realized what many of my friends were talking about—stress incontinence. Not being able to control one's urine is very embarrassing and it complicates your life, but I made up my mind that it wasn't going to control me.

Thoughts: Gravity and childbirth take a toll on women's reproductive organs by pushing them downward. This woman is not going to let stress incontinence curtail her outside activity, which demonstrates a good attitude. What can be done to mitigate her embarrassment and lack of control? Were there any preventive strategies she could have used at an earlier age?

Nursing Assessment

The assessment of the woman experiencing UI includes a history, physical examination, laboratory tests, and possibly urodynamic testing. The onset, frequency, severity, and pattern of incontinence should be determined, as well as any associated symptoms such as frequency, dysuria, urgency, and nocturia. Incontinence may be quantified by asking the woman if she wears a pad and how often the pad is changed. A review of the woman's current medications, including over-the-counter medications, should be included in the history.

A complete physical examination should be carried out by the health care provider; it should include a neurologic assessment and pelvic and rectal examinations. The presence of associated POP should be noted because it can contribute to the woman's voiding problems and may have an impact on diagnosis and treatment. A rectal examination is done to evaluate sphincter tone and perineal sensation. A "cough stress test" can be performed by asking the woman to cough with a full bladder and subsequently observing for leakage of urine from the urethra can also help in assessing the client's ability to control voiding.

A urinalysis is performed to look for hematuria, pyuria, glucosuria, or proteinuria. A urine culture is done if there is pyuria or bacteriuria. Postvoid residual should be measured either with pelvic ultrasound or directly with a catheter. If the residual exceeds the limit set, urodynamic testing is then used to diagnose the incontinence.

Nursing Management

Incontinence can be devastating and can cause psychosocial concerns and isolation. Nurses can encourage women with troublesome symptoms to seek help. Discuss the treatment options with the client, including benefits and potential outcomes, and encourage her to select the continence treatment best for her lifestyle. Provide education about good bladder habits and strategies to reduce the incidence or severity of incontinence (Teaching Guidelines 7.2). Provide support and encouragement to ensure adherence to the guidelines. Remember that aging can increase the risk of incontinence, but incontinence is not an inevitable part of aging. Review the anatomy and physiology of the urinary system and offer simple explanations to help the woman cope with urinary alterations. Therapeutic listening is important. Be aware of the courage it takes for a woman to disclose an embarrassing condition.

TEACHING GUIDELINES 7.2
Managing Urinary Incontinence

- Avoid drinking too much fluid (i.e., 1.5 L total daily limit), but do not decrease your intake of fluids.
- Reduce intake of fluids and foods that are bladder irritants and precipitate urgency, such as chocolate, caffeine, sodas, alcohol, artificial sweetener, hot spicy foods, orange juice, tomatoes, and watermelon.
- Increase fiber and fluids in your diet to reduce constipation.
- Control blood glucose levels to prevent polyuria.
- Treat chronic cough.
- Remove any barriers that delay you from reaching the toilet.
- Practice good perineal hygiene by using mild soap and water. Wipe from front to back to prevent urinary tract infections.
- Become aware of adverse drug effects.
- Take your medications as prescribed.
- Continue to do pelvic floor muscle exercises.

Dumoulin, C., Cacciari, L. P., & Hay-Smith, E. J. C. (2018). Pelvic floor muscle training verses no treatment, or inactive control treatments, for urinary incontinence in women. *Cochrane Database of Systematic Reviews 2018,* Issue 10. Art No: CD005654. https://doi.org/10.1002/14651858.CD005654.pub4; Lukacz, E. S. (2019). Treatment of urinary incontinence in women. *UpToDate.* Retrieved June 4, 2020, from https://www.uptodate.com/contents/treatment-of-urinary-incontinence-in-women; and International Urogynecological Association (IUGA). (2019). *Female incontinence*. Retrieved June 16, 2020, from https://www.womens-health-concern.org/help-and-advice/factsheets/female-incontinence/

TAKE NOTE!

Simple diet and lifestyle alterations combined with a proper pelvic floor muscle strengthening program can often produce significant improvements for women of all ages.

BENIGN GROWTHS

The most common benign growths of the reproductive tract include cervical, endocervical, and endometrial polyps; uterine fibroids (leiomyomas); genital fistulas; Bartholin cysts; and ovarian cysts.

Polyps

Polyps are small, usually benign growths. The incidence of malignancy in cervical polyps is one in 1,000. Malignancy is more common in perimenopausal or postmenopausal women (Kinkel et al., 2018). The cause of polyp growth is not well understood, but they are frequently the result of infection, chronic inflammation, an abnormal local response to increased levels of estrogen, or local congestion of the cervical vasculature (Oyelowo & Johnson, 2018). Single or multiple polyps might occur. They are most common in multiparous women. Polyps can appear anywhere but are most common at or near the cervical os and in the uterus (Fig. 7.3).

Endocervical polyps are commonly found in multiparous women ages 40 to 60. Endocervical polyps are more common than cervical polyps with stalks of varied widths and lengths. Endometrial polyps are benign tumors or localized overgrowths of the endometrium. Most are solitary, and they rarely occur in women younger than 20 years of age. The incidence of these polyps rises steadily with increasing age, peaks in the fifth decade of life, and gradually declines after menopause. They are present in up to 25% of women who are seen for abnormal bleeding (Steegers et al., 2019).

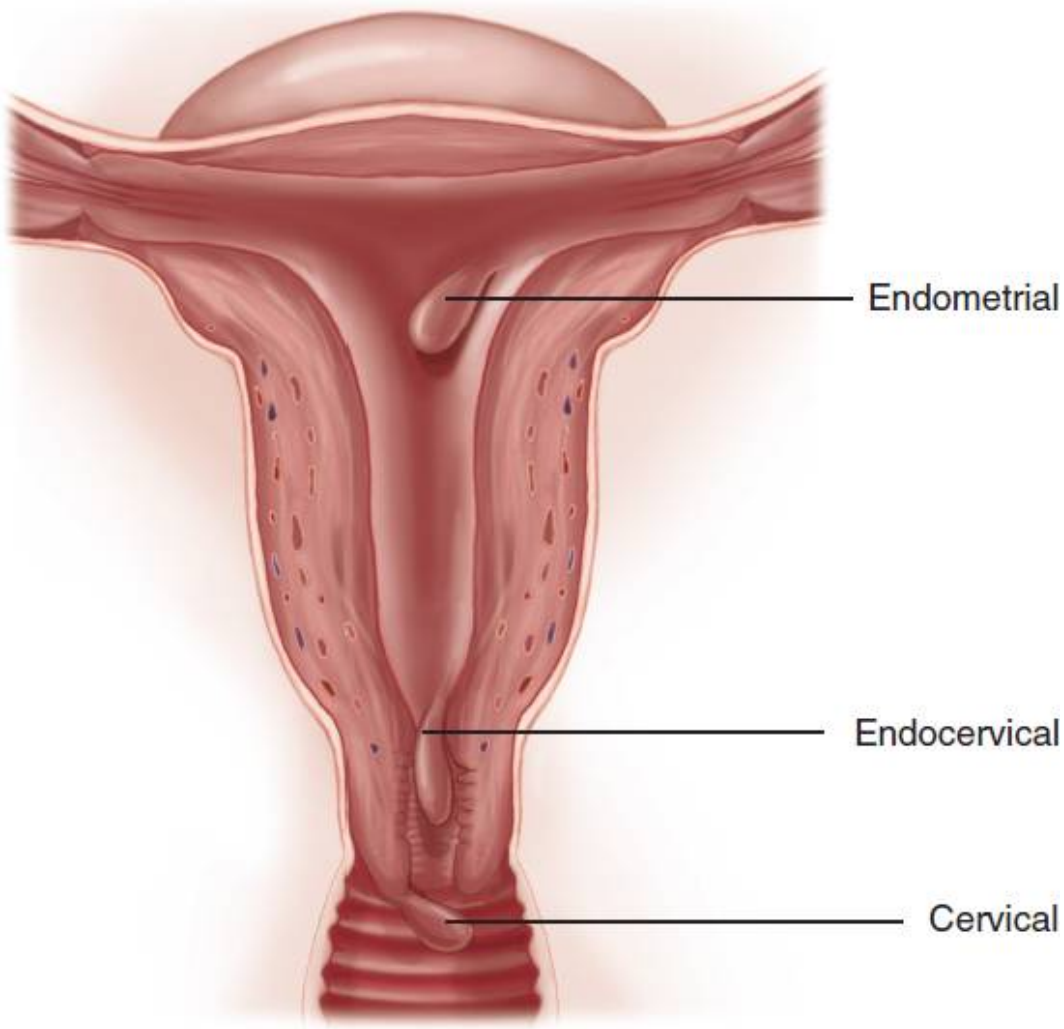

FIGURE 7.3. Cervical, endocervical, and endometrial polyps.

Therapeutic Management

Treatment of polyps usually consists of simple removal with small forceps done on an outpatient basis, removal during hysteroscopy, or dilation and curettage. The polyp base can be removed by laser vaporization. Because many polyps are infected, an antibiotic may be ordered after removal as a preventive measure or to treat early signs of infection.

Although polyps are rarely cancerous, a specimen should be sent after surgery to a pathology laboratory to exclude malignancy. A cervical biopsy typically reveals mildly atypical cells and signs of infection. Polyps rarely return after they are removed. Regularly

scheduled Pap smears are suggested for women with cervical polyps to detect any future abnormal growths that may be malignant.

Nursing Assessment

Nursing assessment for a woman with polyps includes assisting with the physical examination and preparing the collected specimen to be sent to the cytologist.

CLINICAL MANIFESTATIONS

Assess for clinical manifestations of polyps. Most endocervical polyps are cherry red, while most cervical polyps are grayish white (Magowan et al., 2018). Cervical and endocervical polyps are often asymptomatic, but they can produce mild symptoms such as abnormal vaginal bleeding (after intercourse, between menses) or discharge. The most common clinical manifestation of endometrial polyps is irregular, acyclic bleeding.

PHYSICAL EXAMINATION AND LABORATORY AND DIAGNOSTIC STUDIES

Typically, cervical polyps are diagnosed when the cervix is visualized through a speculum during the woman's annual gynecologic examination (Jarvis, 2019). Endometrial polyps are not detected on physical examination but rather with ultrasound or hysteroscopy (introduction of a small camera through the cervix to visualize the uterine cavity).

Nursing Management

Nursing management of polyps involves explaining the condition and the rationale for removal and giving follow-up care instructions. The nurse also assists the health care provider with the removal procedure.

Uterine Fibroids

Uterine fibroids, also known as myomas or leiomyomas, are benign tumors composed of smooth muscle and fibrous connective tissue in the uterus. They can vary in size from that of a small apple seed to larger than a grapefruit. Unlike cancerous tumors, fibroids usually grow more slowly, responding to present estrogen levels, and their cells do not break away and invade other parts of the body. Fibroids are classified according to their position in the uterus and on the uterine layer most involved (Fig. 7.4):

- *Subserosal fibroids:* lie underneath the outermost peritoneal layer of the uterus and grow outside the uterus. They are attached to the uterus by a stalk or peduncle
- *Intramural fibroids:* grow within the wall of the uterus and are the most common type
- *Submucosal fibroids:* grow from immediately below the inner uterine surface (endometrium) into the uterine cavity (Magowan et al., 2018)

Fibroids are estrogen-dependent and thus grow rapidly during the childbearing years when estrogen is plentiful, but they shrink during menopause when estrogen levels decline. It is believed that these benign tumors develop in up to 80% to 90% of all women over 30 years of age, but up to 50% are asymptomatic (Oyelowo & Johnson, 2018). It is difficult to be precise because fibroids may cause no symptoms, and thus many women do not know they have them.

Fibroids are the most common indication for hysterectomy in the United States. The peak incidence occurs around age 45, and they are three times more prevalent in African American women than in White women (Steegers et al., 2019).

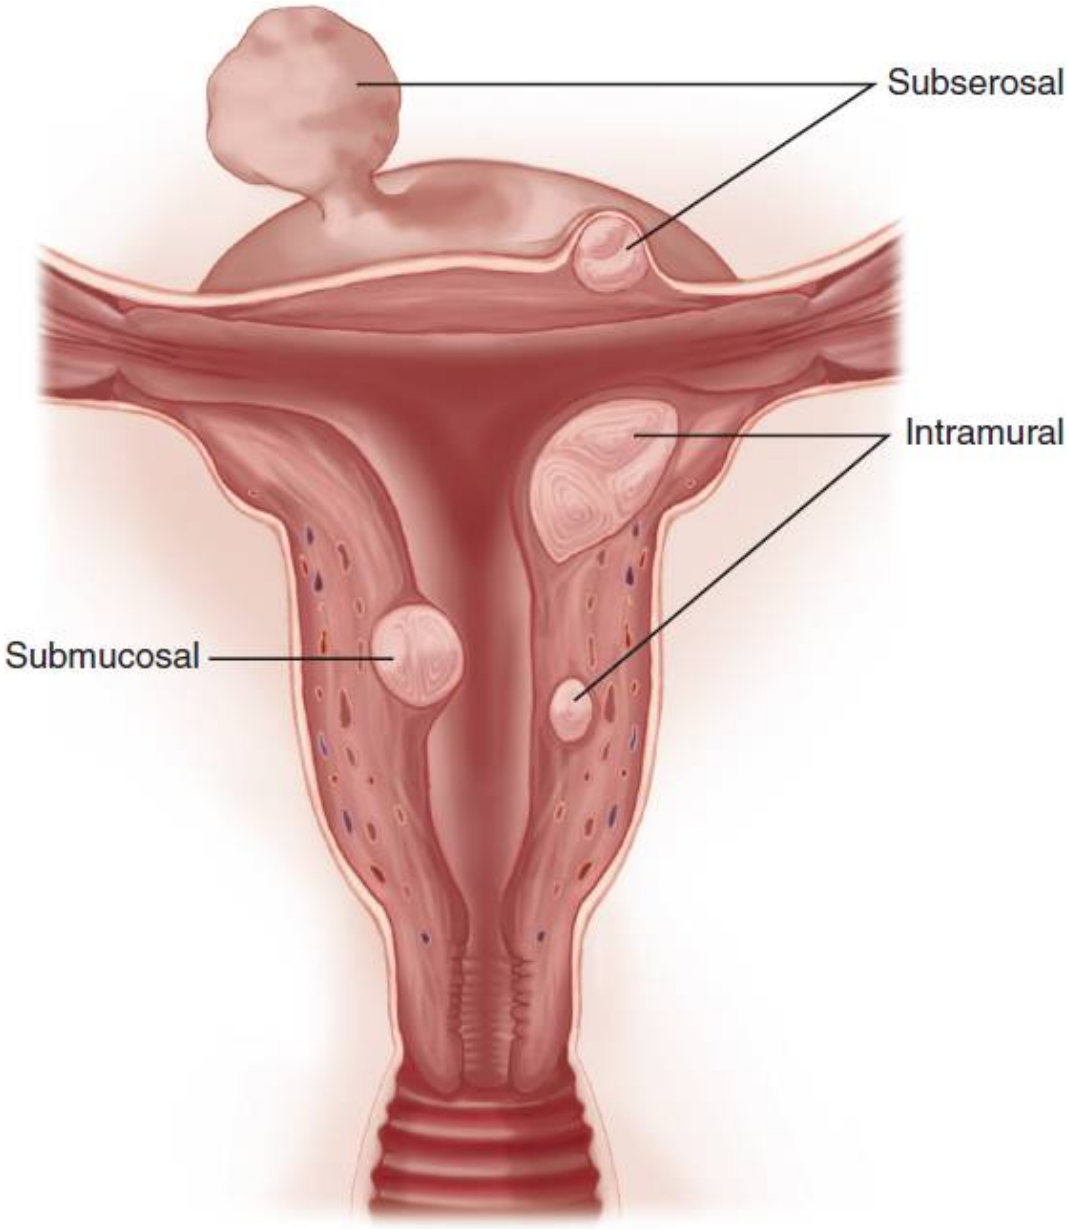

FIGURE 7.4. Submucosal, intramural, and subserosal fibroids.

Etiology

Although the cause of fibroids is unknown, several predisposing factors have been identified, including:

- Age (late reproductive years)
- Genetic predisposition
- African American ethnicity
- Hypertension

- Nulliparity
- Polycystic ovary syndrome
- Diabetes
- Obesity (Oyelowo & Johnson, 2018)

Therapeutic Management

Treatment depends on the size of the fibroids and the woman's symptoms, which can include heavy or painful menses, feeling "full" in the lower pelvis, urinating frequently, pain during sexual relations, lower back pain, and infertility (NIH, 2018). Several treatment options exist, ranging from watchful waiting to surgery.

MEDICAL MANAGEMENT

The goals of medical therapy are to reduce symptoms and/or to reduce the tumor size. This can be accomplished with pain medications to treat mild or occasional pain from fibroids; birth control pills to control heavy menses; or gonadotropin-releasing hormone (GnRH) agonists such as leuprolide (Lupron), nafarelin (Synarel), or goserelin (Zoladex), which stop ovulation and the production of estrogen, or low-dose mifepristone, a progestin antagonist. Both produce regression and reduce the size of the tumors without surgery, but long-term therapy is expensive and not well tolerated by most women. The side effects of GnRH medications include hot flashes, headaches, mood changes, vaginal dryness, musculoskeletal malaise, bone loss, and depression. Ulipristal acetate can be used to decrease proliferation of uterine fibroid cells, which reduce the fibroid size (Skidmore-Roth, 2021). Long-term mifepristone therapy can result in endometrial hyperplasia, which increases the risk of endometrial malignancy. Once either therapy is stopped, fibroids typically recur.

Uterine artery embolization (UAE) is an option in which polyvinyl alcohol pellets are injected into selected blood vessels via a catheter to block circulation to the fibroid, causing it to shrink and producing symptom resolution. The procedure is carried out by an interventional radiologist who makes a tiny incision in the groin,

introduces a fine catheter into the main artery leading to the uterus, and injects tiny particles of plastic or gelatin sponge into the artery that supplies blood to the fibroid. These particles stop the flow of blood, causing the fibroid to shrink or disappear completely over time. UAE has short-term advantages over surgery. Over the mid and long term, the benefits were similar, except for a higher reintervention rate after UAE (Kohi & Spies, 2018). The decision to offer UAE should be based on the desire of the client with the knowledge of other treatment alternatives and their success rates, limitations, and side effects (Kroncke & David, 2019).

Magnetic resonance-guided focused ultrasound (MRGFUS) creates coagulative necrosis, which destroys fibroids by using high-intensity ultrasound that directs focused ultrasound waves through the skin. This procedure is performed on an outpatient basis with sedation and no incisions. It is usually recommended for women with large fibroids. Overall, this option has been shown to be effective for decreasing fibroid size and/or volume. Case studies have documented successful pregnancy outcomes following MRGFUS (Stewart & Purdy, 2019).

SURGICAL MANAGEMENT

For women with large fibroids or severe uterine bleeding, surgery is preferred over medical treatment. Surgical management might involve myomectomy, laser surgery, or hysterectomy.

Myomectomy. Myomectomy involves removing the fibroid alone and leaves the healthy areas of the uterus intact to preserve fertility. A myomectomy is performed via laparoscopy, through an abdominal incision or via the vagina. The advantage is that only the fibroid is removed; fertility is not jeopardized because this procedure leaves the uterine muscle walls intact. Myomectomy relieves symptoms but does not affect the underlying process; thus, fibroids grow back and further treatment will be needed in the future.

Laser Surgery. Laser surgery (or electrocauterization) involves destroying small fibroids with lasers. Laser therapy can be done using a vaginal approach or laparoscopically. The laser treatment preserves the uterus, but the process may cause scarring and adhesions, thus impairing fertility (Chodankar & Allison, 2018). Fibroids can return after this procedure. Controversy remains as to whether laser treatment weakens the uterine wall and thus may contribute to uterine rupture in the future.

Hysterectomy. A hysterectomy is the surgical removal of the uterus. It is the most effective treatment for symptomatic fibroids with no recurrence. After cesarean section, it is the second most frequently performed surgical procedure for women in the United States. Approximately 500,000 hysterectomies are performed annually in the United States (Centers for Disease Control and Prevention [CDC], 2019). The top three conditions associated with hysterectomies are fibroids, endometriosis, and uterine prolapse (CDC, 2019). A hysterectomy to remove fibroids eliminates both the symptoms and the risk of recurrence, but it also terminates the woman's ability to bear children. Three types of hysterectomy surgeries are available: vaginal hysterectomy, laparoscopically assisted vaginal hysterectomy, and abdominal hysterectomy.

In a vaginal hysterectomy, the uterus is removed through an incision in the posterior vagina. Advantages include a shorter hospital stay and recovery time and no abdominal scars. Disadvantages include a limited operating space and poor visualization of other pelvic organs.

In a laparoscopically assisted vaginal hysterectomy, the uterus is removed through a laparoscope, through which structures within the abdomen and pelvis are visualized. Small incisions are made in the abdominal wall to permit the laparoscope to enter the surgical site. Advantages include a better surgical field, less pain, lower cost, and a shorter recovery time. Disadvantages include potential injury to the bladder and the inability to remove enlarged uteruses and scar tissue.

In an abdominal hysterectomy, the uterus and other pelvic organs are removed through an incision in the abdomen. This procedure allows the surgeon to visualize all pelvic organs and is typically used when a malignancy is suspected or the woman has a very large uterus. Disadvantages include the need for general anesthesia, a longer hospital stay and recovery period, more pain, higher cost, and a visible scar on the abdomen.

Complications of hysterectomy vary based on route of surgery and technique. The most common complications include infection, venous thromboembolism, genitourinary and gastrointestinal injuries, and hemorrhage (Steegers et al., 2019). With astute nursing observations and assessments, these complications can be reduced or minimized. A summary of treatment options for uterine fibroids is presented in Table 7.1.

TABLE 7.1 Summary of Treatment Options for Uterine Fibroids

Method	Advantages	Disadvantages
Hormones	Noninvasive Reduces size of fibroids Symptom improvement	Serious side effects with long-term use Fibroids regrow when meds stopped
Uterine artery embolization	Minimally invasive Dramatic decrease in symptoms Future fertility possible	Procedure frequently painful Requires radiation and contrast dye Permanently implanted material Possible negative fertility impact
Myomectomy	Performed as minor surgery Uterus is preserved	Requires general anesthesia New growth of fibroids occurs
Hysterectomy	Complete removal of fibroids Immediate symptom relief	Requires general anesthesia Major surgery with associated risks Fertility not preserved
Laser surgery	Can be done as an outpatient procedure to destroy small fibroids.	Vaporization process can cause scarring and adhesions, affecting future fertility.
Magnetic resonance-focused ultrasound	Noninvasive treatment with a short recovery time; rapid resolution of symptoms	Typically used for large fibroids and can be expensive

Nursing Assessment

Nursing assessment for the woman with uterine fibroids includes a thorough health history, physical examination, and laboratory and diagnostic studies.

HEALTH HISTORY AND CLINICAL MANIFESTATIONS

The history should include questions about the woman's menstrual cycle, including alterations in the menstrual pattern (e.g., pain or pressure, aggravating and alleviating factors), history of infertility, and any history of spontaneous abortion, which might indicate a space-occupying uterine lesion. Ask if any female relatives have had fibroids, because there is a familial predisposition. Assess for clinical manifestations of uterine fibroids. Symptoms of fibroids depend on the size and location and may include:

- Chronic pelvic pain
- Low back pain
- Iron-deficiency anemia secondary to bleeding
- Bloating
- Constipation
- Infertility (with large tumors)
- Dysmenorrhea
- Miscarriage
- Sciatica
- Dyspareunia
- Urinary frequency, urgency, incontinence
- Irregular vaginal bleeding (menorrhagia)
- Feeling of heaviness in the pelvic region

PHYSICAL EXAMINATION AND LABORATORY AND DIAGNOSTIC STUDIES

The bimanual examination performed by the health care provider typically shows an enlarged, irregular uterus. The uterus may be palpable abdominally if the fibroid is very large. Ultrasound may be used to confirm the diagnosis.

Nursing Management

The level of support that nurses can provide women with fibroids depends on the type of treatment offered and her choice of them.

Nurses should be able to explain any current treatment options and the implications of a diagnosis of fibroids. Many women have not yet heard of fibroids and need reassurance that they are both common and benign. If medication is prescribed, it is essential to explain the possible side effects and why medication can only be taken for a limited duration. If surgery is selected, verbal and written information about it and the aftercare should be addressed (Box 7.2).

A woman undergoing a hysterectomy for the treatment of fibroids often needs special care and can benefit from presurgical and postsurgical support provided by nurses. Personalized nursing, tailored to the individual woman's needs, enhances the client's coping strategies and alleviates different adverse psychological sequelae following gynecologic surgery. Women must cope with a variety of psychological adjustment difficulties related to the changes in self-image, self-esteem, loss of femininity or identity, and sexual dysfunction. The incidence of postsurgical problems can be reduced greatly with proper client-centered perioperative nursing care.

BOX 7.2 Nursing Interventions for a Woman Undergoing a Hysterectomy

Preoperative Care

- Instruct the client and her family about the procedure and postoperative care.
- Provide interventions to reduce anxiety (due to perceived threats to the woman's self-concept and role functioning) and fear of alteration in body image, complications, and pain. Prepare the woman so that she knows what to expect throughout her perioperative experience. Explain postoperative pain management procedures that will be used. Identify the high-risk woman early to reduce her stress.
- Teach turning, deep breathing, and coughing before surgery to prevent postoperative atelectasis and respiratory complications such as pneumonia.
- Encourage the woman to discuss her feelings. Some women equate their femaleness with their reproductive capability, and loss of the uterus could evoke grieving.
- Complete all preoperative orders in a timely manner to allow for rest.

Postoperative Care

- Provide comfort measures.
- Administer analgesics promptly or use a patient-controlled anesthesia pump.
- Administer antiemetics to control nausea and vomiting per order.
- Change the client's linens and gown frequently to promote hygiene.
- Change the client's position frequently and use pillows for support to promote comfort and pain management.
- Assess the incision, the dressing, and vaginal bleeding and report if bleeding is excessive (soaking perineal pad within an hour).
- Monitor elimination and provide increased fluids and fiber to prevent constipation and straining.
- Encourage ambulation and active range-of-motion exercises when in bed to prevent thrombophlebitis and venous stasis.
- Monitor vital signs to detect early complications.
- Be comfortable discussing sexual concerns with the client.

Discharge Planning

- Advise the client to reduce her activity level to avoid fatigue, which might inhibit healing.
- Advise the client to rest when she is tired and when ready, to increase her activity level slowly.
- Educate the client on the need for pelvic rest (nothing in the vagina) for 6 weeks.
- Instruct the client to avoid heavy lifting or straining for about 6 weeks to prevent an increase in intra-abdominal pressure, which could weaken her sutures.

- Teach the client the signs and symptoms of infection.
- Advise the woman to take showers instead of tub baths to reduce the risk for infection.
- Encourage the client to eat a healthy diet with increased intake of fluids to prevent dehydration and fluid and electrolyte imbalance.
- Instruct the client to change her perineal pad frequently to prevent infection.
- Explain and schedule follow-up care appointments as needed.
- Provide information about community resources for support and help.

Genital Fistulas

Genital fistulas are an underestimated problem worldwide and have devastating consequences for women. Each year, hundreds of thousands of women and girls worldwide are affected (WHO, 2020a). Genital fistulas are abnormal openings between a genital tract organ and another organ, such as the urinary tract or the gastrointestinal tract. A fistula can result from a congenital anomaly, surgical complications, Bartholin gland abscesses, radiation, or malignancy, but the majority of fistulas that occur worldwide are related to obstetric trauma and female genital cutting (WHO, 2020). During normal labor, the bladder is displaced upward into the abdomen, and the anterior vaginal wall, the base of the bladder, and the urethra are compressed between the fetal head and the posterior pubis. When labor is obstructed or prolonged, this unrelieved compression causes ischemia, which causes pressure necrosis and subsequent fistula formation.

Common types of fistulas include:

- *Vesicovaginal:* communication between the bladder and genital tract
- *Urethrovaginal:* communication between the urethra and the vagina
- *Rectovaginal:* communication between the rectum or sigmoid colon and the vagina

The direct consequences of this damage include urinary incontinence and fecal incontinence if the rectum is involved. This condition has plagued women since the beginning of history. An estimated 2 million women globally live with untreated fistulas

(United Nations Population Fund [UNPF], 2019). Another major cause of genital trauma leading to the development of genital fistulas is female genital cutting (FGC). This comprises all procedures that involve partial or total removal of the external female genitalia, specifically the clitoris. This cultural practice, primarily carried out in Africa and Asia, is receiving worldwide attention as part of the international public health agenda to move toward reducing and stopping its incidence. Reasons for continuing this practice include rite of passage, preserving chastity, ensuring marriageability, religion, hygiene, improving fertility, and enhancing sexual pleasure for men (WHO, 2020b). Despite being internationally recognized as a human rights violation, 200 million girls and women alive today have undergone FGC, and if current rates persist, an estimated 68 million more will be cut by 2030 (UNPF, 2020). Because of migration, health care providers are increasingly confronted with the range of negative urogynecologic effects that result from this practice. Nurses need to have a deeper understanding of the history, cultural beliefs, medical complications, and methods of surgical reconstruction to provide culturally competent care to this unique group of women. This cultural practice will be addressed in detail in Chapter 9.

Therapeutic Management

Many small fistulas will heal without treatment, but large fistulas often require surgical repair; surgery may be postponed until the edema or inflammation in the surrounding tissues has dissipated. Surgical repair of fistulas is associated with a high success rate if it is done in a timely manner, but larger fistulas and those of long duration have a poorer prognosis (Wall, 2019).

Nursing Assessment

The history should include questions about any changes in the woman's urinary and bowel patterns. Assess for common signs and symptoms of fistulas, which are related to the type of fistula. If the opening involves the rectum, feces and flatus will leak through the vagina. If it involves the bladder, urine will leak from the vagina.

Depending on the location and size of the fistula, the woman may or may not experience discomfort. The health care provider can detect these abnormal openings through inspection and palpation during the pelvic examination. Diagnostic or laboratory tests are generally not ordered once this condition is found.

Nursing Management

Provide guidance and support. Offer information to help the woman learn about her condition and with appropriate intervention, to improve her quality of life. Begin by making sure the woman understands her anatomy and why she is having such symptoms. Provide a thorough explanation of the treatment options so that she can make an informed decision. Be sensitive to the woman's feeling of shame and fear about her incontinence; these feelings may be why she delayed seeking treatment. Address all of the woman's needs, both physical and emotional.

Bartholin Cysts

Bartholin cysts are swollen, fluid-filled, sac-like structures that result when one of the ducts of the Bartholin gland becomes blocked. The cyst may become infected and an abscess may develop in the gland. The Bartholin glands are two mucus-secreting glandular pea-sized structures with duct openings bilaterally at the base of the labia minora near the opening of the vagina that provide lubrication during sexual arousal. Normally these glands cannot be felt or seen unless they are infected. Bartholin cysts are the most common cystic growths in the vulva, affecting approximately 2% of women at some time in their lives (Chen, 2019).

Therapeutic Management

Treatment can be conservative or surgical depending on the symptoms, the size of the cyst, and whether it is infected or not. Small asymptomatic cysts do not require treatment. Sitz baths along with analgesics are used to reduce discomfort. Antibiotics are

prescribed if the gland is infected. The aim of treatment for a cyst or abscess is to create a fistulous tract from the dilated duct to the outside vulva by incision and drainage. However, cysts or abscesses tend to return if this option is used.

Other treatment options beyond incision and drainage include placement of a Word catheter or a small loop of plastic tubing secured in place to prevent closure and to allow drainage. The use of a carbon dioxide laser to remove the cyst is also possible. After the Word catheter is inserted, the balloon tip is inflated and it is left in place for 4 to 6 weeks. The follow-up of the plastic tubing for removal is in approximately 3 weeks. Both procedures are safe and effective alternatives to surgery (Magowan et al., 2018). Treatment for a pregnant woman with a Bartholin cyst depends on the severity of the symptoms and whether an infection is present. Surgery may be delayed until after the woman gives birth if there are no symptoms.

Nursing Assessment

Nursing assessment for the woman with a Bartholin cyst includes a thorough health history, physical examination, and laboratory and diagnostic tests.

HEALTH HISTORY

The history should include questions about the woman's sexual practices and protective measures used. Assess for common signs and symptoms of Bartholin cysts. The woman may be asymptomatic if the cyst is small (less than 5 cm) and not infected. If infection is present, symptoms include varying degrees of pain, especially when walking or sitting; unilateral edema; redness around the gland; and dyspareunia. Extensive inflammation may cause systemic symptoms. Abscess formation occurs when the cystic fluid becomes infected. An abscess usually develops rapidly over a 2- to 3-day period and may spontaneously rupture. A history of sudden relief of pain following profuse discharge is highly suggestive of spontaneous rupture (Oyelowo & Johnson, 2018).

PHYSICAL EXAMINATION AND LABORATORY AND DIAGNOSTIC STUDIES

The diagnosis of Bartholin cysts or abscesses is primarily made during a physical examination when a protruding tender labial mass is located. In women over the age of 40, there is an increased risk of malignancy, typically sarcomas, which account for 2% of all invasive vulvar malignancies. They are characterized by rapid growth, high metastatic potential, frequent recurrences, aggressive behavior, and high mortality rate (Dey, 2019). Cultures of the purulent abscess fluid and of the cervix should be obtained for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* to rule out a sexually transmitted infection.

Nursing Management

Nurses must be aware of and knowledgeable about vulvar cysts and treatment options. The woman may be aware of a vulvar cyst secondary to the pain or may be unaware of it if it is asymptomatic. A Bartholin cyst may be an incidental finding during a routine pelvic examination. Explain the cause of the cyst and assist with cultures if needed. Provide reassurance and support.

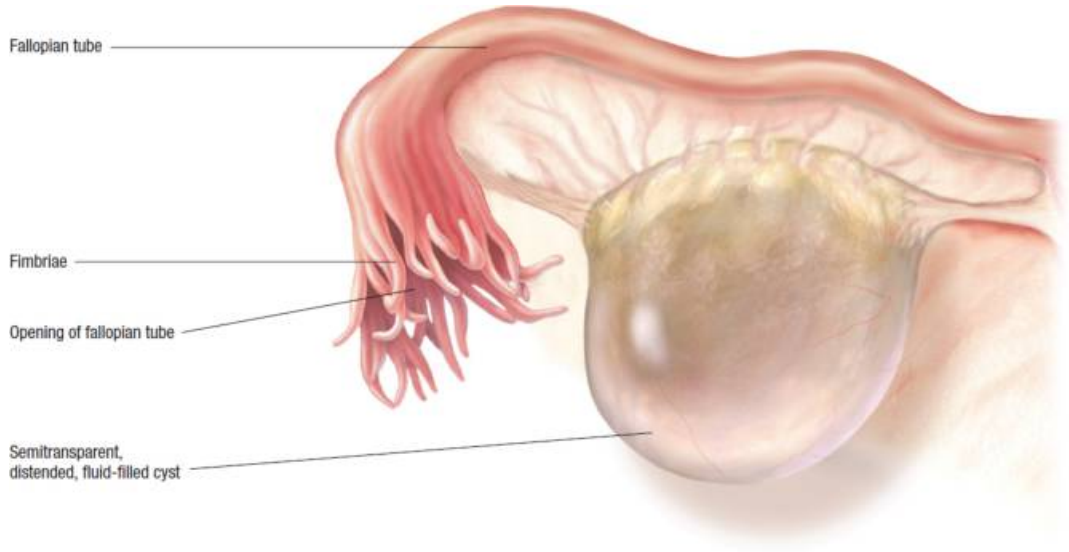

FIGURE 7.5. Ovarian cyst. (Asset provided by Anatomical Chart Co.)

Ovarian Cysts

An ovarian cyst is a fluid-filled sac that forms on the ovary (Fig. 7.5). These common growths are benign 90% of the time and are asymptomatic in many women. The cysts are discovered incidentally during an ultrasound or routine pelvic exam. Ovarian cysts occur in 30% of women with regular menses, 50% of women with irregular menses, and 7% of postmenopausal women (Hopkins, 2019). When the cysts grow large and exert pressure on surrounding structures, women often seek medical help.

Types of Ovarian Cysts

The most common benign ovarian cysts are follicular cysts, corpus luteum (lutein) cysts, and theca-lutein cysts. Although polycystic ovary syndrome (PCOS) includes the term “cyst,” the “cysts” that form are actually follicles. However, the condition will be discussed here.

FOLLICULAR CYSTS

Small follicular cysts are commonly found in the ovaries of prepubertal girls and women of reproductive age, and in most cases, they are of no clinical significance. They are usually self-limiting and resolve spontaneously. Follicular cysts are caused by the failure of the ovarian follicle to rupture at the time of ovulation. Follicular cysts seldom grow larger than 5 cm in diameter; most regress and require no treatment. They can occur at any age and are rare after menopause. They are detected by vaginal ultrasound.

CORPUS LUTEUM (LUTEIN) CYSTS

A corpus luteum cyst forms when the corpus luteum becomes cystic or hemorrhagic and fails to degenerate after 14 days. These cysts might cause pain and delay the next menstrual period. A pelvic ultrasound helps to make this diagnosis. Typically, these cysts appear after ovulation and resolve without intervention.

THECA-LUTEIN CYSTS

Prolonged abnormally high levels of human chorionic gonadotropin (hCG) stimulate the development of theca-lutein cysts. Although rare, these cysts are associated with hydatidiform mole, choriocarcinoma, polycystic ovary syndrome, and Clomid therapy.

POLYCYSTIC OVARY SYNDROME

Polycystic ovary syndrome (PCOS) is the most common endocrine condition in women of reproductive age. It affects 5% to 20% of women. It is a heterogeneous condition that involves the presence of multiple inactive follicles within the ovary that interfere with ovarian function. In PCOS, the follicles have a cyst-like appearance. With normal functioning, the egg would mature and the follicle would release it, but with PCOS, the eggs never mature and ovulation does not occur. It is a multifaceted disorder, and central to its pathogenesis are hyperandrogenemia and hyperinsulinemia, which are targets for treatment (Lucidi, 2019). It is associated with obesity; hyperinsulinemia; elevated luteinizing hormone levels (linked to ovulation); elevated androgen levels (virilization); hirsutism (male-pattern hair growth); obstructive sleep apnea; follicular atresia (ovarian growth failure); ovarian growth and cyst formation; anovulation (failure to ovulate); infertility; type 2 diabetes; sleep apnea, amenorrhea (absence of menstruation or irregular periods); metabolic syndrome; which is characterized by abdominal obesity (waist circumference greater than 35 in); dyslipidemia (triglyceride level higher than 150 mg/dL, high-density lipoprotein cholesterol level lower than 50 mg/dL); elevated blood pressure; a proinflammatory state characterized by an elevated C-reactive protein level; and a prothrombotic state characterized by elevated PAI-1 and fibrinogen levels. Recent studies also indicate that PCOS is associated with an increase in the risk of uterine fibroids, depression, adverse pregnancy outcomes, and neonatal complications. A recent meta-analysis found that women with PCOS demonstrated a significantly higher risk of developing gestational

diabetes, gestational hypertension, preeclampsia, preterm birth, and a higher cesarean section rate when compared to controls (Gilbert et al., 2018). With an estimated prevalence of 5% to 10% of all females, PCOS is the most common cause of medically treatable infertility and is responsible for 70% of cases of anovulatory subfertility and up to 20% of infertility cases (Pasquali, 2018).

TAKE NOTE!

Careful attention should be given to this condition because affected women are at increased risk for long-term health problems such as cardiovascular disease, hypertension, dyslipidemia, type 2 diabetes (half of all women), infertility, and cancer (endometrial, breast, and ovarian) (Gilbert et al., 2018).

Initially, PCOS was called Stein–Leventhal syndrome after its researchers, but it is now recognized as an anabolic syndrome. Unfortunately, less than two-thirds of women are aware of their diagnosis or the concomitant high risk for developing type 2 diabetes mellitus and cardiovascular disease related to metabolic syndrome. Its etiology is not clearly understood, but studies suggest a genetic (autosomal-dominant) component. Women with PCOS have abnormalities in the metabolism of androgens and estrogen and in the control of androgen production. In addition, they have peripheral insulin resistance and hyperinsulinemia and obesity (Oyelowo & Johnson, 2018). All of these clinical manifestations must be addressed throughout the lifespan with an emphasis on prevention of cardiometabolic risks in the treatment plan.

Therapeutic Management

Diagnosis is based on the presence of at least two of the following criteria: hyperandrogenism (evidenced by testosterone excess, hirsutism); ovarian dysfunction (anovulation); and the detection of specific polycystic ovarian morphology. Treatment is centered on the clinical manifestations and should be initiated early to prevent or limit long-term complications such as metabolic syndrome, diabetes,

endometrial carcinoma, and infertility (Pasquali, 2018). Oral contraceptives, antidiabetic agents, and statins are some of the common therapies used to address the symptoms of this complex hormonal condition. Weight loss and surgery may also be beneficial as nondrug options.

Treatment of ovarian cysts focuses on differentiating a benign cyst from a solid ovarian malignancy. Transvaginal ultrasound is useful in distinguishing fluid-filled cysts from solid masses. Laparoscopy may be needed to remove the cyst if it is large and pressing on surrounding structures. For smaller cysts, monitoring with repeat ultrasounds every 3 to 6 months might be indicated (Mitchell-Levy & Marsh, 2018). Oral contraceptives are often prescribed to suppress gonadotropin levels, which may help resolve the cysts. Pain medication is also prescribed if needed.

Medical management of PCOS is aimed at the treatment of metabolic derangements, anovulation, hirsutism, and menstrual irregularity. This includes both drug and nondrug therapy, along with lifestyle modifications. Goals of therapy focus on reducing the production and circulating levels of androgens, protecting the endometrium against the effects of unopposed estrogens, supporting lifestyle changes to achieve ideal body weight, lowering the risk of cardiovascular disease, avoiding the effects of hyperinsulinemia on the risk of cardiovascular disease and diabetes, and inducing ovulation to achieve pregnancy if desired. Treatment modalities for PCOS are highlighted in Box 7.3.

BOX 7.3 Treatment Modalities for PCOS

- Oral contraceptives to treat menstrual irregularities and acne
- Mechanical hair removal (shaving, waxing, plucking, or electrolysis) to treat hirsutism
- Glucophage (metformin), which improves insulin uptake by fat and muscle cells, to treat hyperinsulinemia; thiazolidinediones (Actos, Avandia) to decrease insulin resistance
- Ovulation induction agents (Clomid) to treat infertility
- Lifestyle changes (e.g., weight loss, exercise, balanced low-fat diet)
- Referral to support groups to help improve emotional state and build self-esteem

Nursing Assessment

Nursing assessment for the woman with PCOS includes a thorough health history, physical examination, and laboratory and diagnostic tests.

HEALTH HISTORY

The history should include questions about the woman's symptoms, including onset, location, frequency, quality, intensity, and aggravating and alleviating factors of her discomfort. Note the last menstrual period and whether or not her cycles are regular. Ask about her overall general health and any changes recently noticed, such as a change in abdominal girth without a concomitant weight gain. Assess for common signs and symptoms of ovarian cysts. Findings might include:

- Hirsutism (face and chin, upper lip, areola, lower abdomen, and perineum)
- Alopecia (frontal region and crown of head)

- Virilization (clitoral hypertrophy, deepening of voice, increased muscle mass, breast atrophy, male-pattern baldness)
- Menstrual irregularity and infertility (menorrhagia, anovulation)
- Polycystic ovaries (12 or more follicles on ovaries)
- Obesity (occurs in more than 50% of women with PCOS; occurs in abdominal region with an increase in the waist–hip ratio)
- Insulin resistance (chronic hyperinsulinemia leads to type 2 diabetes)
- Metabolic syndrome (elevated cholesterol, triglycerides, and low-density lipoprotein; risk of cardiovascular disease)
- Increased risk for endometrial cancer, ovarian cancer, breast cancer
- Psychological impact (depression, frustration, anxiety, eating disorders; see Evidence-Based Practice 7.2)
- Acne (face and shoulders) (Lucidi, 2019)

PHYSICAL EXAMINATION AND LABORATORY AND DIAGNOSTIC STUDIES

The physical examination includes inspection, auscultation, and palpation of the abdomen because large ovarian masses may cause visible changes in the abdomen. A complete pelvic examination is performed to assess the location, size, shape, texture, mobility, and tenderness of any palpable mass.

Diagnostic tests include a pregnancy test to rule out ectopic pregnancy. Gonorrhea and chlamydia testing is warranted if an ovarian abscess is suspected. An ultrasound may be ordered to differentiate between functional or simple ovarian cysts and a solid tumor. Additional tests may be performed depending on the findings.

Remember Liz, the client with irregular menses, facial hair, and acne? Her glucose level is elevated, multiple cysts were felt on her ovaries during the pelvic examination, and laboratory tests found elevated lipid and lipoprotein levels. What education should the nurse provide Liz regarding her PCOS diagnosis? What medications might be prescribed to address her abnormal laboratory values?

Nursing Management

Nursing care should include education about the condition, treatment options, diagnostic test arrangements, and referral for surgery if needed. Provide support and reassurance during the diagnostic period to allay anxiety in the client and her family. Reassure the woman that the majority of ovarian cysts are benign, but continue to stress the importance of follow-up care. Listen to the woman's concerns about her appearance, infertility, and facial hair growth. Offer suggestions to help the woman feel better about herself and her health.

EVIDENCE-BASED PRACTICE 7.2

Psychiatric Disorders in Women with Polycystic Ovary Syndrome: A Systematic Review and Meta-Analysis

STUDY

Polycystic ovary syndrome (PCOS) is a common endocrine disorder affecting up to 15% of women of reproductive age. Prior research studies have suggested that PCOS can be associated with mood and psychiatric disorders. The purpose of this study is to assess the prevalence of any psychiatric disorder in women with PCOS.

Findings

The review included 57 studies involving 172,040 women. The majority of the studies addressed depression and anxiety, but a few studies focused on bipolar and obsessive-compulsive disorders. Using various scales, the severity of symptoms of depression, anxiety, bipolar disorder, obsessive-compulsive disorder, and somatization disorders were higher among women with PCOS compared to those without it.

Nursing Implications

Based on this study, it is important for nurses to understand that PCOS is associated with an increased risk of diagnosis of depression, anxiety, and bipolar and obsessive-compulsive disorders. It is associated with worsening symptoms of depression, anxiety, obsessive-compulsive disorder, and somatization complaints. The high prevalence rate of these psychological disorders in this population suggests that initial evaluation of all women with PCOS should also include an

assessment of their mental health. Psychological support by nurses should take on an important role in the management of the affected women with PCOS. This does not suggest that medical treatment of PCOS is not required, but a thorough cooperation between medical treatment and psychological support would improve the situation of PCOS affected women. The physical and psychosocial aspects of management of PCOS go hand in hand. Meeting physical management goals (e.g., weight loss, reduction in hyperandrogenism manifestations) can lessen some of the distressing psychosocial effects, and enhance self-esteem.

Adapted from Brutocao, C., Zaiem, F., Alsawas, M., Morrow, A. S., Murad, M. H., & Javed, A. (2018). Psychiatric disorders in women with polycystic ovary syndrome: A systematic review and meta-analysis. Endocrine, 62(2), 318–325.

Nurses can have a positive impact on women with PCOS through counseling and education. Provide support for women dealing with negative self-image secondary to the physical manifestations of PCOS. Through education, help the woman understand the syndrome and its associated risk factors to prevent long-term health problems. Encourage the woman to make positive lifestyle changes. Make community referrals to local support groups to help the woman build her coping skills.

Liz returns to the clinic a month later for reevaluation of her PCOS. She has been taking metformin to reduce her insulin resistance and has followed her exercise regimen and reduced her caloric intake to lose weight, but she still complains about her facial hair and acne. What interventions might be helpful to address this problem? What medication might also be prescribed to regularize her menses and relieve the hirsutism?

KEY CONCEPTS

- Pelvic floor disorders such as pelvic organ prolapse and urinary and fecal incontinence are prevalent conditions in aging women. They cause significant physical and psychological morbidity, negatively affecting women's social interactions, emotional well-being, and overall quality of life.
- The four most common types of genital prolapse are cystocele, rectocele, enterocele, and uterine prolapse.
- The purpose of pelvic floor muscle exercises is to increase the muscle volume, which will result in a stronger muscular contraction. These exercises might limit the progression of mild prolapse and alleviate mild prolapse symptoms, including low back pain and pelvic pressure.
- Urinary incontinence is the involuntary loss of urine sufficient enough to be a social or hygiene problem. It affects approximately 15 million women in the United States.
- The three most common types of incontinence are urge incontinence (overactive bladder caused by detrusor muscle contractions), stress incontinence (inadequate urinary sphincter function), and mixed incontinence (involves both stress and urge incontinence).
- The most common benign growths of the reproductive tract include cervical, endocervical, and endometrial polyps; uterine fibroids (leiomyomas); genital fistulas; Bartholin cysts; and ovarian cysts.
- PCOS involves the presence of multiple inactive follicles within the ovary that interfere with ovarian function. Hyperandrogenism, insulin resistance, and chronic anovulation characterize PCOS. Careful attention should be given to this condition because women with it are at increased risk for long-term health problems such as cardiovascular disease, hypertension, dyslipidemia, infertility, type 2 diabetes, and cancer (endometrial, breast, and ovarian).

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. When you are interviewing a client with uterine fibroids, what subjective data would you expect to find in her history?

   a. Cyclic migraine headaches
   b. Urinary tract infections
   c. Chronic pelvic pain
   d. Chronic constipation

2. Conservative treatment options available for women with pelvic organ prolapse are

   a. pessaries and PFMEs.
   b. external pelvic fixation devices.
   c. weight gain and yoga.
   d. firm panty-and-girdle garments.

3. Which dietary and lifestyle modification might the nurse recommend to help prevent pelvic relaxation as women age?

   a. Eat a high-fiber diet to avoid constipation and straining.
   b. Avoid sitting for long periods; get up and walk around frequently.
   c. Limit the amount of exercise to prevent overdeveloping muscles.
   d. Space children a year apart to reduce wear and tear on the uterus.

4. Women with PCOS are at increased risk for developing which long-term health problem?

   a. Osteoporosis

b. Lupus
c. Type 2 diabetes
d. Migraine headaches

5. Side effects experienced by women taking GnRH agonists for the treatment of fibroids closely resemble those of

a. anorexia nervosa.
b. osteoarthritis.
c. depression.
d. menopause.

6. In securing a health history of a 65-year-old woman, which clinical manifestation described by the client would the nurse suspect is related to pelvic organ prolapse?

a. Chronic abdominal pain
b. Heavy feeling or dragging in vagina
c. Uterine cramping and backache
d. Weight gain and edema of ankles

CRITICAL THINKING EXERCISES

1. Faith, a 42-year-old multiparous woman, presents to the women's health clinic complaining of pelvic pain, heavy menstrual bleeding, and vaginal discharge. She says she has been having these problems for several months. Upon examination, her uterus is enlarged and irregular in shape. Her blood studies reveal anemia.

a. What condition might Faith have based on her symptoms?
b. What treatment options are available to address this condition?
c. What educational interventions should the nurse discuss with Faith?

STUDY ACTIVITIES

1. Prepare an educational session to teach women how to do pelvic floor muscle exercises to prevent stress incontinence and pelvic floor relaxation.
2. In a small group, discuss the personal, social, and sexual issues that might affect a woman with pelvic organ prolapse. How might these issues affect her socialization? How might a support group help?
3. List the symptoms that a woman with uterine fibroids might have. Discuss how these symptoms might mimic a more frightening condition and why the woman might delay seeking treatment.
4. A bladder that herniates into the vagina is a _____.
5. A rectum that herniates into the vagina is a _____.

BRINGING IT ALL TOGETHER: A CASE STUDY

Elizabeth, a 52-year-old woman presents to the gynecologic clinic to discuss a “horrible personal problem” that is ruining her life. She appears very distressed and only wants to talk to the nurse in private about it. A few months ago, when she was out walking her dog, she experienced a sudden rectal urgency that she thought was gas, but she expelled feces instead. Over the past few months, her fecal incontinence has increased in severity and frequency causing her extreme stress. To avoid embarrassment, she has had to cover and excuse herself from work situations and turn down social invitations. She now has to wear a protective pad and disposable pants.

ASSESSMENT

Elizabeth is otherwise healthy and takes no prescription medications presently. She has had five vaginal births with three episiotomies. She has a body mass index of 27, mild

stress urinary incontinence, and a low-grade rectocele with slightly decreased anal sphincter tone. Her pelvic exam demonstrated pelvic organ prolapse. The digital rectal exam ruled out fecal impaction and any rectal mass. A detailed history of her incontinence episodes was also taken.

Go to thePoint to find questions to consider about this case.

8

Cancers of the Female Reproductive Tract

WOW

WORDS OF WISDOM

The word “cancer” can strike fear into anyone who hears it. But when it involves a reproductive organ, this fear is often magnified.

KEY TERMS

cervical cancer

cervical dysplasia (ser´vĭ-kăl dis-plā´zē-ă)

colposcopy (kol-pos´kŏ-pē)

endometrial cancer (en´dō-mē´trē-ăl kan´ser)

gestational cancer

human papillomavirus (hyū´măn pap´i-lō´mă-vī´rŭs)

ovarian cancer

Papanicolaou (Pap) test (pa-pă-ni´kō-low test)

vaginal cancer

vulvar cancer

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Analyze the national and global statistics related to reproductive cancer rates in women.
2. Plan, implement, and evaluate using the nursing process for women with cancer of the reproductive tract.
3. Describe the assessment, collaborative care, and nursing management of women with a diagnosis of ovarian cancer.
4. Identify the clinical manifestations, diagnostic procedures, and treatment options for women with endometrial cancer.
5. Examine lifestyle changes and health screenings that reduce the risk of or prevent cervical cancers.
6. Outline the nursing and collaborative management needed for a woman diagnosed with vaginal cancer.
7. Appraise the psychological distress felt by women diagnosed with any reproductive cancer and resources available to her.

Carmella is an obese, 55-year-old woman who presents to her woman's health care provider with vaginal bleeding. She has been through menopause and wonders why she is having a period again. Her history includes infertility and hypertension. Three years ago, she had a mastectomy for breast cancer, and she has been taking tamoxifen (Nolvadex) to prevent recurrent breast cancer since her surgery. What risk factors in Carmella's history might predispose her to a reproductive tract cancer? What additional information is needed to make a diagnosis?

INTRODUCTION

Cancer is the second leading cause of death for women in the United States, surpassed only by cardiovascular disease (Centers for Disease Control and Prevention [CDC], 2019a). Cardiovascular disease is and should continue to be a major focus of efforts in women's health. However, this should not overshadow the fact that many women between the ages of 35 and 74 are developing and dying of cancer (National Cancer Institute [NCI], 2019a). Women have a one-in-three lifetime risk of developing cancer, and one out of every four deaths is from cancer (NCI, 2019a). African American women have the highest death rates from both heart disease and cancer (CDC, 2019a). The American Cancer Society (ACS, 2020a) estimated that in 2020, there were about 1.8 million new cancer cases diagnosed and about 606,520 cancer deaths in the United States.

Scientific evidence suggests that about one third of all cancer deaths are related to obesity, physical inactivity, and poor nutrition, and thus could have been prevented. Certain cancers are related to infectious agents, such as hepatitis B virus (HBV), human papillomavirus (HPV), human immunodeficiency virus (HIV), and *Helicobacter pylori* (*H. pylori*), and can be prevented through behavioral changes, vaccines, and/or antibiotics (NCI, 2019b). In addition, many of the more than 2 million skin cancers that are

diagnosed annually could be prevented by protecting the skin from the sun's rays and avoiding indoor tanning. Sunburns, especially if they occur repetitively in childhood, may lead to melanoma. Most melanomas are treated successfully if discovered early, but metastatic melanoma has little effective treatment (American Academy of Dermatology, 2020; Hanlon, 2018).

In the United States, approximately half of all premature deaths, one third of acute disabilities, and one half of chronic disabilities are preventable, including some cancers (NCI, 2019b). Nurses need to focus their energies on screening, education, and early detection to reduce these numbers. Because cancer risk is strongly associated with lifestyle and behavior, screening programs are of particular importance for early detection. There is evidence that prevention and early detection have reduced cancer mortality rates and prevented reproductive cancers (CDC, 2019a).

This chapter begins with a nursing process overview of the care of women with reproductive cancer. It then describes selected cancers of the reproductive system: ovarian, endometrial, cervical, vaginal, and vulvar cancer. The chapter discusses the nurse's role through diagnosis, intervention, and follow-up care. Cancer management requires a multidisciplinary approach, including specialists in surgical, medical, and radiation oncology. The nurse can provide guidance and support to the client as she finds her way through the health care maze.

Nursing Process Overview for Women with Cancer of the Reproductive Tract

The word “cancer” is associated with fear and dread. These feelings may worsen when the cancer involves a woman’s reproductive tract. The diagnosis of a reproductive tract cancer can have a profound impact on a woman’s sexuality because it affects the parts of the body associated with these functions. The loss of the reproductive body part as well as the possible loss of childbearing ability can have a significant effect on women and their partners. Nurses need to remember this when counseling women and their partners about cancer treatment and side effects as well as potential changes in gender roles and sexuality.

When a woman is first diagnosed with a reproductive tract cancer, two primary needs arise: information and emotional support. When the diagnosis is made, the woman typically has many questions, such as “What is going to happen to me?” “How will this change my life?” and “Will I survive?” Nurses can play a major role in helping women find the answers to their questions and directing them to the resources they need. Two reliable sources of general cancer information are the National Cancer Institute and the American Cancer Society. They can be reached via the internet or by phone.

The nurse also plays a key role in offering emotional support, determining appropriate sources of support, and helping the woman use effective coping strategies. A recent research study found that social support from the woman’s family, friends, and coworkers is one of the strongest predictors of how well she will cope (Bradley et al., 2018). Implications for nurses working with women following a cancer diagnosis include assessing women’s definitions and availability of support; respecting varied needs for informational support; providing a supportive clinical environment; educating clinicians, family, and friends regarding unsupportive

responses within the cultural context; and validating women's control and balancing of support needs. Nurses are well positioned to provide women with anticipatory guidance from diagnosis to the end of treatment (Mitchell et al., 2018). Women without a social support network may need a social work referral or may need to be guided toward support groups to receive the emotional support they need. The care provided by nurses to women undergoing treatment and recovery are invaluable in maintaining their quality of life and managing the unpleasant side effects that many women experience.

In addition, cancer clients have a strong need for hope. Strategies for inspiring hope may include active listening, touch, presence, and helping clients overcome communication barriers. A cancer diagnosis does not determine how strong a person is, but rather, do they have the courage to face cancer, the tenacity and the strength to battle it. Often it is not what nurses say or do, but just their presence that counts. The ability for women to depend on a trusted nurse during this difficult time in their lives is something that can have a profound effect on their emotional state and energy levels during their recovery process.

Assessment

Assessment of a woman with cancer of the reproductive tract involves a thorough history and physical examination. In addition, various laboratory and diagnostic tests may be done to evaluate for a malignancy.

Health History and Physical Examination

Interview the woman carefully to determine any current or past factors that might increase her risk of cancer, such as early menarche, late menopause, sexually transmitted infections (STIs), use of hormonal agents, or infertility. Find out if the woman has a family history of cancer. Be thorough in obtaining the woman's past medical history, especially her reproductive, obstetric, and gynecologic history. Ask about her lifestyle and behaviors, including risky behaviors such as engaging in unprotected sexual intercourse or sexual intercourse with multiple partners. Find out if she has had routine or recommended screening procedures.

Ask if the woman has had any symptoms, such as abnormal vaginal bleeding or discharge or vaginal discomfort. Often the symptoms of cancer are vague and nonspecific, and the woman may attribute them to another problem, such as aging, stress, or improper diet.

Perform a complete physical examination, including a review of body systems and a pelvic examination. Observe for lesions or masses in the perineal area. Note any masses when palpating the abdomen or when performing the pelvic examination.

Laboratory and Diagnostic Testing

Some of the laboratory and diagnostic tests used to help diagnose cancer of the reproductive tract are discussed in Common Laboratory and Diagnostic Tests 8.1.

COMMON LABORATORY AND DIAGNOSTIC TESTS 8.1

Test	Explanation	Indications	Nursing Implications
Clinical breast examination	Assessment of the breast for abnormal findings; client may discover lump herself; high-risk history for breast cancer	Identifies palpable mass, skin change, inverted nipple, or unresolved rash	• Educate client to perform breast self-examination and report any abnormalities of high risk. • Reinforce the need for frequent clinical breast examinations if risk factors are present.
Mammography	Screening modality for breast cancer or any distortion in breast tissue architecture	Detects calcifications, densities, and nonpalpable cancer lesions	Stress the importance of annual mammograms for all women after the age of 40 or 50, depending on their risk history.
Pap test	Cervical cytology screening to diagnose cervical cancers	Aids in detecting abnormal cells of the cervix (from squamocolumnar junction of the cervix; most cervical cancers arise here)	Encourage all sexually active women to receive a pelvic examination, including a Pap test if they have a high-risk profile, to promote early detection of cervical cancer.
Transvaginal ultrasound	Screening for pelvic pathology to assist in diagnosing endometrial cancers	Allows measurement of endometrial thickness to determine if endometrial biopsy is needed for postmenopausal bleeding	• Review the risk factors for the development of endometrial cancer and reason for this screening test. • Assist in preparing the client for this examination.

CA-125	Nonspecific blood test used as a tumor marker	Elevation of marker suggests malignancy but is not specific to ovarian cancer.	• Review risk factors for ovarian cancer and explain that a series of diagnostic tests may be performed (transvaginal ultrasound, CT scan, CA-125) to assist in the diagnosis and treatment plan. • Elevated marker levels are not specific to ovarian cancer; they can be elevated in other types of cancer.

Nursing Analyses and Related Interventions

Upon completion of a thorough assessment, the nurse might identify several nursing analyses, including:

- Lack of knowledge
- Altered body image perception
- Anxiety
- Fear
- Pain

Nursing goals, interventions, and evaluation for women with reproductive tract cancer are based on the nursing analyses. Nursing Care Plan 8.1 may be used as a guide in planning nursing care for women with reproductive tract cancer. It should be individualized based on the woman's symptoms and needs.

Nurses have traditionally served as advocates in the health care arena and should continue to be on the forefront of health education and diagnosis, acting as leaders in the fight against cancer. Over half a million women in the United States will be diagnosed with cancer this year alone and more than half will die of it (CDC, 2019b). The public needs to know that not only are these deaths preventable, but many of the cancers themselves are preventable. Nurses need to work to improve the availability and quality of cancer-screening services, making them accessible to underserved and socioeconomically disadvantaged clients. Through the unified effort of health care providers, health policy experts, government agencies, health insurance companies, the media, educational institutions, and women themselves, along with consistency and continuity, nurses can offer quality care to all women with cancer.

Educating to Prevent Cancer

Globally, there are nearly 13 million new cases of cancer and 10 million deaths from cancer each year. Worldwide, about one in six deaths is due to cancer. The most prevalent cause of cancer is tobacco, which causes more than 30% of cancer deaths. Dietary factors, including obesity, are estimated to cause around 25% of cancer deaths, and alcohol about 6% of cancer deaths (World Health Organization [WHO], 2019). All of these factors associated with cancer are preventable. Between 30% and 50% of all cancers are preventable by avoiding risk factors and implementing existing evidence-based prevention strategies (WHO, 2019). Nurses need to provide clients with information to help prevent disease and enhance quality of life. Educate women about the importance of consistent and timely screenings to identify cancer early. Emphasize the importance of having an annual pelvic examination. Also stress the need for follow-up screenings as recommended. Provide clients with information if further diagnostic testing is required. Nurses also play a key role in promoting cancer awareness, prevention, and control. Advocate improving the availability of cancer-screening services and work to provide public education about risk factors for cancer.

Nurses can be instrumental in helping women identify and change behaviors that put them at risk for various reproductive tract cancers (Teaching Guidelines 8.1). Do not limit your interventions to providing preventive education only; inform women about the consequences of doing nothing about their conditions and what the long-term outcomes might be without treatment. For example, stress the importance of visiting a health care provider if certain signs and symptoms appear:

- Blood in a bowel movement
- Unusual vaginal discharge or chronic vulvar itching
- Persistent abdominal bloating or constipation
- Irregular vaginal bleeding
- Persistent low backache not related to standing
- Elevated or discolored vulvar lesions
- Bleeding after menopause
- Pain or bleeding after sexual intercourse

TEACHING GUIDELINES 8.1

Reducing Your Risk for Cancer

- Do not smoke; smoking is linked to lung cancer development.
- Drink alcohol only in moderation (no more than one drink daily).
- Be physically active daily.
- Receive the HPV vaccine.
- Eat a healthy diet.
- Stay current with immunizations.
- Use a condom with every sexual encounter.
- Reach and maintain a healthy weight.
- Take preventive medicines if needed.
- Get recommended screening tests:
  - Body mass index (BMI) to identify obesity
  - Mammogram every 1 to 2 years starting at age 40
  - Pap smear every 1 to 3 years if sexually active, starting at age 21
  - Cholesterol checked annually starting at age 45
  - Blood pressure checked at least every 2 years
  - Diabetes test if hypertensive or hypercholesterolemia
  - Check for STIs if sexually active

Centers for Disease Control and Prevention (CDC). (2019g). Cancer prevention and control. Retrieved June 16, 2020, from https://www.cdc.gov/cancer/dcpc/prevention/screening.htm; National Cancer Institute (NCI). (2019b). *PDQ cancer prevention overview*. Retrieved April 8, 2020, from https://www.ncbi.nlm.nih.gov/books/NBK66016/

Teaching the Client about Her Diagnosis

Provide information about tests that may be required to confirm or rule out the diagnosis. Review with the woman what she has been told about her diagnosis and her understanding of her condition. It is not unusual for the woman to hear the diagnosis and then become overwhelmed by the thought of cancer, blocking out whatever is said after that. Answer any questions she may have. Go slowly and repeat the information as necessary. Use written materials to explain and reinforce the teaching. Provide information about the condition and recommended therapies. For example, if a client is undergoing surgery, discuss postoperative issues such as incision care, pain, and activity level. Instruct the client on health maintenance activities after treatment, and inform her and her family about available support resources.

NURSING CARE PLAN 8.1 Overview of a Woman with a Reproductive Tract Cancer

Molly, a thin 28-year-old woman, comes to the free health clinic complaining of a thin, watery vaginal discharge and spotting after sex. Molly says she has had multiple sex partners since the age of 15. She had an abnormal Pap smear "a while back" but didn't return to the clinic for follow-up. Cervical cancer is suspected.

NURSING ANALYSIS: Anxiety related to uncertainty of diagnosis, possible diagnosis of cancer, and eventual outcome as evidenced by client's report of signs and symptoms and statements of being worried and not knowing what she would do

OUTCOME IDENTIFICATION AND EVALUATION

The client will demonstrate measures to cope with anxiety as evidenced by statements acknowledging anxiety, use of positive coping strategies, and verbalization that anxiety has decreased.

INTERVENTIONS: *Reducing Anxiety*

- Encourage client to express her feelings and concerns *to reduce her anxiety and to determine appropriate interventions*.
- Assess the meaning of the diagnosis to the client, clarify misconceptions, and provide reliable, realistic information *to enhance her understanding of her condition, subsequently reducing her anxiety*.
- Assess client's psychological status *to determine the degree of emotional distress related to diagnosis and treatment options*.
- Identify and address verbalized concerns, providing information about what to expect *to decrease uncertainty about the unknown*.
- Assess the client's use of coping mechanisms in the past and their effectiveness *to foster use of positive strategies*.
- Teach client about early signs of anxiety and help her recognize them (e.g., fast heartbeat, sweating, or feeling flushed) *to minimize escalation of anxiety*.
- Provide positive reinforcement that the client's condition can be managed *to relieve her anxiety*.

NURSING ANALYSIS: Lack of knowledge related to diagnosis, prevention strategies, disease course, and treatment as evidenced by client's statements about hoping nothing bad is wrong, lack of follow-up for previous abnormal Pap test, and high-risk behaviors

OUTCOME IDENTIFICATION AND EVALUATION

The client will demonstrate an understanding of diagnosis as evidenced by making health-promoting lifestyle choices, verbalizing appropriate health care practices, describing condition once diagnosed, and adhering to measures to comply with therapy.

INTERVENTIONS: *Providing Client Teaching*

- Assess client's current knowledge about her diagnosis and proposed therapeutic regimen *to establish a baseline from which to develop a teaching plan.*
- Review contributing factors associated with development of reproductive tract cancer, including lifestyle behaviors, *to foster an understanding of the etiology of cervical cancer.*
- Review information about treatments and procedures and recommendations for healthy lifestyle, obtaining feedback frequently *to validate adequate understanding of instructions.*
- Discuss strategies, including using condoms and limiting the number of sexual partners, *to reduce the risk of transmission of STIs*, including HPV, which is associated with cervical cancer.
- Encourage client to obtain prompt treatment of any vaginal or cervical infections *to minimize the risk for cervical cancer*.
- Urge the client to have an annual Pap smear and/or HPV test *to allow screening and early detection*.
- Describe the treatment measures used *to provide client with knowledge of what may be necessary*.
- Provide written material with pictures *to allow for client review and to help her visualize what is occurring in her body*.
- Inform client about available community resources and make appropriate referrals as needed *to provide additional education and support*.
- Document details of teaching and learning *to allow for continuity of care and further education if needed*.

NURSING ANALYSIS: Altered body image perception related to suspected reproductive tract cancer and impact on client's sexuality and sense of self as evidenced by statement of being worried about not being the same

OUTCOME IDENTIFICATION AND EVALUATION

The client will verbalize or demonstrate a positive self-esteem in relation to body image as evidenced by positive statements about self, sexuality, and participation in activities with others.

INTERVENTIONS: *Promoting Healthy Body Image*

- Assess client's use of self-criticism *to determine client's current state of coping and adjustment*.
- Determine if the client's change in body image has contributed *to social isolation to provide a direction for care*.
- Provide opportunities for client to explore her feelings related to issues of sexuality, including past behaviors that may have placed her at risk, *to minimize feelings of guilt about her condition*.
- Acknowledge the client's feelings about possible changes in her body and sexuality and her illness *to foster trust and allow client to ventilate feelings and concerns*.
- Facilitate contact with other clients with the same type of cancer *to promote sharing of feelings and decrease feelings of isolation*.
- Initiate referrals for counseling and community support groups as necessary *to assist client in gaining a positive image of herself*.

Providing Emotional Support

Once the diagnosis is made, provide the woman and her family with emotional support. Validate the client's feelings and provide realistic hope, using a nonjudgmental approach and therapeutic communication skills during all interactions. Nurses can be invaluable when assisting women who are coping with the uncertainty of their future by providing positive communication and support. Nurses need to focus on the physical, psychosocial, and economic concerns from diagnosis through treatment and if applicable, until the end of life for all of the women for whom they care. Individualize the care based on the client's cultural traditions and beliefs as explained in the following section.

Ensuring Cultural Humility

Cultural diversity in America is increasing, and as diverse cultures interact, conflicts inevitably ensue. These conflicts can affect health care outcomes. Demonstrating cultural humility with cancer care can improve outcomes and decrease disparities in care. If nurses are to meet the needs of ethnically diverse populations, they must be culturally sensitive, appreciative of differing health beliefs and practices, and flexible in the way they approach health care. It is nurses who must adapt, expand, and learn. Cultural humility encourages developing an attitude of *not knowing* the client's culture and learning about it from the client.

Nurses have the opportunity to learn about diverse cultures, religions, and faith traditions that support clients and families during their cancer journeys and while facing a serious life-limiting illness. Nursing care practices should embrace all clients with whom they come in contact, and by having a better understanding of diverse groups, nurses can build trust in clients seeking oncology care needs that range from detection to diagnosis to treatment and possibly through palliative and end-of-life care.

Be aware of the client's cultural background, religion, migration history, degree of acculturation, living conditions, educational level,

and legal status, because each of these factors can affect the client's understanding of her diagnosis and the eventual outcome. A woman's reaction to a cancer diagnosis and her decisions about treatment are influenced by her cultural values and how the community views cancer. A diagnosis of cancer carries deep physical, psychosocial, and cultural implications. Sensitive cross-cultural communication and cultural competence are vital for all nurses to deliver equal care to all cancer clients. Nurses need to understand the disparities and the influence of those disparities on health outcomes. Women with cancer reflect the demographic changes occurring across the United States, representing increasing differences in culture, religion, socioeconomic status, race, and lifestyle. Nurses need to relinquish the role of expert to the client, and instead become the student of the client, explicitly expressing that the client is a capable and full partner in the therapeutic alliance. Nurses need to realize the importance of recognizing diversity and applying cultural humility for successful outcomes (Foronda, 2020).

In some cultures, sharing news of a serious illness like cancer is considered disrespectful and impolite. For example, some Europeans view such sharing as inhumane; some Asian cultures view a cancer diagnosis as unnecessarily cruel. Out of respect for aging family members, some Chinese people may withhold discussions of serious illness to avoid causing unnecessary anxieties (Liu et al., 2018). Integrate this knowledge in your care to ensure a culturally competent approach.

TAKE NOTE!

When a diagnosis of cancer is made, assessing an individual's strengths and weaknesses from a cultural perspective will help the nurse provide culturally competent care.

As life becomes increasingly multilingual, multicultural, and multi-religious, learning about clients' values and cultural beliefs becomes challenging. Be willing to learn about client preferences; doing so promotes caring and cultural humility.

Gestational Cancer

Gestational cancer is defined as a new cancer diagnosis during pregnancy or in the first year postpartum. Cancer during pregnancy is a rare event, occurring approximately once per 1,000 pregnancies annually (Hepner et al., 2019). The incidence is increasing because women in Western societies are increasingly delaying childbearing to the third and fourth decades of life; therefore, gestational cancer will be encountered more often in the future by nurses. The most frequent malignancies diagnosed during pregnancy are breast cancer, cervical cancer, thyroid, hematologic malignancies (lymphomas and acute leukemia), and melanoma. Breast cancer is the most common cancer diagnosed in pregnant women which affects approximately one in 3,000 pregnancies (McCormick & Peterson, 2018).

Theoretically, changes in the mother's immune system during pregnancy can increase the risk of malignancy because cell-mediated immunity, which is suppressed in pregnant women, normally protects the body against cancerous tumors. With the cooperation of multidisciplinary teams, treatment of cancer during pregnancy with normal fetal outcomes is feasible (Litton, 2019). The incidence of endometrial cancer in women below the age of 40 is very low and rarely diagnosed before giving birth. Since the uterus itself is involved, definitive treatment during pregnancy, if discovered, is impossible. An observational approach is usually followed until the women has given birth (Eriksson et al., 2019). Adenocarcinoma associated with pregnancy is typically endometrioid, focal, well differentiated, and minimally invasive. Active treatment of endometrial cancer is incompatible with the continuation of the pregnancy. Since routine screening for endometrial cancer is currently not recommended in the general

population, few cases would be detected in the relatively young pregnant population (King et al., 2019).

Cervical cancer is more common in the pregnant population than other reproductive malignancies, and it can affect the woman's health status and the pregnancy. Approximately 30% of women diagnosed with cervical cancer are in their reproductive years, while 3% of cervical cancers are diagnosed during pregnancy (Karam, 2019). Management of cervical cancer during pregnancy depends on the following factors:

- Stage of the disease (and the tumor size)
- Nodal status
- Histologic subtype of the tumor
- Term of the pregnancy
- Whether the client wishes to continue her pregnancy
- Woman's desire for future fertility

In women with early-stage disease and absence of nodal involvement who are diagnosed during the first two trimesters of pregnancy, there is an increasing tendency to preserve the pregnancy while awaiting fetal maturity. The birth (when the fetal maturity is attained) should be performed by cesarean section (ACS, 2020b). Treatment decisions are influenced by the stage of the cancer, the histologic type, the stage of the pregnancy, and the client's wishes. Both maternal and fetal safety and well-being have to be taken into account. Termination of pregnancy is not indicated in all cases. Pregnancy preservation in tumors diagnosed during early gestation is feasible in carefully selected cases. Discussion with the client and her family is essential, and treatment has to be individualized (ACS, 2020b).

Nurses caring for young clients with cervical cancer must be aware of the surgical fertility preservation options, which clients are candidates for these surgeries, and the options for future assisted reproductive technology. Nurses need to be able to coordinate care for these clients with gynecologic oncologists and reproductive endocrinologists in order to facilitate optimal outcomes.

Women diagnosed with any malignancy during pregnancy must confront the reality of the disease, its impact on their future fertility, and the risk of future recurrence. The prognosis for a pregnant woman with cancer is often the same as that of other women of the same age with the same type of cancer (Cancer.Net, 2018). The wishes of the pregnant woman and her family are of paramount importance when making decisions about continuing the pregnancy and undergoing cancer treatment. Some women will decide to terminate the pregnancy for the sake of their own health; others will undergo treatment during the pregnancy to preserve the life of the unborn child. Regardless of the woman's decision, provide support, hope, and education during treatment, birth, and beyond.

OVARIAN CANCER

Ovarian cancer is a malignant neoplastic growth of the ovary (Fig. 8.1). It is the fifth most common cancer among women and the most common cause of cancer deaths for women in the United States. It accounts for more deaths than any other cancer of the reproductive system (ACS, 2020c). A woman's risk of getting invasive ovarian cancer in her lifetime is about one in 78. Her lifetime chance of dying from invasive ovarian cancer is about one in 108 (ACS, 2020c). This cancer mainly develops in older women. About half of the women who are diagnosed with ovarian cancer are 63 or older. It is more common among White women than among African American women (ACS, 2020c).

The most important variable influencing the prognosis is the extent of the disease. About 75% of women with ovarian cancer receive their diagnosis when the disease is stage III or IV; and about 70% of women will face a recurrence (National Ovarian Cancer Coalition [NOCC], 2020). Survival depends on the stage of the tumor, grade of differentiation, gross findings at surgery, amount of residual tumor after surgery, and effectiveness of any adjunct treatment postoperatively. Many women with ovarian cancer will experience recurrence despite best efforts to eradicate the cancer through

surgery, radiation, or chemotherapy to eliminate residual tumor cells. The likelihood of long-term survival in the event of recurrence is low (Nitecki et al., 2020). The 5-year survival rates (the percentage of women who live at least 5 years after their diagnosis) are shown in Table 8.1 according to stage.

Pathophysiology

Ovarian cancer, the cause of which is unknown, can originate from different cell types. Most ovarian cancers are thought to originate in the ovarian epithelium. New insights now propose a pivotal role for the fallopian tube during ovarian cancer pathogenesis. Increasing evidence suggests that serous ovarian cancer originates from the fimbriated distal end of the fallopian tube, while the ovary gets involved at a later stage. These represent 50% to 60% of all epithelial ovarian cancers. Based on this finding, a post-reproductive salpingectomy deserves consideration as a prophylactic intervention that may confer protection against an often-deadly disease (Green, 2019).

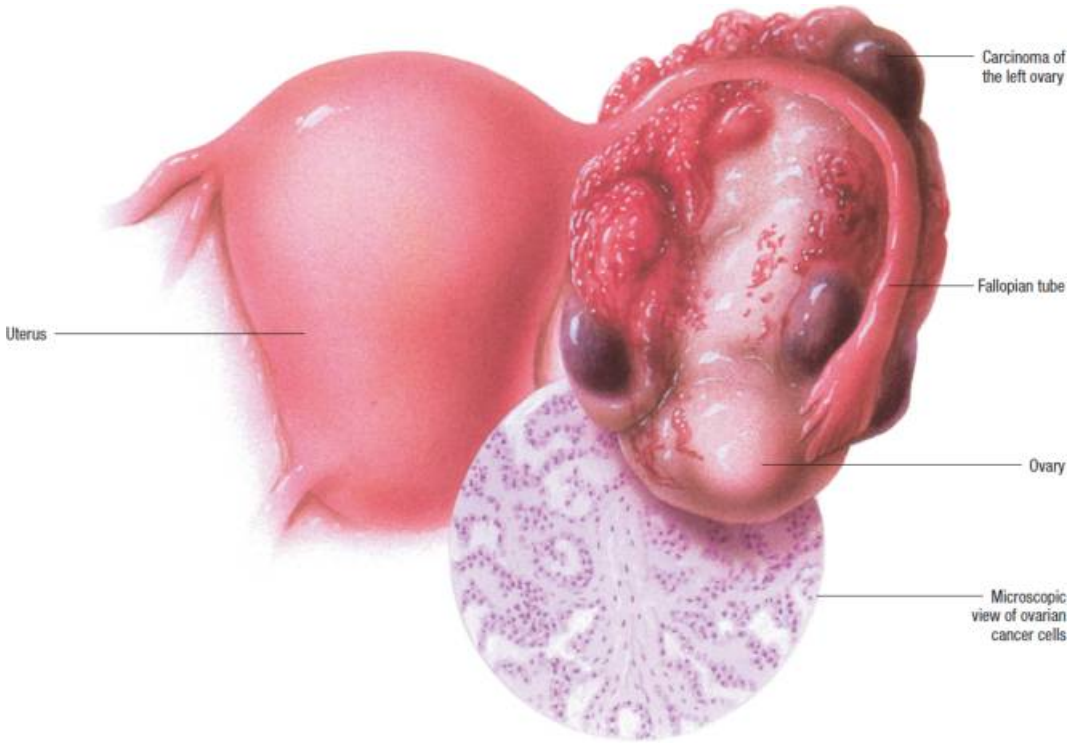

FIGURE 8.1. Ovarian cancer. (Asset provided by Anatomical Chart Co.)

TABLE 8.1 Five-Year Survival Rates for Ovarian Cancer

Stage	Five-Year Relative Survival Rates (%)
Localized	92
Regional spread	76
Distant spread	30
All stages combined	47

Adapted from American Cancer Society (ACS). (2020q). *Survival rates for ovarian cancer, by stage*. Reviewed on January 9, 2020, from https://www.cancer.org/cancer/ovarian-cancer/detection-diagnosis-staging/survival-rates.html

Tumors usually present as solid masses that have spread beyond the ovary and seeded into the peritoneum prior to diagnosis. A

thorough understanding of the true pathogenesis of this cancer's origin could lead to the development of new and more effective therapies as well as novel biomarkers in early detection.

Screening and Diagnosis

Women with ovarian cancer are typically diagnosed at a late stage, when the cancer has spread into the peritoneal cavity and complete surgical removal is challenging. Late discovery of ovarian cancer is common primarily because there is still no adequate screening test. The 5-year survival time for women diagnosed at this stage is 30% in contrast with a 5-year survival of 90% for women diagnosed at an early stage (Green, 2019). The U.S. Preventive Services Task Force (USPSTF, 2018), along with the American College of Obstetricians and Gynecologists (ACOG) and the American Medical Association (AMA), recently reviewed the evidence for ovarian cancer screening and did not recommend screening for women at average risk. However, women with increased risk related to BRCA 1 or 2 mutations or a family history of ovarian cancer should be considered for genetic counseling to further evaluate their risk (USPSTF, 2018).

Two genes, *BRCA1* and *BRCA2*, are linked with hereditary breast and ovarian cancers. Blood tests can be performed to assess DNA in white blood cells to detect mutations in the *BRCA* genes. These genetic markers do not predict whether the person will develop cancer. Rather, they provide information regarding the risk of developing cancer: a woman who is BRCA-positive may have up to an 80% chance of developing breast cancer and a 40% chance of developing ovarian cancer (Moore & Markham, 2020).

To assist in screening, researchers have developed an ovarian cancer symptom index that includes pelvic and abdominal pain, urinary frequency and urgency, increased abdominal size (bloating), and difficulty eating (feeling full). But this symptom index is not much help in detecting the disease early as these symptoms tend to go unrecognized or are attributed to other issues, leading to delays in diagnosis. When the presentation of such symptoms triggers a medical evaluation for ovarian cancer, the disease is diagnosed in

only one in 100 women. The NCI reports that the present symptom index has a “low positive predictive value,” especially for early-stage disease discovery (2019c).

Specific clinical guidelines for ovarian cancer screening have not been developed, so the disease is often not diagnosed until it has metastasized. The USPSTF recommends against routine screening for ovarian cancer with serum CA-125, a transvaginal ultrasound, or a bimanual pelvic exam because earlier detection would have a small effect, at best, on mortality. CA-125 is a biologic tumor marker associated with ovarian cancer. Although its levels are elevated in many women with ovarian cancer, CA-125 is not specific for this cancer, and the levels may be elevated with other malignancies too (pancreatic, liver, colon, breast, and lung cancers). Despite the discovery that CA-125 and other serum markers increase before the clinical onset of ovarian cancer, it has proven surprisingly difficult to devise a successful screening program for asymptomatic women with ovarian cancer. Currently, it is not sensitive enough to serve as a screening tool alone (Patni, 2019).

Therapeutic Management

Treatment options for ovarian cancer vary depending on the stage and severity of the disease. Usually, a laparoscopy (abdominal exploration with an endoscope) is performed for diagnosis and staging, as well as evaluation for therapy. In stage I, the cancer is limited to the ovaries. In stage II, the growth involves one or both ovaries, with pelvic extension. Stage III cancer has spread to the lymph nodes and other organs or structures inside the abdominal cavity. In stage IV, the cancer has metastasized to distant sites (ACS, 2020d). Figure 8.2 shows the likely metastatic sites for ovarian cancer.

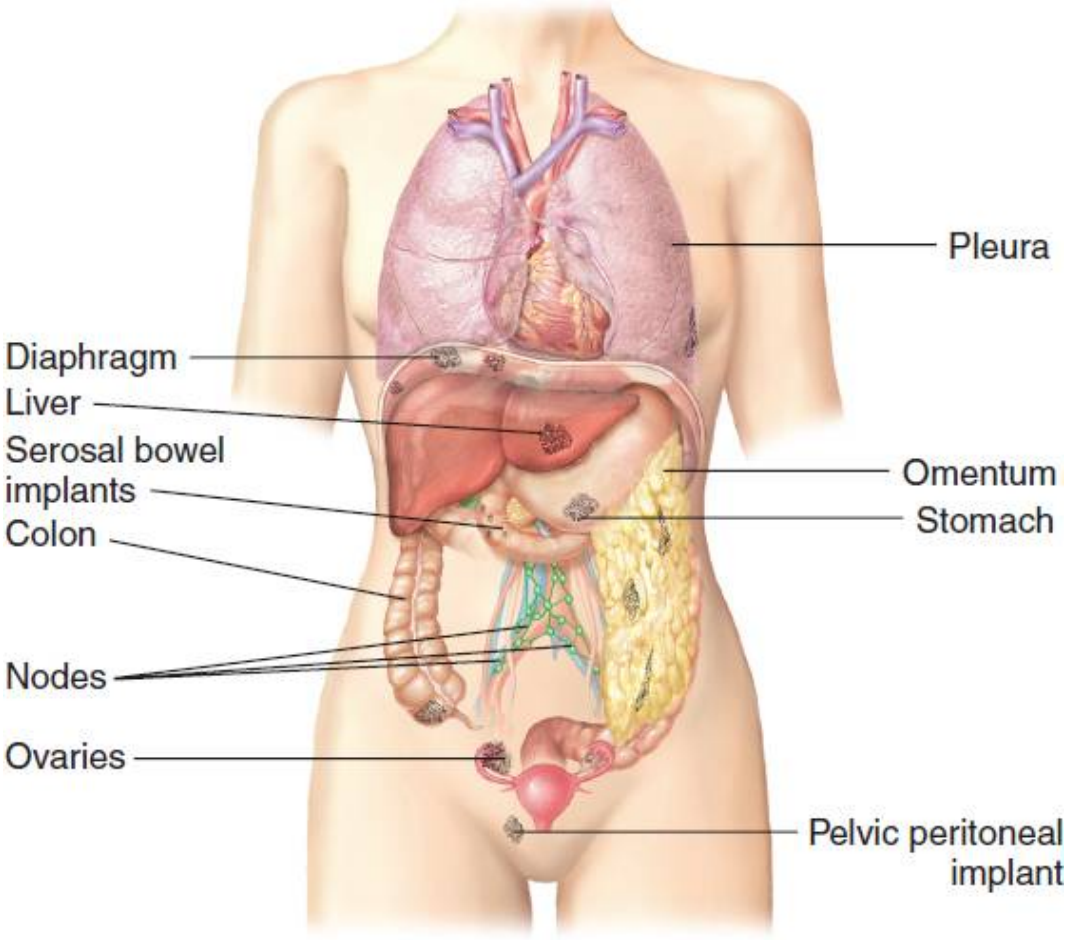

FIGURE 8.2. Common metastatic sites for ovarian cancer. (Asset provided by Anatomical Chart Co.)

Surgical intervention remains the mainstay of management of ovarian cancer. Surgery generally includes a total abdominal hysterectomy, bilateral salpingo-oophorectomy, peritoneal biopsies, omentectomy (excision of all or part of the omentum, which is a sheet of fat covered by the peritoneum that protects the abdominal structures), and pelvic para-aortic lymph node sampling to evaluate cancer extension (Green, 2019). Because most women are diagnosed with advanced-stage ovarian cancer, aggressive management involving debulking or cytoreductive surgery is commonly performed. This surgery involves resecting all visible tumors from the peritoneum, taking peritoneal biopsies, sampling lymph nodes, and removing all reproductive organs and the

omentum. This aggressive surgery has been shown to improve long-term survival rates.

Additional therapy with radiation may be warranted. Chemotherapy is recommended for all stages of ovarian cancer. Intraperitoneal chemotherapy, combined with surgery, has produced encouraging results for overall survivals at acceptable morbidity and mortality rates. The landscape of maintenance drug therapy to prevent reoccurrence is evolving with the FDA approving a few mediations with promising results. Despite all of these therapies, virtually the only agreement about treatment for advanced disease is that surgery and chemotherapy both play a role, and current treatment is ineffective in far too many women (Walsh, 2020).

Nursing Assessment

Ovarian cancers are considered the worst of all the gynecologic malignancies, primarily because they develop slowly and remain silent without symptoms until the cancer is far advanced. It has been described as the “overlooked disease” or “silent killer” because women and health care providers often ignore or rationalize early symptoms. For example, women may attribute gastrointestinal problems to stress and midlife changes. However, these vague complaints may precede more obvious symptoms by months. The most common early symptoms include abdominal bloating, early satiety, fatigue, vague abdominal pain, urinary frequency, diarrhea or constipation, malaise, and unexplained weight loss or gain. The later symptoms include anorexia, dyspepsia, ascites, a palpable abdominal mass, pelvic pain, and back pain (ACS, 2020e).

Obtain a thorough history of the woman’s symptoms, including their onset, duration, and frequency. Review the woman’s history for risk factors such as:

- Nulliparity
- Early menarche (before 12 years old)
- Late menopause (after 55 years old)
- Increasing age after menopause
- High-fat diet

- Obesity
- Persistent ovulation over time
- First-degree relative with ovarian cancer
- Genetics—women of Ashkenazi Jewish decent
- Use of perineal talcum powder or hygiene sprays
- Older than 30 years at first pregnancy
- Positive BRCA1 and BRCA2 mutations
- Personal history of breast, bladder, or colon cancer
- Hormone replacement therapy (HRT) for more than 10 years
- Infertility (CDC, 2019c)

Perform a complete physical examination. Inspect the abdomen, noting any distention or bloating. Palpate the abdomen. Be alert for a mass or pain on palpation. Anticipate further testing to confirm the diagnosis.

Nursing Management

The complexities of ovarian cancer make a multidisciplinary approach necessary for optimal management. With the subtle nature and high risk of recurrence and mortality of this condition, most women find it an emotionally exhausting and devastating experience. The presence of hope is essential for women at the time of the diagnosis; they want to believe in being cured and able to continue life as usual with loved ones, friends, and relatives. Still, the newly received cancer diagnosis makes women oscillate between hope and hopelessness, between positive expectations of getting cured and frightening feelings of the disease taking command. Nurses are invaluable resources in inspiring clients to find hope in life when diagnosed with cancer. Nursing management needs to focus on measures to promote early detection, educate the woman about the disease and its treatments, and provide emotional support. Nurses should show a positive attitude that communicates understanding and reassurance.

Promoting Early Detection

Nurses need to ensure that women are aware of the risk factors for ovarian cancer. Urge women not to dismiss seemingly innocuous symptoms as "just a part of aging." Encourage women to describe such nonspecific complaints at health visits.

Assess the woman's family and personal history for risk factors and encourage genetic testing for women with affected family members. Outline screening guidelines for women with hereditary cancer syndrome and inform women at high risk about the appropriate screening strategies.

Urge women to have yearly bimanual pelvic examinations and a transvaginal ultrasound to allow identification of ovarian masses in their early stages. After menopause, a mass on an ovary is not a cyst; physiologic cysts can arise only from a follicle that has not ruptured or from the cystic degeneration of the corpus luteum. Ovarian cancer is not always silent and may manifest with several vague gastrointestinal symptoms. Although screening the general population is not recommended, nurses need to know what factors place women at high risk and listen carefully to women's complaints to detect this type of cancer before it becomes advanced.

TAKE NOTE!

A small ovarian "cyst" found on ultrasound in an asymptomatic postmenopausal woman should arouse suspicion. Any mass or ovary palpated in a postmenopausal woman should be considered cancerous until proven otherwise. Approximately 90% of ovarian cancers are of epithelial cell origin. These tumors occur in older women, are diagnosed in advanced stages, and have a high mortality rate (Office on Women's Health, 2019).

Educating the Client

Education is a major focus of nursing care. This teaching involves risk reduction and health promotion. Teach the woman about risk reduction strategies; for instance, pregnancy, use of oral contraceptives, and breastfeeding reduce the risk of ovarian cancer. Instruct women to avoid using talc and hygiene sprays on their genitals. Review the lifetime risks related to *BRCA1* and *BRCA2*

genes and options available should the woman test positive for these genes. Help promote community awareness of ovarian cancer by educating the public about risk-reducing behaviors. See research on primary prevention of reproductive cancer.

Instruct the woman about the importance of healthy lifestyles. Stress the importance of maintaining a healthy weight to reduce risk. Encourage women to eat a low-fat diet. Factors associated with a reduced risk of ovarian cancer include the use of oral contraceptives for 3 years or longer, maintaining a healthy weight range, pregnancy and breastfeeding before the age of 30, bilateral tubal ligation, and removal of the ovaries (Ovarian Cancer Research Alliance, 2020).

For the woman who is diagnosed with ovarian cancer, describe in simple terms the tests, treatment modalities, and follow-up needed. For example, if the woman will be having surgery, the nurse needs to provide thorough teaching about what to expect before, during, and after surgery. Outline the treatment options and the implications of choices. Assist the woman and her family in deciphering the large amount of information related to staging, tests, and treatments. Teach the woman about additional treatment measures, such as radiation therapy or chemotherapy, including how to handle the common adverse effects of treatment.

Supporting the Client and Family

The diagnosis of ovarian cancer, like any cancer, can be overwhelming. In addition, the treatments and their effects can be highly stressful, both physically and emotionally. Provide one-to-one support for women facing treatment for ovarian cancer. Ovarian cancer involves the reproductive system, which has a direct impact on the woman's view of herself. Encourage open discussion of sexuality and the impact of cancer. Listen and support the woman and her family as they try to cope with this disease. By being aware of women's individual needs and different coping strategies, nurses can improve support to women in this vulnerable situation. Encourage the use of appropriate coping strategies to allow for the best quality of life. Try to restore hope to women with ovarian cancer,

and stress treatment compliance. Nurses should not forget about the family caregivers who need help with managing emotions about prognosis, balancing their own and the client's needs, work, and decision-making when there is uncertainty. If appropriate, encourage participation in clinical trials to offer hope for all women. Continue to offer support to the woman and her family members as they experience sadness and grief.

CONSIDER THIS

I felt I was a lucky woman because I had been in remission from breast cancer for 12 years, and I had been given the gift of life to share with my beloved family. Recently, I became ill with stomach problems like pain, indigestion, bloating, and nausea. My doctor treated me for gastric reflux disease, but the symptoms persisted. I was then referred to a gastroenterologist, a urologist, and then a gynecologist, who did an ultrasound, which was negative. I received reassurance from all three that there was nothing wrong with me. As time went by, I experienced more pain, more symptoms, and increased frustration. Six months after seeing all three specialists, a repeat ultrasound revealed I had ovarian cancer, and I needed surgery as soon as possible. I underwent a complete hysterectomy and my surgeon found I was in stage III. Since then, I have undergone chemotherapy and participated in a clinical cancer study that wasn't successful for me. Now I am facing the fact that I am going to die soon.

Thoughts: This woman has tried everything to save her life, but time has run out for her with advanced ovarian cancer. Women diagnosed with breast cancer are at a significant risk for developing ovarian cancer later in life. Of the string of doctors she saw, why did no one order more extensive testing, given her history of breast cancer? We are often haunted with the question: If health care providers had made different choices, would clients be faced with advanced diagnoses? We will never know.

ENDOMETRIAL CANCER

Endometrial cancer (also known as uterine cancer) is a malignant neoplastic growth of the uterine lining. It is the fourth most common gynecologic malignancy in the United States and sixth most common cancer globally. It accounts for 7% of all cancers in women in the United States (one in 40 women). The NCI (2019d) estimates that about 65,620 new cases will be diagnosed in women in 2020 and that approximately 12,590 of these women will die. Endometrial cancer is diagnosed in over 382,069 women annually worldwide (World Cancer Research Fund, 2019). It is uncommon before the age of 63, but as women age, the risk of endometrial cancer increases. Approximately 80% of these malignancies are carcinomas of the endometrium. Because endometrial cancer is usually diagnosed in the early stages, it has a better prognosis than cervical or ovarian cancer (ACS, 2020f).

The increasing incidence and prevalence of endometrial cancer can be explained by the increase in life expectancy, increased caloric intake, having metabolic syndrome, increased obesity rates, infertility, nulliparity (never bearing children), diabetes type 2, older age of first pregnancy, polycystic ovary syndrome, and long-term use of unopposed estrogens for HRT. Protection against endometrial cancer includes increased parity, daily physical activity, use of combined oral contraceptives, and increased age of women at last childbirth (ACS, 2020g).

Pathophysiology

Two mechanisms are believed to be involved in the development of endometrial cancer: hormone exposure and obesity. A history of exposure to unopposed estrogen is the cause in the majority of cases of women in the past. An increase in obesity rates (adipose fat converts androstenedione to estrone, thereby increasing circulating estrogen levels) contributes to increasing rates of endometrial cancer. Obesity, diabetes, and hypertension (triple syndrome of

endometrial cancer) are all high risk factors for this cancer (McCance & Huether, 2019).

Endometrial cancer may originate in a polyp or in a diffuse multifocal pattern. The pattern of spread partially depends on the degree of cellular differentiation. Well-differentiated tumors tend to limit their spread to the surface of the endometrium. Metastatic spread occurs in a characteristic pattern and most commonly involves the lungs, inguinal and supraclavicular nodes, liver, bones, brain, and vagina (NCI, 2019e). Early tumor growth is characterized by friable and spontaneous bleeding. Later tumor growth is characterized by myometrial invasion and growth toward the cervix (Fig. 8.3).

Adenocarcinoma of the endometrium is typically preceded by hyperplasia. Carcinoma in situ is found only on the endometrial surface. Type I carcinomas, the most common, begin as endometrial hyperplasia and progress to carcinomas. Giving estrogen preparations without progestin for HRT leads to an increased risk for endometrial cancer. Type I is generally found at an earlier stage and treatment results are more favorable.

Unlike type I endometrial carcinoma, type II carcinomas appear spontaneously, are associated with a poorly differentiated cell type, and have a poor prognosis. They account for less than 10% of all endometrial cancers but contribute to the majority of all endometrial deaths. This type is unrelated to estrogen or endometrial hyperplasia (ACS, 2020h).

Remember Carmella, the woman with postmenopausal bleeding? In postmenopausal women, any bleeding is abnormal and warrants further assessment. What diagnostic testing would the nurse anticipate to determine the diagnosis? What would be the nurse's role during this testing?

Screening and Diagnosis

There is no specific screening test currently available to detect endometrial cancer. Screening for endometrial cancer is not routinely done because it is not practical or cost-effective. The ACS (2020i)

recommends women be informed about the risks and symptoms of endometrial cancer at the onset of menopause and strongly encouraged to report any unexpected bleeding or spotting to the health care provider. A pelvic examination is frequently normal in the early stages of the disease. Changes in the size, shape, or consistency of the uterus or its surrounding support structures may exist when the disease is more advanced.

During the past two decades, the role of ultrasound in the evaluation of postmenopausal bleeding has changed markedly, from little or no role to a major role today. In the intervening years, numerous studies have shown that ultrasound is at least as sensitive as endometrial biopsy for endometrial cancer and that ultrasound can reliably exclude cancer without the need for biopsy in some women with postmenopausal bleeding. The depth of myometrium is an important diagnostic factor. In particular, numerous studies have shown that women with an endometrial thickness of 4 mm or less have an extremely low likelihood of endometrial cancer and thus do not need to undergo endometrial biopsy. Ultrasound can also help in the selection of an appropriate biopsy technique. In a woman with postmenopausal bleeding and a thick endometrium, a sonohysterogram can determine whether the endometrium is diffusely thick or has focal areas of thickening. With diffuse thickening, an endometrial biopsy is appropriate. When one or more focal areas of thickening are present, hysteroscopic biopsy is likely to be the better choice. Typically, the noninvasive transvaginal ultrasound is done first before an invasive endometrial biopsy is attempted (ACOG, 2018a).

Transvaginal ultrasound can be used to evaluate the endometrial cavity and measure the thickness of the endometrial lining. It can be used to detect endometrial hyperplasia. If the endometrium measures less than 4 mm, then the client is at low risk for malignancy. Large prospective studies have shown that an endometrial thickness of 4 mm or less on transvaginal ultrasound in postmenopausal women with bleeding has a low risk of malignancy. Thus, in postmenopausal clients with bleeding, biopsy is not

indicated when endometrial thickness is 4 mm or less, thereby avoiding invasive diagnostics (ACOG, 2018a).

Endometrial biopsy is an office procedure that is used after a suspicious transvaginal ultrasound has been done in the diagnosis of endometrial cancer in a woman with postmenopausal bleeding. The biopsy is obtained through an endometrial suction catheter that is inserted through the cervix into the uterine cavity and a tissue sample is taken. The sensitivity and specificity of the biopsy procedure tend to be in the range of 95% for detection of endometrial cancer or other pathologies (NCI, 2019f).

As indicated earlier, staging is the process of looking at all of the information the doctors have learned about the tumor to determine how much the cancer may have spread. The stage of endometrial cancer is the most important factor in choosing a treatment plan. It can spread locally to other parts of the uterus or regionally to nearby lymph nodes. The regional lymph nodes are found in the pelvis and farther away along the aorta. Finally, the cancer can spread (metastasize) to distant lymph nodes or organs such as lung, liver, bone, brain, and others.

In stage I, the tumor is confined to the corpus uteri. In stage II, it has spread to the cervix, but not outside the uterus. In stage III, it has spread locally and regionally. In stage IV, it has invaded the bladder mucosa and bowel mucosa, with distant metastases to the lungs, liver, and bone (NCI, 2019e).

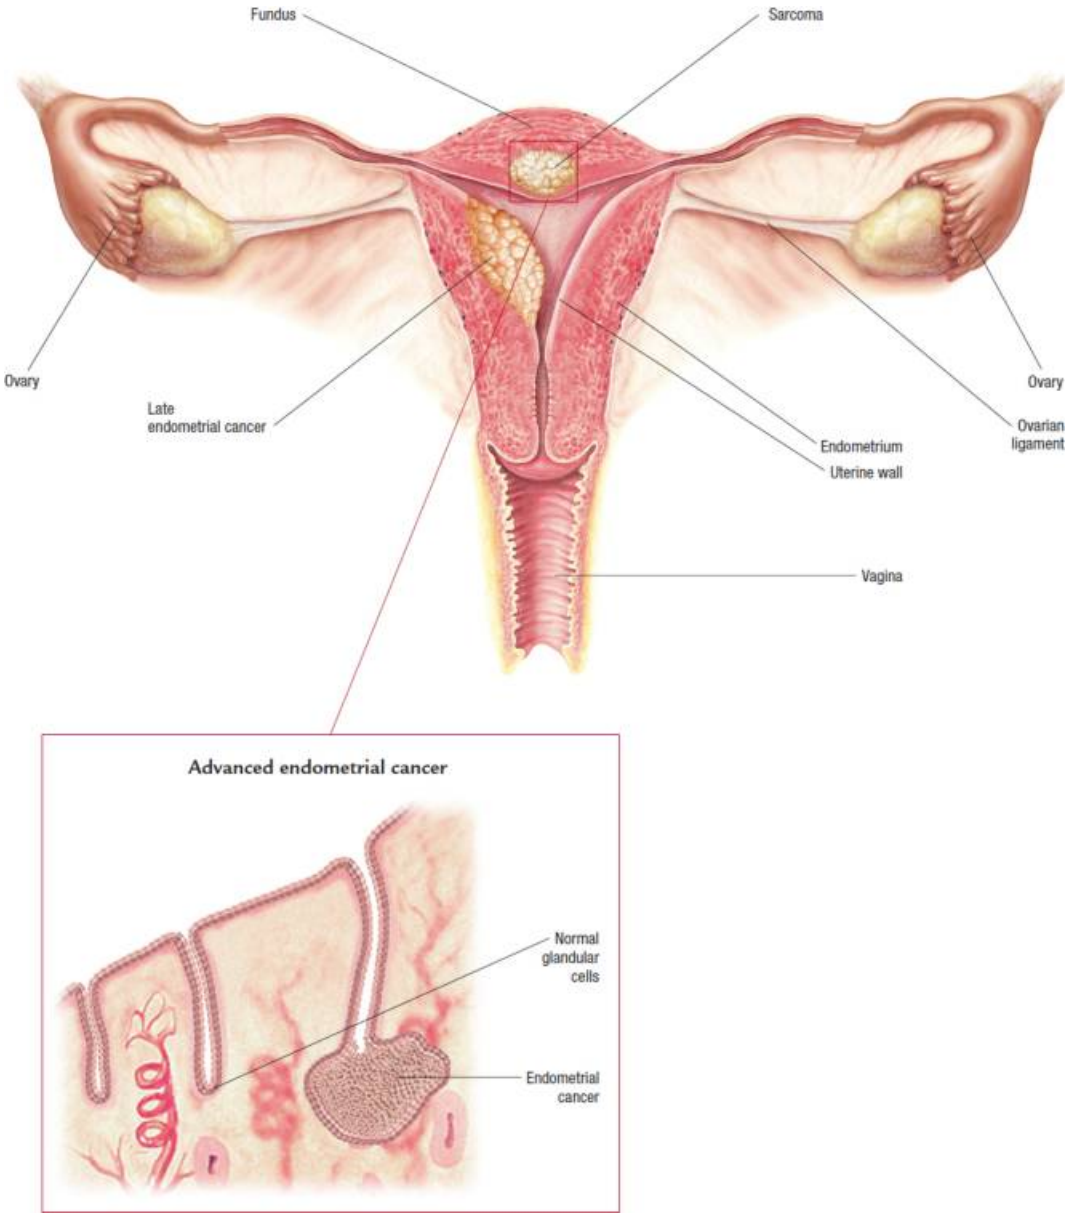

FIGURE 8.3. Progression of endometrial cancer. (Image 1 provided by Anatomical Chart Co.)

Therapeutic Management

Typically, the stage of the disease directs treatment. It usually involves surgery with adjunct therapy based on pathologic findings. Surgery most often involves removal of the uterus (hysterectomy) and the fallopian tubes and ovaries (salpingo-oophorectomy). Removal of the fallopian tubes and ovaries is recommended

because tumor cells spread early to the ovaries, and any dormant cancer cells could be stimulated to grow by ovarian estrogen. In more advanced cancers, radiation and chemotherapy are used as adjuncts to surgery. Routine surveillance intervals for follow-up care are typically every 3 to 4 months for the first 2 years, since 85% of recurrences occur in the first 3 years after diagnosis (Mirza, 2020).

Nursing Assessment

Obtain a thorough history from the woman, ascertaining her primary complaint. Most commonly, the major initial symptom of endometrial cancer is abnormal and painless vaginal bleeding. Obtain a menstrual history and inquire if the woman is taking any hormones. Also ascertain if she has a personal or family history of breast, ovarian, or colon cancer. These key pieces of information will assist in identifying the woman at high risk for endometrial cancer.

TAKE NOTE!

Any episode of bright red bleeding that occurs after menopause should be investigated. Abnormal uterine bleeding is rarely the result of uterine malignancy in a young woman, but in the postmenopausal woman, it should be regarded with suspicion.

Also review the woman's history for any risk factors, including:

- Nulliparity
- Obesity (more than 50 lb overweight)
- Liver disease
- Infertility
- Diabetes mellitus
- Hypertension
- History of pelvic radiation
- Polycystic ovary syndrome
- Early menarche (before 12 years old)
- High-fat diet

- Use of prolonged exogenous unopposed estrogen with an intact uterus
- Endometrial hyperplasia
- Family history of endometrial cancer
- Personal history of hereditary nonpolyposis colon cancer
- Personal history of breast, colon, or ovarian cancer
- History of uterine fibroids
- Late onset of menopause (after age 55)
- Tamoxifen use
- Chronic anovulation (Oyelowo & Johnson, 2018)

Assess the woman for additional manifestations, such as dyspareunia, low back pain, purulent genital discharge, dysuria, pelvic pain, weight loss, and a change in bladder and bowel habits. These may suggest advanced disease.

Perform a physical examination or assist with a pelvic examination as appropriate. Observe for vaginal discharge. Note any changes in the size, shape, or consistency of the uterus or surrounding structures or client reports of pain during examination. Anticipate the need for transvaginal ultrasound to identify endometrial hyperplasia (usually greater than 4 mm) and endometrial biopsy if needed to identify malignant cells.

Nursing Management

Ensure that the woman understands all of the treatment options. Address any concerns the woman expresses, including questions about sexuality. Ensure that follow-up appointments are scheduled appropriately. Refer the client to a support group. Offer the woman and family explanations and emotional support throughout the experience.

Educate the client about preventive measures or follow-up care if she has been treated for cancer. Education may be the most important tool currently available for the early detection of endometrial cancer. Many risk factors for endometrial cancer are modifiable or treatable, including obesity, hypertension, and diabetes. Educating women about risk factors and ways to decrease

the risks is essential so that women can learn about their own risk profiles and can become partners in the fight against this gynecologic cancer (Teaching Guidelines 8.2).

TEACHING GUIDELINES 8.2
Preventive and Follow-Up Measures for Endometrial Cancer

- Schedule regular pelvic examinations after the age of 21.
- Visit health care practitioner for early evaluation of any abnormal bleeding after menopause.
- Maintain a low-fat diet throughout life.
- Exercise daily.
- Manage weight to discourage hyperestrogenic states, which predispose clients to endometrial hyperplasia.
- Pregnancy serves as a protective factor by reducing estrogen.
- Ask your doctor about the use of combination estrogen and progestin pills.
- When combination oral contraceptives are taken to facilitate the regular shedding of the uterine lining, take risk reduction measures.
- Be aware of risk factors for endometrial cancer and make modifications as needed.
- Report any of the following symptoms immediately:
  - Bleeding or spotting after sexual intercourse
  - Bleeding that lasts longer than a week
  - Reappearance of bleeding after 6 months or more of no menses
- After cancer therapy, schedule follow-up appointments for the next few years.
- After cancer therapy, frequently communicate with your health care provider concerning your status.
- After surgery, maintain a healthy weight.

Carmella's endometrial biopsy indicates endometrial adenocarcinoma. Her health care provider recommends surgery and adjuvant radiation therapy. How long will Carmella need to follow up after surgery? What lifestyle changes will the nurse need to stress with Carmella?

CERVICAL CANCER

Cervical cancer is a malignancy located in the uterine cervix. The majority of cervical cancers are caused by human papilloma virus (HPV). Other HPV-related cancers include oropharyngeal, anal, penile, vaginal, and vulvar cancers. HPV is transmitted through vaginal intercourse, anal and oral sex, and other intimate skin-to-skin contact (NCI, 2020). It is the third most common genital malignancy in women in the United States after cancers of the endometrium and the ovary. The ACS (2020j) estimates that 13,800 cases of invasive cervical cancer will be diagnosed in the United States in women in 2020 and approximately 4,290 of these women will die. Worldwide, cervical cancer is the third most frequently diagnosed cancer in women with over 500,000 new cases diagnosed annually, but it develops over time, and is one of the most preventable types of cancer (WHO, 2020). Some researchers estimate that noninvasive cervical cancer (carcinoma in situ) is about four times more common than invasive cervical cancer. The 5-year survival rate for all stages of cervical cancer is about 70% (ACS, 2020k). Cervical cancer is five to eight times more common in women affected with HIV or AIDS than in those who are not. Hispanic women are most likely to get cervical cancer, followed by African American, Asian and Pacific Islander, and White women.

Cervical cancer remains a disease of socioeconomic disparity. The high mortality rates of minorities are indicative of barriers to health care among those living in poverty. Hispanic women also have the highest rates of poverty, poor access to health care, and language and cultural barriers. Barriers to screening and prevention of cervical cancer include procrastination, fear of finding out that they have cancer, and embarrassment about having a Papanicolaou (Pap) test.

In addition, many women have little to no knowledge about HPV and its link with cancer (CDC, 2020).

The incidence and mortality rates of cervical cancer have decreased noticeably in the past several decades, with most of the reduction attributed to the Pap and HPV screening tests, which detect cervical cancer and some precancerous lesions. The **Papanicolaou (Pap) test** (also known as a Pap smear) is a procedure used to obtain cells from the cervix for cytology screening. Cervical cancer is one of the most treatable cancers when detected at an early stage (ACS, 2020j). *Healthy People 2030* identifies several goals that address cervical cancer (U.S. Department of Health & Human Services [USDHHS], 2019). See *Healthy People 2030* 8.1. Cervical cancer tends to occur in midlife. Most cases are found in women younger than age 50. It rarely develops in women younger than age 20. Many older women do not realize that the risk of developing cervical cancer is still present as they age. The probability of a woman in the United States developing cervical cancer is approximately one in 120, but this statistic is age-dependent; the highest incidence is in women 35 to 44 years of age (National Cervical Cancer Coalition [NCCC], 2020).

Objectives	Nursing Significance
C-2030-01 Reduce the overall cancer death rate.	• Will help improve mortality rates and quality of life for women, and reduce health care costs related to treatment of malignancies.
C-2030-04 Reduce the female breast cancer death rate.	• Will help to promote screening and early detection. Regular Pap smear screening decreases cervix cancer incidence and mortality tremendously. Many women diagnosed with invasive cervical cancer have never had a Pap smear or haven't had one recently. • Will raise awareness of cancer screening and prevention on a local and national level to improve and promote the health of all women.
C-2030-05 Increase the proportion of women who receive a breast cancer screening based on the most recent guidelines.	• Will reduce the number of new cancer cases, as well as the illness, disability, and death caused by cancer. • Will reflect the importance of promoting evidence-based screening for cervical and breast cancer by lower mortality rates.
C-2030-09 Increase the proportion of women who receive a cervical cancer screening based on the most recent guidelines.	
C-2030-10 Reduce the proportion of adolescents in grades 9 through 12 who report sunburn.	

C-2030-11 Increase the proportion of cancer survivors who are living 5 years or longer after diagnosis.

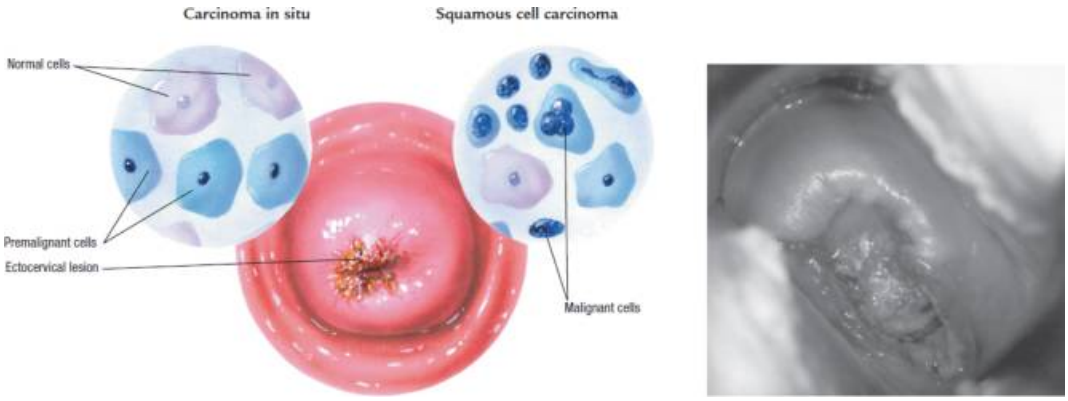

FIGURE 8.4. Cervical cancer. (Illustration is from The Anatomical Chart Company. [2009]. *Atlas of pathophysiology* [3rd ed.]. Lippincott Williams & Wilkins.)

Pathophysiology

Cervical cancer starts with abnormal changes in the cellular lining or surface of the cervix. Typically, these changes occur in the squamous–columnar junction of the cervix. Here, cylindrical secretory epithelial cells (columnar) meet the protective flat epithelial cells (squamous) from the outer cervix and vagina in what is termed the transformation zone. The continuous replacement of columnar epithelial cells by squamous epithelial cells in this area makes these cells vulnerable to taking up foreign or abnormal genetic material

(ACS, 2020b). Figure 8.4 shows the pathophysiology of cervical cancer.

Human papillomavirus (HPV) infection must be present for cervical cancer to occur. HPV infections occur in a high percentage of sexually active women, but a successful immune response results in viral control or clearance of HPV. Most people who have HPV are asymptomatic and therefore do not realize they have the virus. More than 90% of squamous cervical cancers contain HPV DNA, and the virus is now accepted as a major causative factor in the development of cervical cancer and its precursor, **cervical dysplasia** (disordered growth of abnormal cells). Since only a small proportion of HPV infections progress to cancer, other factors must be involved in the process of carcinogenesis (CDC, 2019d).

Screening and Diagnosis

Screening for cervical cancer is effective because the presence of a precursor lesion, cervical intraepithelial neoplasia, helps determine whether further tests are needed. Lesions start as dysplasia and progress in a predictable fashion over a long period, allowing ample opportunity for intervention at a precancerous stage. Progression from low-grade to high-grade dysplasia takes an average of 9 years, and progression from high-grade dysplasia to invasive cancer takes up to 2 years. Three main factors have been postulated to influence the progression of low-grade dysplasia to high-grade dysplasia. These include the type and duration of viral infection, with high-risk HPV type and persistent infection predicting a higher risk for progression; host conditions that compromise immunity, such as multiparity or poor nutritional status; and environmental factors such as smoking, oral contraceptive use, or vitamin deficiencies. In addition, various gynecologic factors, including age of menarche, age of first intercourse, and number of sexual partners, significantly increase the risk for cervical cancer (Boardman, 2019).

Widespread use of the Pap test is credited with saving thousands of women's lives and decreasing deaths from cervical cancer. Routine Pap smear testing for all sexually active women has been

one of the primary screening methods for early detection of cervical irregularities related to HPV and is crucial for the prevention of cervical cancer.

Despite its outstanding record of success as a screening tool for cervical cancer (it detects approximately 90% of early cancer changes), the conventional Pap smear has a 20% false-negative rate. High-grade abnormalities missed by human screening are frequently detected by computerized instruments (NCI, 2019g). Thus, many technologies have been developed to improve the sensitivity and specificity of Pap testing, including:

- *Thin-Prep:* In this liquid-based technique, the cervical specimen is placed into a vial of preservative solution rather than on a glass slide.
- *Computer-assisted automated Pap test rescreening (Autopap):* An algorithm-based decision-making technology identifies slides that should be rescreened by cytopathologists by selecting samples that exceed a certain threshold for the likelihood of abnormal cells.
- *HPV-DNA typing (Hybrid Capture):* This system uses the association between certain types of HPV (16, 18, 31, 33, 35, 45, 51, 52, and 56) and the development of cervical cancer. This system can identify high-risk HPV types and improves detection and management.
- *Computer-assisted technology (Cytyc CDS-1000, AutoCyte, AcCell):* These computerized instruments can detect abnormal cells that are sometimes missed by technologists (CDC, 2019e).

The high rate of false-negative results may also be due to other factors, including errors in sampling the cervix, in preparing the slide, and in client preparation. Although cytology-based nationwide cervical screening has been helpful in identifying abnormal cervical cells, the sensitivity of cytology for the detection of high-grade precursor lesions is limited. Additionally, adenocarcinoma and its precursors are often missed by cytology. The current insight that infection with HPV is the causative agent of cervical cancer and its precursors has led to the development of molecular tests for the detection of HPV. Strong evidence now supports the use of HPV testing in the prevention of cervical cancer. It is evident that HPV can

be detected in urine-based testing which might eventually become a helpful tool in cervical cancer screening and HPV surveillance efforts. Nurses need to keep up to date on the latest research developments as well as the strengths and weaknesses of various screening methods (Ford, 2019).

Although professional medical organizations disagree as to the recommended frequency of screening for cervical cancer, ACOG (2018b) recommends that cervical cancer screening should begin at age 21 years (regardless of sexual history), since women younger than age 21 are at very low risk of cancer. In addition, ACOG advises Pap smears every 3 years for women between ages 21 and 29 years and every 3 years for women between ages 30 and 65 years. A HPV co-test should be done every 5 years for this older age group. Cervical cancer screening can be stopped for women over age 65 who have an adequate screening history. Women who have had a hysterectomy should stop screening. Women who have received the HPV vaccine should be screened according to the same guidelines as women who have not been vaccinated. In addition, women must have a clear understanding of the results of Pap smear testing and follow-up guidelines. High-risk women should continue to have annual Pap smears throughout their lives (Table 8.2).

Pap smear results are classified using the Bethesda system (Box 8.1), which provides a uniform diagnostic terminology that allows clear communication between the laboratory and the health care provider. The information provided by the laboratory is divided into three categories: specimen adequacy, general categorization of cytologic findings, and interpretation or result (Crum & Huh, 2019).

Therapeutic Management

Treatment for abnormal Pap smears depends on the severity of the results and the health history of the woman. Therapeutic choices all involve destroying as many affected cells as possible. With the introduction of multimodality therapy for cervical cancer, many women will be long-term survivors in need of comprehensive

surveillance care. Obesity and smoking are significant comorbidities that may complicate care in cervical cancer survivors. Nurses can focus their interventions on modifying these risk factors to increase the quality of life for cervical cancer survivors. Box 8.2 describes treatment options.

Using the Bethesda system, the following management guidelines for abnormal Pap results were developed by the NCI to provide direction to health care providers and clients:

- *ASC-US:* Repeat the Pap smear in 4 to 6 months or refer for colposcopy.
- *ASC-H:* Refer for colposcopy with HPV testing.
- *Atypical glandular cells (AGCs) and adenocarcinoma in situ (AIS):* Immediate colposcopy; follow-up is based on the findings.

TABLE 8.2 Pap Test Guidelines

First Pap	Cervical cancer screening should begin at age 21. Women under age 21 should not be tested.
Ages 21–29 years	Should have a Pap smear every 3 years. HPV testing should not be used in this age group unless it is needed after an abnormal Pap test result.
Ages 30–65 years	Should have a Pap smear plus an HPV test every 5 years. This is the preferred approach, but having a Pap smear alone every 3 years is also acceptable.
Ages >65 years	Women who have had regular cervical testing with normal results should not be tested for cervical cancer. Women with a history of serious cervical precancer lesions should continue testing for at least 20 years after that diagnosis, even if it continues after age 65.
HPV vaccination	Women who have received the HPV vaccine should follow the screening recommendations for her age group.

BOX 8.1 The Bethesda System for Classifying Pap Smears

Specimen Type: Conventional Pap smear versus liquid-based
Specimen Adequacy: Satisfactory or unsatisfactory for evaluation
General Categorization: (optional)

- Negative for intraepithelial lesion or malignancy
- Epithelial cell abnormality. See interpretation/result

Automated Review: If case was examined by automated device or not
Ancillary Testing: Provides a brief description of the test methods and report results so that the health care provider understands
Interpretation/Result:

- Negative for intraepithelial lesion or malignancy
- Organisms: *Trichomonas vaginalis*; fungus; bacterial vaginosis; herpes simplex
- Other non-neoplastic findings: Reactive cellular changes associated with inflammation, radiation, intrauterine devices, atrophy
- Other: Endometrial cells in a woman over 40 years of age
- Epithelial cell abnormalities:
  - *Squamous cell*
    - Atypical squamous cells
    - Of undetermined significance (ASC-US)
    - Cannot exclude HSIL (ASC-H)
    - Low-grade squamous intraepithelial lesion (LSIL): Encompassing HPV/mild dysplasia/CIN-1
    - High-grade squamous intraepithelial lesion (HSIL)
    - Encompassing moderate and severe dysplasia CIS/CIN-2 and CIN-3
    - With features suspicious for invasion
    - Squamous cell carcinoma
  - *Glandular cell:* Atypical
    - Endocervical, endometrial, or glandular cells
    - Endocervical cells—favor neoplastic
    - Glandular cells—favor neoplastic
    - Endocervical adenocarcinoma in situ
    - Adenocarcinoma: Endocervical, endometrial, extrauterine
  - Other malignant neoplasms (specify)

Educational Notes and Suggestions: (optional)

Crum, C. P., & Huh, W. K. (2019). Cervical and vaginal cytology: Interpretation of results (Pap test report). *UpToDate*. Retrieved May 26, 2020, from https://www.uptodate.com/contents/cervical-and-vaginal-cytology-interpretation-of-results-pap-test-report; American Cancer Society (ACS). (2020t). *Screening tests for cervical cancer*. Retrieved January 3, 2020, from https://www.cancer.org/cancer/cervical-cancer/detection-diagnosis-staging/screening-tests/pap-test.html

Colposcopy is a microscopic examination of the lower genital tract using a magnifying instrument called a colposcope. Specific patterns of cells that correlate well with certain histologic findings can be visualized.

Nursing Assessment

Obtain a thorough history and physical examination of the woman. Investigate her history for risk factors such as:

- Early age at first intercourse (within 1 year of menarche)
- Lower socioeconomic status
- Promiscuous male partners

BOX 8.2 Treatment Options for Cervical Cancer

- Cryotherapy—destroys abnormal cervical tissue by freezing with liquid nitrogen, Freon, or nitrous oxide. Studies show a 90% cure rate (NCI, 2018i). Healing takes up to 6 weeks, and the client may experience a profuse, watery vaginal discharge for 3 to 4 weeks.
- Cone biopsy or conization—removes a cone-shaped section of cervical tissue. The base of the cone is formed by the ectocervix (outer part of the cervix) and the point or apex of the cone is from the endocervical canal. The transformation zone is contained within the cone sample. The cone biopsy is also a treatment and can be used to completely remove any precancers and very early cancers. Two methods are commonly used for cone biopsies:
  - LEEP (loop electrosurgical excision procedure) or LLETZ (large loop excision of the transformation zone)—the abnormal cervical tissue is removed with a wire that is heated by an electrical current. For this procedure, a local anesthetic is used. It is performed in the health care provider's office in approximately 10 minutes. Mild cramping and bleeding may persist for several weeks after the procedure.
  - Cold knife cone biopsy—a surgical scalpel or a laser is used instead of a heated wire to remove tissue. This procedure requires general anesthesia and is done in a hospital setting. After the procedure, cramping and bleeding may persist for a few weeks.
- Laser therapy—destroys diseased cervical tissue by using a focused beam of high-energy light to vaporize it (burn it off). After the procedure, the woman may experience a watery brown discharge for a few weeks. Very effective in destroying precancers and preventing them from developing into cancers.
- Hysterectomy—removes the uterus and cervix surgically.
- Radiation therapy—delivered by internal radium applications to the cervix or external radiation therapy that includes lymphatics of the pelvis.
- Chemoradiation—weekly cisplatin therapy concurrent with radiation (ACS, 2020s).

- Unprotected sexual intercourse
- Family history of cervical cancer (mother or sisters)
- Sexual intercourse with uncircumcised men
- Female offspring of mothers who took diethylstilbestrol (DES)
- Infections with genital herpes or chronic chlamydia
- Multiple sex partners
- Cigarette smoking
- Immunocompromised state
- HIV infection

- Oral contraceptive use
- Moderate dysplasia on Pap smear within past 5 years
- HPV infection (CDC, 2019f)

Question the woman about any signs and symptoms. Clinically, the first sign is abnormal vaginal bleeding, usually after sexual intercourse. Also be alert for reports of vaginal discomfort, malodorous discharge, and dysuria. In some cases, the woman is asymptomatic, with detection occurring at an annual gynecologic examination and Pap test.

Perform a physical examination. Inspect the perineal area for vaginal discharge or genital warts. Perform or assist with a pelvic examination, including the collection of a Pap smear as indicated (Nursing Procedure 8.1).

NURSING PROCEDURE 8.1 Assisting with Collection of a Pap Smear

Purpose: To Obtain Cells from the Cervix for Cervical Cytology Screening

1. Explain procedure to the client (Fig. A).
2. Instruct client to empty her bladder.
3. Wash hands thoroughly.
4. Assemble equipment, maintaining sterility of equipment (Fig. B).
5. Position client on stirrups or foot pedals so that her knees fall outward.
6. Drape client with a sheet for privacy, covering the abdomen but leaving the perineal area exposed.
7. Open packages as needed.
8. Encourage client to relax.
9. Provide support to client as the practitioner obtains a sample by spreading the labia; inserting the speculum; inserting the cytobrush and swabbing the endocervix; and inserting the plastic spatula and swabbing the cervix (Figs. C–H).
10. Transfer specimen to a container (Fig. I) or a slide. If a slide is used, spray the fixative on the slide holding the spray container about 12 in away from the slide.
11. Place sterile lubricant on the practitioner's fingertip when indicated for the bimanual examination.
12. Wash hands thoroughly.
13. Label specimen according to facility policy.
14. Rinse reusable instruments and dispose of waste appropriately (Fig. J).
15. Wash hands thoroughly.
16. Assist the client up after the exam is completed.

TAKE NOTE!

Suspect advanced cervical cancer in women with pelvic, back, or leg pain, weight loss, anorexia, weakness and fatigue, and fractures.

Prepare the woman for further diagnostic testing if indicated, such as a colposcopy. In a colposcopy, the woman is placed in the lithotomy position and her cervix is cleansed with acetic acid solution. Acetic acid makes abnormal cells appear white, which is referred to as "acetowhite." These white areas are then biopsied and sent to the pathologist for assessment. Although this test is not painful, it has minor side effects (minor bleeding, cramping, and a risk of an infection developing after the biopsy). It can be performed safely in the clinic or office setting, though women may be apprehensive or anxious about it because it is done to identify and confirm potential abnormal cell growth. Some health care providers

request that the woman premedicate with a mild analgesic such as ibuprofen prior to undergoing the procedure.

Nursing Management

The nurse's role involves primary prevention by educating women about risk factors and ways to prevent cervical dysplasia. Cervical cancer rates have decreased in the United States because of the widespread use of Pap testing, which can detect precancerous lesions of the cervix before they develop into cancer.

Concept Mastery Alert

Cervical Cancer Prevention

The key points to remember in cervical cancer prevention education are smoking cessation, limiting alcohol consumption, and encouraging teens to refrain from early sexual activity and having multiple partners.

Gardasil 9 is the vaccine currently approved by the U.S. Food and Drug Administration to protect girls, boys, and women from HPV, thus preventing cervical or penile cancer starting at the age of 9 to 45 years old. The vaccines prevent infection from nine strains of HPV which are responsible for the majority of penile and cervical cancers. Clinical trials indicate that the vaccine has high efficacy in preventing persistent HPV infection, cervical cancer precursor lesions, vaginal and vulvar cancer precursor lesions, and genital warts. The vaccine is administered by intramuscular injection, and the recommended schedule is a two-dose series over 6 months. The vaccine protects against infection with these types of HPV for about 10 years. It is not known if the protection lasts longer. The vaccines do not protect women who are already infected with HPV (Kaiser Family Foundation [KFF], 2020). This vaccine is not a substitute for routine cervical cancer screening, and vaccinated women should have Pap smears as recommended. See Evidence-Based Practice 8.1.

EVIDENCE-BASED PRACTICE 8.1 Improving Vaccination Uptake among Adolescents

STUDY

Adolescents represent 25% of the global population, but vaccination coverage is low. The World Health Association recommends several vaccines for adolescents (ages 10 to 19), such as the human papillomavirus (HPV). Many adolescents do not get this recommended vaccine which is effective against several cancers, including penile, cervical, oral, and anal. Governments and professional organizations have tried different approaches to change this. This Cochrane Review study aimed to assess the effects of a variety of approaches to increase the number of adolescents who receive the HPV vaccines. HPV vaccination coverage among adolescents is currently suboptimal, so various interventions need to be evaluated to improve adolescent vaccination rates.

Findings

Sixteen relevant studies were included in this review containing interventions targeting adolescent boys and girls, parents, and providers. Four approaches were found to improve vaccination coverage:

1. Target adolescents, their parents, and communities by providing them information about the HPV vaccine; reminding them when the vaccines are due; or giving them gifts if they follow through.
2. Target health care providers with information, reminders, or feedback about their practice.
3. Make vaccines more accessible to people by making them free or cheap, or by offering them closer to home, including at schools.
4. Pass laws about vaccination in which students have to prove that they have been vaccinated before attending schools.

It was found that educating adolescents and their parents about the importance of receiving the HPV vaccine; passing laws stating that adolescents must be vaccinated to attend school; and using a multifaceted package of interventions for health care providers improved adolescent vaccination coverage.

Nursing Implications

Nurses are on the frontlines of providing vaccinations and encouraging adolescents and their parents to receive them for their own protection against a variety of cancers. Nurses need to understand the factors that influence hesitancy, acceptance, and demand for adolescent vaccination in different settings. Using these targeted approaches to improve vaccination rates in adolescents will help foster improved vaccination compliance and overall health.

Abdullahi, L. H., Kagina, B. M., Ndze, V. N., Hussey, G. D., & Wiysonge, C. S. (2020). Improving vaccination uptake among adolescents. Cochrane Database of Systematic Reviews 2020, Issue 1, Art. No.: CD011895. https://doi.org/10.1002/14651858.CD011895.pub2.

Focus primary prevention education on the following:

- Identify high-risk behaviors in clients and teach them how to reduce such behaviors.
- Take steps to prevent STIs.
- Practice sexual abstinence.
- Avoid early sexual activity.
- Avoid long-term use of oral contraceptives.
- Faithfully use barrier methods of contraception.
- Avoid active and passive exposure to smoking.
- Receive the HPV vaccine.
- Instruct women on the importance of screening for cervical cancer by having Pap smears. Outline the proper preparation before having a Pap smear (Teaching Guidelines 8.3). Reinforce specific guidelines for screening:
  - Avoid vaginal intercourse, douching, use of tampons or vaginal creams, foams, jellies 48 hours prior to cervical screening. They

would interfere with evaluation of the sample.
- Schedule screening at least 5 days after the end of menstrual cycle bleeding, not when client is on monthly menstrual cycle.
- Empty bladder before screening starts (NCI, 2019h).

TEACHING GUIDELINES 8.3
Strategies to Optimize Pap Test Results

- Schedule your Pap smear appointment at least a week after your menses ends to increase the chance of getting the best sample of cervical cells without menses.
- Refrain from intercourse for 48 hours before the test because additional matter such as sperm can obscure the specimen.
- Do not douche within 48 hours before the test to prevent washing away cervical cells that might be abnormal.
- Do not use tampons, birth control foams, jellies, vaginal creams, or vaginal medications for 72 hours before the test, because they could cover up or obscure the cervical cell sample.
- Cancel your appointment if vaginal bleeding occurs, because the presence of blood cells interferes with visual evaluation of the sample.

Nurses also can advocate for clients by making sure that the Pap smear is sent to an accredited laboratory for interpretation. Doing so reduces the risk of false-negative results. The identification and treatment of early precancerous lesions is critical to prevention of cervical cancer. Prevention measures should include educating women that the risk of infection can be reduced by delaying the onset of sexual activity, decreasing the number of sexual partners, using condoms consistently, receiving the HPV vaccine, and never smoking.

Secondary prevention focuses on reducing or limiting the area of cervical dysplasia. Tertiary prevention focuses on minimizing disability or the spread of cervical cancer. Explain in detail all procedures that might be needed. Encourage the client who has

undergone any cervical treatment to allow the pelvic area to rest for approximately 1 month. Discuss this rest period with the client and her partner to gain his or her cooperation. Outline alternatives to vaginal intercourse, such as cuddling, holding hands, and kissing. Remind the woman about any follow-up procedures that are needed and assist her with scheduling if necessary.

Tertiary prevention of cervical cancer involves the diagnosis and treatment of confirmed cases of cancer. Treatment is typically through surgery, radiotherapy, and, frequently, chemotherapy. Palliative care is provided to women when the disease has already reached an incurable stage. Knowing that the woman and her family have been told about her prognosis, the nurse is in a position to support them when the impact of the diagnosis is realized.

Throughout the process, provide emotional support to the woman and her family. During the decision-making process, the woman may be overwhelmed by the diagnosis and all the information being presented. Refer the woman and her family to appropriate community resources and support groups as indicated. It is crucial for all women to be given correct information regarding safe sexual practices, informed about the preventive role of the HPV vaccination, and educated about the role of the Pap test as a secondary screening measure for cervical cancer. The emotional needs of the woman diagnosed with cancer can best be met by a warm, friendly personality, an attitude of empathy rather than sympathy, and skilled communication. Nurses across all settings are in a powerful position to be advocates for safe health care practices of women through education at personal, community, and national levels.

VAGINAL CANCER

Vaginal cancer is a rare malignant tissue growth arising in the vagina. Only about one of every 1,100 women will develop vaginal cancer in her lifetime. In 2020, the ACS (2020l) estimates that more than 6,000 new cases will be diagnosed in women, and more than 1,500 of those women will die from this cancer. The peak incidence

of vaginal cancer occurs over age 60. The prognosis of vaginal cancer depends largely on the stage of disease and the type of tumor. The overall 5-year survival rate for any type of vaginal cancer in all stages is 47% (Cancer.net, 2019a). Vaginal cancer can be effectively treated, and when found early, it is often curable.

Pathophysiology

The etiology of vaginal cancer has not been identified. Malignant diseases of the vagina are either primary vaginal cancers or metastatic forms from adjacent or distant organs. About 80% of vaginal cancers are metastatic, primarily from the cervix and endometrium. These cancers invade the vagina directly. Cancers from distant sites that metastasize to the vagina through the blood or lymphatic system are typically from the colon, kidneys, skin (melanoma), or breast. Tumors in the vagina commonly occur on the posterior wall and spread to the cervix or vulva (NCI, 2019j).

Squamous cell carcinomas (SCCs) that begin in the epithelial lining of the vagina account for about 85% of vaginal cancers. This type of cancer usually occurs in women over age 60. SCCs develop slowly over a period of years, commonly in the upper third of the vagina. They tend to spread early by directly invading the bladder and rectal walls. They also metastasize through blood and lymphatics. The remaining 15% are adenocarcinomas, which differ from SCC by an increase in pulmonary metastases and supraclavicular and pelvic node involvement (NCI, 2019k).

Therapeutic Management

Treatment of vaginal cancer depends on the type of cells involved and the stage of the disease. If the cancer is localized, radiation, laser surgery, or both may be used. If the cancer has spread, radical surgery might be needed, such as a hysterectomy, or removal of the upper vagina with dissection of the pelvic nodes in addition to radiation therapy.

Nursing Assessment

Begin the history and physical examination by reviewing for risk factors. Although direct risk factors for the initial development of vaginal cancer have not been identified, associated risk factors include advancing age (over 60 years old), previous pelvic radiation, exposure to diethylstilbestrol (DES) in utero, vaginal trauma, history of genital warts (HPV infection), HIV infection, cervical cancer, chronic vaginal discharge, vaginal adenosis, consuming alcohol, long-term use of vaginal pessaries causing chronic irritation, smoking, and low socioeconomic level (ACS, 2020m).

Question the woman about any symptoms. Most women with vaginal cancer are asymptomatic. Those with symptoms have painless vaginal bleeding (often after sexual intercourse), abnormal vaginal discharge, dyspareunia, dysuria, constipation, a mass in the vaginal wall that can be palpated, and pelvic pain (NCI, 2019k). During the physical examination, observe for any obvious vaginal discharge or genital warts or changes in the appearance of the vaginal mucosa. Anticipate colposcopy with biopsy of suspicious lesions to confirm the diagnosis.

Nursing Management

Nursing management for this cancer is similar to that for other reproductive tract cancers, with emphasis on sexuality counseling and referral to local support groups. Women undergoing radical surgery need intensive counseling about the nature of the surgery, risks, potential complications, changes in physical appearance and physiologic function, and sexuality alterations. Nurses should focus their care on client education, client pain and symptom management, communication with the woman and her family, and coordination of care across of all settings.

VULVAR CANCER

Vulvar cancer is a rare but aggressive gynecologic malignancy. It is an abnormal neoplastic growth on the external female genitalia including the clitoris, vaginal lips, and opening to the vagina (Fig. 8.5). Vulvar cancer accounts for approximately 4% of all female genital malignancies. In the United States, women have a 1-in-333 chance of developing vulvar cancer at some point in their lifetimes (NCI, 2019l). The ACS (2020n) estimates that in 2020, more than 6,000 cancers of the vulva will be diagnosed in the United States and more than 1,300 women will die of this cancer. When detected early, it is highly curable. Typically, vulvar cancer can be advanced at diagnosis, though it is a visible cancer that can be seen by the woman as an abnormal lesion or growth in her genital region.

Vulvar cancer is found most commonly in older women in their mid-60s to mid-70s, but the incidence in women younger than 35 years old has increased during the past few decades. The overall 5-year survival rate if localized is 86%, but it drops to 53% when the lymph nodes have been invaded. Survival rate for all stages combined is 71% (ACS, 2020n).

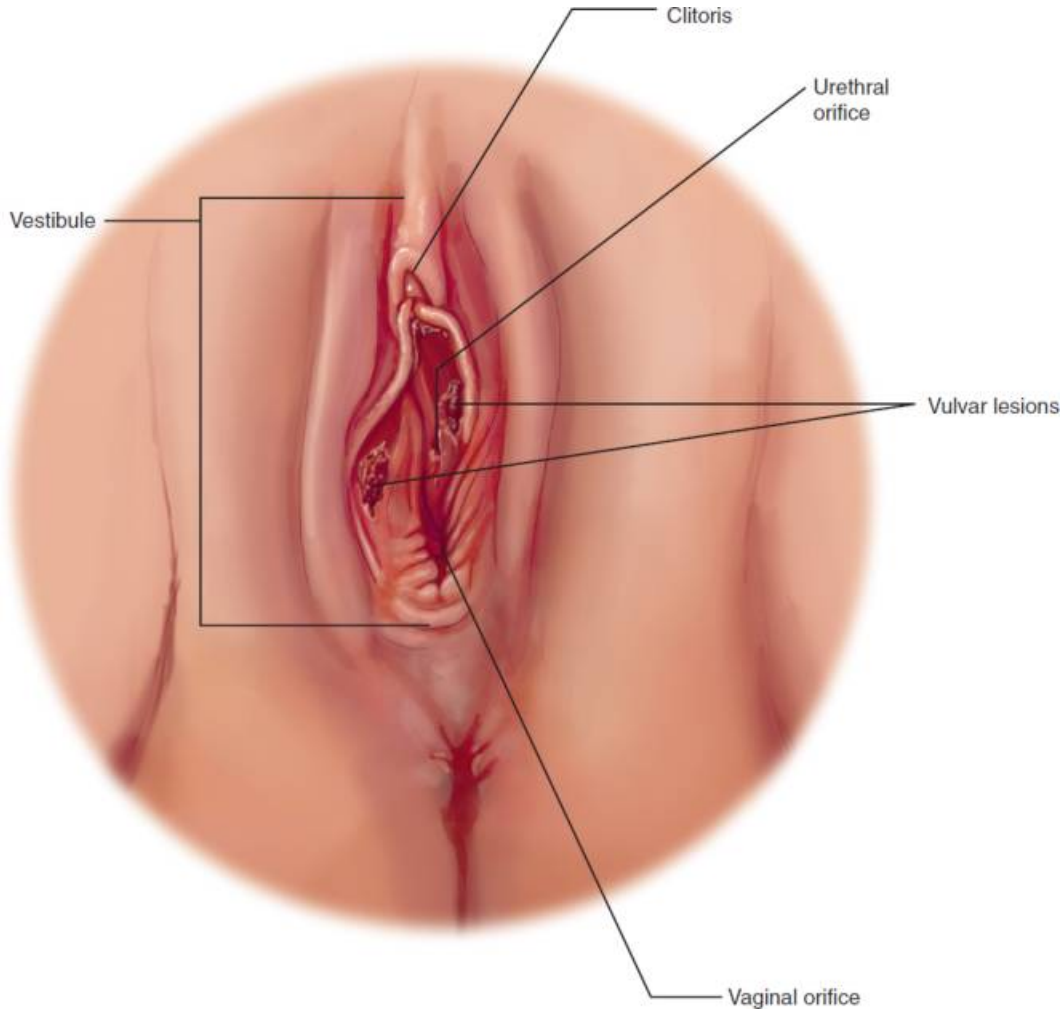

FIGURE 8.5. Vulvar cancer. (The Anatomical Chart Company. [2009]. *Atlas of pathophysiology* [3rd ed.]. Lippincott Williams & Wilkins.)

Pathophysiology

Vulvar cancer can be classified into two groups according to predisposing factors. The first type correlates with HPV infection and occurs mostly in younger women. The second group is not HPV associated and occurs in elderly women without cancerous disorders. Approximately 85% of vulvar tumors are SCCs. This type of cancer forms slowly over several years and is usually preceded by precancerous changes. These precancerous changes are termed vulvar intraepithelial neoplasia (VIN). The two major types of VIN are classic (undifferentiated) and simplex (differentiated). Classic VIN,

the more common one, is associated with HPV infection (genital warts due to types 16, 18, 31, 33, 35, 45, and 54) and smoking (McCance & Huether, 2019). It typically occurs in women between 30 and 40 years old. In contrast to classic VIN, simplex VIN usually occurs in postmenopausal women and is not associated with HPV but instead chronic irritation over time (Cancer.net, 2019b).

Screening and Diagnosis

Annual vulvar examination is the most effective way to prevent vulvar cancer. Careful inspection of the vulva during routine annual gynecologic examinations remains the most productive diagnostic technique. Liberal use of biopsies of any suspicious vulvar lesion is usually necessary to make the diagnosis and to guide treatment. However, many women do not seek health care evaluation for months or years after noticing an abnormal lump or lesion. Leading presenting complaints of women with vulvar cancer include dyspareunia, long history of pruritus, ulcers on the "outside" genitalia, vulvar swelling, a change in appearance of an existing vulvar mole, vulvar bleeding, and urinary problems (Cancer.net, 2019c). The diagnosis of vulvar cancer is made by a biopsy of the suspicious lesion, which is usually found on the labia majora.

TAKE NOTE!

Vulvar pruritus or a lump is present in the majority of women with vulvar cancer. Lumps should be biopsied even if the woman is asymptomatic.

Therapeutic Management

Treatment varies depending on the extent of the disease. Surgery, radiation therapy, and chemotherapy are the typical treatment options, depending on the cancer stage. Laser surgery, cryosurgery, or electrosurgical incision may be used. Larger lesions may need more extensive surgery and skin grafting. The traditional treatment

for vulvar cancer has been radical vulvectomy, but more conservative techniques are being used to improve psychosexual outcomes and less morbidity, without compromising survival (Cancer.Net, 2019d).

Nursing Assessment

Typically, no single specific clinical symptom heralds this disease, so diagnosis is often delayed significantly. Therefore, it is important to review the woman's history for risk factors such as:

- Exposure to HPV type 16
- Age over 50 years
- HIV infection
- VIN
- Lichen sclerosus (a patchy skin disorder)
- Melanoma or atypical moles
- Exposure to HSV type 2
- Multiple sex partners
- Smoking
- Herpes simplex
- History of breast cancer
- Immune suppression
- Hypertension
- Diabetes mellitus
- Obesity (ACS, 2020o)

In most cases, the woman reports persistent vulvar itching, burning, and edema that do not improve with the use of creams or ointments. A history of condyloma, gonorrhea, and herpes simplex are some of the factors for greater risk for VIN. Diagnosis of vulvar carcinoma is often delayed. Women neglect to seek treatment for an average of 6 months from the onset of symptoms. In addition, a delay in diagnosis often occurs after the client presents to her physician. In many cases, a biopsy of the lesion is not performed until the problem fails to respond to numerous topical therapies. During the physical examination, observe for any masses or thickening of the vulvar area. A vulvar lump or mass is most often

noted. The vulvar lesion is usually raised and may be fleshy, ulcerated, leukoplakic (looking like white patches), or warty. The cancer can appear anywhere on the vulva, though about three fourths arise primarily on the labia (Berek & Karam, 2020). Less commonly, the woman may present with vulvar bleeding, discharge, dysuria, and pain.

Nursing Management

Women with vulvar cancer must clearly understand the disease, treatment options, and prognosis. To accomplish this, provide information and establish effective communication with the client and her family. Act as an educator and advocate.

Teach the woman about healthy lifestyle behaviors, such as smoking cessation and measures to reduce risk factors. For example, instruct the woman how to examine her genital area, urging her to do so monthly between menstrual periods. Tell her to look for any changes in appearance (e.g., whitened or reddened patches of skin); changes in feel (e.g., areas of the vulva becoming itchy or painful); or the development of lumps, moles (e.g., changes in size, shape, or color), freckles, cuts, or sores on the vulva. Urge the woman to report these changes to the health care provider (ACS, 2020p).

Teach the woman about preventive measures such as not wearing tight undergarments and not using perfumes and dyes in the vulvar region. Also educate her about the use of barrier methods of birth control (e.g., condoms) to reduce the risk of contracting HIV, herpes simplex virus, and HPV. Other prevention measures include delaying first sexual intercourse, avoiding sexual intercourse with multiple partners, not starting smoking or quitting if a smoker already, and getting the HPV vaccine available for all boys and girls and women between 9 and 26 years old.

For the woman diagnosed with vulvar cancer, provide information and support. Discuss potential changes in sexuality if radical surgery is performed. Encourage her to communicate openly with her partner. Refer her to appropriate community resources and support

groups. All nurses should come in contact with women in their clinical practices who have the potential to become cancer clients, already have suspicious signs or symptoms of cancer, are already undergoing cancer treatment, or are terminal cancer clients. The nurse should be involved with all aspects of cancer, from diagnosis through palliative care. Each nurse has an obligation to keep informed of current developments in the cancer field to function effectively and be able to educate the woman and her family.

KEY CONCEPTS

- Women have a one-in-three lifetime risk of developing cancer, and one out of every four deaths is from cancer; thus, nurses must focus on screening and educating all women regardless of risk factors.
- The nurse plays a key role in offering emotional support, determining appropriate sources of support, and helping the woman use effective coping strategies when facing a diagnosis of cancer of the reproductive tract. Although reproductive tract cancer is rare during pregnancy, the woman's vigilance and routine screenings should continue throughout the pregnancy.
- A woman's sexuality and culture are inextricably interwoven, and it is essential that nurses working with women of various cultures recognize this and remain sensitive to the vast changes that will take place when the diagnosis of cancer is made.
- Ovarian cancer is a common cancer among women and the fifth most common cause of cancer deaths for women in the United States, accounting for more deaths than any other cancer of the reproductive system.
- Ovarian cancer has been described as the "overlooked disease" or "silent killer" because women and health care practitioners often ignore or rationalize early symptoms. It is typically diagnosed in advanced stages.
- Unopposed endogenous and exogenous estrogens, obesity, nulliparity, menopause after the age of 55, and diabetes are the major etiologic risk factors associated with the development of endometrial cancer.
- The American Cancer Society recommends that women be informed about risks and symptoms of endometrial cancer at the onset of menopause and strongly encouraged to report any unexpected bleeding or spotting to their health care providers.
- Malignant diseases of the vagina are either primary vaginal cancers or metastatic forms from adjacent or distant organs. Vaginal cancer tumors can be effectively treated and when found early, are often curable.
- Cervical cancer incidence and mortality rates have decreased noticeably in the past several decades, with most of the reduction

attributed to the Pap test, which detects cervical cancer and precancerous lesions.
- The nurse's role involves primary prevention of cervical cancer through education of women regarding risk factors and preventive vaccines to avoid cervical dysplasia.
- The majority of diagnosed vaginal cancers are metastatic, primarily from the cervix and endometrium. These cancers invade the vagina directly.
- Vulvar cancer is often delayed significantly because there is no single specific clinical symptom that heralds it. The most common presentation is persistent vulvar itching that does not improve with the application of creams or ointments.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. When describing ovarian cancer to a local women's group, the nurse states ovarian cancer often is not diagnosed early because

   a. the disease progresses slowly.
   b. the early stages produce vague symptoms.
   c. the disease is usually diagnosed only at autopsy.
   d. clients do not follow up on acute pelvic pain.

2. A postmenopausal woman reports that she has started spotting again. Which action would the nurse take?

   a. Instruct the client to keep a menstrual diary for the next few months.
   b. Tell her not to worry since this a common but not serious event.
   c. Have her start warm-water douches to promote healing.
   d. Anticipate that the doctor will assess her endometrium thickness.

3. Which of the following would the nurse identify as the priority psychosocial need for a woman diagnosed with reproductive cancer?

   a. Research findings
   b. Hand-holding
   c. Cheerfulness
   d. Offering of hope

4. When teaching a group of women about screening and early detection of cervical cancer, the nurse would include which procedure as most effective?

a. Fecal occult blood test
b. CA-125 blood test
c. Pap smear and HPV test
d. Sigmoidoscopy

5. After teaching a group of students about reproductive tract cancers, the nursing instructor determines that the teaching was successful when the students identify which as the deadliest type of female reproductive cancer?

a. Vulvar
b. Ovarian
c. Endometrial
d. Cervical

6. The nurse is attempting to reassure her obese female client about the discovery of an ovarian cyst after her pelvic exam. Which statement is accurate?

a. Frequently seen in polycystic kidney disease
b. Always painful and need to be removed surgically
c. A precursor to ovarian carcinoma
d. May be a syndrome that includes hypertension and diabetes

7. Which is considered a risk factor for vulvar cancer?

a. Vitamin B12 deficiency
b. Epstein–Barr virus
c. Human papillomavirus
d. Adenovirus

CRITICAL THINKING EXERCISES

1. A 27-year-old sexually active White woman visits the Health Department family planning clinic and requests information about the various available methods of contraception. In taking her history, the nurse learns that she started having sex at age 15 and has had multiple

sex partners since then. She smokes two packs of cigarettes daily. Because she has been unemployed for a few months, her health insurance policy has lapsed. She has never previously obtained any gynecologic care.

a. Based on her history, which risk factors for cervical cancer are present?
b. What recommendations would you make for her and why?
c. What are this client's educational needs concerning health maintenance?

2. A 60-year-old nulliparous woman presents to the gynecologic oncology clinic after her health care provider palpated an adnexal mass on her right ovary. In taking her history, the nurse learns that she has experienced mild abdominal bloating and weight loss for the past several months but felt fine otherwise. She was diagnosed with breast cancer 15 years ago and was treated with a lumpectomy and radiation. She has occasionally used talcum powder in her perineal area over the past 20 years.
A transvaginal ultrasound reveals a complex mass in the right adnexa. She undergoes a total abdominal hysterectomy and bilateral salpingo-oophorectomy and lymph node biopsy. Pathology confirms a diagnosis of stage III ovarian cancer with abdominal metastasis and positive lymph nodes.

a. Is this client's profile typical for a woman with this diagnosis?
b. What in her history might have increased her risk for ovarian cancer?
c. What can the nurse do to increase awareness of this cancer for all women?

STUDY ACTIVITIES

1. During your surgical clinical rotation, interview a female client undergoing surgery for cancer of her reproductive organs. Ask her to recall the symptoms that brought her to the health care provider. Ask her what thoughts, feelings, and emotions went through her mind before and after her diagnosis. Finally, ask her how this experience will change her life in the future.
2. Visit an oncology and radiology treatment center to find out about the various treatment modalities available for reproductive cancers. Contrast the various treatment methods and report your findings to your class.
3. Visit one of the websites listed in the extensive list of websites provided on to explore a topic of interest concerning reproductive cancers. How correct and current is the content? What is its level? Share your assessment with your classmates.
4. Taking oral contraceptives provides protection against _____ cancer.
5. Two genes, BRCA1 and BRCA2, are linked with hereditary _____ and _____ cancers.

BRINGING IT ALL TOGETHER: A CASE STUDY

Jill, a 38-year-old obese female with a history of infertility and irregular bleeding, returns to her OB/GYN as a follow-up appointment. She had a D&C the week before to stop a profuse bleeding episode. She is informed by the doctor that her pathology report came back from the D&C showing endometrial adenocarcinoma. She is in shock over the diagnosis at her age.

ASSESSMENT

The nurse takes Jill's history, which includes irregular menstrual cycles since her menarche. She has a BMI of 32. She takes medication to manage her diabetes and hypertension. She had been previously diagnosed with

polycystic ovary syndrome (PCOS) when she was a teenager. Her pelvic exam demonstrates an enlarged uterus. She had been to see her doctor several times because of her irregular bleeding, but she had been treated with medications until a D&C was done after months of unsuccessful drug therapy.

Go to thePoint to find questions to consider about this case.

9

Violence and Abuse

WOW

WORDS OF WISDOM

After being traumatized, women can decide to stay in the shallow end of the pool or they can find support and swim in the ocean.

KEY TERMS

acquaintance rape

battered woman syndrome

cycle of violence
date rape
female genital cutting (FGC)
human trafficking
incest
intimate partner violence (IPV)
post-traumatic stress disorder (PTSD)
rape
sexual abuse
statutory rape

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Examine the incidence of violence against women.
2. Outline the role of the nurse who cares for abused women.
3. Characterize the cycle of violence and appropriate interventions.
4. Evaluate the various myths and facts about violence.
5. Select the resources available to women experiencing abuse.
6. Analyze the dynamics of rape and sexual abuse.

Dorothy came to the prenatal clinic with a complaint of recurring headaches. She had been in twice this week already but insisted she be seen today and started to cry. When the nurse called her into the examination room, Dorothy's cell phone rang. She hurried to answer it and told the person on the other end that she was at the store. When the nurse asked if she was afraid at home, Dorothy answered "at times." What cues did the nurse pick up on to ask that question? How frequent is this problem among women?

INTRODUCTION

Violence against women is an international epidemic of global concern. Women are not safe from brutality in any country of the world. Violence against women in the United States affects a staggering one in three American women and is devastating to families, the local community, and the nation (United Nations News, 2019). Globally, the World Health Organization (WHO) estimates that 18 women die daily due to gender-related violence (WHO, 2020a). Imagine if you were subjected to assault, rape, sexual slavery, torture, verbal abuse, mutilation, even murder, because of your gender. This abuse is the most pervasive human rights violation in the world today, and yet remains silent to many ears around the globe. The United Nations (2019a) defines violence against women as any act of gender-based violence that results in or is likely to result in physical, sexual, or mental harm or suffering to women, including threats of such acts, coercion, or arbitrary deprivation of liberty whether occurring in public or private life.

Gender-based violence is a major global public health and human rights problem and one that often goes unrecognized and unreported. It is a common source of physical, psychological, and emotional morbidity. It occurs in all countries, irrespective of social, economic, religious, or cultural status. No segments of society are immune to this problem. Due to the unequal power relations between men and women, women may be subject to violations in their families, communities, or countries in which they live. The causes are multidimensional and are social, economic, cultural, political, and religious. Unfortunately, each form of abuse begets interrelated kinds of violence and the “cycle of abuse” is often continued from exposed children into their adult relationships, and finally to the care of the elderly.

Pregnancy is a time of unique vulnerability to intimate partner violence (IPV) victimization because of changes in a woman’s physical, social, emotional, and economic needs during this period. Although the true prevalence of violence during pregnancy is unclear, research suggests it is substantial and often continues into the postpartum period. All pregnant women should be screened for

violence at each visit and be provided with interventions and referrals to services if needed (Bermele et al., 2018).

Additionally, female-perpetrated violence against male partners receives little attention. Although women are victims of violence more frequently than men are, the prevalence of violence against men nonetheless represents a significant public health concern. One out of every four men has experienced rape, physical violence, and/or stalking by an intimate partner in their lifetimes (National Coalition Against Domestic Violence [NCADV], 2020a).

Although women can be violent toward men and same-sex partners, the overwhelming burden of partner violence is borne by women at the hands of men. Nearly one in five women and one in nine men in the United States have experienced rape, physical violence, and/or stalking by a partner with IPV-related impact in their lifetimes (National Sexual Violence Resource Center [NSVRC], 2019).

For all the strides Americans have made in the past 100 years, obliterating violence against women is not one of them. Violence against women is a growing problem, and in many other countries, it is still accepted as part of normal behavior. According to the Federal Bureau of Investigation (FBI, 2018), up to half of all women in the United States will experience some form of physical violence during their lifetimes. In North America, 40% to 60% of murders of women are committed by intimate partners (FBI, 2018). Recently, the FBI has broadened its definition of rape. The new definition, as it appears on the FBI website is “penetration, no matter how slight, of the vagina or anus with any body part or object, or oral penetration by a sex organ of another person without the consent of the victim.” This broader definition will have a dramatic impact on the way rape is tracked and reported nationwide (FBI, 2018).

Federal funding for the problem is trickling down to local programs, but it is not reaching victims fast enough. For example, the United States has three times more shelters for animals than for abused women (Miller-Perrin, Perrin, & Renzetti, 2018). In many cases, a victim escapes her abuser only to be turned away from a local shelter because it is full. The number of abused women is

staggering; in the United States, every 12 seconds, a woman is being physically abused (CDC, 2019a).

Nurses play a major role in assessing women who have suffered some type of violence. Nurses have a central ethic of caring and an agenda of early intervention and health promotion for their clients to improve their health status and well-being. Often, after a woman is victimized, she will complain about physical ailments that will give her the opportunity to visit a health care setting. A visit to a health care agency is an ideal time for women to be assessed for violence. Because nurses are viewed as trustworthy and sensitive about personal subjects, women often feel comfortable confiding in them and discussing these issues with them. As a professional nurse, the act of screening women seen in every health care setting is often the first step for a victim to start thinking about a better future. Remember, your words carry weight with your client who looks to you for help, support, and encouragement.

TAKE NOTE!

Nurses will come in contact with violence and sexual abuse no matter what health care setting they work in. Nurses must be ready to ask the right questions and to act on the answers, because such action could be lifesaving.

This chapter addresses several types of gender-based violence: IPV, sexual violence, female genital cutting (FGC), and human trafficking. All of these types of violence against women have devastating and costly consequences for all of society.

INTIMATE PARTNER VIOLENCE

Intimate partner violence (IPV) is actual or threatened physical or sexual violence or psychological/emotional abuse. Research suggests that physical violence in intimate relationships is often accompanied by psychological abuse and in one third to over one half of cases by sexual abuse (CDC, 2019b). Intimate partners

include individuals who are currently in dating, cohabitating, or marital relationships, or those who have been in such relationships in the past. Some of the common terms used to describe IPV are domestic abuse, spouse abuse, domestic violence, gender-based violence, and rape. IPV affects a distressingly high percentage of the population and has physical, psychological, social, and economic consequences.

Because a nurse may be the first health care provider to assess and identify the signs of IPV, a nurse can have a profound impact on a woman's decision to seek help. Thus, it is important for nurses to be able to identify abuse and aid the victim. IPV can leave significant psychological scars, and a well-trained nurse can have a positive impact on the victim's mental and emotional health.

Incidence

Overall, lifetime, and 1-year estimates for sexual violence, stalking, and IPV are alarmingly high for adult Americans, with IPV alone affecting more than 44 million people each year. On average, 20 persons per minute are victims of rape, physical violence, or stalking by an intimate partner in the United States, which equates to more than 10 million women and men. Women are disproportionately affected. The estimated cost of violence in the United States exceeds $3.6 trillion each year. Each year, IPV results in an estimated 2,500 deaths and 3 million injuries among women (CDC, 2019c).

Women are at risk for violence at nearly every stage of their lives. No woman is ever completely safe from the risk of IPV. Current or former spouses or lovers kill over half of the murdered women in the United States. IPV against women causes more serious injuries and deaths than automobile accidents, rapes, and muggings combined. Additionally, IPV is expensive. The costs associated with IPV include medical and surgical care, counseling, child care, burden on the justice system, incarceration, attorney fees, and loss of work productivity (CDC, 2019c).

IPV is pervasive and crosses all boundaries of sexual orientation, race, and class. Violence within these relationships may go unreported for fear of harassment or ridicule. The medical community's efforts to address IPV have often neglected members of the lesbian, gay, bisexual, transgender, and intersex (LGBTI) population. Heterosexual women are primarily targeted for IPV screening and intervention despite the similar prevalence of IPV in LGBTI individuals and its detrimental health effects (Gosselin, 2019). Perhaps because of the multiple barriers that confront LGBTI abuse victims and the invisibility of the problem in the context of IPV services, the role of the nurse as advocate for these clients is all the more critical.

Little is known about the national prevalence of IPV, sexual violence, and stalking among the LGBTI community in the United States. Research indicates that rates of IPV among LGBTI individuals are equal to or greater than rates among heterosexual individuals. Risk factors are also similar to those of heterosexual individuals, as are needs related to help with leaving and the recovery process (NCADV, 2020b). Current findings seem to also indicate some disparities in perceptions of what constitutes abuse among same- and opposite-sex couples (Rape, Abuse & Incest National Network [RAINN], 2020a). The Violence Against Women Act was last reauthorized in April of 2019 by the House of Representatives for 5 years, but not by the Senate at the time of printing of this book, being updated to include coverage of same-sex partners.

Background

Until the mid-1970s, American society tended to legitimize a man's power and control over a woman. The U.S. legal and judicial systems considered intervention into family disputes wrong and a violation of the family's right to privacy. IPV was often tolerated and sometimes even considered socially acceptable. However, attitudes and laws have changed to protect women and punish abusers. *Healthy People 2030* 9.1 shows there are violence prevention

objectives. In addition to those objectives, there are two developmental objectives that focus on preventing sexual violence across the lifespan and preventing different forms of partner violence including physical and sexual violence, emotional abuse, and stalking by a current or former partner.

Characteristics of Intimate Partner Violence

Although more research is needed in this area, studies have found certain risk factors that are associated with men committing IPV. These risk factors can be divided into four different categories: individual factors, relationship factors, community factors, and societal factors. Specific risk factors within each category are listed in Table 9.1.

HEALTHY PEOPLE *2030 • 9.1*

Violence Prevention Objectives	Nursing Significance
IVP-2030-01 Reduce fatal injuries.	Will increase men and women's quality and years of healthy life.
IVP-2030-08 Reduce homicides.	Will eliminate health disparities for survivors of violence.
IVP-2030-09 Reduce nonfatal physical assault injuries.	Goal is to have improved adherence to screening for IPV by health care providers.
IVP-2030-10 Reduce physical fighting among adolescents.	Will reflect the importance of early detection, intervention, and evaluation to prevent morbidity and mortality.
IVP-2030-11 Reduce gun carrying among adolescents.	
IVP-2030-12 Reduce firearm-related deaths.	
IVP-2030-13 Reduce nonfatal firearm-related injuries.	
IVP-2030-14 Reduce child abuse and neglect deaths.	
IVP-2030-15 Reduce nonfatal child abuse and neglect.	
IVP-2030-16 Reduce adolescent sexual violence by anyone.	
IVP-2030-17 Reduce adolescent dating violence (sexual or physical).	
IVP-2030-18 Reduce nonfatal intentional self-harm injuries.

TABLE 9.1 Risk Factors for Committing Intimate Partner Violence

Individual Factors	Relationship Factors	Community Factors	Societal Factors
Young age	Marital conflict	Weak sanctions against IPV	Traditional gender norms
Heavy drinking	Economic stress	Poverty	Social norms supportive of violence
Personality disorders	Dysfunctional family	Low social capital	
Depression	Marital instability		
Low academic achievement	Male dominance in family		
Witnessing violence as a child	Cohabitation		
Low income and/or unemployment	Having outside sexual partners		
Experiencing violence as a child	Taking aggression out on others while growing up		
Desire for power and control in all relationships			
Anger and hostility

Epidemiology and health consequences. *UpToDate*. Retrieved March 3, 2020, from https://www.uptodate.com/contents/intimate-partner-violence-epidemiology-and-health-consequences

Generation-to-Generation Continuation of Violence

Violence is a learned behavior that, without intervention, can be self-perpetuating. It is a cyclical health problem. The long-term effects of violence on victims and children can be profound. Children who witness one parent abuse another are more likely to become batterers themselves because they see abuse as an integral part of a close relationship. Thus, an abusive relationship between parents can perpetuate future abusive relationships. Violence in childhood and adolescence is linked to the child's perception of the family as a hostile environment and of violence against women as a corrective measure, making insults, swearing, and humiliation by a partner acceptable (Kimmel & Gardiner, 2019). The psychological consequences are huge, stemming from the paradox of the victim being abused by a member of the family with whom they expect to have a supportive, loving, and respectful relationship. Research has found that children who witness IPV are at risk for developing psychiatric disorders, fear of harm or abandonment, low frustration tolerance, sadness, post-traumatic stress disorder (PTSD), developmental problems, school failure, violence against others, and low self-esteem (Edwards, 2019).

Childhood maltreatment is a major health problem associated with a wide range of physical conditions, and it leads to high rates of psychiatric morbidity and social problems in adulthood. Consequences of violence extend far beyond the physical and mental suffering of victims and their families and have an impact on schools, neighborhoods, businesses, and the legal and health care systems. Children who receive no love, care, support, or guidance will carry the scars into adulthood. Women who were physically or sexually abused as children have an increased risk of victimization, fear of crime, poor general health, and higher rates of mental health conditions like depression, anxiety, and low self-esteem as adults (Jaffee et al., 2018).

In many cases when a parent is abused, the children are abused as well. Approximately one in eight children is abused annually in the United States. The lifetime economic cost to society of childhood maltreatment is estimated to be $130 billion (Shaffer et al., 2018). Young children who live with family violence represent a disempowered group. Developmentally, young children have relatively limited verbal skills and emotional literacy. In addition, the environment becomes one of secrecy and intimidation, as well as reduced emotional availability from the child's main caregiver. These factors severely restrict these young children's capacity and opportunity to make their voices and needs heard (Gosselin, 2019). Exposure to violence has a negative impact on children's physical, emotional, and cognitive well-being. The cycle continues into another generation through learned responses and violent acting out. Although there are always exceptions, most children deprived of their basic physical, psychological, and spiritual needs do not develop healthy personalities. They grow up with feelings of fear, behavioral problems, substance abuse, relationship difficulties, inadequacy, anxiety, anger, hostility, guilt, and rage. They often lack coping skills, blame others, demonstrate poor impulse control, have early delinquent behavior, and generally struggle with authority (Heim, 2018). Unless this cycle is broken, more than half become abusers themselves (CDC, 2019d).

The Cycle of Violence

In an abusive relationship, the **cycle of violence** (Fig. 9.1) comprises three distinct phases: the tension-building phase, the physically abusive phase, and the honeymoon, or reconciliation, phase (Alvarez & Bachman, 2020). The cyclical behavior begins with a time of tension-building arguments, progresses to violence, and settles into a making-up or calm period called the honeymoon phase. This cycle of violence increases in frequency and severity as it is repeated over and over again. The cycle can cover long or short periods of time. The honeymoon phase gradually shortens and eventually disappears altogether. Abuse in relationships typically

becomes accelerated and thus more dangerous over time. The abuser no longer feels the need to apologize and indulge in a honeymoon phase as the woman becomes increasingly disempowered in the relationship.

PHASE 1: TENSION BUILDING

During the first—and usually the longest—phase of the cycle, tension escalates between the partners. Excessive drinking, jealousy, or other factors might lead to name-calling, hostility, and friction. The woman might sense that her partner is reacting to her more negatively, that they are on edge and react heatedly to any trivial frustration. A woman will often accept her partner's building anger as legitimately directed toward her. She internalizes what she perceives as her responsibility to keep the situation from exploding. In her mind, if she does her job well, they remain calm. But if she fails, the resulting violence is her fault.

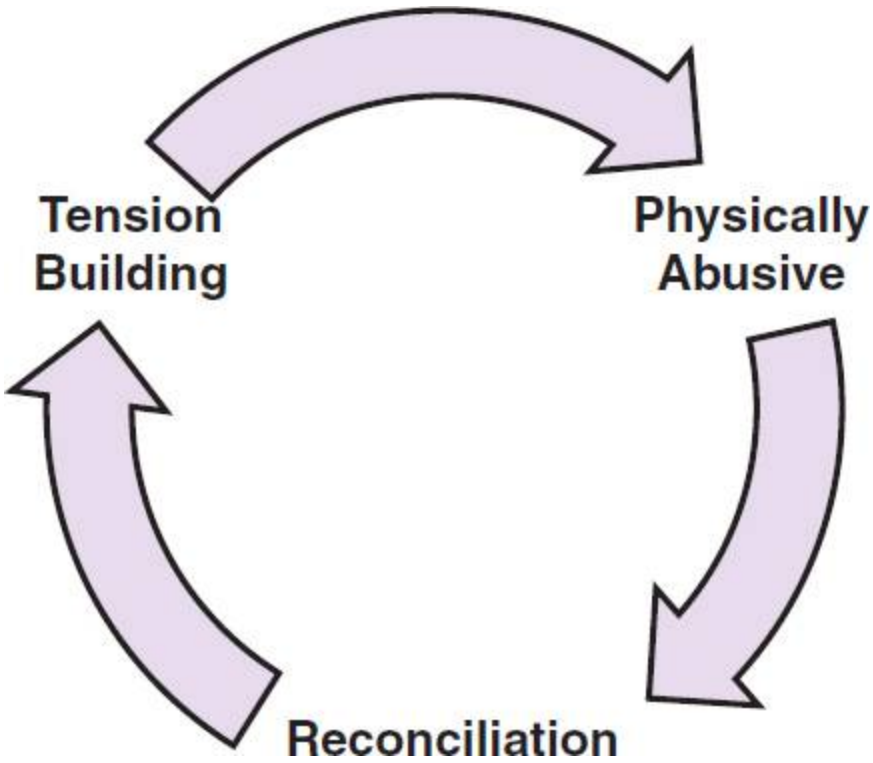

FIGURE 9.1. The cycle of violence.

PHASE 2: PHYSICALLY ABUSIVE PHASE

The second phase of the cycle is the explosion of violence. The abuser loses control both physically and emotionally. This is when the victim may be assaulted or murdered. After a physically violent episode, most victims consider themselves lucky that the abuse was not worse, no matter how severe their injuries. They often deny the seriousness of their injuries and may refuse to seek medical treatment.

PHASE 3: HONEYMOON

The third phase of the cycle is a period of calm, loving, and contrite behavior on the part of the abuser. They may be genuinely sorry for the pain caused to the partner. They attempt to make up for the brutal behavior and believe they can control the violence and will never hurt the woman again. The victim wants to believe that her partner really can change. She feels responsible, at least in part, for causing the incident, and she feels responsible for her partner's well-being (Box 9.1).

Types of Abuse

Abusers may use whatever it takes to control a situation—from emotional abuse and humiliation to physical assault. Victims often tolerate emotional, physical, financial, and sexual abuse. Many remain in abusive relationships because they believe they deserve the abuse. Others feel they have no means of escape, and often an attempt to escape can be fatal for the woman.

BOX 9.1 Cycle of Violence

- *Phase 1—Tension building:* Verbal or minor physical abuse occurs. Almost any subject, such as housekeeping or money, may trigger the buildup of tension. There is a breakdown of communication. The victim attempts to calm the abuser. Victim feels like "walking on egg shells" around the abuser.
- *Phase 2—Physically abusive phase:* Characterized by uncontrollable discharge of tension. Violence is rarely triggered by the victim's behavior; she is physically abused no matter what her response. The start of the episode is unpredictable and beyond the victim's control.
- *Phase 3—Honeymoon (reconciliation)/calm phase:* First, the abuser is ashamed of the behavior. The abuser tries to minimize the abuse and blame it on the partner. The abuser becomes loving, kind, and apologetic and expresses guilt. Then the abuser works on making the victim feel responsible. This loving behavior strengthens the bond between partners and will probably convince the victim, once again, that leaving the relationship is not necessary.

Gosselin, D. K. (2019). *Family & intimate partner violence: Heavy hands* (6th ed.). Pearson Education; National Coalition Against Domestic Violence (NCADV). (2020c). *Dynamics of abuse*. Retrieved June 16, 2020, from https://ncadv.org/dynamics-of-abuse.

Emotional Abuse

Emotional abuse includes:

- Promising, swearing, or threatening to harm the victim
- Forcing the victim to perform degrading or humiliating acts
- Threatening to harm children, pets, or close friends
- Humiliating the woman by name-calling and insults
- Threatening to leave the woman and the children
- Isolation from family and friends
- Destroying valued possessions
- Controlling the victim's every move

Physical Abuse

Physical abuse includes:

- Hitting or grabbing the victim so hard that it leaves marks
- Throwing things at the victim

- Slapping, spitting at, biting, burning, pushing, choking, or shoving the victim
- Kicking or punching the victim, or slamming her against things
- Attacking the victim with a knife, gun, rope, or electrical cord
- Controlling access to health care for injury

Financial Abuse

Financial abuse includes:

- Preventing the woman from getting a job
- Sabotaging a current job
- Controlling how all money is spent
- Failing to contribute financially

Sexual Abuse

Sexual abuse includes:

- Forcing the woman to have vaginal, oral, or anal intercourse against her will
- Biting the victim's breasts or genitals
- Shoving objects into the victim's vagina or anus
- Forcing the woman to do something sexual that she finds degrading or humiliating
- Forcing the victim to perform sexual acts on other people or animals

Myths and Facts about Intimate Partner Violence

Table 9.2 lists many of the myths about IPV. Health care providers should take steps to dispel these myths.

TABLE 9.2 Common Myths and Facts about Intimate Partner Violence

Myths	Facts
Physical abuse of women occurs only in lower socioeconomic classes.	Violence occurs in all socioeconomic classes.
Substance abuse causes the violence.	Violence is a learned behavior and can be changed. The presence of drugs and alcohol can make a bad problem worse.
Men have the right to discipline their partners. Physical abuse is not a crime.	In the past, our patriarchal legal system afforded men the right to physically chastise their wives and children; we no longer live under that system. Women and children are no longer considered the property of men, and violence against them is a crime in every state.
Violence occurs to only a small percentage of women.	One in four women will be victims of violence in their lifetimes.
Intimate partner violence (IPV) is typically a one-time, isolated occurrence.	IPV is a pattern of coercion and control that one person exerts over another. It is repeated using a number of tactics, including intimidation, threats, physical injury, economic deprivation, isolation, and sexual abuse. The various forms of abuse utilized by abusers help maintain power and control over their victims.
Women can easily choose to leave an abusive relationship.	Women stay in abusive relationships because they feel they have no options. Frequently, leaving presents the greatest risk to the woman's life.
Only men with mental health problems commit violence against women.	Abusers often seem normal and do not appear to suffer from personality disorders or other forms of mental illness.
Pregnant women are protected from abuse by their partners.	One in five women is physically abused during pregnancy. The effects of violence on infant outcomes can include preterm delivery, fetal distress, low birth weight, and child abuse.
Women provoke their partners to abuse them.	Women may be willing to blame themselves for someone else's bad behavior, but nobody deserves to be abused.

Violent tendencies have gone on for generations and are accepted.	The police, justice system, and society are making IPV socially unacceptable, and it is now considered a crime.
IPV is only a heterosexual issue.	There is as much IPV in the LGBTI population as in heterosexual relationships with the added psychological abuse of "outing," when one partner threatens to disclose the other's sexual preference in an effort to maintain power and control.

Abuse Profiles

Victims

Victims often will not describe themselves as abused. In **battered woman syndrome**, the woman has experienced deliberate and repeated physical or sexual assault by an intimate partner over an extended period of time. She is terrified and feels trapped, helpless, and alone. She reacts to any expression of anger or threat by avoidance and withdrawal behavior. Some women believe that the abuse is caused by a personality flaw or inadequacy in themselves (e.g., inability to keep the partner happy). These feelings of failure are reinforced and exploited by their partners. After being told repeatedly that they are "bad," some women begin to believe it. Many victims were abused as children and may have poor self-esteem, poor health, PTSD, depression, insomnia, low education achievement, or a history of suicide attempts, injury, or drug and alcohol abuse (Valles et al., 2019).

Abusers

Abusers come from all walks of life and often feel insecure, powerless, and helpless; feelings that are not in line with the image of strength they would like to project. The abuser expresses feelings of inadequacy through violence or aggression toward others (Miller-Perrin, Perrin, & Renzetti, 2018).

Violence typically occurs at home and is usually directed toward the intimate partner or the children who live there. Abusers refuse to share power and choose violence to control their victims. They often exhibit childlike aggression or antisocial behaviors. They may fail to accept responsibility or blame others for their own problems. They might also have a history of substance abuse problems; trouble with the justice system; few close relationships; a sensitivity to criticism; a tendency to hold grudges; involvement in power struggles; emotional dysregulation; a lack of insight; feelings of being misunderstood, mistreated, or victimized; mental illness; troubled relationships; obsessive jealousy; controlling behaviors; generally violent behavior; erratic employment history; and financial problems (Gosselin, 2019).

Violence against Pregnant Women

Many think of pregnancy as a time of celebration and planning for the unborn child's future, but in a troubled relationship it can be a time of escalating violence. The strongest predictor of abuse during pregnancy is prior abuse. Violence against pregnant women seems to be more prevalent than diseases routinely investigated during prenatal care, such as preeclampsia and diabetes (Jordan et al., 2019). For women who have been abused before, beatings and violence during pregnancy seem like "business as usual."

Women are at a higher risk for violence during pregnancy. Recent research findings indicate that having children does not protect women from IPV. On the contrary, IPV appears to last longer if women have children, and this also seems to be the case even after the partnership has come to an end (Morgan et al., 2018). Pregnant women are vulnerable during this time, and abusers can take advantage of it. Prevalence rates of IPV during pregnancy are up to 10%, but this is likely a low estimate due to underreporting (CDC,

2019a). Abuse during pregnancy poses special risks and dynamics. Various factors may lead to violence during this time, including:

- Inability of the couple to cope with the stressors of pregnancy
- Young age at the time of pregnancy
- Having less than a high school education for both partners
- Unemployment for either or both in partnership
- Violence in the family of origin
- Cohabitation and single marital status
- Sexual possessiveness on the part of the abuser
- Heavy drinking by the abuser
- Resentment toward the interference of the growing fetus and change in the woman's shape
- Doubts about paternity or the expectant mother's fidelity during pregnancy
- Perception that the baby will be a competitor
- Outside attention the pregnancy brings to the woman
- Unwanted pregnancy
- The woman's new interest in herself and her unborn baby
- Insecurity and jealousy about the pregnancy and the responsibilities it brings
- Financial burden related to expense of pregnancy and loss of income
- Stress of role transition to parent of a child
- Physical and emotional changes of pregnancy that make the woman vulnerable
- Previous isolation from family and friends that limit the couple's support system

Abuse during pregnancy threatens the well-being of the mother and fetus. Physical violence may involve injuries to the head, face, neck, thorax, breasts, and abdomen. The mental health consequences are also significant. Several studies have confirmed the relationship between abuse and poor mental health, especially depression and PTSD; low self-esteem, negative self-image, and poor quality of life; increased distress, fearfulness, anxiousness, and stress; and increased use of tobacco, alcohol, and/or illicit drugs

(Hrelic, 2019). For the pregnant woman, many of these conditions most often manifest during the postpartum period.

TAKE NOTE!

Frequently, the fear of harm to her unborn child will motivate a woman to try to escape an abusive relationship.

Women assaulted during pregnancy are at risk for:

- Injuries to themselves and the fetus
- Depression
- Panic disorder
- Fetal and maternal deaths
- Chronic anxiety
- Miscarriage
- Stillbirth
- Poor nutrition
- Insomnia
- Placental abruption
- Uterine rupture
- Excessive weight gain or loss
- Smoking and substance abuse
- Delayed or no prenatal care
- Preterm labor
- Higher rate of surgical births
- Chorioamnionitis
- Vaginitis
- Sexually transmitted infections (STIs)
- Urinary tract infections
- Premature and low-birth-weight infants (Jordan et al., 2019)

EVIDENCE-BASED PRACTICE 9.1

Decreasing Intimate Partner Violence during Pregnancy through Routine Screening

STUDY

Intimate partner violence during pregnancy is a significant, yet preventable public health problem that globally affects millions of women annually. Women are especially vulnerable to IPV when pregnant, as violence is more likely to begin or intensify. During this gestational period, women are being seen for prenatal visits. Screening for IPV is a standard of care recommended by the USPSTF and other professional organizations; however a deficiency in health care provider preparedness, comfort, and consistency are lacking. Direct complications of IPV include preterm labor, fetal injury, substance abuse, depression, and death. Nurses are in an adventitious position to screen these women for IPV as they are able to build rapport with them.

The purpose of this study was to determine if health care providers routinely screen for IPV during pregnancy and if it would lower the IPV incidence. Twelve studies met the inclusion criteria and were utilized, including 15,767 screened pregnant women. Each of the 12 studies had multiple strengths.

Findings

The results of this study found that nurses or health care practitioners should routinely screen their clients for IPV each prenatal visit to reduce the incidence of it. Nurses and other health care providers are in a unique position to identify IPV and their families in ending IPV. All 12 studies agreed that nurses are in an ideal role to screen women during their prenatal visits. It was also found that screening for IPV should be done multiple times during the client's pregnancy, as initially a client may not

feel comfortable disclosing this information and/or may be accompanied by the abusive partner. Based on this study, screening did reduce the incidence of IPV and increased awareness.

Nursing Implications

Pregnancy presents a great opportunity for nurses to screen women for IPV, as their care requires frequent office or clinic visits. Nurses can build therapeutic rapport with their pregnant clients over the course of their pregnancies, resulting in a trusting relationship. Based on the findings, screening at each prenatal visit for IPV does reduce the incidence of it and brings about awareness to the woman and family. It is essential for nurses to serve as advocates for women suffering from IPV by supporting them in their decisions and making necessary referrals.

Adapted from Gonzalez, B. (2018). Decreasing intimate partner violence during pregnancy through routine screening. Journal of Women's Health Care, *7*(1), 413. https://doi.org/10.4172/2167-0420.1000413.

Dorothy, whom you met at the beginning of the chapter, has been frequenting the clinic with vague somatic complaints in recent weeks and admits she is sometimes afraid at home. She tells the nurse her partner doesn't want her to work, though he is only sporadically employed at low-paying jobs. What cues in her assessment might indicate abuse? What physical signs might the nurse observe?

Signs of abuse can emerge during pregnancy and may include poor attendance at prenatal visits, unrealistic fears, weight fluctuations, difficulty with pelvic examinations, and nonadherence to treatment. See Evidence-Based Practice 9.1 for prenatal screening used for pregnant women experiencing IPV.

Uncovering abuse in pregnant women requires a consistent and direct approach to every client by the nurse. Multiple assessments may enhance reporting by enabling the nurse to establish trust and rapport with the woman and identify changes in her behavior. Once abuse is discovered in a pregnant woman, interventions should

include safety assessment, emotional support, counseling, referral to community services, and ongoing prenatal care to avoid adverse health outcomes (Kaiser Family Foundation, 2020).

Violence against Older Women

Elder abuse is an umbrella term that may include physical, sexual, or emotional abuse; financial exploitation; and neglect, abandonment, or self-neglect to the vulnerable elder by a caregiver. Older women can experience the same forms of violence as younger women do, but the intersections of ageism and sexism, as well as factors such as illness, disability, isolation, and widowhood increase the risk of violence to them (United Nations, 2019a). IPV affects women of all ages, but often the literature focuses on women in the childbearing years, ignoring the problems of aging women who experience abuse. All 50 states have laws requiring health care providers to report elder or vulnerable person abuse. It is estimated that one in six older Americans experience abuse, but only one out of 14 cases are reported (Carney, 2020). Research suggests that female elders are abused at a higher rate than males and that the older one is, the more likely one is to be abused. Elder abuse is expected to increase as the population ages (WHO, 2020b). Although an injury may bring the older woman into the health care system, the physical and emotional sequelae of IPV may be more subtle and may include depression, insomnia, chronic pain, difficulty trusting others, low self-esteem, thoughts of suicide, substance abuse, anger issues, atypical chest pain, or other kinds of somatic symptoms. Research suggests that older women usually have endured long-term abuse; have developed unhealthy strategies to cope (substance abuse, keeping the family together at all costs, and physical and mental health consequences); and shoulder blame from their adult children, yet have developed empowerment from within to be able to cope with the abuse (U.S. Preventive Services Task Force [USPSTF], 2019).

Accurate detection and assessment of abuse in older women are essential duties of all nurses. Bruises, grip marks, and lacerations are just some of the potential indications of elder abuse. Nurses

have frequent contact with older victims of abuse, giving nurses the opportunity to play a significant role in detecting, reporting, and intervening in such cases. As part of a thorough screening, nurses should determine what the client has done to attempt to resolve the abuse and the effectiveness of those strategies. Actions taken by the client prior to revealing her abuse issue to the nurse might have included passive acceptance, calling law enforcement, counseling, or other measures. In addition, taking time to establish rapport with older women builds a sense of trust, safety, and openness. Nurses must listen carefully and nonjudgmentally. Judging or criticizing the victim for her decisions might lead to the impression that she deserves the abuse or that she is to blame. Finally, nurses should attempt to stay current in their knowledge of referral resources to assist the older woman experiencing abuse. Some of these resources include housing, transportation, medical services, employment, social services, and local support groups. A coordinated and comprehensive response to IPV is essential to reduce its sequelae.

Nursing Management of Intimate Partner Violence Victims

Nurses encounter thousands of abuse victims each year in their practice settings, but many victims slip through the cracks. As practicing universal violence assessment has increased in recent years, nurses need to be aware of not only how to screen for violence but how to respond in a way that is helpful, sincere, nonjudgmental, and legally adequate. This will require nurses to move beyond a description of violence toward a response that is action oriented and evidence based, which includes safety planning and referrals. There are many things nurses can do to help victims. Early recognition and intervention can significantly reduce the morbidity and mortality associated with IPV. To stop the cycle of violence, nurses need to know how to assess for and identify IPV and implement appropriate actions.

Assessment

Routine screening for IPV is the first way to detect abuse. The nurse should build rapport by listening, showing an interest in the concerns of the woman, and creating an atmosphere of openness. Communicating support through a nonjudgmental attitude and telling the woman that no one deserves to be abused are first steps toward establishing trust and rapport. Rather than overlooking abused women as “chronic complainers,” astute nurses need to be vigilant for subtle clues of abuse. Learning how to assess for abuse is critical. Some basic assessment guidelines follow.

SCREEN FOR ABUSE DURING EVERY HEALTH CARE VISIT

Screening for violence takes only a few minutes and can have an enormously positive effect on the outcome for the abused woman. Any woman could be a victim; no single sign marks a woman as an abuse victim, but the following clues may be helpful:

- *Injuries*—Bruises on the chest and abdomen, scars from blunt trauma, minor lacerations, or weapon wounds on the face, head, and neck.
- *Injury sequelae*—Headaches, hearing loss from ruptured ear drums, joint pain, sinus infections, teeth marks, clumps of hair missing, dental trauma, pelvic pain, and breast or genital injuries.
- Reported history of injury that is not consistent with the actual presenting problem.
- *Mental health problems*—Depression, anxiety, substance abuse, eating disorders, suicidal ideation or suicide attempts, anger toward health care provider, and PTSD.
- Frequent tranquilizer or sedative use.
- Delay in seeking medical attention and patterns of repeated injury.
- Bruises to the upper arm, neck and face, abdomen, or breasts.
- Comments about emotional or physical abuse of “a friend”.
- STIs or pelvic inflammatory disease.
- Appearing nervous, ashamed, or evasive when asked questions.

- Frequent health care visits for chronic, stress-related disorders such as chest pain, headaches, back or pelvic pain, insomnia, injuries, anxiety, and gastrointestinal disturbances.
- Partner's behavior at the health care visit: appears overly solicitous or overprotective, is unwilling to leave the client alone with the health care provider, answers questions for her, and attempts to control the situation (Cavner, 2019).

ISOLATE CLIENT IMMEDIATELY FROM FAMILY

If abuse is detected, immediately isolate the woman to provide privacy and prevent potential retaliation from the abuser. Asking about abuse in front of the perpetrator may trigger an abusive episode during the interview or at home. Ways to ensure the woman's safety would be to take the victim to an area away from the abuser to ask questions. The assessment can take place anywhere that is private and away from the abuser, for example, an x-ray area, ultrasound room, elevator, restroom, or laboratory.

If abuse is detected, the nurse can do the following to enhance the nurse–client relationship:

- Educate the woman about the connection between the violence and her symptoms.
- Help the woman acknowledge what has happened to her and begin to deal with the situation.
- Offer the woman referrals so she can get the help that will allow her to begin to heal.

Dorothy returns to the prenatal clinic a month later with anemia, inadequate weight gain, bruises on her face and neck, and second-trimester bleeding. This time she is accompanied by her partner, who stays close to Dorothy. What questions should the nurse ask to assess the situation? Where is the appropriate location to ask these questions? What legal responsibilities does the nurse have concerning her observations?

ASK DIRECT OR INDIRECT QUESTIONS ABOUT ABUSE

Violence against women is often unseen, unknown, and hidden in families. Questions to screen for abuse should be routine and handled just like any other questions. Many nurses feel uncomfortable asking questions of this nature, but broaching the subject is important, even if the answer comes later. Opening up the possibility for women to express themselves about their experience of abuse to a nurse sends out a clear message that violence should never be tolerated and not kept hidden; it also conveys the message that nurses care about the woman's experiences and want to offer a best practice initial response. Just knowing that someone else knows about the abuse offers a victim some relief and may help her disclose it.

Ask difficult questions in an empathetic and nonthreatening manner and remain nonjudgmental in all responses and interactions. Choose the type of question that makes you most comfortable. Direct and indirect questions produce the same results. "Does your partner hit you?" or "Have you ever been or are you now in an abusive relationship?" are direct questions. If that approach feels uncomfortable, try indirect questions: "We see many women with injuries or complaints like yours and often they are being abused. Is that what is happening to you?" or "Many women in our community experience abuse from their partners. Is anything like that happening in your life?" With either approach, nurses need to maintain a nonjudgmental acceptance of whatever answers the woman offers. The SAVE Model is a screening protocol that nurses can use when assessing women for violence (Box 9.2).

ASSESS IMMEDIATE SAFETY

It is essential to assist the woman by assessing her safety and the safety of her children. To do this, speak to the woman alone and ask her:

- Does she feel safe going home after her meeting with you?
- Does she need an immediate place of safety for herself or her children?

- Does she have a plan of escape if she becomes at risk for her safety?
- Does she need to consider an alternative exit from this building?
- Who are the people she could contact for help or support?

BOX 9.2 SAVE Model

SCREEN all of your clients for violence by asking:

- Within the last year, have you been physically hurt by someone?
- Do you feel you are in control of your life?
- Within the last year, has anyone forced you to engage in sexual activities?
- Can you talk about your abuse with me now?
- In general, how would you describe your present relationship?

ASK direct questions in a nonjudgmental way:

- Begin by normalizing the topic with the woman.
- Make continuous eye contact with the woman.
- Stay calm; avoid emotional reactions to what she tells you.
- Never blame the woman, even if she blames herself.
- Do not dismiss or minimize what she tells you, even if she does.
- Wait for each answer patiently. Do not rush to the next question.
- Do not use formal, technical, or medical language.
- Avoid using leading questions; be direct and to the point.
- Use a nonthreatening, accepting approach.

VALIDATE the client by telling her:

- You believe her story.
- You do not blame her for what happened.
- It is brave of her to tell you this.
- Help is available for her.
- Talking with you is a hopeful sign and a first big step.

EVALUATE, educate, and refer this client by asking her:

- What type of violence was it?
- Is she now in any danger?
- How is she feeling now?
- Does she know that there are consequences to violence?
- Is she aware of community resources available to help her?

Retrieved June 16, 2020, from https://www.aafp.org/news/health-of-the-public/20180504violence.html; Kaiser Family Foundation. (2020). *Intimate partner violence screenings and counseling services in clinical settings.* Retrieved December 2, 2019, from https://www.kff.org/womens-health-policy/issue-brief/intimate-partner-violence-ipv-screening-and-counseling-services-in-clinical-settings/

The Danger Assessment Tool (Box 9.3) helps women and health care providers assess the potential for homicidal behavior in an

ongoing abusive relationship. It is based on research that showed several risk factors for abuse-related murders:

- Increased frequency or severity of abuse
- Presence of firearms
- Sexual abuse
- Substance abuse
- Precipitated by arguments and conflicts
- Generally violent behavior outside of the home
- Control issues (e.g., daily chores, friends, job, money)
- Physical abuse during pregnancy
- Suicide threats or attempts (victim or abuser)
- Child abuse (Gosselin, 2019)

BOX 9.3 Danger Assessment Tool

Several risk factors have been associated with increased risk of homicides of women and men in violent relationships. No one can predict what will happen in your case, but we would like you to be aware of the danger of homicide in situations of abuse and for you to see how many of the risk factors apply to your situation. ("He" refers to your husband, partner, ex-husband, ex-partner, or whoever is currently physically hurting you).[a]

_____1. Has the physical violence increased in severity or frequency over the past year?

_____2. Does he own a gun?

_____3. Have you left him after living together during the past year?

_____4. Is he unemployed?

_____5. Has he ever used a weapon against you or threatened you with a lethal weapon?

_____6. Does he threaten to kill you?

_____7. Has he avoided being arrested for domestic violence?

_____8. Do you have a child who is not his?

_____9. Has he ever forced you to have sex when you did not wish to do so?

____10. Does he ever try to choke you?

____11. Does he use illegal drugs? By drugs, I mean "uppers" or amphetamines, meth, speed, angel dust, cocaine, crack, street drugs, or mixtures.

____12. Is he an alcoholic or problem drinker?

____13. Does he control most or all of your daily activities? For instance, does he tell you who you can be friends with, when you can see your family, how much money you can use, or when you can take the car?

____14. Is he violently and constantly jealous of you? For instance, does he say "If I can't have you, no one can?"

____15. Have you ever been beaten by him while you were pregnant?

____16. Has he ever threatened or tried to commit suicide?

____17. Does he threaten to harm your children?

____18. Do you believe he is capable of killing you?

____19. Does he follow or spy on you, leave threatening notes or messages on your voicemail or e-mail, destroy your property, or call you when you don't want him to?

____20. Have you ever threatened or tried to commit suicide?

_____ Total "Yes" Answers

Thank you. Please talk to your nurse, advocate, or counselor about what the Danger Assessment means in terms of your situation.

[a]Men are not the only perpetrators of violence. Alter your language to match the gender identities of the victim and abuser.

March of Dimes Danger Assessment questionnaire. From Campbell, J. (1986). Nursing assessment for risk of homicide with battered women. Advances in Nursing Science, *8*(4), 36–51.

DOCUMENT AND REPORT YOUR FINDINGS

If the interview reveals a history of abuse, accurate documentation is critical because this evidence may support the woman's case in court. Documentation must include details about the frequency and severity of abuse; the location, extent, and outcome of injuries; and any treatments or interventions. When documenting, use direct quotes and be specific: "He choked me." Describe any visible injuries, and use a body map (outline of a woman's body) to show where the injuries are. Obtain photos (with informed consent) or document her refusal if the woman declines photos. Pictures or diagrams can be helpful. Figure 9.2 shows a sample documentation form for IPV.

Laws in many states require health care providers to alert the police to any injuries that involve knives, firearms, or other deadly weapons or that present life-threatening emergencies. If assessment reveals suspicion or actual indication of abuse, nurses can explain to the woman that they are required by law to report it.

Nursing Analysis

When violence is suspected or validated, the nurse needs to formulate nursing analyses based on the completed assessment. Possible nursing analyses related to violence against women might include:

- Deficient knowledge related to understanding the cycle of violence and availability of resources
- Anxiety related to threat to self-concept, situational crisis of abuse
- Situational low self-esteem related to negative family interactions
- Powerlessness related to lifestyle of helplessness
- Impaired individual and family coping related to abusive patterns

Interventions

The response of nurses to abused women can have a profound effect on their willingness to open up or seek help. Some responses to assist successful communication in these circumstances could include:

- *Listening*—"I hear and understand what you are saying." Being listened to can be an empowering experience for a woman who has been abused.
- *Communicating belief*—"That must have been frightening for you."
- *Validating the decision to disclose*—"It must have been difficult for you to talk about this today."
- *Emphasizing the unacceptability of this violence*—"You don't deserve to be treated this way."

If abuse is identified, nurses can undertake interventions that can increase the woman's safety and improve her health. The goal of intervention is to enable the victim to gain control of her life. Provide sensitive, predictable care in an accepting setting. Offer step-by-step explanations of procedures. Provide educational materials about violence. Allow the victim to actively participate in her care and have control over all health care decisions. Pace your nursing interventions and allow the woman to take the lead. Communicate support through a nonjudgmental attitude. Carefully document all of your assessment findings and nursing interventions.

Concept Mastery Alert

Priorities in Intimate Partner Violence Interventions

Although it is important that the woman in an abusive situation is safe, it is most important for a woman to regain a sense of control in her life. A lack of control is what can prevent a woman from escaping an abusive situation.

A public health approach to violence prevention requires input from and coordination across sectors, including those of health, education, social services, justice, and policy. The goal of public health is to improve the health of the entire community or society. Depending on when in the cycle of violence, the nurse encounters the abused woman, goals may fall into three groups:

- *Primary prevention*—aimed at breaking the abuse cycle through community educational initiatives by nurses, physicians, law enforcement, teachers, and clergy.
- *Secondary prevention*—focuses on screening high-risk individuals and dealing with victims and abusers in early stages with the goal of preventing progression of abuse.
- *Tertiary prevention*—geared toward helping severely abused women and children recover and become productive members of society and rehabilitating abusers to stop the cycle of violence; these activities are typically long-term and expensive.

A modified tool developed by Holtz and Furniss (1993) called the ABCDES provides a framework for providing sensitive nursing interventions to abused women (Box 9.4). Specific nursing interventions for the abused woman include educating her about community services, providing emotional support, and offering a safety plan.

BOX 9.4 The ABCDES of Caring for Abused Women

- **A** is reassuring the woman that she is not alone. The isolation by her abuser keeps her from knowing that others are in the same situation and that health care providers can help her.
- **B** is expressing the belief that violence against women is not acceptable in any situation and that it is not her fault. Demonstrate by your actions and words that you believe her disclosure.
- **C** is confidentiality, since the woman might believe that if the abuse is reported, the abuser will retaliate. Interview her in private, without her partner or family members present. Assure her that you will not release her information without her permission.
- **D** is documentation, which includes:
  - A clear quoted statement about the abuse in the woman's own words.
  - Accurate descriptions of injuries and the history of them.
  - Information on the first, the worst, and the most recent abusive incident.
  - Photos of the injuries (with the woman's consent).
- **E** is education about the cycle of violence and that it will escalate:
  - Educate about abuse and its health effects.
  - Help her understand that she is not alone.
  - Offer appropriate community support and referrals.
  - Display posters and brochures to foster awareness of this public health problem.
- **S** is safety, the most important aspect of the intervention, to ensure that the woman has resources and a plan of action to carry out if and when she decides to leave.

Centers for Disease Control and Prevention (CDC). (2019a). *Intimate partner violence.* https://www.cdc.gov/violenceprevention/intimatepartnerviolence/datasources.html; The National Domestic Hotline. (2019). *Get help*. Retrieved June 16, 2020, from https://www.thehotline.org/; and Morgan, I. A., Robbins, C. L., & Basile, K. C. (2018). Addressing intimate partner violence to improve women's preconception health. Journal of Women's Health, *27*(10), 1189–1194.

EDUCATE THE WOMAN ABOUT COMMUNITY SERVICES

A wide range of support services are available to meet the needs of victims of violence. Nurses should be prepared to help the woman take advantage of these opportunities. Services will vary by community but might include psychological counseling, legal advice,

social services, crisis services, support groups, hotlines, housing, vocational training, and other community-based referrals.

Give the woman information about shelters or services even if she initially rejects it. Give the woman the National Domestic Violence hotline number: (800) 799–7233. The Joint Commission, American Medical Association (AMA), American College of Obstetrician Gynecologists (ACOG), and the USPSTF all recommend routine IVP screening, counseling, and referrals in all health care agencies (USDHHS, 2019b).

PROVIDE EMOTIONAL SUPPORT

Providing reassurance and support to a victim of abuse is essential if the violence is to end. The physical, psychological, and emotional effects of IPV on women and their children can be severe and long-lasting. Nurses in all clinical settings can help victims feel a sense of personal power and provide them with a safe and supportive environment. Appropriate action can help victims express their thoughts and feelings in constructive ways, manage stress, and move on with their lives. Appropriate interventions include:

- Strengthen the woman's sense of control over her life by:
  - teaching coping strategies to manage her stress.
  - assisting with activities of daily living to improve her lifestyle.
  - allowing her to make as many decisions as she can.
  - educating her about the symptoms of PTSD and their basis.
- Encourage the woman to establish realistic goals for herself by:
  - teaching problem-solving skills.
  - encouraging social activities to connect with other people.
- Provide support and allow the woman to grieve for her losses by:
  - listening to and clarifying her reactions to the traumatic event.
  - discussing shock, disbelief, anger, depression, and acceptance.
- Explain to the woman that:
  - abuse is never OK. She didn't ask for it and she doesn't deserve it.
  - she is not alone, and help is available.
  - abuse is a crime, and she is a victim.

- alcohol, drugs, money problems, depression, and jealousy do not cause violence, but these things can give the abuser an excuse for losing control and abusing her.
- the actions of the abuser are not her fault.
- her history of abuse is believed.
- making a decision to leave an abusive relationship can be hard and dangerous and takes time.

OFFER A SAFETY PLAN

The choice to leave must belong to the victim. Nurses cannot choose a life for the victim; they can only offer choices. Leaving is a process, not an event. Victims may try to leave their abusers as many as seven or eight times before succeeding. Frequently, the final attempt to leave results in the death of the victim. Women planning to leave an abusive relationship should have a safety plan (Teaching Guidelines 9.1).

TEACHING GUIDELINES 9.1
Safety Plan for Leaving an Abusive Relationship

- When leaving an abusive relationship, take the following items:
  - Driver's license or photo ID
  - Social Security number or green card/work permit
  - Birth certificates for you and any children
  - Phone numbers for social services or women's shelter
  - The deed or lease to your home or apartment
  - Any court papers or orders
  - Prescription medications
  - A change of clothing for you and your children
  - Pay stubs, checkbook, credit cards, and cash
  - Health insurance cards
- If you need to leave a domestic violence situation immediately, turn to authorities for assistance in gathering this material.
- Develop a plan for leaving and rehearse it.
- Don't use phone cards; they leave a trail to follow.

Nurses need to remember that their role is that of a guide, not a savior. A woman will make the best decision she sees fit at that moment in time. A nurse may be her most effective resource in her stress-filled environment. Just allowing the woman to talk may be the most valuable intervention. The impact of the nurse's presence and support will stay with the woman, no matter what decision she makes.

SEXUAL VIOLENCE

Sexual violence exacerbates inequalities of gender, race or ethnicity, class, age, sexuality, ability status, citizenship status, and nationality. It is both a public health problem and a human rights violation. Sexual violence includes IPV, human trafficking, incest, FGC, forced prostitution, bondage, exploitation, neglect, infanticide, and sexual assault. It occurs worldwide and affects up to one third of women over a lifetime (Thompson, 2020). Every 73 seconds, an American is sexually assaulted. Once every 2 minutes, 30 times an hour, 1,871 times a day, girls and women in America are raped. One in six women and one in 33 men will be sexually assaulted during their lifetimes (RAINN, 2020b). Rape has been reported against females from ages 6 months to 93 years, and it remains one of the most underreported violent crimes in the United States. Nine out of 10 victims of rape are women (RAINN, 2020b). The National Center for Prevention and Control of Sexual Assault (2019) estimates that two thirds of sexual assaults will not be reported. Over the course of their lives, women may experience more than one type of violence.

Sexual violence can have a variety of devastating short- and long-term effects. Women can experience psychological, physical, and cognitive symptoms that affect them daily. They can include chronic pelvic pain, headaches, backache, STIs, pregnancy, anxiety, denial, fear, withdrawal, sleep disturbances, guilt, nervousness, phobias, substance abuse, depression, sexual dysfunction, and PTSD. Many contemplate suicide (CDC, 2019e). A traumatic experience not only damages a woman's sense of safety in the world, but it also has the potential to reduce her self-esteem and her ability to continue her education, to earn money and be productive, to have children, and if she has children, to nurture and protect them. Overall, sexually assaulted women may exhibit lower functioning as adults afterward based on structural alterations in brain regions (Berman et al., 2020).

TAKE NOTE!

Globally, up to 1 billion children under the age of 18 have experienced physical, sexual, or emotional violence or neglect in their lifetime (WHO, 2019). This can have a lifelong impact on their health and well-being.

Characteristics of Assailants

Assailants, like their victims, come from all backgrounds; there is no typical profile. More than half are under age 25, and the majority are married and leading “normal” sex lives. Why do men rape? No theory provides a satisfactory explanation. So few assailants are caught and convicted that a clear profile remains elusive. What is known is that many assailants have trouble dealing with the stresses of daily life. Such men become angry and experience feelings of powerlessness. They become jealous easily; do not view women as equals; frequently are hot tempered; have a need to be reassured of their manhood; and do not handle stress in their lives well. They commit a sexual assault as an expression of power and control (Gosselin, 2019).

Sexual Abuse

Sexual abuse occurs when a woman is forced to have sexual contact of any kind (vaginal, oral, or anal) without her consent. Current estimates indicate that one of five girls is sexually abused, and the peak ages of such abuse are from 8 to 12 years of age. Child sexual abuse is a silent epidemic. At every age in the lifespan, females are more likely to be sexually abused by a father, brother, family member, neighbor, boyfriend, husband, partner, or ex-partner than by a stranger or anonymous assailant. Sexual abuse knows no economic or cultural barriers. Many children after being abused will stay silent for decades, and some never tell (Lauren’s Kids Foundation, 2020). Marriage does not constitute a tacit agreement for a spouse to inflict one’s demands on the other without permission.

Childhood sexual abuse is any type of sexual exploitation that involves a child younger than 18 years old. It might include disrobing, nudity, masturbation, fondling, digital penetration, forced performance of sexual acts on the perpetrator, and intercourse. Estimates in the United States are devastating and stunning. It is surmised that nearly 42 million people are living with histories of

sexual abuse during childhood. Research indicates that one in four girls and one in six boys are likely to experience this type of abuse (Melmer & Gutovitz, 2019). Childhood sexual abuse has a lifelong impact on its survivors. There is strong evidence that sexual assault in childhood or adolescence is a serious risk factor for mental illness (Gosselin, 2019). Women who were sexually abused during childhood are at a heightened risk for repeat abuse. This is because the early abuse lowers their self-esteem and their ability to protect themselves and set firm boundaries. Childhood sexual abuse is a trauma that influences the way victims form relationships, deal with adversity, cope with daily problems, relate to their children and peers, protect their health, and live. See Evidence-Based Practice 9.2 for research regarding childhood maltreatment. Studies have shown that the more victimization an individual experiences, the more likely they will be revictimized later in life (Engel, 2019).

Interventions for sexually abused children or women should include referral for mental health counseling. Follow-up for any medical problems (e.g., genitourinary complaints) should be arranged with the victim's primary care physician. If the community has an abuse referral center, refer the victim there for follow-up care according to local protocol.

The medical consequences of sexual abuse require the prophylaxis and treatment of STIs, emergency contraception, and treatment of any injuries that resulted from the abuse. Victims with post-assault bleeding require an emergent evaluation and may need emergency treatment by a gynecologist for repair of genital injury. The psychosocial aspects of sexual abuse must also be addressed because appropriate therapeutic follow-up is essential to the victim's future emotional well-being.

Incest

Incest is defined as sexual activity between persons so closely related that marriage between them is legally or culturally prohibited (Gosselin, 2019). The exact incidence of childhood incest victimization is unknown. Such sexual abuse is not only a crime but

also a symptom of acute and irreversible family dysfunction. Childhood incest abuse involves any kind of sexual exploitation between a child and another person that violates the social taboos of family roles; children cannot yet understand these activities and cannot give informed consent. Adult women with a history of incest exhibit a clinical syndrome that includes low self-esteem, difficulty with intimate relationships, sexual dysfunction, flashbacks and nightmares, repeated victimization, suicidality, depressive symptomatology, eating disorders, and substance abuse (Garner, 2019). Survivors of incest are often tricked, coerced, or manipulated. All adults appear powerful to children. Perpetrators might threaten victims so that they are afraid to disclose the abuse or might tell them the abuse is their fault. Often these threats serve to silence victims.

EVIDENCE-BASED PRACTICE 9.2

Reexperiencing Violence across the Life Course: Histories of Childhood Maltreatment and Elder Abuse Victimization

This study addresses the associations between histories of childhood maltreatment (i.e., neglect, emotional, physical, and sexual abuse) and elder abuse victimization and explores whether gender affects the associations.

STUDY

The research was a secondary data analysis of 5,968 older adults (mean age was 71 years old). Using retrospective self-reports of childhood and current reports within the past year and victimization experiences, logistic regression analyses were conducted to estimate the effects of early life maltreatments on the likelihood of elder abuse victimization.

Findings

The results indicated that childhood emotional abuse and childhood sexual abuse were associated with a greater risk of being abused as older adults, after controlling for childhood and adult background factors. It was also found that the effect of childhood sexual abuse on elder abuse victimization was weaker for women than men.

Nursing Implications

Knowledge of this study's findings will assist the nurse in identifying adult clients that have been maltreated as children and are at increased risk of being revictimized as an adult. The findings suggest that the phenomenon of revictimization may occur not only in early and middle adulthood but also in later life.

Nurses should take a thorough history of each client's childhood to determine if any maltreatment occurred. With sexually abused adults, nurses have the opportunity to assist adult survivors. The most important aspect of working with survivors is a caring, reliable nurse who creates a therapeutic environment. Many empowerment support strategies can be used to help the survivor. Nurses must be knowledgeable of potential vulnerabilities of adults who have experienced maltreatment as a child and protect them.

Adapted from King, J., & Easton, S. D. (2018). Re-experiencing violence across the life course: Histories of childhood maltreatment and elder abuse victimization. Journals of Gerontology, Series B, gby035. https://doi.org/10.1093/geronb/gby035.

Incestuous relationships in the home endanger not only the child's intellectual and moral development, but also the health of the child. Many children do not ask for help because they do not want to expose the "secret." For this reason, just the tip of the iceberg is statistically visible: serious injuries, internal damage, STIs, or pregnancy. Incest can have serious long-term effects on its victims, which may include eating disorders, sexual problems in adult life, difficulty in interpersonal relationships, anxiety, PTSD, intense guilt and shame, low self-esteem, depression, and self-destructive behavior (National Center for Victims of Crime [NCVC], 2019a).

Whether an incest victim endured an isolated incident of abuse or ongoing assaults over an extended period, recovery can be painful and difficult. The recovery process begins with admission of abuse and the recognition that help and services are needed. Resources for incest victims include books, self-help groups, workshops, therapy programs, and possibly legal remedies. In addition to listening to and believing incest victims, nurses need to search for ways to prevent future generations from enduring such abuse and from continuing the cycle of abuse in their own family and relationships. Nurses have the ability and the responsibility to function within an interdisciplinary system responsible for the

assessment and ongoing treatment of incestuous families. Nurses can fulfill their roles as advocates for children while at the same time adding necessary referrals to social services and legal authorities. Forming this partnership with the social service and judicial communities will help protect the child from future abuse and ensure the child a safe environment in which to grow and develop.

TAKE NOTE!

Childhood sexual abuse is a trauma that can affect every aspect of the victim's life.

CONSIDER THIS

At 53 years old, I stood and looked at myself in the mirror. The image staring back at me was one of a frightened, middle-aged, cowardly woman hiding her past. I had been sexually abused by my father for many years as a child and never told anyone. My mother knew of the abuse but felt helpless to make it stop. I married right out of high school to escape and felt I lived a "happy normal life" with my husband and three children. My children have left home and live away, and my husband recently died of a sudden heart attack. I am now experiencing dreams and thoughts about my past abuse and feeling afraid again.

Thoughts: This woman suppressed her abusive past for most of her life and now her painful experience has surfaced. What can be done to reach out to her at this point? Did her health care providers miss the "red flags" that are common to women with a history of childhood sexual abuse all those years?

Rape

Rape is an expression of violence, not a sexual act. Rape distorts one of the most intimate forms of human interaction. It is not an act

of lust or an overzealous release of passion; it is a violent, aggressive assault on the victim's body and integrity. Those who rape do so for a number of reasons generally involving motives of anger, power, eroticized cruelty, dominance, and opportunistic mating (Shpancer, 2019). Rape is a legal rather than a medical term. It denotes penile penetration of the vagina, mouth, or rectum of the female or male without consent. It may or may not include the use of a weapon. **Statutory rape** is sexual activity between an adult and a person under the age of 18 and is considered to have occurred even if the underage person was willing because someone who is underage is not legally considered capable of giving consent (RAINN, 2020c). Nine out of every 10 rape victims are female (The Rape Crisis Center, 2019). Enforcement of laws, education, and community empowerment are all needed to prevent rape.

Many people believe rape occurs on a dark night when a stranger assaults a provocatively dressed, promiscuous woman. They believe rapists are sex-starved people seeking sexual gratification. These myths are destructive beliefs about sexual aggression (i.e., its scope, causes, context, and consequences) that serve to deny, downplay, or justify sexually aggressive behavior that men commit against women. A rape victim's recovery is frequently complicated by the public's failure to believe the victim and restore justice (Rape Recovery Center, 2020). These myths serve to blame victims and exonerate perpetrators. Such myths and the actual facts are presented in Table 9.3.

TABLE 9.3 Common Myths and Facts about Rape

Myths	Facts
Women who are raped get over it quickly.	It can take many years to recover emotionally and physically from rape.
Most rape victims tell someone about it.	The majority of women never tell anyone about it. In fact, almost two thirds of victims never report it to the police.
Once the rape is over, a survivor can again feel safe in her life.	The victim feels vulnerable, betrayed, and insecure afterward.
If a woman does not really want to be raped, it cannot happen.	A woman can be physically forced and overpowered by most men.
Women who feel guilty after having sex then lie and say they were raped.	Few women lie about rape. It is very traumatizing to be a victim, and coming forward with a rape allegation is often retraumatizing and detrimental to the victim's life.
Victims should report the violence to the police and judicial system.	Fewer than one in five sexual assaults result in an arrest and two thirds are never convicted if arrested (Statista Research Department, 2019). Additionally, legal proceedings are extensive and often traumatic for the victim.
Women blame themselves for the rape, believing they did something to provoke the rape.	Women should never blame themselves for being the victim of someone else's violence.
When it comes to sex, men can be aroused to "a point of no return."	Men are physically able to stop at any point during sexual activity. Rape is not an act of impulsive, uncontrolled passion; it is a premeditated act of violence. A woman has a right to end a sexual encounter at any moment.
Women who wear certain clothes, drink alcohol, or are sex workers are "asking for it."	No victim invites sexual assault regardless of her clothing, lifestyle choices, or decision to be a sex worker.

Women have rape fantasies and want to be raped.	Reality and fantasy are different. Rape is always an act of violence on the part of the perpetrator, not sexual expression.
Only attractive women are raped.	Anyone can be raped, and since rape is an act of violence, attractiveness is not a relevant factor.
Medication can help women forget about the rape.	Initially medication can help, but counseling is needed. Further, the goal for a survivor should be to learn how to cope and live a full life, not necessarily to forget the assault.

Acquaintance Rape

In **acquaintance rape**, someone is forced to have sex by a person they know. Rape by a coworker, a teacher, a husband's friend, or a boss is considered acquaintance rape. **Date rape**, an assault that occurs within a dating relationship or marriage without consent of one of the participants, is a form of acquaintance rape. Acquaintance and date rapes commonly occur on college campuses. Studies have shown that acquaintance rape is the most common type of rape, as it is estimated to make up 60% to 80% of all rapes (Wiemann & Miller, 2020). One in four college women has been raped, and it is estimated that more than 90% will not report assaults (Wiemann & Miller, 2020).

Acquaintance and date rape are physically and emotionally devastating for the victims. Research indicates that the survivors of acquaintance rape report similar levels of depression, anxiety, complications in subsequent relationships, and difficulty attaining

prerape levels of sexual satisfaction to those reported by survivors of stranger rape. Acquaintance rape remains a controversial topic because there is lack of agreement on the definition of consent. Despite the violation and reality of physical and emotional trauma, victims of acquaintance assault often do not identify their experience as sexual assault. Instead of focusing on the violation of the sexual assault, victims of acquaintance rape often blame themselves for the assault (RAINN, 2020d).

Although acquaintance rape and date rape do not always involve drugs, a rapist might use alcohol or other drugs to sedate his victim. In 1996, the federal government passed a law making it a felony to give an unsuspecting person a “date rape drug” with the intent of raping him or her. Even with penalties of large fines and up to 20 years in prison, the use of date rape drugs is growing (USDHHS, 2019a). Date rape drugs are also known as “club drugs” because they are often used at dance clubs, fraternity parties, and all-night raves. The most common is rohypnol (also known as “roofies,” “forget pills,” “mind erasers,” or the “drop drug”). It comes in the form of a liquid or pill that quickly dissolves in liquid with no odor, taste, or color. This drug is 10 times as strong as diazepam (Valium). The effects can be felt within 30 minutes and produces memory loss for up to 8 hours. Gamma hydroxybutyrate (GHB; called “liquid ecstasy” or “easy lay”) produces euphoria, an out-of-body high, sleepiness, increased sex drive, and memory loss. GHB takes effect in about 15 minutes and can last 3 to 4 hours. It comes in a white powder or liquid and may cause unconsciousness, depression, and coma. The third date rape drug, ketamine (known as “special K,” “vitamin K,” or “super acid”), acts on the central nervous system very quickly to separate perception and sensation. Combining ketamine with other drugs can be fatal (USDHHS, 2019a). Date rape drugs are dangerous, and while society must be taught their use is unacceptable, in the meantime, women can protect themselves against them in a variety of ways (Teaching Guidelines 9.2).

TEACHING GUIDELINES 9.2
Protecting Oneself against Date Rape Drugs

While society must work to shift to educate people not to harm each other, those who may be harmed must continue to be taught how to protect themselves. Tips to avoid getting drugged include:

- Avoid parties where alcohol is being served.
- Never leave a drink of any kind unattended.
- Don't accept a drink from someone else.
- Accept drinks from a bartender or in a closed container only.
- If a drink is left unattended, pour it out, and don't drink it.
- Don't drink anything that tastes or smells strange.
- Don't drink from a punch bowl or a keg.
- If you think someone drugged you, call 911.

Rape Recovery

Rape survivors take a long time to heal from their traumatic experiences. Some women never heal and never get professional counseling, but most develop ways to cope. Rape is viewed as a situational crisis that the survivor is unprepared to handle because it is an unforeseen event. Survivors typically go through four phases of recovery following rape (Table 9.4).

TABLE 9.4 Four Phases of Rape Recovery

Phase	Survivor's Response
Acute phase (disorganization)	Shock, fear, disbelief, anger, shame, guilt, feelings of uncleanliness, insomnia, nightmares, and sobbing
Outward adjustment phase (denial)	Appears outwardly composed and returns to work or school; refuses to discuss the assault and denies need for counseling
Reorganization	Denial and suppression do not work, and the survivor attempts to make life adjustments by moving or changing jobs, using emotional distancing to cope
Integration and recovery	Survivor begins to feel safe and starts to trust others; she may become an advocate for other rape victims

Help Guide Organization. (2019). *Recovering from rape and sexual trauma*. Retrieved October 2019, from https://www.helpguide.org/articles/ptsd-trauma/recovering-from-rape-and-sexual-trauma.htm/; International Association of Forensic Nurses. (2019). *SANE 365*. Retrieved June 16, 2020, from https://www.forensicnurses.org/page/SANE365

A significant proportion of women who are raped also experience symptoms of **post-traumatic stress disorder (PTSD)**. PTSD develops when an event outside the range of normal human experience occurs that produces marked distress in the person. Symptoms of PTSD are divided into four groups:

1. Intrusion (reexperiencing the trauma, including nightmares, flashbacks, recurrent thoughts)
2. Avoidance (avoiding trauma-related stimuli, social withdrawal, emotional numbing)
3. Hyperarousal (increased emotional arousal, exaggerated startle response, irritability)
4. Cognitive and mood symptoms (negative thoughts, excessive guilt, self-blame)

Not every victim of rape develops full-blown or even minor PTSD. Symptoms usually begin within 3 months of the incident but occasionally may only emerge years later. They must last more than a month to be considered PTSD. The condition varies from person to

person. Some women recover within months, while others have symptoms for much longer. In some people, the condition becomes chronic (National Center for PTSD, 2019a).

Nursing Management of Rape Victims

Health care providers, along with sexual assault nurse examiners (SANE), can make a difference in the lives of survivors by understanding the facts, the effects this violence can have on mental and physical health, where to find information for themselves and their clients, and how to properly care for a survivor. A SANE is a registered nurse specially trained to conduct sexual assault evidentiary examinations for rape victims. In addition to the collection of forensic evidence, they also provide access to crisis intervention, STI testing, and emergency contraception (International Association of Forensic Nurses, 2019).

Research has found that rape survivors undergo profound and complex trauma. Exposure therapy has been used to help victims confront their trauma-related memories, feelings, and stimuli that evoke fear and anxiety (National Center for PTSD, 2019b). The survivor should be provided with a safe and comfortable environment for a forensic examination. Nursing care of the rape survivor should focus on providing supportive care, collecting and documenting evidence, assessing for STIs, preventing pregnancy, and assessing for PTSD. Once initial treatment and evidence collection have been completed, follow-up care should include counseling, medical treatment, and crisis intervention. There is mounting evidence that early intervention and immediate counseling can accelerate a rape survivor's recovery. Early intervention means implementation in the initial hours, days, or weeks after the traumatic event (Thompson, 2020). Nursing Care Plan 9.1 highlights a sample plan of care for a victim of rape.

TAKE NOTE!

Many rape survivors seek treatment in the hospital emergency department if no rape crisis center is available. Unfortunately, many emergency department doctors and nurses have little training in how to treat rape survivors or in collecting evidence. To make matters worse, if survivors have to wait for hours in public waiting rooms, they may leave the hospital, never receiving treatment or supplying the evidence needed to arrest and convict their assailants if they decide to take legal action.

PROVIDING SUPPORTIVE CARE

Establishing a therapeutic and trusting relationship will help the survivor describe her experience. Take the woman to a secure, isolated area away from family, friends, and other clients and staff so she can be open and honest when asked about the assault. Provide a change of clothes, access to a shower and toiletries, and a private waiting area for family and friends.

COLLECTING AND DOCUMENTING EVIDENCE

The victim should be instructed to bring all clothing, especially undergarments, worn at the time of the assault to the medical facility. The victim should not shower or bathe before presenting for care. Typically, a SANE will collect the evidence from the victim.

ASSESSING FOR SEXUALLY TRANSMITTED INFECTIONS

As part of the assessment, a pelvic examination will be done to collect vaginal secretions to rule out any STIs. This examination can be emotionally stressful for many women and should be carried out gently and sensitively, explaining every step of the process to minimize further emotional trauma.

PREVENTING PREGNANCY

An essential element in the care of rape survivors involves offering them pregnancy prevention. After unprotected intercourse, including rape, pregnancy can be prevented by using an emergency contraceptive pill, sometimes called postcoital contraception or the “morning-after pill.” Emergency contraceptive pills involve high doses of the same oral contraceptives that millions of women take every day. The emergency regimen consists of one dose taken within 72 to 120 hours of the unprotected intercourse. Emergency contraception works by preventing ovulation, fertilization, or implantation. It does not disrupt an established pregnancy and should not be confused with mifepristone (RU-486), a drug approved by the Food and Drug Administration for abortion in the first 49 days’ gestation. Emergency contraception is most effective if it is taken within 12 hours of the rape; it becomes less effective with every 12 hours of delay thereafter.

NURSING CARE PLAN 9.1 Overview of the Woman Who Is a Victim of Rape

Lucy, a 20-year-old college junior, was admitted to the emergency room after police found her when a passerby called 911 to report an assault. She stated, "I was raped at a fraternity party a few hours ago. The stranger found me when I was walking back to my dorm room." Assessment reveals the following: numerous cuts and bruises of varying sizes on her face, arms, and legs; lip swollen and cut; right eye swollen and bruised; jacket and shirt ripped and bloodied; hair matted with grass and debris; vital signs within acceptable parameters; client tearful, clutching her clothing, and trembling; perineal bruising and tearing.

NURSING ANALYSIS: Acute psychological trauma related to recent sexual assault

OUTCOME IDENTIFICATION AND EVALUATION

Client will demonstrate adequate coping skills related to effects of rape as evidenced by her ability to discuss the event, verbalize her feelings and fears, and exhibit appropriate actions to return to her precrisis level of functioning.

INTERVENTIONS: *Promoting Adequate Coping Skills*

- Stay with the client *to promote feelings of safety*.
- Explain the procedures to be completed based on facility's policy *to help alleviate client's fear of the unknown*.
- Assist with physical examination for specimen collection *to obtain evidence for legal proceedings*.
- Administer prophylactic medication as ordered *to prevent pregnancy and STIs*.
- Provide care to wounds as ordered *to prevent infection*.
- Assist client with hygiene measures as necessary *to promote self-esteem*.
- Allow client to describe the events as much as possible *to encourage ventilation of feelings about the incident*; engage in active listening and offer nonjudgmental support *to facilitate coping and demonstrate understanding of the client's situation and feelings*.
- Help the client identify positive coping skills and personal strengths used in the past *to aid in effective decision-making*.
- Assist client in developing additional coping strategies and teach client relaxation techniques *to help deal with the current crisis and anxiety*.
- Contact the rape counselor in the facility *to help the client deal with the crisis*.

- Arrange for follow-up visit with rape counselor *to provide continued care and to promote continuity of care*.
- Encourage the client to contact a close friend, partner, or family member *to accompany her home to provide support*.
- Provide the client with the telephone number of a counseling service or community support groups *to help her cope and obtain ongoing support*.
- Provide written instructions related to follow-up appointments, care, and testing *to ensure adequate understanding*.

ASSESSING FOR POST-TRAUMATIC STRESS DISORDER

Nurses can begin to assess the extent to which a survivor is suffering from PTSD by asking the following questions:

- To assess the presence of intrusive thoughts:
  - Do upsetting thoughts and nightmares of the trauma bother you?
  - Do you feel as though you are actually reliving the trauma?
  - Does it upset you to be exposed to anything that reminds you of that event?
- To assess the presence of avoidance reactions:
  - Do you find yourself trying to avoid thinking about the trauma?
  - Do you stay away from situations that remind you of the event?
  - Do you have trouble recalling exactly what happened?
  - Do you feel emotionally numb?
- To assess the presence of physical symptoms:
  - Are you having trouble sleeping?
  - Have you been experiencing extreme tension and anxiety?
  - Do you have memory trouble?
  - Have you felt irritable or experienced outbursts of anger?
  - Do you have heart palpitations and sweating?
  - Do you have muscle aches and pains all over? (NCVC, 2019b)

With a growing body of knowledge about rape-related PTSD, help is available through most rape crisis and trauma centers. Support groups have been established where survivors can meet regularly to share experiences to help relieve the symptoms of PTSD. For some survivors, medication prescribed along with therapy is the best combination to relieve the pain. Just as in the treatment of any other

illness, at the first opportunity, the woman should be encouraged to talk about the traumatic experience. This provides a chance to receive needed support and comfort, as well as an opportunity to begin processing the experience. To diminish symptoms of PTSD, survivors must work to come to terms with the past and alleviate stress in the present (Gore, 2019).

In order to have a better understanding of the aftermath of criminal victimization such as sexual assault, nurses must begin to accept the reality that crime is random, senseless, and can happen to anyone regardless of the precautions that are taken to prevent it. Nurses must also understand that a victim's life is turned upside down when they become a victim of crime. In order to help victims trust society again and regain a sense of balance and self-worth, nurses must educate all those who come in contact with victims and survivors to be sensitive to their needs.

Female Genital Cutting

Violence affects women and girls throughout the world and crosses cultural and economic boundaries. One major indicator of gender inequality is **female genital cutting (FGC)**, sometimes called female genital mutilation (FGM) or female circumcision. This is often correlated with child marriage, forced sexual experience, and health complications throughout the lifespan. FGC involves any injury of the external female genitalia for cultural or nontherapeutic reasons. It confers severe health consequences for girls and women. The international community views this practice as a human rights violation and is considered an extreme form of discrimination against women (ACOG, 2019). The category of FGC is determined by the surgical removal of the portion or portions of the genitalia of female infants, girls, and women: the clitoris (type I); the clitoris and labia minora (type II); and the clitoris, labia minora, labia majora, and then suturing of the remaining tissue, known as fibulation, to leave only a small opening for urination, menstruation, intercourse, and childbirth (type III). Type IV encompasses all other mutilations of the female genital area such as pricking, piercing, cutting, cauterizing, and

scraping of the vaginal tissue; incisions to the clitoris and vagina; and burning, scarring, or cauterizing of tissue with the aim of tightening or narrowing the vagina (Orchid Project Organization, 2020).

FGC is a worldwide practice that affects millions of women and girls. According to the WHO (2020c) and UNICEF (2020), 200 million women are victims of FGC with about 130 million girls between infancy and age 15 undergoing FGC every year. Countries where this is practiced include 30 African countries and parts of the Middle East and Asia. Prevalence in countries such as Sudan and Egypt has been estimated to be as high as 99% (Atkinson et al., 2019). The exact origins of FGC are not known. Although FGC may be interwoven into the culture, it is not mandated by any religion. This practice predates both Islam and Christianity (The World Bank, 2019). In some cultures, it is associated with feminine beauty and often signifies a rite of passage from childhood to adulthood. FGC is performed to decrease a woman's sexual desires and to ensure her chastity until marriage and receipt of a dowry from the prospective groom (Clark, 2018). Ultimately, the reality of being ostracized by the community and the possibility of being ineligible to marry create enormous social pressure to have FGC performed, pressure that exceeds the physical and emotional damage of this practice (NSPCC, 2020).

Notable complications include physical, psychological, social, and sexual harms to women who undergo this procedure. Complications vary, depending on the type of cutting and the way it was performed. It is frequently performed without anesthesia under nonsterile conditions. Cutting tools can be anything from razor blades to knives to pieces of glass or tin can lids. Complications can include infertility, dysmenorrhea, dyspareunia, sexual dysfunction, infection, hemorrhage after the procedure, vaginal stenosis, chronic vaginitis, pelvic inflammatory disease, chronic urinary tract infections, incontinence, genital fistulas, recurrent abscesses, transmission of HIV and hepatitis during the procedure, severe pain and shock after the procedure, difficulty walking or using stairs due to severe scarring, urinary retention, inability to experience orgasm, and

difficulty in giving birth. Long-term complications related to FGC include chronic pain, dyspareunia, and difficult childbirth. The most common long-term complication is the formation of inclusion clitoral dermoid cysts and labial fusion. These can become as large as a grapefruit and can lead to difficulty in walking and sitting, sometimes causing psychological distress from the deformity. The psychological effects range from eating disorders, neuroses, insomnia, anxiety, flashbacks, depression, PTSD, and negative effects on the women's self-esteem and identity (Ziegler & Reeves, 2020).

As immigration to the United States increases, nurses are increasingly likely to encounter women affected by FGC and its complications. The psychological pressure and trauma of being torn between two cultures and feeling different may lie heavily on the women in a new setting where FGC is foreign and banned. Nurses need updated education regarding women with FGC so that appropriate care for this population can be provided for this very sensitive health care problem. Well-informed nurses represent the best opportunity to provide culturally sensitive care to this population. Nurses are in a unique position to contact and educate women who have been cut or are at risk for mutilation. To advocate for these women, a thorough understanding of the practice of FGC, its cultural significance, religious implications, and psychosocial effects is needed.

TAKE NOTE!

From a Western perspective, FGC is hard to comprehend. Because it is not talked about openly in communities that practice it, women who have undergone it accept it without question and assume it is done to all girls (Griffin & Jordal, 2019).

BOX 9.5 Four Major Types of Female Genital Mutilation Procedures

- *Type I:* Excision of the prepuce with excision of part or the entire clitoris
- *Type II:* Excision of the clitoris and part or all of the labia minora
- *Type III (Infibulation):* Excision of all or part of the external genitalia and stitching/narrowing of the vaginal opening
- *Type IV:* Pricking, piercing, or incision of the clitoris or labia
- Stretching of the clitoris and/or labia
- Cauterizing by burning the clitoris and surrounding tissues
- Scraping or cutting the vaginal orifice
- Introduction of a corrosive substance into the vagina
- Placing herbs into the vagina to narrow it

Background

Reasons for performing the ritual reflect the ideology and cultural values of each community that practices it. Some consider it a rite of passage into womanhood; others use it as a means of preserving virginity until marriage. In cultures where it is practiced, it is an important part of culturally defined gender identity. In any case, all the reasons are cultural and traditional and are not rooted in any religious texts (WHO, 2020c). Since FGC has no health benefits and often leaves women with lifelong physical and emotional trauma, there is a human rights justification to end the practice. International pressure to end FGC has been mounting since 1997, when the WHO, UNICEF, and UNFPA issued a joint statement to call on governments to ban the practice (USAID, 2020). Box 9.5 lists types of FGC procedures.

Nursing Management of the Client with Female Genital Cutting

Because of increasing migration, nurses throughout the world are increasingly exposed to women who have experienced these procedures, and thus they need to know about its impact on women's reproductive health. Helping women who have had an FGC procedure requires good communication skills and often an interpreter, since many may not speak the nurse's language. As nurses, we are educated to provide comprehensive, culturally sensitive care regardless of our client's circumstances. Nurses must keep in mind that FGC is considered normal in many cultures and to not have it done would be unthinkable. Nurses have the opportunity to educate clients by providing accurate information and positive health care experiences. Make sure that you are comfortable with and aware of your own feelings about this practice before dealing with clients. Some guidelines include:

- Let the client know you are concerned and interested and want to help.
- Speak clearly and slowly, using simple, accurate terms.
- Use the term or name for this practice that the recipient uses, not "female genital cutting" or "mutilation."
- Use pictures and diagrams to help the woman understand what you are saying.
- Be patient in allowing the client to answer questions.
- Include male family members in any education, as they are influential in this practice.
- Repeat back your understanding of the client's statements.
- Always look and talk directly to the client, not the interpreter.
- Place no judgment on the cultural practice.
- Maintain respect for older women who have experienced FGC.
- Encourage the client to express herself freely.
- Maintain strict confidentiality.
- Provide culturally attuned care to all women.

In short, FGC is a form of violence against women, and it is only through education and empowerment of women that real changes in this practice can be made. Because this practice often defines a woman and becomes a part of her identity, nurses must understand this to be able to assist women who have had this done to them.

Nurses are in a unique position to contact and educate women who have been cut or are at risk for mutilation. To advocate for these women, a nurse must have a thorough understanding of this practice, its cultural significance, physical implications, and psychosexual effects. Only through intense education will the next generation of girls be saved from this practice.

Human Trafficking

The United Nations defines **human trafficking** as the recruitment, transportation, transfer, harboring, or receipt of persons by means of the threat or use of force, abduction, fraud, or deception to achieve the consent of a person having control over another person for the purpose of exploitation (United Nations Office on Drugs and Crime [UNODC], 2020). Human trafficking is a global phenomenon to which no country is immune. Modern slavery is a human rights abuse of our own making. Ending it is a choice the world has to make.

In the United States, forced labor is predominantly found in these sectors:

- Prostitution and sex industry (46%)
- Domestic servitude (27%)
- Agriculture (10%)
- Sweatshops and factories (5%)
- Restaurant and hotel work (4%) (Global Slavery Index, 2019)

A girl who was just 14 years old was held captive in a tiny trailer room, where she was forced to have sex with as many as 30 men a day. On her nightstand was a teddy bear that reminded her of her childhood in Mexico from where she was abducted and forced into sexual slavery. Human trafficking responds to and is driven by demand, and this demand persists at the expense of many vulnerable women and girls.

This scenario describes human trafficking, the enslavement of humans for profit in America. Within our borders, thousands of foreign nationals and U.S. citizens, many of them children, are forced or coerced into sex work or various forms of labor every year

(Polaris Project Organization, 2020a). Human trafficking is both a global problem and a domestic problem. The United States is a major receiver of trafficked persons. It wasn't made illegal in the United States until 2000. Human trafficking is a modern form of slavery that affects nearly 40.3 million people worldwide and approximately 50,000 individuals in the United States annually (U.S. Department of State, 2019). Women and children are the primary victims of human trafficking, many in the sex trade and others through forced-labor domestic servitude. Poverty and lack of economic opportunity make women and children potential victims of traffickers associated with international criminal organizations. They are vulnerable to false promises of job opportunities in other countries. Many of those who accept these offers from what appear to be legitimate sources find themselves in situations where their documents are destroyed, they or their families threatened with harm, or they are bonded by a debt that they have no way of repaying.

Trafficking persons is hugely profitable: one estimate places global profits at approximately $150 billion annually. Among illegal enterprises, trafficking is second only to drug dealing and is tied with the illegal arms industry in its ability to generate money (Polaris Project Organization 2020b).

The United States is a profitable destination country for traffickers, and these profits contribute to the development of organized criminal enterprises worldwide. According to findings of the Victims of Trafficking and Violence Protection Act of 2000 (NCSL, 2020):

- Victims are primarily women and children who lack education, employment, and economic opportunities in their own countries.
- Traffickers promise victims employment as nannies, maids, dancers, factory workers, sales clerks, or models in the United States.
- Traffickers transport the victims from their counties to unfamiliar destinations away from their support systems.
- Once they are in the United States, traffickers coerce victims, using rape, torture, starvation, imprisonment, threats, or physical force,

into prostitution, pornography, the sex trade, forced labor, or involuntary servitude.

Victims of human trafficking are exposed to serious and numerous health risks such as rape; physical injury such as cigarette burns, fractures, and bruises; tuberculosis; pregnancy; torture; HIV/AIDS; STIs; cervical cancer; violence; hazardous work environments; malnourishment; and drug and alcohol addiction (Even, 2019). Health care is one of the most pressing needs of these victims, but no comprehensive care is available to undocumented immigrants. Nurses and other health care providers who encounter victims of trafficking often do not realize they are being trafficked, and opportunities to intervene are lost. Although no one sign can demonstrate with certainty when someone is being trafficked, clinicians should be aware of certain indicators. It is important to be alert for trafficking victims in any setting and to recognize cues (Box 9.6).

Nursing interventions in the care of trafficking victims include:

- Building trust as the top priority
- Knowing the at-risk groups for trafficking in the community

BOX 9.6 Identifying Victims of Human Trafficking

Look beneath the surface and ask yourself: Is this person…

- A female or a child in poor health?
- Foreign-born and doesn't speak English?
- Lacking immigration documents?
- Acting fearful, anxious, depressed, submissive, and/or tense?
- Avoiding eye contact?
- Refusing to change into a gown and/or cooperate with a physical exam?
- Giving an inconsistent explanation of injury?
- Exhibiting behavior that doesn't align with injury or complaint?
- Refusing treatment that takes place during a follow-up appointment?
- Reluctant to give any information about self, injury, home, or work?
- Fearful of authority figure or "sponsor" if present? ("Sponsor" might not leave victim alone with health care provider.)
- Living with the employer?

Sample questions to ask the potential victim of human trafficking:

- Can you leave your job or situation if you wish?
- Can you come and go as you please?
- Have you been threatened if you try to leave?
- Has anyone threatened your family with harm if you leave?
- What are your working and living conditions?
- Do you have to ask permission to go to the bathroom, eat, or sleep?
- Is there a lock on your door so you cannot get out?
- What brought you to the United States? Is your situation now in line with those plans?
- Are you free to leave your current work or home situation?
- Who has your immigration papers? Why don't you have them?
- Are you paid for the work you do?
- Are there times you feel afraid?
- How can your situation be changed?

United Nations Office on Drugs and Crime (UNODC). (2019). *Human trafficking*. Identifying human trafficking victims among your patients. *Joint Commission Organization.* Retrieved June 16, 2020, from https://www.jointcommission.org/dateline_tjc/identifying_human_trafficking_victims_among_your_patients/.

- Observing the relationship between the client and accompanying person
- Taking the time to listen and develop a rapport

- Screening in a private place to ensure confidentiality and safety
- Reassuring the potential victim
- Providing one-on-one interactions
- Thoroughly examining all injuries, even if they seem unintentional
- Assessing hydration, nutrition, and hygiene
- Not relying on the client's interpreter if English isn't spoken
- Specifically asking about the client's safety
- Offering paraphrased stories to clarify and therapeutically reflect the client's statements
- Staying calm and on an even keel
- Understanding the risk these victims are taking by disclosing their plight
- Documenting your suspicion in your notes
- Calling the human trafficking hotline for guidance at 1-866-US-TIPLINE

Human trafficking is a violation of human rights. Few crimes are more repugnant than the sex trafficking of vulnerable people. Nurses are one of the few groups of professionals likely to interact with trafficked victims while they are still in captivity. They have the opportunity to screen, identify, intervene, and rescue these victims. Nurses are well positioned to identify and assist trafficked individuals as well as those who may be at risk for exploitation. If you suspect a trafficking situation, notify local law enforcement and a regional social service organization that has experience in dealing with trafficking victims. It is imperative to reach out to these victims and stop the cycle of abuse by following through on your suspicions. Nurses can also reach out within their communities to bring about awareness through community education to human trafficking to uncover the hard truth about it to our nation's blind eyes.

Across the world, in communities both large and small, individual stories of suffering and injustice make up the ugly mosaic of human trafficking. No matter the impetus, nurses are not defenseless in the fight of human trafficking. Rather, they are a powerful part of the solution.

SUMMARY

The causes of violence against women are complex. Previously, violence against women was largely invisible, considered natural and trivial. Many laughed at the notion that intimate or community violence against women should be seen as a human rights violation. Raising awareness and developing evidence-based programs, practices, and policies to prevent IPV and sexual assault are essential in stopping violent behavior before it starts. Many women will experience some type of violence in their lives, and it can have a debilitating effect on their health and future relationships. Nurses have the skills, professional experience, and perspective to be an important part of comprehensive violence prevention efforts in communities. Violence is a preventable public health problem if multiple sectors understand patterns of violence and implement prevention strategies to reduce it (WHO, 2020a).

Violence frequently leaves a legacy of pain to future generations. Nurses can empower women and encourage them to move forward and take control of their lives. When women live in peace and security, free from violence, they have an enormous potential to contribute to their own communities and to the national and global society. Nurses can play an important role in working toward the creation of a violence-free community, but they must first become informed. Nurses must insist that health care agencies that employ them accept this responsibility and work together to reach out to those being abused. The time is ripe for nurses to act and ensure serious inroads are made in improving the health and well-being of all women across the world.

Violence against women is not normal, legal, or acceptable, and it should never be tolerated or justified. It can and must be stopped by the entire world community. Early education and prevention provide the best hope for creating healthy futures and fostering a global society without violence. As a global society, nurses have the opportunity and responsibility to address violence to effectively intervene within families, schools, and communities to inject resiliency, help, and healing.

KEY CONCEPTS

- Violence against women is a major public health and social problem because it violates a woman's human rights and causes numerous mental and physical health sequelae.
- Every woman has the potential to become a victim of violence.
- There are *Healthy People 2030* objectives that focus on reducing the rate of physical assaults and the number of rapes and attempted rapes.
- Abuse may be mental, physical, or sexual in nature, or it may be a combination of all of these.
- The cycle of violence includes three phases: tension building, physically abusive, and honeymoon.
- Pregnancy can precipitate violence toward the woman or escalate it.
- Many women experience PTSD after being sexually assaulted. PTSD can inhibit a survivor from adapting or coping in a healthy manner.
- FGC is practiced worldwide, and nurses in the United States need to become knowledgeable about it and place no judgment on this cultural practice.
- Human trafficking is a violation against human rights, and nurses who suspect it should report it to stop the cycle of abuse against young children and women.
- The nurse's role in dealing with survivors of violence is to establish rapport; open up lines of communication; apply the nursing process to assess and screen all clients in all settings; and implement and intervene as appropriate.

Unfolding Patient Stories: Brenda Patton • Part 1

Brenda Patton is 18 years old and pregnant with her first child. When her live-in boyfriend accompanies her to a prenatal visit, the nurse notices that Brenda seems nervous around him. Brenda also has some bruises on her arm. Explain what the nurse should do if she suspects intimate partner violence. What counseling and resource information should the nurse provide to Brenda in this situation? (Brenda Patton's story continues in Chapter 10.)

Care for Brenda and other patients in a realistic virtual environment: vSim for Nursing (**thepoint.lww.com/vSimMaternity**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. The primary goal of intervention in working with abused women is to
   a. set up an appointment with a mental health counselor for the victim.
   b. convince them to set up safety plans to use when they leave.
   c. help them develop courage and financial support to leave their abusers.
   d. empower them and improve their self-esteem to regain control of their lives.

2. The first phase of the abuse cycle is characterized by
   a. the woman provoking the abuser to bring about abuse.
   b. tension building and verbal or minor battery.
   c. a honeymoon period that lulls the victim into forgetting.
   d. an acute episode of physical abuse.

3. Women recovering from abusive relationships need to learn ways to improve their
   a. educational levels by getting college degrees.
   b. earning power so they can move to better neighborhoods.
   c. self-esteem and communication skills to increase assertiveness.
   d. relationship skills so they will be better prepared to deal with their partners.

4. Which statement might empower abuse victims to take action?

a. “You don’t deserve to be treated this way.”
b. “Your children deserve to grow up in a two-parent family.”
c. “Try to figure out what you do to trigger his abuse and stop it.”
d. “Give your partner more time to come to his senses about this.”

5. If a woman thinks she is being stalked when driving, a good safety measure is to

a. drive to a local police or fire department.
b. take shortcuts through back streets to lose the stalker.
c. wave a handgun to intimidate the stalker.
d. roll down the window and confront the stalker.

6. Nurses play an important role in screening and assessment of any client abuse or violence. Which statement is correct?

a. Most clients are extremely reluctant to come forth with private matters.
b. Any intimate partner violence questions should be asked in the presence of both partners.
c. To invite disclosure, assure the woman that you won’t document her statements.
d. The best statement to make to the abused victim is, “You don’t deserve this.”

7. What should the nurse do if a victim of intimate partner violence chooses not to disclose information about her abusive relationship during the interview?

a. Confront the victim with the physical evidence and telltale signs of abuse.
b. Contact family members to tell you about the abusive relationship.
c. Call the local police department to inquire about domestic disturbance calls.

d. Respect the client's right of self-determination and provide her with resources.

8. Which client behavior would raise a "red flag" to the nurse that the client may be a human trafficking victim?

a. Looks nurse straight in the eyes when responding to questions
b. Appears calm and cooperative during examination
c. Acts like it is "no big deal," even with concerning injuries
d. Changes into examination gown quickly without hesitation

CRITICAL THINKING EXERCISES

1. Mrs. Bennett has three children under the age of 5 and is 6 months pregnant with her fourth child. She has made repeated unscheduled visits to your clinic with vague somatic complaints regarding the children as well as herself but has missed several scheduled prenatal appointments. On occasion, she has worn sunglasses to cover bruises around her eyes. As a nurse, you sense there is something else bothering her, but she doesn't seem to want to discuss it with you. She appears sad and the children cling to her.

a. Outline your conversation when you broach the subject of abuse with this client.
b. What is your role as a nurse in caring for a family in which you suspect abuse is occurring?
c. What ethical and legal considerations are important in planning care for this family?

STUDY ACTIVITIES

1. Visit the National Domestic Violence Hotline website for victims of violence. Discuss what you discovered on this site and your reactions to it.

2. Research the statistics about violence against women in your state. Are law enforcement and community interventions reducing the incidence of sexual assault and intimate partner violence?
3. Attend a dorm orientation at a local college to hear about measures in place to protect women's safety on campus. Find out the number of sexual assaults reported and what strategies the college uses to reduce this number.
4. Volunteer to spend a weekend evening at the local sheriff's department 911 hotline desk to observe the number and nature of calls received reporting intimate partner violence. Interview the dispatch operator about the frequency and trends of these calls.
5. Identify three community resources that could be useful to a victim of violence. Identify their sources of funding and the services they provide.

BRINGING IT ALL TOGETHER: A CASE STUDY

A 23-year-old pregnant female presents to the public health maternity clinic for the third time in a month with many vague complaints including insomnia, diffuse body aches and pains, poor appetite, fatigue, and constipation. This is her first pregnancy, and it was unplanned. Her recent OB examination findings and laboratory survey are within normal limits. Her past medical history is remarkable for anxiety and depression. According to the client, she does not drink or smoke. She does not work outside of the home.

ASSESSMENT

On physical examination, the nurse notes a well-dressed, pleasant, but anxious young female. Her husband of a year usually accompanies her to the office visits but is absent today. She tends to avoid eye contact with the nurse when asked questions about her symptoms. Her vital signs and fetal heart rate are all within the normal range. On further examination, the nurse notices several bruises on her upper

arms and thighs. When questioned about these marks, the client looks away.

Go to thePoint to find questions to consider about this case.

Fetal Development and Genetics

WOW

WORDS OF WISDOM

Being a nurse without awe is like food without spice. Nurses only have to witness the miracle of life to find their lost awe.

KEY TERMS

allele
blastocyst
embryonic stage
fertilization
fetal stage
genes
genetic counseling
genetics
genome
genomics
genotype
heterozygous
homozygous
karyotype
morula
mosaicism
mutation
phenotype
placenta
teratogen
trisomy
trophoblast
umbilical cord
zona pellucida
zygote

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Characterize the process of fertilization, implantation, and cell differentiation.

2. Examine the functions of the placenta, umbilical cord, and amniotic fluid.
3. Outline normal fetal development from conception through birth.
4. Compare the various inheritance patterns, including nontraditional patterns of inheritance.
5. Analyze examples of ethical and legal issues surrounding genetic testing.
6. Research the role of the nurse in genetic counseling and genetic-related activities.

Robert and **Kate Shafer**, have just received the good news that Kate's pregnancy test is positive. It had been a long and anxious 3 years of trying to start a family. Although both are elated about the prospect of becoming parents, they are concerned about the possibility of a genetic problem because Kate is 38 years old. What might be their first step in looking into their genetic concern? As a nurse, what might raise concerns for you?

INTRODUCTION

Human reproduction is one of the most intimate spheres of an individual's life. Pregnancy is a dynamic and precisely coordinated process involving systemic and local changes that will support the fetus for growth in utero and in subsequent lactation. For conception to occur, a healthy ovum from the woman is released from the ovary, passes into an open fallopian tube, and starts its journey downward. Sperm from the male is deposited into the vagina and swims approximately 7 in to meet the ovum at the outermost portion of the fallopian tube, the area where fertilization takes place. This process occurs in about an hour (Webster et al., 2018). When one spermatozoon penetrates the ovum's thick outer membrane, pregnancy begins. All this activity takes place within a 5-hour time span.

Nurses caring for the childbearing family need to have a basic understanding of conception and prenatal development so they can identify problems or variations and can initiate appropriate interventions should any problems occur. This chapter presents an overview of fetal development, beginning with conception. It also discusses hereditary influences on fetal development and the nurse's role in genetic counseling.

FETAL DEVELOPMENT

Fetal development during pregnancy is measured in number of weeks after fertilization. The duration of pregnancy is about 40 weeks from the time of fertilization. This equates to nine calendar months or approximately 266 to 280 calendar days. The stages of human development during pregnancy are:

1. Zygotic stage: fertilization of sperm and egg through the second week.
2. Blastocyst stage: Zygote divides into a solid ball of cells which attaches to the uterus.
3. Embryonic stage: Major organs and structures begin to emerge by end of the second week through the eighth week.
4. Fetal stage: Differentiation and structures specialize by end of the eighth week until birth.

Fetal circulation is a significant aspect of fetal development that spans all three stages.

Zygotic Stage

The zygotic stage begins with fertilization, also called *conception.* **Fertilization** is the fusing of ovum and sperm, which is the starting point of pregnancy. Fertilization typically occurs around 2 weeks after the last normal menstrual period in a 28-day cycle (Jordan et al., 2019).

Fertilization requires a timely interaction between the release of the mature ovum at ovulation and the ejaculation of enough healthy,

mobile sperm to survive the hostile vaginal environment through which they must travel to meet the ovum. All things considered; the act of conception is difficult at best. To say merely that it occurs when the sperm unites with the ovum is overly simple because this union requires an intricate interplay of hormonal preparation and overcoming an overwhelming number of natural barriers. A human being is truly an amazing outcome of this elaborate process.

Prior to fertilization, the ovum and the spermatozoon undergo the process of meiosis. The primary oocyte completes its first meiotic division before ovulation. The secondary oocyte begins its second meiotic division just before ovulation. Primary and secondary spermatocytes undergo meiotic division while still in the testes (Fig. 10.1).

Although more than 200 million sperm/mL are contained in the ejaculated semen, only one is able to enter the ovum to fertilize it. All others are blocked by the clear protein layer called the **zona pellucida**. The zona pellucida disappears in about 5 days. Once the sperm reaches the plasma membrane, the ovum resumes meiosis and forms a nucleus with half the number of chromosomes (23). When the nucleus from the ovum and the nucleus of the sperm make contact, they lose their respective nuclear membranes and combine their maternal and paternal chromosomes. Because each nucleus contains a haploid number of chromosomes (23), this union restores the diploid number (46). The resulting zygote begins the process of a new life. The genetic information from both ovum and sperm establishes the unique physical characteristics of the individual. Sex determination is also determined at fertilization and depends on whether the ovum is fertilized by a Y-bearing sperm or an X-bearing sperm. Approximately half of sperm carry the XX chromosome and the other half carries XY. An XX zygote will become a female and an XY zygote will become a male (Fig. 10.2). That is why it is scientifically correct to say that the sex of the infant is determined by the father and not by the mother.

Fertilization takes place in the outer third of the ampulla of the fallopian tube. When the ovum is fertilized by the sperm (now called a **zygote**), a great deal of activity immediately takes place. Mitosis,

or *cleavage,* occurs as the zygote is slowly transported into the uterine cavity by tubal muscular movements (Fig. 10.3). After a series of four cleavages, the 16 cells appear as a solid ball of cells, or **morula**, meaning “little mulberry.” The morula reaches the uterine cavity about 72 hours after fertilization. As fluid, which provides nutrients, from the uterine cavity enters the morula, the blastocyst is formed (Blackburn, 2018).

Blastocyst Stage

With additional cell division, the morula divides into specialized cells that will later form fetal structures. Within the morula, an off-center, fluid-filled space appears, transforming it into a hollow ball of cells called a blastocyst (Fig. 10.4). The inner surface of the blastocyst will form the embryo and amnion. The outer layer of cells surrounding the blastocyst cavity is called a **trophoblast**. Eventually, the trophoblast develops into one of the embryonic membranes, the chorion, and helps to form the placenta.

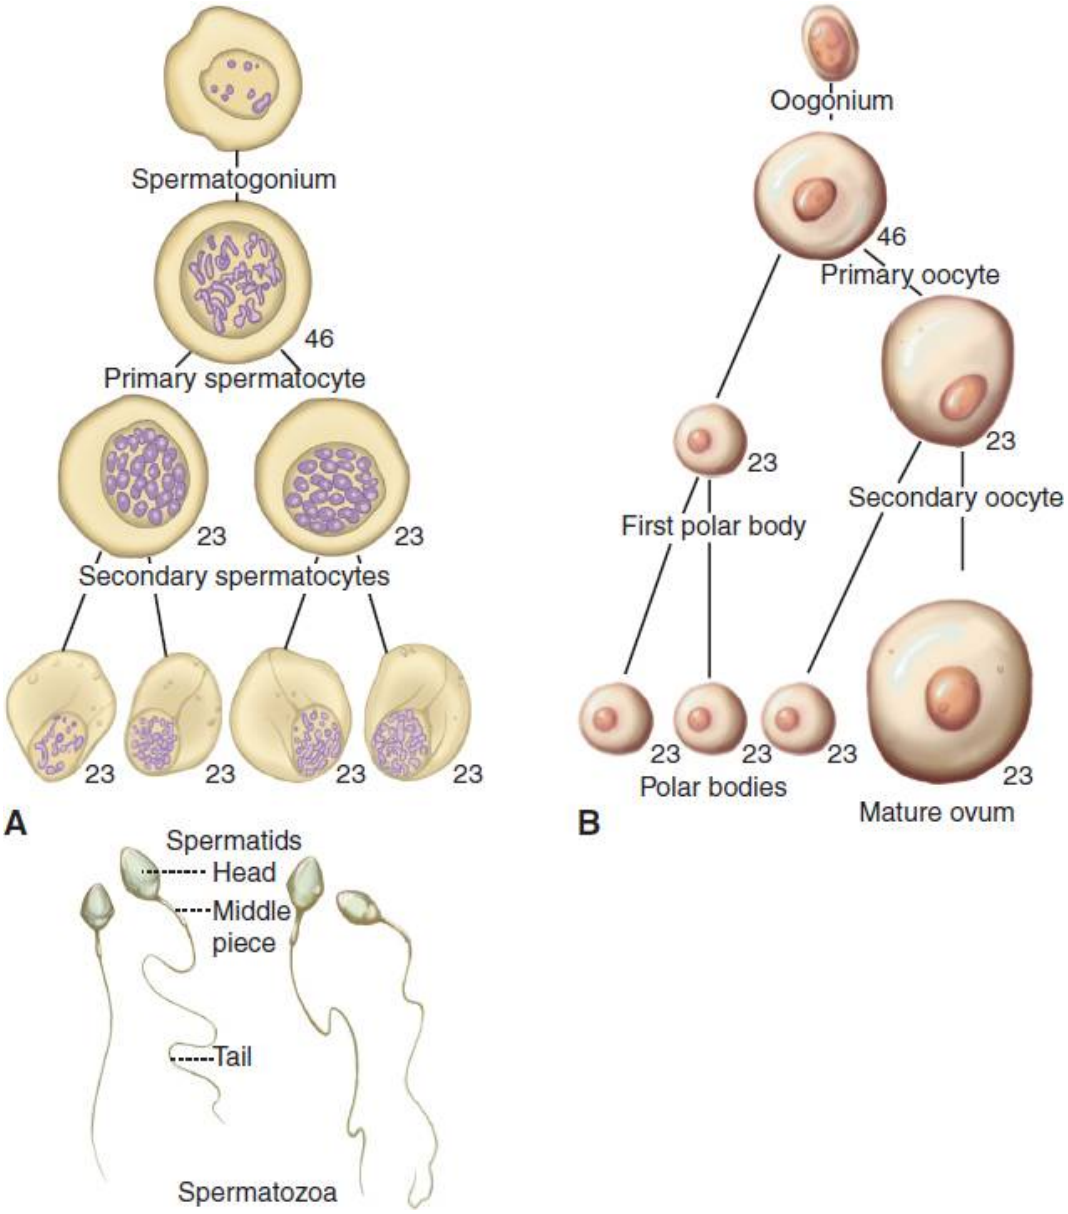

FIGURE 10.1. The formation of gametes by the process of meiosis is known as gametogenesis. **A.** Spermatogenesis. One spermatogonium gives rise to four spermatozoa. **B.** Oogenesis. From each oogonium, one mature ovum and three abortive cells are produced. The chromosomes are reduced to one half the number characteristic for the general body cells of the species. In humans, the number in the body cells is 46, and that in the mature spermatozoon and secondary oocyte is 23.

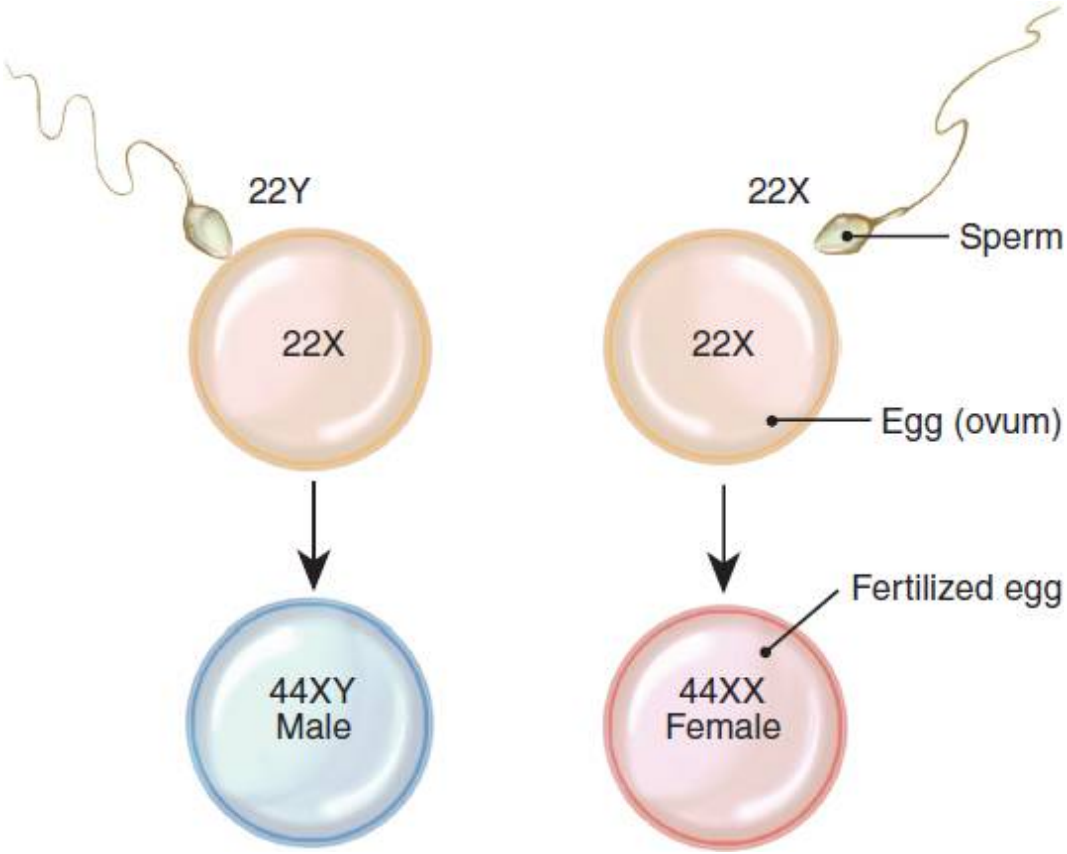

FIGURE 10.2. Inheritance of gender. Each ovum contains 22 autosomes and an X chromosome. Each spermatozoon (sperm) contains 22 autosomes and either an X chromosome or a Y chromosome. The gender of the zygote is determined at the time of fertilization by the combination of the sex chromosomes of the sperm (either X or Y) and the ovum (X).

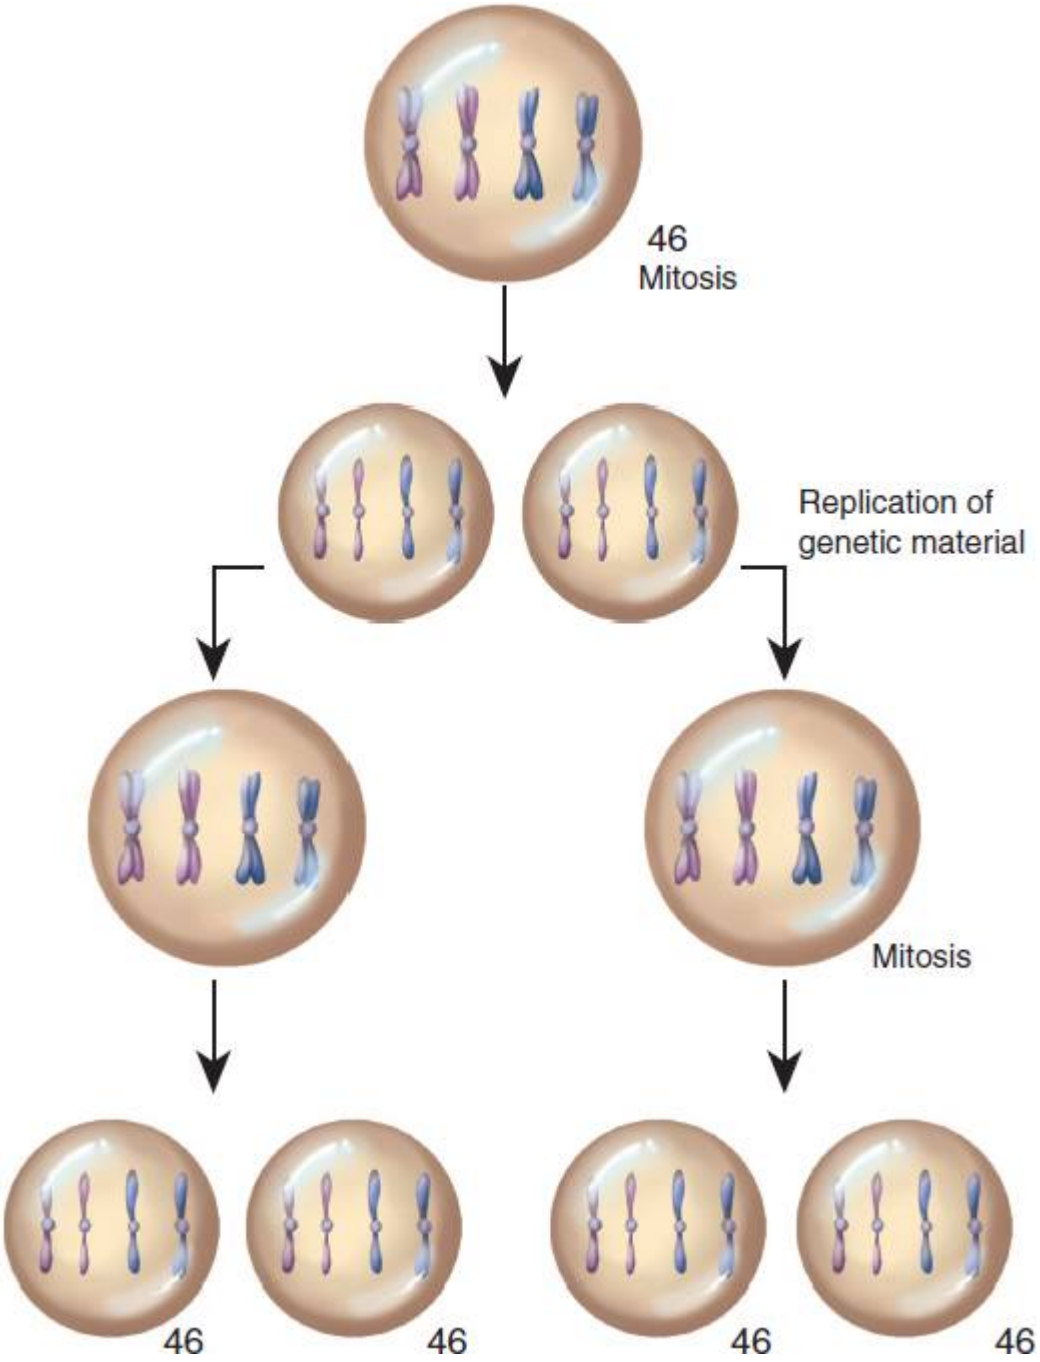

FIGURE 10.3. Mitosis of the stoma cells.

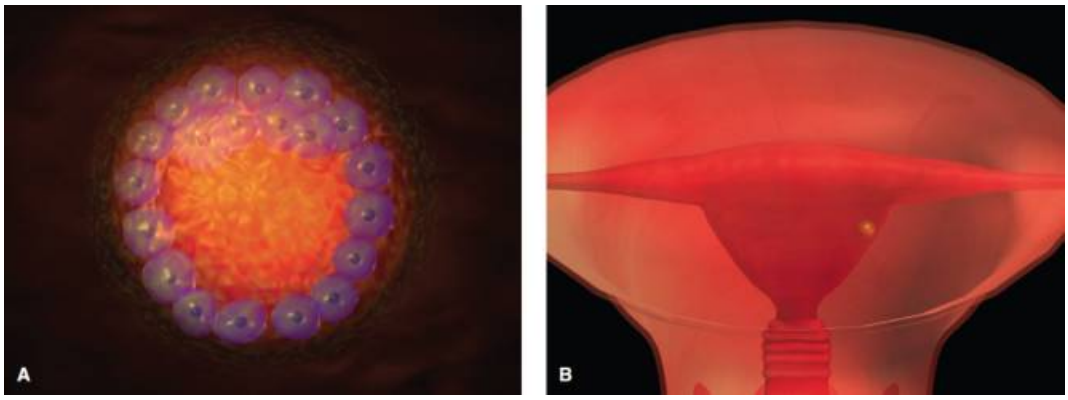

FIGURE 10.4. **A.** Fertilized human egg (zygote) having reached the blastocyst stage. Zygote contains 20 to 30 eggs and a fluid-filled blastocele is beginning to form. **B.** Implantation. Stylized image showing a frontal view of a uterus with a blastocyst about to implant into endometrium of the uterus. (Images from LifeART image copyright (c) 2011 Lippincott Williams & Wilkins. All rights reserved.)

At this time, the developing blastocyst needs more food and oxygen to keep growing. The trophoblast attaches itself to the surface of the endometrium for further nourishment. Normally, implantation occurs in the upper uterus (fundus), where a rich blood supply is available. This area also contains strong muscular fibers, which clamp down on blood vessels after the placenta separates from the inner wall of the uterus. Additionally, the lining is thickest here so the placenta cannot attach so strongly that it remains attached after birth. The process of attachment and placental formation is termed implantation. This involves a complex interaction between the trophoblasts and the maternal decidua. From a medical perspective, a pregnancy has not occurred until successful implantation has taken place (Cunningham et al., 2018). Figure 10.5 shows the process of fertilization and implantation.

Embryonic development starts with the fusion of oocyte and sperm cell. This single cell eventually differentiates into three germ layers. Concurrent with the development of the trophoblast and implantation, further differentiation of the inner cell mass occurs. Some of the cells become the embryo itself, and others give rise to the membranes that surround and protect it. The three embryonic layers of cells formed are:

1. Ectoderm—forms the central nervous system, special senses, skin, and glands.
2. Mesoderm—forms the skeletal, urinary, circulatory, and reproductive organs.
3. Endoderm—forms the respiratory system, liver, pancreas, and digestive system.

These three layers are formed at the same time as the embryonic membranes, and all tissues, organs, and organ systems develop from these three primary germ cell layers (Chiras, 2019). Box 10.1 summarizes preembryonic development.

Despite the intense and dramatic activities going on internally to create a human life, many women are unaware that pregnancy has begun. Several weeks will pass before even one of the presumptive signs of pregnancy—missing the first menstrual period—will take place.

Embryonic Stage

The **embryonic stage** of development begins at day 15 after conception and continues through week 8. Basic structures of all major body organs and the main external features are completed during this time period. Table 10.1 and Figure 10.6 summarize embryonic development.

BOX 10.1 Summary of Preembryonic Development

- Fertilization takes place in ampulla of the fallopian tube.
- Union of sperm and ovum forms a *zygote* (46 chromosomes).
- Cleavage cell division continues to form a *morula* (mass of 16 cells).
- The inner cell mass is called *blastocyst,* which forms the embryo and amnion.
- The outer cell mass is called *trophoblast,* which forms the placenta and chorion.
- Implantation occurs 7 to 10 days after conception in the endometrium.

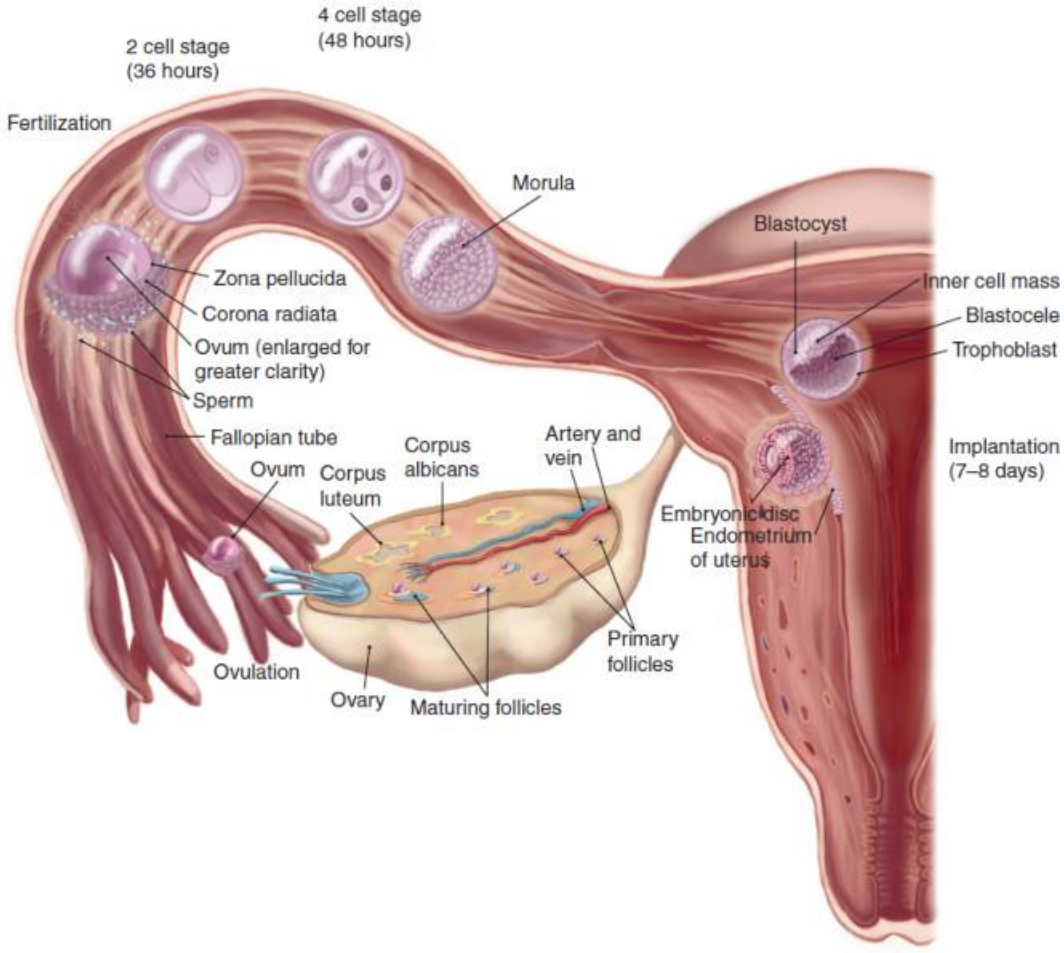

FIGURE 10.5. Fertilization and tubal transport of the zygote. From fertilization to implantation, the zygote travels through the fallopian tube, experiencing rapid mitotic division (cleavage). During the journey toward the uterus the zygote evolves through several stages, including morula and blastocyst.

The embryonic membranes (Fig. 10.7) begin to form around the time of implantation. The chorion consists of trophoblast cells and a mesodermal lining. It has fingerlike projections called *chorionic villi* on its surface. The amnion originates from the ectoderm germ layer during the early stages of embryonic development. It is a thin protective membrane that contains amniotic fluid. As the embryo grows, the amnion (inner layer) expands until it touches the chorion (outer layer). These two fetal membranes form the fluid-filled

amniotic sac, or bag of waters, that protects the floating embryo (Cunningham et al., 2018).

Amniotic fluid surrounds the embryo and increases in volume as the pregnancy progresses, reaching approximately 1 L at term. Amniotic fluid is derived from two sources: fluid transported from the maternal blood across the amnion and fetal urine. Its volume changes constantly as the fetus swallows and voids. Sufficient amounts of amniotic fluid help maintain a constant body temperature for the fetus, permit symmetric growth and development, cushion the fetus from trauma, allow the umbilical cord to be relatively free from compression, and promote fetal movement to enhance musculoskeletal development. Amniotic fluid is composed of 98% water and 2% organic matter. It is slightly alkaline and contains albumin, urea, bile pigments, renin, glucose, hormones, uric acid, creatinine, bilirubin, lecithin, sphingomyelin, epithelial cells, vernix, and fine hair called lanugo. The composition of amniotic fluid changes with gestation. Adequate amniotic fluid volume is necessary for proper fetal growth and development (Resnik et al., 2019).

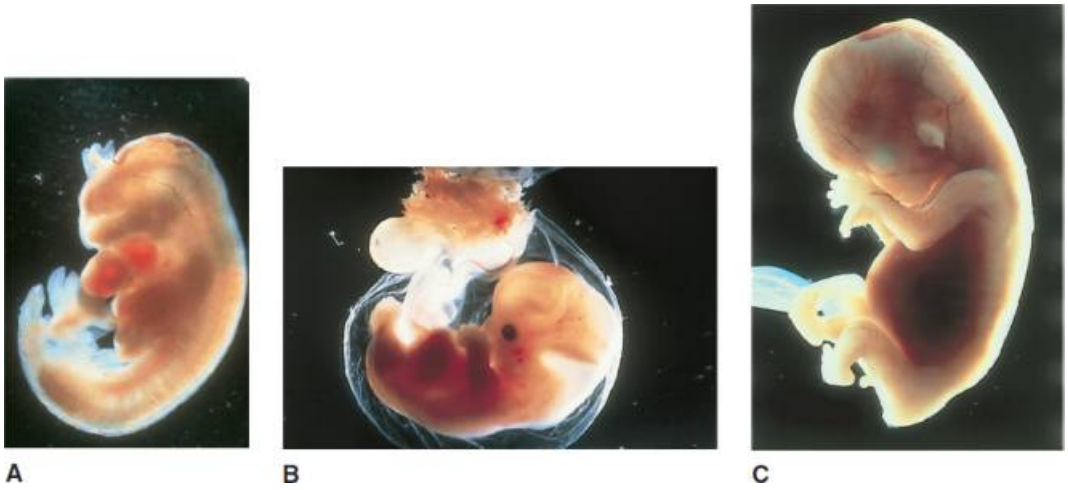

FIGURE 10.6. Embryonic development. **A.** 4-week embryo. **B.** 5-week embryo. **C.** 6-week embryo.

TABLE 10.1 Embryonic and Fetal Development

WEEK 3
Beginning development of brain, spinal cord, and heart
Beginning development of the gastrointestinal tract
Neural tube forms, which later becomes the spinal cord
Leg and arm buds appear and grow out from body

WEEK 4
Brain differentiates
Limb buds grow and develop more
Stomach, pancreas, and liver begin to form

4 weeks

WEEK 5
Heart now beats at a regular rhythm
Beginning structures of eyes and ears
Some cranial nerves are visible
Muscles innervated

WEEK 6
Beginning formation of lungs
Fetal circulation established
Liver produces RBCs
Further development of the brain
Primitive skeleton forms
Central nervous system forms
Brain waves detectable

WEEK 7
Straightening of trunk
Nipples and hair follicles form
Elbows and toes visible
Arms and legs move

Diaphragm formed
Fetal heartbeat can be heard
Mouth with lips and early tooth buds

WEEK 8

Rotation of intestines
Facial features continue to develop
Heart development complete
Resembles a human being (Blackburn, 2018)

8 weeks

WEEKS 9–12

Sexual differentiation continues
Buds for all 20 temporary teeth laid down
Digestive system shows activity

Head comprises nearly half the fetus size
Face and neck are well formed
Urogenital tract completes development
Red blood cells are produced in the liver
Urine begins to be produced and excreted
Fetal gender can be determined by week 12
Limbs are long and thin; digits are well formed

12 weeks

WEEKS 13–16

A fine hair develops on the head called lanugo
Fetal skin is almost transparent
Bones become harder
Head still dominant
Fetus makes active movement
Sucking motions are made with the mouth
Amniotic fluid is swallowed
Fingernails and toenails present
Weight quadruples
Fetal movement (also known as quickening) detected by mother

16 weeks

WEEKS 17–20

Rapid brain growth occurs
Fetal heart tones can be heard with stethoscope
Kidneys continue to secret urine into amniotic fluid
Vernix caseosa, a white greasy film, covers the fetus
Eyebrows and head hair appear
Sebaceous glands appear
Brown fat deposited to help maintain temperature
Nails are present on both fingers and toes
Muscles are well developed

20 weeks

WEEKS 21–24

Eyebrows and eyelashes are well formed
Fetus has a hand grasp and startle reflex
Alveoli forming in lungs
Body is lean but fairly well proportioned
Skin is translucent and red
Lungs begin to produce surfactant

25 weeks

WEEKS 25–28

Fetus reaches a length of 15 in
Rapid brain development
Eyelids open and close
Nervous system controls some functions
Fingerprints are set

Blood formation shifts from spleen to bone marrow
Fetus usually assumes head-down position

28 weeks

WEEKS 29–32

Rapid increase in amount of body fat
Increased central nervous system control over body functions
Rhythmic breathing movements occur
Lungs are not fully mature
Fetus stores iron, calcium, and phosphorus

32 weeks

WEEKS 33–38

Testes are in scrotum of male fetus
Lanugo begins to disappear
Increase in body fat
Fingernails reach the ends of fingertips
Small breast buds are present on both sexes

Mother supplies fetus with antibodies against disease
Fetus is considered full term at 38 weeks
Fetus fills uterus (Blackburn, 2018)

The volume of amniotic fluid is important in determining fetal well-being. It gradually fluctuates throughout the pregnancy. Alterations in amniotic fluid volume can be associated with problems in the fetus. Too little amniotic fluid (<500 mL at term), termed *oligohydramnios,* is associated with uteroplacental insufficiency, fetal renal abnormalities, and a higher risk of surgical births and low–birth-weight infants. Too much amniotic fluid (>2,000 mL at term), termed *hydramnios,* is associated with maternal diabetes, neural tube defects, chromosomal deviations, and malformations of the central nervous system and/or gastrointestinal tract that prevent normal swallowing of amniotic fluid by the fetus. Hydramnios may threaten premature rupture of membranes due to uterine over distention (Scott & Lee, 2020).

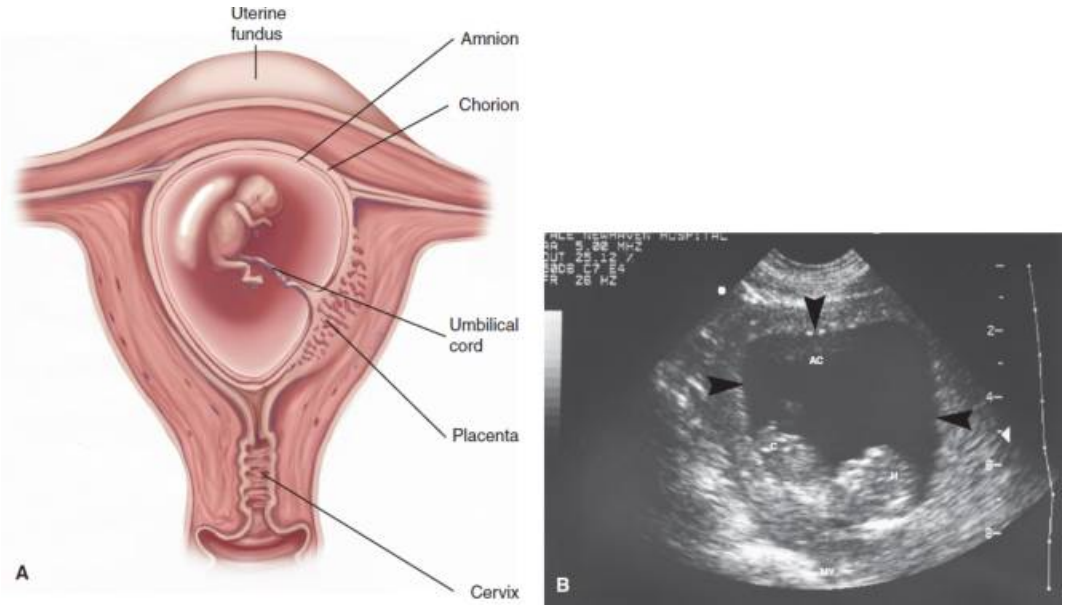

FIGURE 10.7. A. The embryo is floating in amniotic fluid, surrounded by the protective fetal membranes (amnion and chorion). **B.** Longitudinal sonogram of a pregnant uterus at 11 weeks showing the intrauterine gestational sac (*black arrowheads*) and the amniotic cavity (*AC*) filled with amniotic fluid; the fetus is seen in longitudinal section with the head (*H*) and coccyx (*C*) well displayed. The myometrium (*MY*) of the uterus can be identified. (Figure B is courtesy of L Scoutt.)

Development of the placenta is a highly regulated process that is essential for normal fetal growth and development. While the placenta is developing (end of the second week), the **umbilical cord** is also formed from the amnion. It is the lifeline from the mother to the growing embryo. It contains one large vein and two small arteries. Wharton jelly (a specialized connective tissue) surrounds these three blood vessels in the umbilical cord to prevent compression, which would cut off fetal blood and nutrient supply. The cord reaches its maximum length by 30 weeks' gestation. Its length is determined by genetics and intrauterine space and fetal activity, which places tension on the cord. At term, the average umbilical cord is 22 in long and about 1 in wide (King et al., 2019).

The precursor cells of the placenta—the trophoblasts—first appear 4 days after fertilization as the outer layer of cells of the blastocyst. These early blastocyst trophoblasts differentiate into all the cells that form the placenta. When fully developed, the placenta serves as the

interface between the mother and the developing fetus. As early as 3 days after conception, the trophoblasts make human chorionic gonadotropin (hCG), a hormone that ensures that the endometrium will be receptive to the implanting embryo. During the next few weeks the placenta begins to make hormones that control the basic physiology of the mother in such a way that the fetus is supplied with the nutrients and oxygen needed for growth. The placenta also protects the fetus from immune attack by the mother, removes waste products from the fetus, induces the mother to bring more food to the placenta and, near the time of childbirth, and produces hormones that ready fetal organs for life outside the uterus. Placenta function depends on the maternal blood pressure supplying circulation. If there is an interference with blood flow to the placenta, it cannot carry out its functions to the embryo or fetus (Donnelly & Campling, 2019).

Theoretically, at no time during pregnancy does the mother's blood mix with fetal blood because there is no direct contact between their bloods; layers of fetal tissue always separate the maternal blood and the fetal blood. These fetal tissues are called the *placental barrier.* Materials can be interchanged only through diffusion. The maternal uterine arteries deliver the nutrients to the **placenta**, which in turn provides nutrients to the developing fetus; the mother's uterine veins carry fetal waste products away. The structure of the placenta is usually completed by week 12.

The placenta is not only a transfer organ but a hormone factory as well. Placental hormones have profound effects on maternal metabolism, initially building up her energy reserves and then releasing these to support fetal growth in later pregnancy and lactation postnatally. Several hormones are produced that are necessary for normal pregnancy:

- *Chorionic gonadotropin* (CG)—preserves the corpus luteum and its progesterone production so that the endometrial lining of the uterus is maintained; this is the basis for pregnancy tests.
- *Prolactin*—mediates maternal metabolic adaptations to pregnancy by regulating insulin production and sensitivity; and plays an important role in lactation.

- *Human placental lactogen* (hPL)—modulates fetal and maternal metabolism, participates in the development of maternal breasts for lactation, and decreases maternal insulin sensitivity to increase its availability for fetal nutrition.
- *Estrogen* (estriol)—causes enlargement of a woman's breasts, uterus, and external genitalia; stimulates myometrial contractility.
- *Progesterone* (progestin)—maintains the endometrium, decreases the contractility of the uterus, stimulates maternal metabolism and breast development, provides nourishment for the early conceptus.
- *Relaxin*—is a potent vasodilator and regulates maternal hemodynamics. It acts synergistically with progesterone to maintain pregnancy, causes relaxation of the pelvic ligaments, softens the cervix in preparation for birth (Roberts & Myatt, 2019).

The placenta acts as a pass-through between the mother and fetus, not a barrier. Almost everything the mother ingests (food, alcohol, drugs) passes through to the developing conceptus. This is why it is so important to advise pregnant women not to use unprescribed drugs, alcohol, and tobacco, because they can be harmful to the conceptus.

During the embryonic stage, the conceptus grows rapidly as all organs and structures are forming. During this critical period of differentiation, the growing embryo is most susceptible to damage from external sources, including **teratogens** (substances that cause birth defects, such as alcohol and drugs), infections (such as rubella or cytomegalovirus), radiation, and nutritional deficiencies.

Fetal Stage

The average pregnancy lasts 280 days from the first day of the last menstrual period. The **fetal stage** is the time from the end of the eighth week until birth. It is the longest period of prenatal development. During this stage, the conceptus is mature enough to be called a fetus. Although all major systems are present in their basic form, dramatic growth and refinement of all organ systems take place during the fetal period (see Table 10.1). Figure 10.8 depicts a 12- to 15-week-old fetus.

Fetal Circulation

Fetal circulation differs from adult circulation due to the presence of certain vessels and shunts which support the unique physiologic needs of the developing fetus. These shunts will close after birth and most of the vessels will be seen as remnants in the adult circulation. The function of these shunts is to direct oxygen-rich venous blood to the systemic circulation and to ensure that oxygen-depleted venous blood bypasses the underdeveloped pulmonary circulation. The lungs finish their development after birth. Prior to birth, the lungs function is taken over by the placenta during fetal life (Blackburn, 2018). The circulation through the fetus during uterine life differs from that of a child or an adult. In the extrauterine world, oxygenation occurs in the lungs and oxygenated blood returns via the pulmonary veins to the left side of the heart to be ejected by the left ventricle into the systemic circulation. In contrast, fetal circulation oxygenation occurs in the placenta, and the fetal lungs are nonfunctional as far as the transfer of oxygen and carbon dioxide is concerned. For oxygenated blood derived from the placenta to reach the fetus's systemic circulation, it has to travel through a series of shunts to accomplish this.

FIGURE 10.8. Fetal development: A 12- to 15-week fetus.

Thus, fetal circulation involves the circulation of blood from the placenta to and through the fetus, and back to the placenta. A properly functioning fetal circulation system is essential to sustain the fetus. Before it develops, nutrients and oxygen diffuse through the extraembryonic coelom and the yolk sac from the placenta. As the embryo grows, its nutrient needs increase and the amount of tissue easily reached by diffusion increases. Thus, the circulation must develop quickly and accurately (Marty & Lui, 2019).

The circulatory system of the fetus functions much differently from that of a newborn. The most significant difference is that oxygen is received from the placenta during fetal life and via the lungs after birth. In addition, the fetal liver does not perform the metabolic functions that it will after birth, because the mother's body performs them for the growing fetus. Three shunts also are present during fetal life:

1. Ductus venosus—bypasses the liver and connects the umbilical vein to the inferior vena cava.
2. Ductus arteriosus—bypasses the lungs and connects the main pulmonary artery to the descending aorta.
3. Foramen ovale—bypasses the right ventricle and lungs via an anatomic opening between the right and left atrium.

TAKE NOTE!

Fetal circulation functions to carry highly oxygenated blood to vital areas (e.g., heart, brain) while first shunting it away from less important ones (e.g., lungs, liver). The placenta essentially takes over the functions of the lungs and liver during fetal life. As a result, large volumes of oxygenated blood are not needed.

The oxygenated blood is carried from the placenta to the fetus via the umbilical vein. About half of this blood passes through the hepatic capillaries and the rest flows through the ductus venosus into the inferior vena cava. Blood from the vena cava is mostly deflected through the foramen ovale into the left atrium, then to the left ventricle, into the ascending aorta, and on to the head and upper

body. This allows the fetal coronary circulation and the brain to receive the blood with the highest level of oxygenation.

Deoxygenated blood from the superior vena cava flows into the right atrium, the right ventricle, and then the pulmonary artery. Because of high pulmonary vascular resistance, only a small percentage (5% to 10%) of the blood in the pulmonary artery flows to the lungs; the majority is shunted through the patent ductus arteriosus and then to the descending aorta (Resnik et al., 2019). The fetal lungs are essentially nonfunctional because they are filled with fluid, making them resistant to incoming blood flow. They receive only enough blood for proper nourishment. Finally, two umbilical arteries carry the unoxygenated blood from the descending aorta back to the placenta.

At birth, a dramatic change in the fetal circulatory pattern occurs. The foramen ovale, ductus arteriosus, ductus venosus, and umbilical vessels are no longer needed. With the newborn's first breath, the lungs inflate, which leads to an increase in blood flow to the lungs from the right ventricle. This increase raises the pressure in the left atrium, causing a one-way flap on the left side of the foramen ovale, called the septum primum, to press against the opening, creating a functional separation between the two atria. Blood flow to the lungs increases because blood entering the right atrium can no longer bypass the right ventricle. As a result, the right ventricle pumps blood into the pulmonary artery and on to the lungs. Typically, the foramen ovale is functionally closed within 1 to 2 hours after birth. It is physiologically closed by 1 month with deposits of fibrin to seal the shunt. Permanent closure occurs by the sixth month of life.

The ductus venosus, which links the inferior vena cava with the umbilical vein, usually closes with the clamping of the umbilical cord and inhibition of blood flow through the umbilical vein. This fetal structure closes by the end of the first week. The ductus arteriosus constricts partly in response to the higher arterial oxygen levels that occur after the first few breaths. This closure prevents blood from the aorta from entering the pulmonary artery. Functional closure of the ductus arteriosus in a term infant usually occurs within the first 72 hours after birth. Permanent closure occurs at 3 to 4 weeks of age.

Frequently a functional or innocent murmur is auscultated by the nursery nurse when there are delayed fetal shunt closures, but they usually are not associated with a heart lesion (Scott & Lee, 2020). All of these changes at birth leave the newborn with the typical adult pattern of circulation with right ventricle output equaling that of the left. Figure 10.9 shows fetal circulation. Go to for a web link to a video depicting fetal circulation.

GENETICS

Genetics is the study of heredity and its variation. **Genomics**, a relatively new science, is the study of all genes and includes interactions among genes as well as interactions between genes and the environment. Genomics plays a role in complex conditions such as heart disease and diabetes. Another emerging area of research is that of pharmacogenomics, the study of genetic and genomic influences on pharmacodynamics and pharmacotherapeutics. It aims to use an individual's genetic information in order to treat diseases more efficiently and minimize adverse events (Norton et al., 2019). An individual's genetics influences wellness and health issues throughout that person's lifespan. The challenge for health care providers is to find the link between the client's genetic makeup and diseases (Sharma et al., 2019).

According to the Centers for Disease Control and Prevention (CDC), birth defects occur in about 3% of all infants born in the United States, or one in every 33 infants (CDC, 2020a). Traditionally, genetics has been associated with making decisions about childbearing and caring for children with genetic disorders. Recently, genetic and technologic advances are expanding our understanding of how genetic changes affect human diseases such as diabetes, cancer, Alzheimer disease, and other multifactorial diseases that are prevalent in adults. Today's genetic technologies are not yet a crystal ball for seeing a child's future, but scientists are closer to routinely glimpsing at the genetic blueprints of a fetus just months after sperm meets egg (Bell, 2019). Newborn screening is perhaps the most

widely used application of genetics in perinatal and neonatal care. Our ability to diagnose genetic conditions is more advanced than our ability to cure or treat the disorders. However, accurate diagnosis has led to improved treatment and outcomes for those affected with these disorders.

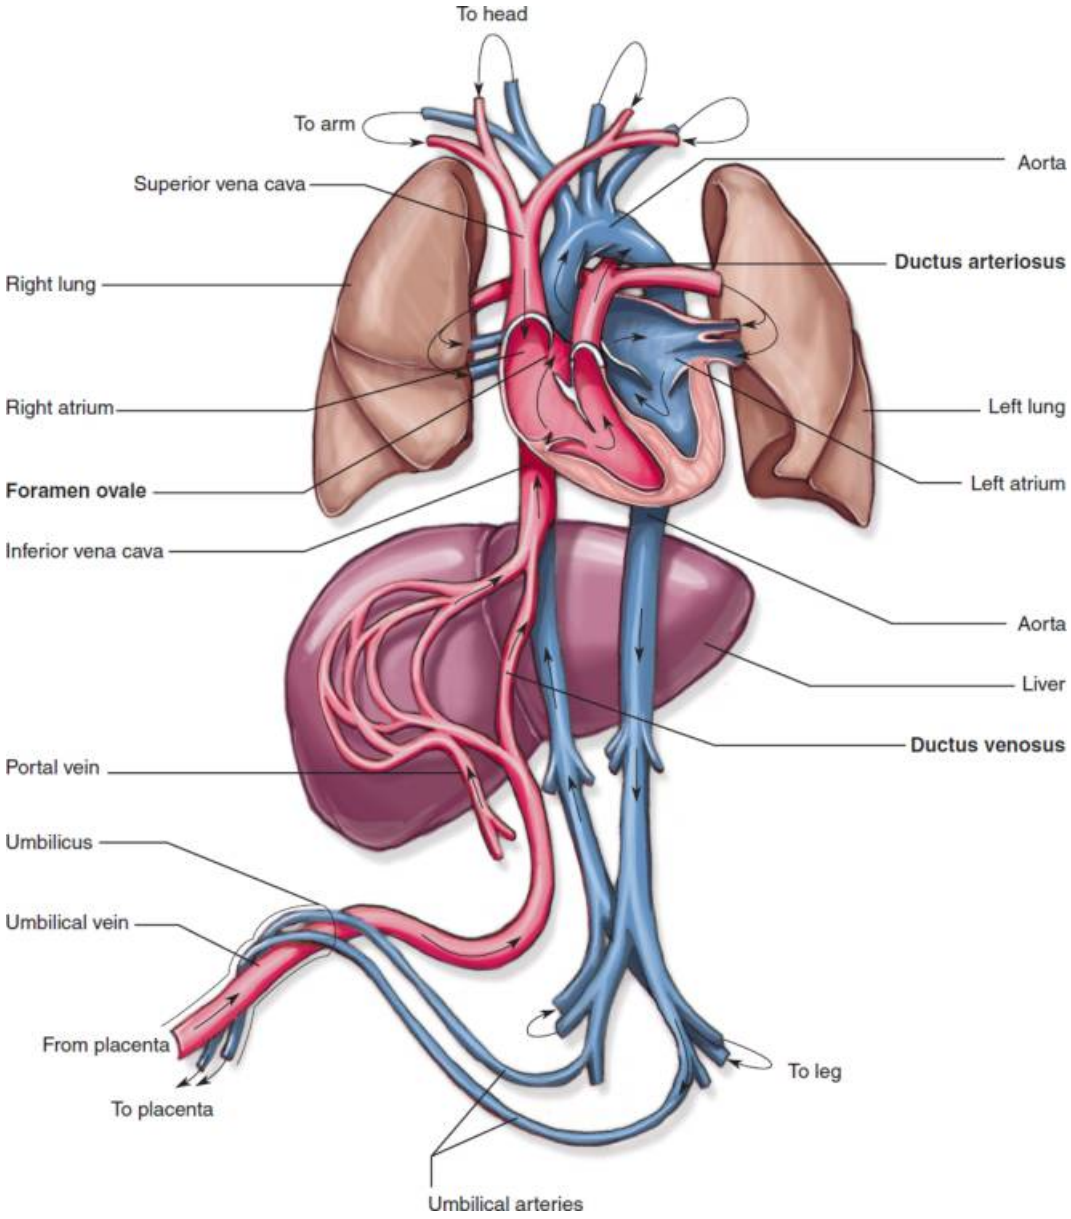

FIGURE 10.9. Fetal circulation. *Arrows* indicate the path of blood. The umbilical vein carries oxygen-rich blood from the placenta to the liver and through the ductus venosus. From there it is carried to the inferior vena cava to the right atrium of the heart. Some of the blood is shunted through the foramen ovale to the left side of the heart, where it is routed to the brain and upper extremities. The rest of the blood travels down to the right ventricle and through the pulmonary artery. A small portion of the blood travels to the nonfunctioning lungs, while the remaining blood is shunted through the ductus arteriosus into the aorta to supply the rest of the body.

TAKE NOTE!

Genetic science has the potential to revolutionize health care with regard to national screening programs, predisposition testing, detection of genetic disorders, and pharmacogenetics.

Genetic and genomic information has the potential to improve perinatal outcomes by improving clinician's ability to identify women at increased risk of disease to genetic disorders and personalize treatment and management. Nurses can take meaningful steps to improve integration of genetics in their practice. Genetics has been a part of perinatal care for decades. Rapid development and implementation of advanced genetics technology in prenatal settings includes the ability to screen for and diagnose a broader range of diseases and conditions of the fetus in early gestational ages. Ultrasounds and maternal serum screening have become routine elements of prenatal care. Preconception carrier screening for conditions such as Tay–Sachs disease has been in place among high-risk populations such as Ashkenazi Jews. Amniocentesis and chorionic villus sampling are diagnostic tests that may confirm a genetic anomaly in a developing fetus, but they are all invasive procedures. A fetal nuchal translucency test, as seen on ultrasound, may be suggestive of the presence of trisomy 21 or Down syndrome if increased nuchal thickness is found (Resnik et al., 2019).

The exponential rate at which genetic testing has been integrated into obstetric care has been amazing. Today, nurses are required to have basic skills and knowledge in genetics, genetic testing, and genetic counseling so they can assume new roles and provide information and support to women, children, and families. Roles for maternity nurses in genetic health care have expanded significantly as genetics education and counseling has become standard of care. Today, nurses may provide preconception counseling for women at risk for the transmission of a genetic disorder. In addition, they may provide prenatal care for women with genetically linked disorders that require specialized care or participate in screening infants for birth defects and genetic disorders. Nurses employed in prenatal

settings need to have accurate information they can provide to women so they understand the benefits and limitations of screening. Timely presentation of information and identification of available resources will help nurses minimize a couple's confusion and provide support for women as they proceed with pregnancy screening. Nurses at all levels should be participating in risk assessment for genetic conditions and disorders, explaining genetic risk and genetic testing, and supporting informed health decisions and opportunities for early intervention. It is essential that with any genetic testing, women have the opportunity to make informed and autonomous decisions that are consistent with their personal needs and values (Knutzen & Stoll, 2019).

It is very clear that genomics will have a profound effect on health and illness at all levels. Modern technology makes it possible to screen for and diagnose conditions prior to birth, such as open neural tube defects, chromosomal aneuploids (i.e., trisomies 13, 18, and 21), congenital defects, and a myriad of single-gene inheritable disorders (i.e., Tay–Sachs disease, cystic fibrosis, Huntington disease, Duchenne muscular dystrophy, and hemophilia) (Norton et al., 2019). In the future, as the era of personalized health care moves forward, nurses will be responsible for ensuring that our practice includes the scientific principles, ethical standards, and professional accountability of genetics and genomics practice. Nurses are increasingly incorporating genetics into their practice as they gain the knowledge and skills necessary to do so. The strength of the nursing voice in genetics and genomic research will be the link to the bedside and the commitment to ensure that new knowledge is translated into competent, safe, valued-based, effective evidence-based client care (Sudhof & Shah, 2019).

Advances in Genetics

Recent advances in genetic knowledge and technology have affected all areas of health. These advances have increased the number of health interventions that can be undertaken with regard to genetic disorders. For example, genetic diagnosis is now possible

before conception and helps parents/couples make more informed decisions concerning their reproductive options and facilitates more effective preconception planning, prenatal diagnosis, condition-specific counseling and care (see Evidence-Based Practice 10.1). Genetic testing can identify presymptomatic conditions in children and adults, and provide carrier screening, prenatal diagnostic testing, newborn screening, confirmation of a diagnosis, forensic and identity testing, preimplantation genetic diagnosis, and pharmacogenetic testing, which provides information on how an individual will respond to certain medications based on genetic variability (National Human Genome Research Institute [NHGRI], 2019; National Institutes of Health [NIH], 2019). Thousands of genetic tests are available for diseases such as Duchenne muscular dystrophy/Becker muscular dystrophy, cystic fibrosis, and sickle cell disease (NIH, 2019). Gene therapy can be used to replace or repair defective or missing genes with normal ones. It is a promising treatment option for many inherited and incurable diseases; however, it currently remains an experimental and risky treatment option (Genetics Home Reference [GHR], 2020a). Clinical trials are underway to test gene therapy for diseases that have no other cures, but currently it is only available in the research setting (GHR, 2020a).

The Human Genome Project (HGP) and continued research by the NHGRI have helped foster much of this progress. The **genome** of an organism is its entire hereditary information encoded in the DNA. The HGP, in an international effort to produce a comprehensive sequence of the human genome, was coordinated by the U.S. Department of Energy and the NIH. It began in October 1990 and was completed in May 2003. Its goals included:

- Identify all of the approximately 20,500 genes in human DNA.
- Determine the sequences of the 3 billion chemical base pairs that make up human DNA.
- Store this information in databases to make it accessible for further study.
- Improve tools for data analysis.
- Transfer related technologies to the private sector.

- Address the ethical, legal, and social implications of this discovery (U.S. Department of Energy Genome Programs, 2019).

EVIDENCE-BASED PRACTICE 10.1

Measuring the Impact of Genetic Knowledge on Intentions and Attitudes of the Community Toward Expanded Preconception Carrier Screening

STUDY

Genetic risk assessment begins with an evaluation of the biologic parents. The appropriate extent of screening must be individualized with identified genetic risks and their personal values. Preconception carrier screening provides the potential to empower couples to make reproductive choices before having an affected child. An important question is what factors influence the decision to use or not use preconception carrier screening. The relationship between knowledge, attitudes and intentions to participate were analyzed using logic regression in 832 participants.

Findings

Two thirds of the participants stated they would take the preconception genetic screening test, with 92% of these supporting screening for diseases reducing the lifespan of children and infants. Those who had good genetic knowledge were seven times more likely to use preconception screening, while those with high genetic knowledge were four times more likely to raise concerns about insurance coverage and confidentiality. Decreasing genetic knowledge correlated with religiosity and apprehension, which correlated negatively with their intent to use preconception genetic carrier screening and may impact informed decision-making.

Nursing Implications

Genetic knowledge is instrumental in influencing participation in preconception carrier screening tests. Having good genetic knowledge may not be enough to understand core concepts of preconception carrier screening. Nurses can continuously educate their clients within communities to reduce misconceptions and increase their awareness of the need to understand the implications of making decisions about their reproductive outcomes prior to conception.

Source: Ong, R., Howting, D., Rea, A., Christian, H., Charman, P., Molster, C., Ravenscroft, G., & Laing, N. G. (2018) Measuring the impact of genetic knowledge on intentions and attitudes of the community towards expanded preconception carrier screening. *Journal of Medical Genetics*, *55*(11), 744–752.

The HGP has led to the discovery of the genetic basis for hundreds of disorders and has advanced our understanding of basic genetic processes at the molecular level. A link to additional information about the HGP is available on thePoint.

One goal of the HGP was to translate the findings into new and more effective strategies for the prevention, diagnosis, and treatment of genetic diseases and disorders.

Genome sequencing has profoundly changed the medical landscape. Current and potential applications for the HGP to health care include rapid and more specific diagnosis of disease, with hundreds of genetic tests available in research or clinical practice; earlier detection of genetic predisposition to disease; less emphasis on treating the symptoms of a disease and more emphasis on looking at the fundamental causes of the disease; new classes of drugs; avoiding environmental conditions that may trigger disease; and repair or replacement of defective genes through gene therapy (U.S. Department of Energy Genome Programs, 2019). This knowledge, along with the commercialization of the technology, can change both professional and parental understanding of genetic disorders. The potential benefits of these discoveries are vast, but so is the potential for misuse. These advances challenge all health care professionals to consider the many ethical, legal, and social ramifications of genetics in human lives. In the near future, risk profiling based on an individual's unique genetic makeup will be used to tailor prevention, treatment, and ongoing management of health conditions. This profiling will raise issues associated with privacy and confidentiality related to workplace discrimination and access to health insurance. Issues of autonomy are equally problematic as society considers how to address the injustices that will inevitably surface when disease risk can be determined years in advance of its occurrence. Nurses will play an important role in developing policies and providing direction and support in this arena, and to do so they will need a basic understanding of genetics, including inheritance and inheritance patterns. Visit thePoint for links to resources on the ethical, social, and legal issues surrounding human genetic research and advances.

Inheritance

The nucleus within the cell is the controlling factor in all cellular activities because it contains chromosomes, long continuous strands of deoxyribonucleic acid (DNA) that carry genetic information. DNA is the hereditary material found in humans which can replicate itself.

Each chromosome is made up of genes. **Genes** are individual units of heredity of all traits and are organized into long segments of DNA that occupy a specific location on a chromosome and determine a particular characteristic in an organism.

DNA stores genetic information and encodes the instructions for synthesizing specific proteins needed to maintain life. DNA is double stranded and takes the form of a double helix. The side pieces of the double helix are made up of a sugar, deoxyribose, and a phosphate, occurring in alternating groups. The cross connections or rungs of the ladder are attached to the sides and are made up of four nitrogenous bases: adenine, cytosine, thymine, and guanine. The sequence of the base pairs as they form each rung of the ladder is referred to as the genetic code (Fig. 10.10) (GHR, 2019b).

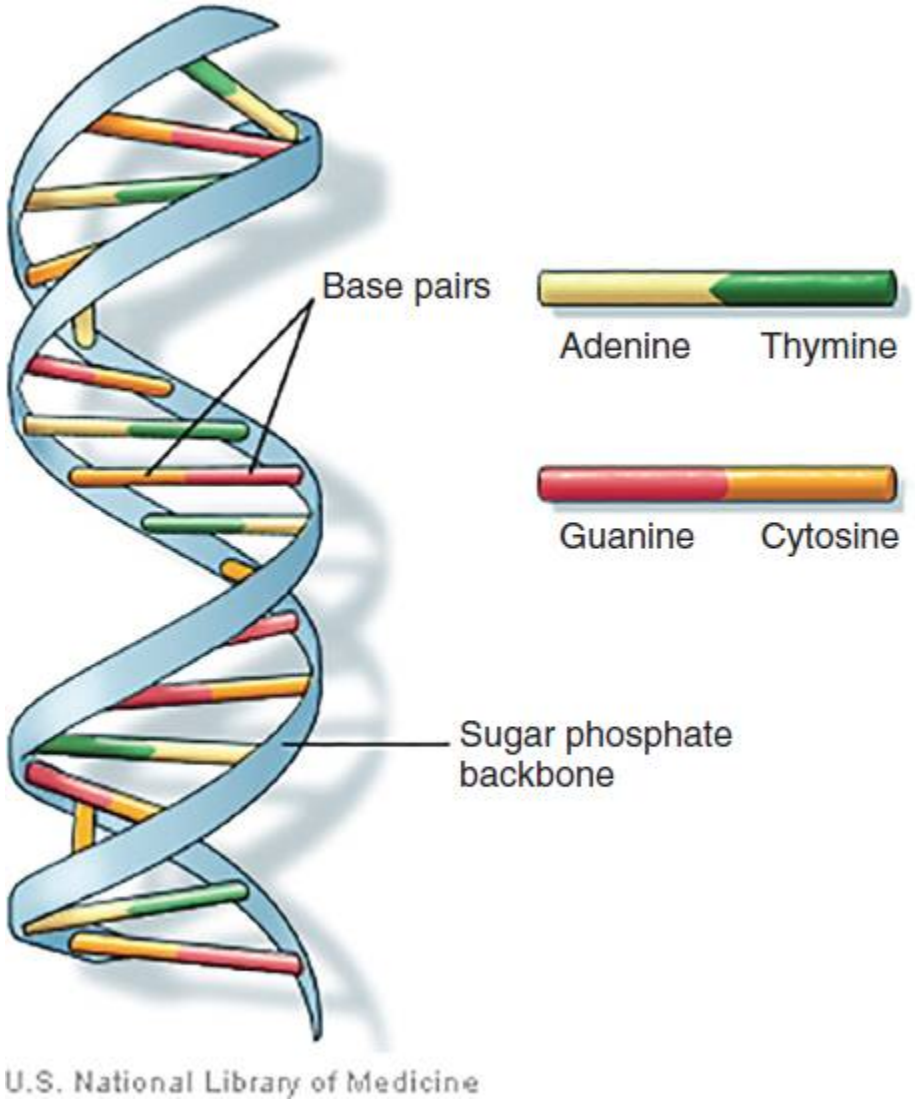

FIGURE 10.10. DNA is made up of four chemical bases. Tightly coiled strands of DNA are packaged in units called chromosomes, housed in the cell's nucleus. Working subunits of DNA are known as genes. (From the National Institutes of Health and National Cancer Institute. [1995]. *Understanding gene testing [NIH Pub. No. 96–3905]*. U.S. Department of Human Services.)

Each gene has a segment of DNA with a specific set of instructions for making proteins needed by body cells for proper functioning. Genes control the types of proteins made and the rate at which they are produced (Norton et al., 2019). Any change in gene structure or location leads to a **mutation**, which may alter the type and amount of protein produced (Fig. 10.11). Genes never act in

isolation; they always interact with other genes and the environment. They are arranged in a specific linear formation along a chromosome.

The **genotype**, the specific genetic makeup of an individual, usually in the form of DNA, is the internally coded inheritable information. It refers to the particular **allele**, which is one of two or more alternative versions of gene at a given position or locus on a chromosome that imparts the same characteristic of that gene. For instance, each human has a gene that controls height, but there are variations of these genes, which are alleles, in accordance with the specific height for which the gene codes. A gene that controls eye color may have an allele that can produce blue eyes or an allele that produces brown eyes. The genotype, together with environmental variation that influences the individual, determines the **phenotype**, or the observed, outward characteristics of an individual. A human inherits two genes, one from each parent. Therefore, one allele comes from the mother and one from the father. These alleles may be the same for the characteristic (**homozygous**) or different (**heterozygous**). For example, WW stands for homozygous dominant; ww stands for homozygous recessive. Heterozygous would be indicated as Ww. If the two alleles differ, such as Ww, the dominant one will usually be expressed in the phenotype of the individual.

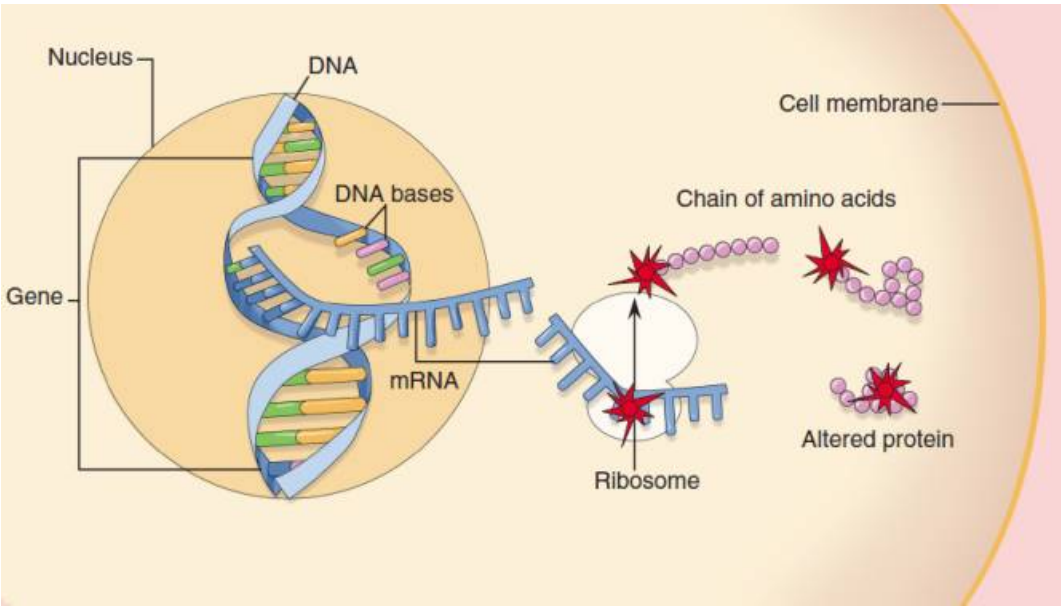

FIGURE 10.11. When a gene contains a mutation, the protein encoded by that gene will be abnormal. Some protein changes are insignificant, while others are disabling. (From the National Institutes of Health and National Cancer Institute. [1995]. *Understanding gene testing [NIH Pub. No. 96–3905]*. U.S. Department of Human Services.)

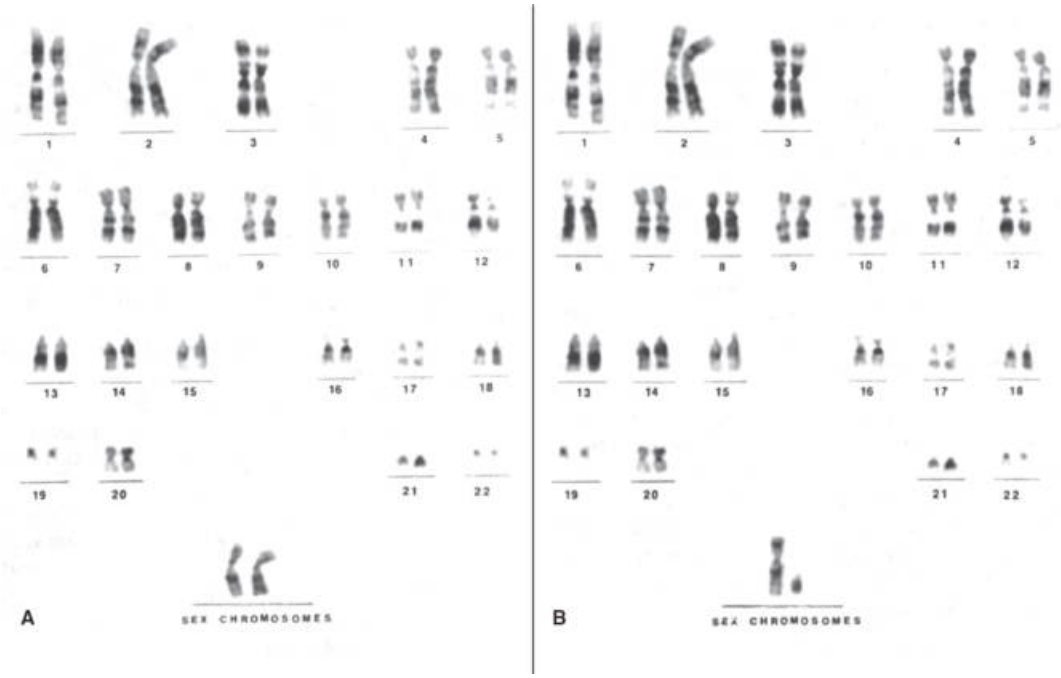

FIGURE 10.12. Karyotype pattern. **A.** Normal female karyotype. **B.** Normal male karyotype.

Human beings typically have 46 chromosomes. This includes 22 pairs of nonsex chromosomes or autosomes and one pair of sex chromosomes (two X chromosomes in females, and an X chromosome and a Y chromosome in males). Offspring receive one chromosome of each of the 23 pairs from each parent.

The pictorial analysis of the number, form, and size of an individual's chromosomes is termed the **karyotype**. This analysis commonly uses white blood cells and fetal cells in amniotic fluid. The chromosomes are numbered from the largest to the smallest, 1 to 22, and the sex chromosomes are designated by the letter X or Y. A female karyotype is designated as 46, XX and a male karyotype is designated as 46, XY. Figure 10.12 illustrates an example of a karyotyping pattern.

Regulation and expression of the thousands of human genes is very complex and is the result of many intricate interactions within each cell. Alterations in gene structure, function, transcription, translation, and protein synthesis can influence an individual's health (Pandya et al., 2020). Gene mutations are a permanent change in the sequence of DNA. Some mutations have no significant effect, whereas others can have a tremendous impact on the health of the individual. Several genetic disorders can result from these mutations, such as cystic fibrosis, sickle cell disease, phenylketonuria, or hemophilia.

Patterns of Inheritance for Genetic Disorders

Patterns of inheritance demonstrate how genetic abnormalities can be passed on to offspring. Although diagnosis of a genetic disorder is usually based on clinical signs and symptoms or on laboratory confirmation of an altered gene associated with the disorder, accurate diagnosis can be aided by the recognition of the pattern of inheritance within a family. In addition, nurses must understand the patterns of inheritance so they can teach and counsel families about the risks of genetic disorders occurring in future pregnancies. Some genetic disorders occur in multiple family members, while others may occur in only a single family member. A genetic disorder is caused

by completely or partially altered genetic material, whereas a familial disorder is more common in relatives of the affected individual but may be caused by environmental influences and not genetic alterations. For a more detailed discussion of specific types of genetic disorders, see Chapter 49.

Mendelian or Monogenic Laws of Inheritance

Principles of inheritance of single-gene disorders are the same principles that govern the inheritance of other traits, such as eye and hair color. These are known as Mendel's laws of inheritance, named for Gregory Mendel, an Austrian naturalist who conducted genetic research. These patterns occur because a single gene is defective and the disorders that result are referred to as monogenic or, sometimes, Mendelian disorders. If the defect occurs on the autosome, the genetic disorder is termed autosomal; if the defect is on the X chromosome, the genetic disorder is termed X-linked. The defect also can be classified as dominant or recessive. Monogenic disorders include autosomal dominant, autosomal recessive, X-linked dominant, and X-linked recessive patterns.

AUTOSOMAL DOMINANT INHERITANCE DISORDERS

Autosomal dominant inherited disorders occur when a single gene in the heterozygous state is capable of producing the phenotype. In other words, the abnormal or mutant gene overshadows the normal gene and the person will demonstrate signs and symptoms of the disorder. The affected person generally has one affected parent. However, there are varying degrees of presentation among individuals in a family. For example, a parent with a mild form of the disorder could have a child with a more severe form (termed *variable expression*). In some autosomal dominant disorders there may be no history of an affected family member. This can be due to the child representing a new mutation or the result of incomplete or reduced penetrance, which means that a person with the genetic mutation

does not develop phenotypic features of the disorder. Incomplete or reduced penetrance may result from a combination of genetic, environmental, and lifestyle factors, age, and gender.

Offspring of an affected parent will have a 50% chance of inheriting two normal genes (disorder free) and a 50% chance of inheriting one normal and one abnormal gene (and, thus, the disorder) (Fig. 10.13) (GHR, 2019c). Females and males are equally affected by autosomal dominant disorders and an affected male can pass the disorder on to his son (GHR, 2019c). This male-to-male transmission is important in distinguishing autosomal dominant inheritance from X-linked inheritance. Common types of genetic disorders that follow the autosomal dominant pattern of inheritance include neurofibromatosis (genetic disorders affecting the development and growth of neural cells and tissues), Marfan syndrome, Huntington disease (a genetic disorder affecting the nervous system characterized by abnormal involuntary movements and progressive dementia), achondroplasia (a genetic disorder resulting in disordered growth and abnormal body proportion), and polycystic kidney disease (a genetic disorder involving the growth of multiple, bilateral, grapelike clusters of fluid-filled cysts in the kidneys that eventually compress and replace functioning renal tissue).

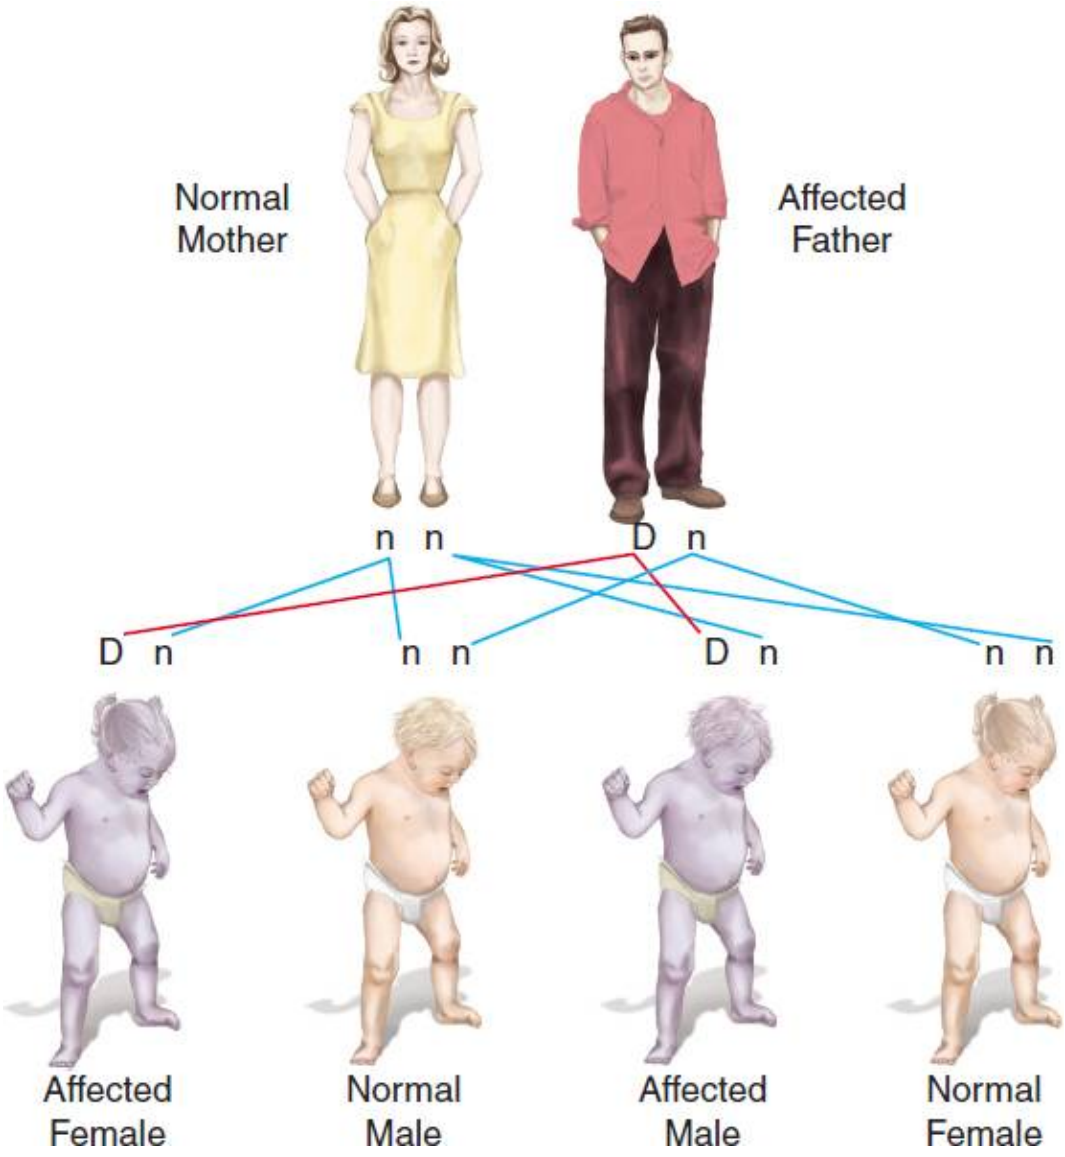

FIGURE 10.13. Autosomal dominant inheritance.

AUTOSOMAL RECESSIVE INHERITANCE DISORDERS

Autosomal recessive inherited disorders occur when two copies of the mutant or abnormal gene in the homozygous state are necessary to produce the phenotype. In other words, two abnormal genes are needed for the individual to demonstrate signs and symptoms of the disorder. Both parents of the affected person must be heterozygous carriers of the gene (clinically normal but carriers of the gene).

Offspring of two carriers of the abnormal gene have a 25% chance of inheriting two normal genes; a 50% chance of inheriting one normal gene and one abnormal gene (carrier); and a 25% chance of inheriting two abnormal genes (and, thus, the disorder) (Fig. 10.14) (GHR, 2019c). Affected people are usually present in only one generation of the family. Females and males are equally affected and a male can pass the disorder on to his son. The chance that any two parents will both be carriers of the mutant gene is increased if the couple has consanguinity (relationship by blood or common ancestry) (GHR, 2019c). Common types of genetic disorders that follow the autosomal recessive inheritance pattern include cystic fibrosis (a genetic disorder involving generalized dysfunction of the exocrine glands), phenylketonuria (a disorder involving a deficiency in a liver enzyme that leads to the inability to process the essential amino acid phenylalanine), Tay–Sachs disease (a disorder due to insufficient activity of the enzyme hexosaminidase, which is necessary for the breakdown of certain fatty substances in the brain and nerve cells), and sickle cell disease (a genetic disorder in which the red blood cells carry an ineffective type of hemoglobin instead of the normal adult hemoglobin).

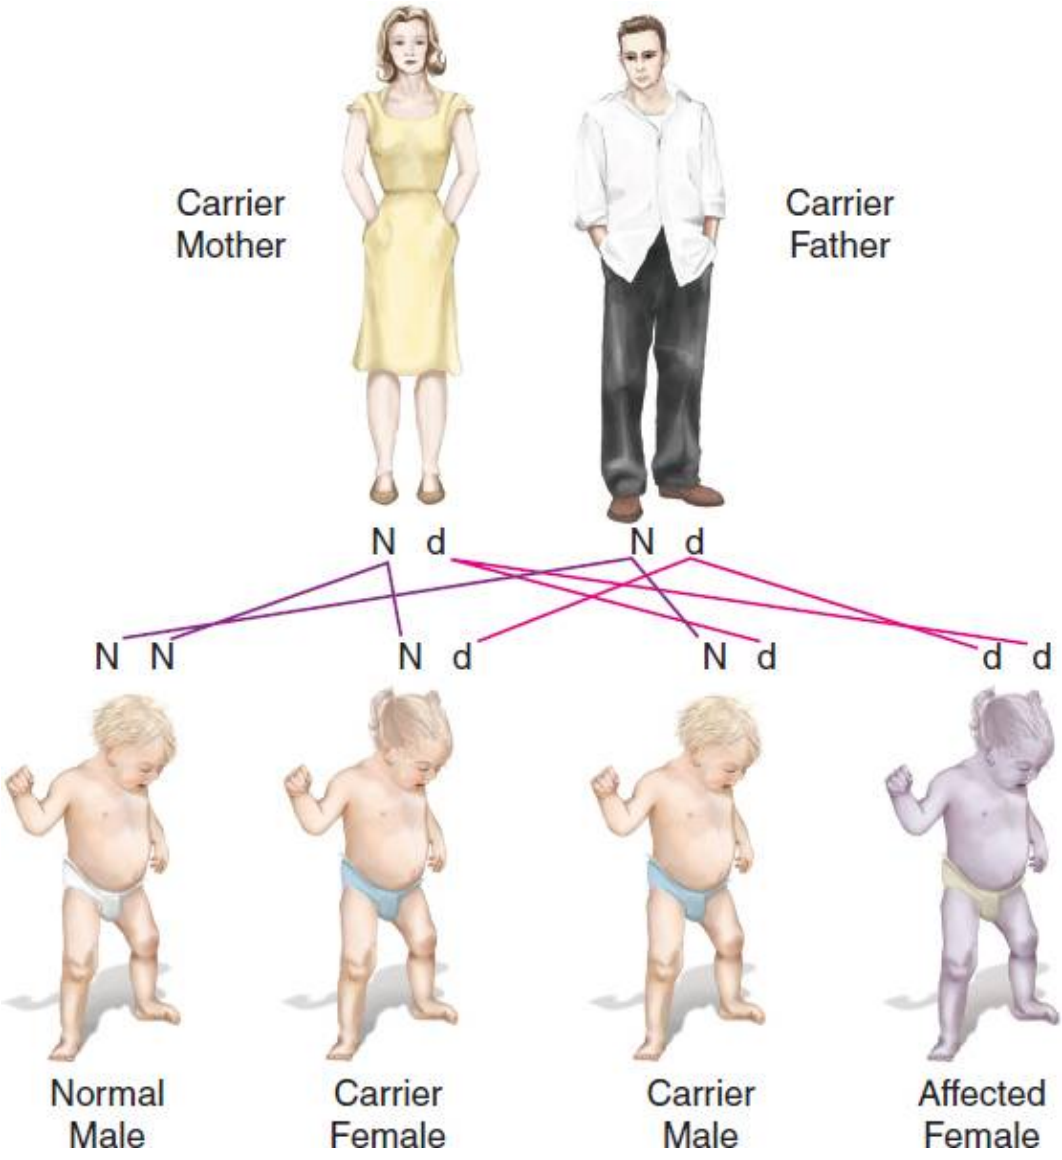

FIGURE 10.14. Autosomal recessive inheritance.

X-LINKED INHERITANCE DISORDERS

X-linked inherited disorders are those associated with altered genes present on the X chromosome. They differ from autosomal disorders. If a male inherits an X-linked altered gene, he will express the condition. This is because a male has only one X chromosome, therefore all the genes on his X chromosome will be expressed (the Y chromosome carries no normal allele to compensate for the altered gene). Because females inherit two X chromosomes, they can be either heterozygous or homozygous for any allele. Therefore,

X-linked disorders in females are expressed similarly to autosomal disorders.

X-LINKED RECESSIVE INHERITANCE

Most X-linked disorders demonstrate a recessive pattern of inheritance (GHR, 2019c). There are more affected males than females because all the genes on a man's X chromosome will be expressed since a male has only one X chromosome (Scott & Lee, 2020). On the other hand, a female will usually need two abnormal X chromosomes to exhibit the disease, and one normal and one abnormal X chromosome to be a carrier of the disease. There is no male-to-male transmission (since no X chromosome from the male is transmitted to male offspring), but any man who is affected with an X-linked recessive disorder will have carrier daughters. If a woman is a carrier, there is a 25% chance she will have an affected son, a 25% chance that her daughter will be a carrier, a 25% chance that she will have an unaffected son, and a 25% chance her daughter will be a noncarrier (Fig. 10.15) (Scott & Lee, 2020). Common types of genetic disorders that follow X-linked recessive inheritance patterns include hemophilia, color blindness, and Duchenne muscular dystrophy (GHR, 2019c).

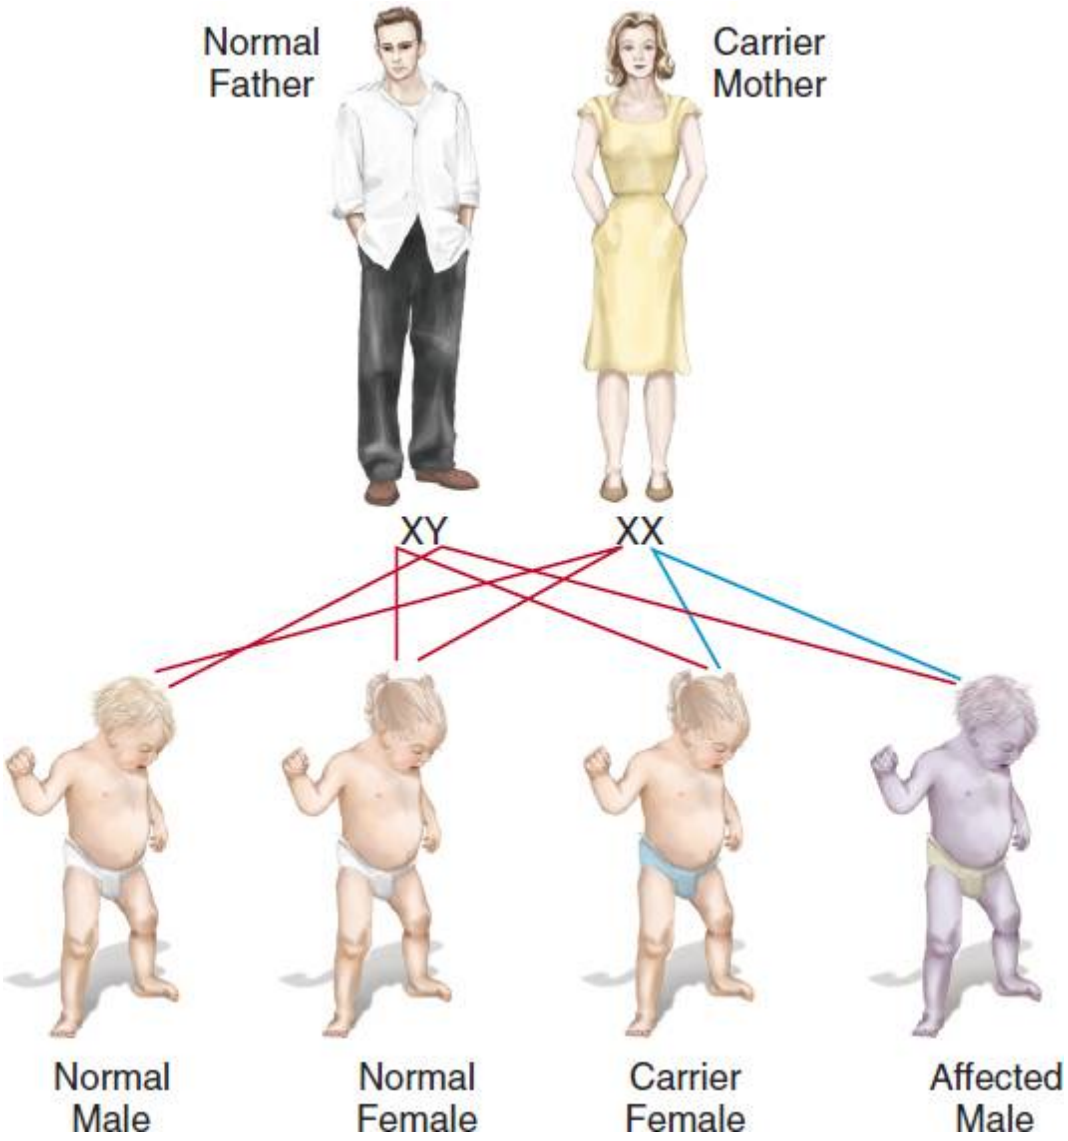

FIGURE 10.15. X-linked recessive inheritance.

X-LINKED DOMINANT INHERITANCE

X-linked dominant inheritance occurs when a male has an abnormal X chromosome or a female has one abnormal X chromosome. All of the daughters and none of the sons of an affected male will inherit the condition, while both male and female offspring of an affected woman have a 50% chance of inheriting the condition (Fig. 10.16) (GHR, 2019c). Males are more severely affected than females. Many X-linked dominant disorders have lethal results in males (Zirn & Mehnert, 2019). In females, even though the gene is dominant,

having a second normal X gene offsets the effects of the dominant gene to some extent resulting in decreasing severity of the disorder. X-linked dominant disorders are rare; examples include hypophosphatemic (vitamin D–resistant) rickets and fragile X syndrome.

Multifactorial Inheritance Disorders

Many of the common congenital malformations, such as cleft lip, cleft palate, spina bifida, pyloric stenosis, clubfoot, congenital hip dysplasia, and cardiac defects, are attributed to multifactorial inheritance (Sharma et al., 2019). These conditions are thought to be caused by multiple gene and environmental factors. That is, a combination of genes from both parents, along with unknown environmental factors, produces the trait or condition. An individual may inherit a predisposition to a particular anomaly or disease. The anomalies or diseases vary in severity, and often a sex bias is present. For example, pyloric stenosis is seen more often in males, while congenital hip dysplasia is much more likely to occur in females. Multifactorial conditions tend to run in families, but the pattern of inheritance is not as predictable as with single-gene disorders. The chance of recurrence is also less than in single-gene disorders, but the degree of risk is related to the number of genes in common with the affected individual. The closer the degree of relationship, the more genes an individual has in common with the affected family member, resulting in a higher chance the individual's offspring will have a similar defect. In multifactorial inheritance the likelihood that both identical twins will be affected is not 100%, indicating that there are nongenetic factors involved.

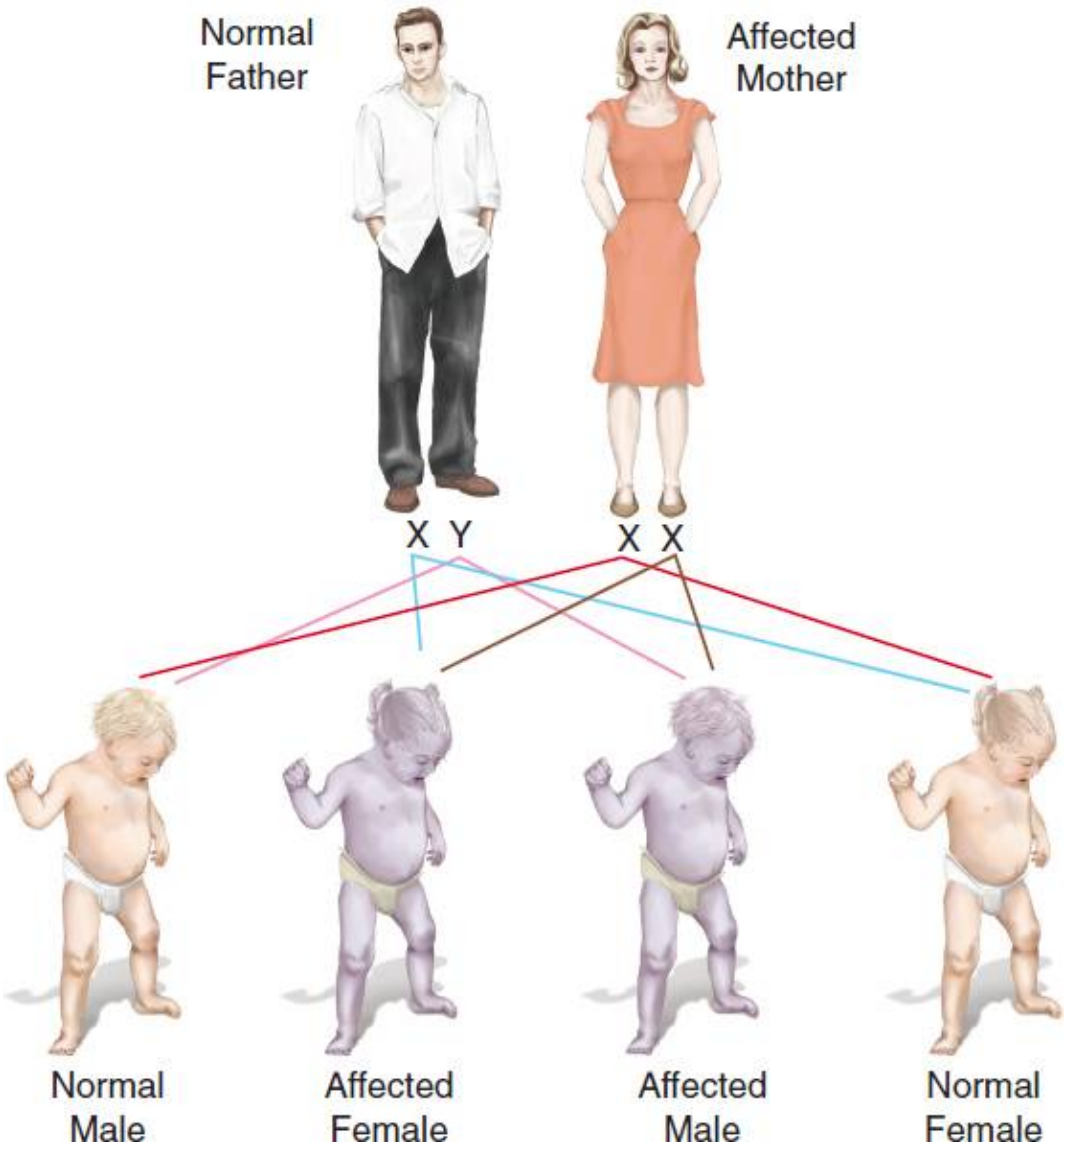

FIGURE 10.16. X-linked dominant inheritance.

Nontraditional Inheritance Patterns

Molecular studies have revealed that some genetic disorders are inherited in ways that do not follow the typical patterns of dominant, recessive, X-linked, or multifactorial inheritance. Examples of nontraditional inheritance patterns include mitochondrial inheritance and genomic imprinting. As the science of molecular genetics advances and more is learned about inheritance patterns, other nontraditional patterns of inheritance may be discovered or found to be relatively common.

MITOCHONDRIAL INHERITANCE

Certain diseases result from mutations in the mitochondrial DNA. Mitochondria (the part of the cell responsible for energy production) are inherited almost exclusively from the mother. Therefore, mitochondrial inheritance is usually passed from the mother to the offspring, regardless of the offspring's sex (differentiating mitochondrial inheritance from X-linked recessive inheritance). These mutations are often deletions and abnormalities and are often seen in one or more organs, such as the brain, eye, and skeletal muscle. They are often associated with energy deficits in cells with high-energy requirements, such as nerve and muscle cells. These disorders tend to be progressive and the age of onset can vary from infancy to adulthood. There is an extreme amount of variability in symptoms within a family. Examples of disorders that follow mitochondrial inheritance include Kearns–Sayre syndrome (a neuromuscular disorder) and Leber's hereditary optic neuropathy (which causes progressive visual impairment).

GENOMIC IMPRINTING

Another nontraditional inheritance pattern results from a process called genomic imprinting. Genomic imprinting plays a critical role in fetal growth and development and placental functioning. It is a phenomenon by which the expression of a gene is determined by its parental origin. In genomic imprinting both the maternal and paternal alleles are present, but only one is expressed; the other is inactive. Genomic imprinting does not alter the genetic sequence itself, but affects the phenotype observed. In these cases, the altered genes in a certain region of the genome have very different expressions depending on whether they were inherited from the mother or the father. Several human syndromes are known to be associated with defects in gene imprinting. Disorders that result from a disruption of imprinting usually involve a growth phenotype and include varying degrees of developmental problems. Common examples include Prader–Willi syndrome (a condition resulting in severe hypotonia and

hyperphagia, leading to obesity and intellectual disability), Angelman syndrome (a neurodevelopmental disorder associated with intellectual disability, jerky movements, and seizures), and Beckwith–Wiedemann syndrome (characterized by somatic overgrowth, congenital malformations, and a predisposition to embryonic neoplasia).

Chromosomal Abnormalities

In some cases of genetic disorders, the abnormality occurs due to problems with the chromosomes. Chromosomal abnormalities do not follow straightforward patterns of inheritance. Although some chromosomal disorders can be inherited, most others occur due to random events during the formation of reproductive cells or in early fetal development. Most chromosomal abnormalities occur due to an error in the egg or sperm. Therefore, the abnormality is present in every cell of the body. Some abnormalities can happen after fertilization, during mitotic cell division, and result in mosaicism. **Mosaicism** or the mosaic form is when the chromosomal abnormalities do not show up in every cell; only some cells or tissues carry the abnormality. In mosaic forms of the disorder the symptoms are usually less severe than if all the cells were abnormal.

Chromosomal abnormalities occur in about one in 150 live-born infants (March of Dimes, 2019a). Congenital anomalies and intellectual disability are often associated with chromosomal abnormalities (Pyeritz et al., 2019). These abnormalities occur on autosomal or nonsex chromosomes as well as sex chromosomes and can result from abnormalities of either chromosome number or chromosome structure.

As mentioned, a karyotype is a pictorial analysis of chromosomes. It depicts a systematic arrangement of chromosomes of a single cell by pairs (see Fig. 10.12). Karyotyping is often used in prenatal testing to diagnose or predict genetic diseases.

Abnormalities of Chromosome Number

Chromosomal abnormalities of number often result due to nondisjunction (failure of separation of the chromosome pair during cell division, meiosis, or mitosis). Few chromosomal numerical abnormalities are compatible with full-term development and most result in spontaneous abortion (Bacino, 2019).

There are some numerical abnormalities that do support development to term because the chromosome on which the abnormality is present carries relatively few genes (such as chromosome 13, 18, 21, or X). Two common abnormalities of chromosome number are monosomies and trisomies. In monosomies, there is only one copy of a particular chromosome instead of the usual pair (an entire single chromosome is missing). In these cases, all fetuses spontaneously abort in early pregnancy. Survival is seen only in mosaic forms of these disorders. In **trisomies**, there are three of a particular chromosome instead of the usual two (an entire single chromosome is added). The most common trisomies include trisomy 21 (Down syndrome), trisomy 18, and trisomy 13. Figure 10.17 shows the karyotype of a child with Down syndrome. (See Chapter 49 for a detailed discussion of these disorders.) Trisomies may be present in every cell or may present in the mosaic form.

Abnormalities of Chromosome Structure

Abnormalities of chromosome structure usually occur when there is a breakage and loss of a portion of one or more chromosomes, and during the repair process the broken ends are rejoined incorrectly. Structural abnormalities usually lead to having too much or too little genetic material. Altered chromosome structure can take on several forms. Deletions occur when a portion of the chromosome is missing or deleted, resulting in a loss of that portion of the chromosome. Duplications are seen when a portion of the chromosome is duplicated and an extra chromosomal segment is present. Clinical findings vary depending on how much chromosomal material is involved. Inversions occur when a portion of the chromosome breaks off at two points and is turned upside down and reattached;

therefore, the genetic material is inverted. With inversion, there is no loss or gain of chromosomal material and carriers are phenotypically normal, but they do have an increased risk for miscarriage and having chromosomally abnormal offspring (GHR, 2019c). Ring chromosomes are seen when a portion of a chromosome has broken off in two places and formed a circle or ring. The most clinically significant structural abnormality is a translocation. This occurs when a portion of one chromosome is transferred to another chromosome and an abnormal rearrangement is present.

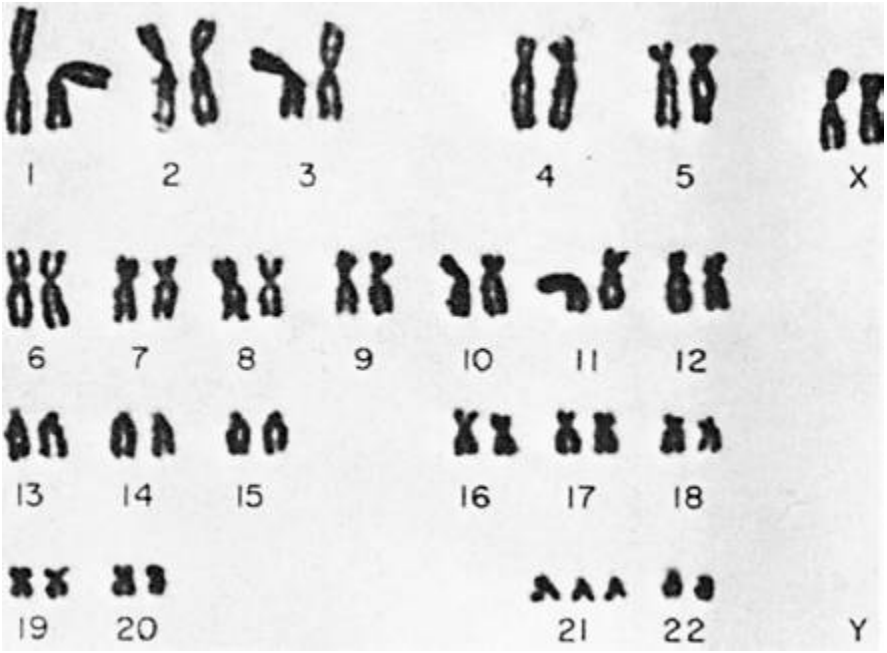

FIGURE 10.17. Karyotype of a child with Down syndrome.

Structural abnormalities can be balanced or unbalanced. Balanced abnormalities involve the rearrangement of genetic material with neither an overall gain nor loss. Individuals who inherit a balanced structural abnormality are usually phenotypically normal but are at a higher risk for miscarriages and having chromosomally abnormal offspring. Examples of structural rearrangements that can be balanced include inversions, translocation, and ring chromosomes. Unbalanced structural abnormalities are similar to numerical abnormalities because genetic material is either gained or lost.

Unbalanced structural abnormalities can encompass several genes and result in severe clinical consequences.

Sex Chromosome Abnormalities

Chromosomal abnormalities can also involve sex chromosomes. These cases are usually less severe in their clinical effects than autosomal chromosomal abnormalities. Sex chromosome abnormalities are gender specific and involve a missing or extra sex chromosome. They affect sexual development and may cause infertility, growth abnormalities, and possibly behavioral and learning problems (Bacino, 2019). However, many affected people lead essentially normal lives. Examples are Turner syndrome in females and Klinefelter syndrome in males. (See Chapter 49 for a more detailed discussion of these disorders.)

GENETIC EVALUATION AND COUNSELING

Genetic counseling is a communication and educational process where the genetic influence of health is explained along with information regarding a specific genetic disorder, its transmission, inheritance, and options available in management and family planning. It helps people understand and adapt to the medical, physiological and familial implications of genetic contributions to disease (CDC, 2020b). There are a variety of reasons a person should be referred for genetic counseling (Box 10.2). In many cases, geneticists and genetic counselors provide information to families regarding genetic diseases. However, an experienced family physician, pediatrician, or nurse who has received special training in genetics may also provide the information. A genetic consultation involves evaluation of an individual or a family. Its purpose is to confirm, diagnose, or rule out genetic conditions; identify medical management issues; calculate and communicate genetic risks to a family; discuss ethical and legal issues; and assist in providing and arranging psychosocial support. Genetic counselors serve as educators and resource persons for other health care providers and

the general public. Nurses have long been on the forefront of genetic counseling for their clients. The knowledge gained from the Human Genome Project is transforming the health care model, with implications for nurses in genetic counseling, practice and research. Genomic developments are changing health care. Discoveries such as mapping the human genome and the illustration of genomic variations associated with disease are being translated into clinical practice. Thus, nurses must be competent in genomics to provide safe, cost-effective, quality health care (International Society of Nurses in Genetics [ISONG], 2019a).

BOX 10.2 Those Who May Benefit from Genetic Counseling

- Maternal age 35 years or older when the baby is born
- Paternal age 50 years or older
- Previous child, parents, or close relatives with an inherited disease, congenital anomalies, metabolic disorders, developmental disorders, or chromosomal abnormalities
- Consanguinity or incest
- Pregnancy screening abnormality, including alpha-fetoprotein, triple/quadruple screen, amniocentesis, or ultrasound
- Stillborn with congenital anomalies
- Two or more pregnancy losses
- Exposure to drugs, medications, radiation, chemicals, or infection
- Teratogen exposure or risk
- Concerns about genetic defects that occur frequently in their ethnic or racial group (e.g., those of African descent are most at risk for having a child with sickle cell anemia)
- Abnormal newborn screening
- Couples with a family history of X-linked disorders
- Carriers of autosomal recessive or dominant diseases
- Child born with one or more major malformations in a major organ system
- Child with abnormalities of growth
- Child with developmental delay, intellectual disability, blindness, or deafness

Retrieved June 16, 2020, from https://www.cdc.gov/genomics/gtesting/genetic_counseling.htm; and Zirn, B. & Mehnert, K. (2019). *Guide for genetic consultation*. Springer Nature.

The ideal time for genetic counseling is before conception. Preconception counseling allows couples to identify and reduce potential pregnancy risks, plan for known risks, and establish early prenatal care. Unfortunately, many women delay seeking prenatal care until their second or third trimester, after the crucial time of organogenesis. Therefore, it is important that preconception counseling is offered to all women as they seek health care throughout their childbearing years, especially if they are contemplating pregnancy. This requires health care providers to take an active role. Consideration of genetics is rapidly becoming a part of routine health care, and all nurses need to be up to date and confident in their understanding of this topic.

CONSIDER THIS

As I waited for the genetic counselor to come into the room, my mind was filled with numerous fears and questions. What does an inconclusive amniocentesis really mean? What if this pregnancy produced an abnormal baby? How would I cope with a special child in my life? If only I had gone to the midwife sooner when I thought I was pregnant, but still in denial. Why did I wait so long to admit this pregnancy and get prenatal care? If only I had started to take my folic acid pills when prescribed. Why didn't I research my family's history to know of any hidden genetic conditions? What about my sister with a Down syndrome child? What must I have been thinking? I guess I could play the "what-if" game forever and never come up with answers. It was too late to do anything about this pregnancy because I was in my last trimester. I started to pray silently when the counselor opened the door….

Thoughts: This woman is reviewing the last several months, looking for answers to her greatest fears. Inconclusive screenings can introduce emotional torment for many women as they wait for validating results. Are these common thoughts and fears for many women facing potential genetic disorders? What supportive interventions might the nurse offer?

Preconception counseling plays a key role in preparing for a pregnancy. The focus should be on identifying social, behavioral, genetic, environmental, and biomedical risks to a woman's pregnancy outcome with the goal of reducing these risks through education, counseling, and appropriate interventions. In couples with a history of recurrent early pregnancy loss, counseling is of particular importance because women are invariably more distressed and require reassurance to avoid future pregnancy losses. Several interventions ranging from genetic testing to lifestyle changes and medications may have a positive effect on the chances of a successful pregnancy. Early pregnancy monitoring and support increases the chance of a live birth and helps to predict potential future pregnancy complications. Recent research suggests that

events that occur in the uterine decidua, even before a woman knows she is pregnant, may have a significant impact on fetal growth and the outcome of pregnancy. With this in mind, shifting future research and clinical practice to focus on the periconceptual period and the very early stages of pregnancy should offer significant benefits to the health of both the mother and her infant. The overall aim should be to effectively use every pregnancy as the health care opportunity of two lifetimes. Screening in the prepregnancy period offers the advantages of identifying couples at risk for genetic diseases to optimize the outcomes when possible (American College of Obstetricians and Gynecologists [ACOG], 2019).

Preconception screening and counseling can raise serious ethical and moral issues for a couple. The results of prenatal genetic testing can lead to the decision to terminate a pregnancy, even if the results are not conclusive but indicate a strong possibility that the child will have an abnormality. The severity of the abnormality may not be known, and some may find the decision to terminate unethical. Another difficult situation that provides an example of the ethical and moral issues surrounding genetic screening and counseling involves disorders that affect only one gender of offspring. A mother may find she is a carrier of a gene for a disorder for which there is no prenatal screening test available. In these cases the couple may decide to terminate any pregnancy where the fetus is the affected sex, even though there is a 50% chance that the child will not inherit the disorder. In these situations, the choice is the couple's and information and support must be provided in a nondirective, nonjudgmental manner.

Genetic counseling is particularly important if a congenital anomaly or genetic disease has been diagnosed prenatally or when a child is born with a life-threatening congenital anomaly or genetic disease. In these cases families need information urgently so they can make immediate decisions. If a diagnosis with genetic implications is made later in life, if a couple with a family history of a genetic disorder or a previous child with a genetic disorder is planning a family, or if there is suspected teratogen exposure, urgency of information is not such an issue. In these situations, the

family needs to take in all the information and explore their options. This may occur during several meetings over a longer period of time.

Genetic counseling involves extensive information gathering about birth history, past medical history, and current health status as well as a family history of congenital anomalies, mental retardation, genetic diseases, reproductive history, general health, and causes of death. A detailed family history is imperative and in most cases will include the development of a pedigree, which is like a family tree (Fig. 10.18). Information is ideally gathered on three generations, but if the family history is complicated, information from more distant relatives may be needed. Families receiving genetic counseling should be told that this information will be necessary so that they can discuss these sensitive issues with family members in advance. When necessary, medical records may be requested for family members, especially those who have a genetic disorder, to help ensure accuracy of the information. Sometimes the process of preparing a pedigree may reveal information that is not known by all family members, such as an adoption, a child conceived through in vitro fertilization, or a husband not being the father of a baby. Therefore, it is extremely important to take steps to maintain confidentiality. After careful analysis of the data obtained, referral to a genetic counselor when indicated is appropriate.

Medical genetic knowledge has increased dramatically over the past few decades. This has greatly expanded the role of the genetic counselor. It is possible not only to detect specific diseases with genetic mutations, but also to test for a genetic predisposition to various diseases or conditions and certain physical characteristics. This leads to complex ethical, moral, and social issues. Health care providers need to maintain privacy and confidentiality and administer care in a nondiscriminatory manner while maintaining sensitivity to cultural differences. It is essential to respect the individual's autonomy and present information in a nondirective manner.

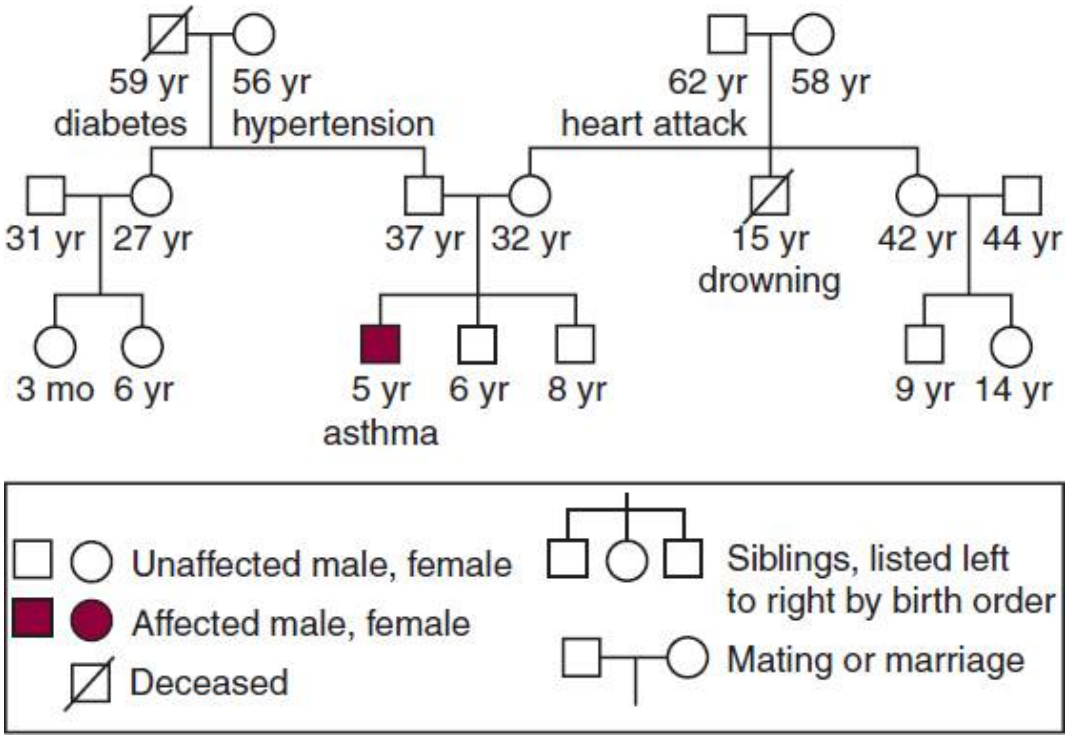

FIGURE 10.18. A pedigree is a diagram made using symbols that demonstrates the links between family members and focuses on medical and health information for each relative.

Nursing Roles and Responsibilities

The nurse is likely to interact with the client in a variety of ways related to genetics—taking a family history, scheduling genetic testing, advocating for autonomy and confidentiality in the informed-decision process, explaining the purposes of all screening and diagnostic tests, answering questions, and addressing concerns raised by family members. Nurses are often the first health care providers to encounter women with preconception and prenatal issues. Nurses play an important role in beginning the preconception counseling process and referring women and their partners for further genetic testing when indicated.

An accurate and thorough family history is an essential part of preconception counseling. Nurses in any practice setting can obtain a client's history during the initial encounter. The purpose is to gather client and family information that may provide clues as to whether

the client has a genetic trait, inherited condition, or inherited predisposition (ISONG, 2019b). At a basic level, all nurses should be able to take a family medical history to help identify those at risk for genetic conditions, and then initiate a referral when appropriate. Box 10.3 presents examples of focused assessment questions that can be used. Based on the information gathered during the history, the nurse must decide whether a referral to a genetic specialist is necessary or whether further evaluation is needed. Families identified with genetic issues need unique clinical care including management of acute illnesses, screening for long-term complications, discussion of the etiology of the condition, connections to social supports, and clarification of the recurrence risks and prenatal testing and treatment options (ISONG, 2019b). Prenatal testing to assess for genetic risks and defects might be used to identify genetic disorders. These tests are described in Common Laboratory and Diagnostic Tests 10.1.

Remember Robert and Kate Shafer? Based on the information gathered from their genetic history, they were referred to a genetic specialist. What prenatal tests might be ordered to assess their risk for genetic disorders? What would be the nurse's role related to genetic counseling?

BOX 10.3 Focused Health Assessment: Genetic History

- What was the cause and age of death for deceased family members?
- Does any consanguinity exist between relatives?
- Do any serious illnesses or chronic conditions exist? If so, what was the age of onset?
- Do any female family members have a history of miscarriages, stillbirths, or diabetes?
- Do any female members have a history of alcohol or drug use during pregnancy?
- What were the ages of female members during childbearing, especially if older than 35?
- Do any family members have mental retardation or developmental delays?
- Do any family members have a known or suspected metabolic disorder such as PKU?
- Do any family members have an affective disorder such as bipolar disorder?
- Have any close relatives been diagnosed with any type of cancer?
- What is your ethnic background (explore as related to certain disorders)?
- Do any family members have a known or suspected chromosomal disorder?
- Do any family members have a progressive neurologic disorder?

Retrieved May 21, 2020, from https://www.uptodate.com/contents/genetic-counseling-family-history-interpretation-and-risk-assessment

Nurses working with families involved with genetic counseling typically have certain responsibilities. These include:

- Using interviewing and active listening skills to identify genetic concerns
- Knowing basic genetic terminology and inheritance patterns
- Explaining basic concepts of probability and disorder susceptibility
- Safeguarding the privacy and confidentiality of clients' genetic information

- Providing complete informed consent to facilitate decisions about genetic testing
- Discussing costs of genetic services and the benefits and risks of using health insurance to pay for genetic services, including potential risks of discrimination
- Recognizing and defining ethical, legal, and social issues
- Providing accurate information about the risks and benefits of genetic testing
- Providing culturally appropriate methods to convey genetic information
- Monitoring clients' emotional reactions after receiving genetic analysis
- Providing information on appropriate local support groups
- Knowing their own limitations and making appropriate referrals (Genetics/Genomics Competency Center, 2019)

COMMON LABORATORY AND DIAGNOSTIC TESTS 10.1 Prenatal Tests to Assess Risk for Genetic Disorders

Test	Description	Indication	Timing
Alpha-fetoprotein	A sample of the woman's blood is drawn to evaluate plasma protein that is produced by the fetal liver, yolk sac, and GI tract, and crosses from the amniotic fluid into the maternal blood.	Increased levels might indicate a neural tube defect, Turner syndrome, tetralogy of Fallot, multiple gestation, omphalocele gastroschisis, or hydrocephaly. Decreased levels might indicate Down syndrome or trisomy 18	Typically performed between 15 and 18 weeks' gestation
Amniocentesis	Amniotic fluid aspirated from the amniotic sac; safety concerns include infection, pregnancy loss, and fetal needle injuries	To perform chromosome analysis, alpha-fetoprotein, DNA markers, viral studies, karyotyping, and identify inborn errors of metabolism	Usually performed between 15 and 20 weeks' gestation to allow for adequate amniotic fluid volume to accumulate; results take 2 to 4 weeks
Chorionic villus sampling	Removal of small tissue specimen from the fetal portion of the placenta, which reflects the fetal genetic makeup; main complications include severe transverse limb defects	To detect fetal karyotype, sickle cell anemia, phenylketonuria, Down syndrome, Duchenne muscular dystrophy, and numerous other genetic disorders	Typically performed between 10 and 12 weeks' gestation, with results available in less than 1 week

	and spontaneous pregnancy loss.		
Percutaneous umbilical blood sampling	Insertion of a needle directly into a fetal umbilical vessel under ultrasound guidance; two potential complications: fetal hemorrhage and risk of infection	Used for prenatal diagnosis of inherited blood disorders such as hemophilia A, karyotyping, detection of fetal infection, determination of acid–base status, and assessment and treatment of isoimmunization	Generally performed after 16 weeks' gestation
Fetal nuchal translucency (FNT)	An intravaginal ultrasound that measures fluid collection in the subcutaneous space between the skin and the cervical spine of the fetus	To identify fetal anomalies; abnormal fluid collection can be associated with genetic disorders (trisomies 13, 18, and 21), Turner syndrome, cardiac deformities, and/or physical anomalies. When the FNT is greater than 2.5 mm, the measurement is considered abnormal	Performed between 10 and 14 weeks' gestation
Level II ultrasound/fetal scan	Use of high-frequency sound waves	Enables evaluation of structural	Typically performed after 18 weeks' gestation

	to visualize the fetus	changes to be identified early	
Triple and quad screening tests	Triple screening includes alpha-fetoprotein, estriol, and beta-hCG; quad screening includes alpha-fetoprotein, estriol, beat-hCG, and inhibin A.	To identify risk for Down syndrome, neural tube defects, and other chromosomal disorders. Elevated hCG combined with lower-than-normal estriol and MSAFP levels indicate increased risk for Down syndrome or other trisomy condition	Performed between 15 and 18 weeks' gestation
Preimplantation genetic diagnosis	Genetic testing of embryos produced through in vitro fertilization (IVF)	Identifies embryos carrying specific genetic alterations that can cause disease, and transfer those without genetic alterations into the woman's uterus to start a pregnancy; prevents inheritable genetic disease before implantation	Usually on day 3 after egg retrieval and 2 days after fertilization, a single blastomere is removed from the developing embryo to be evaluated
Cell-free fetal DNA (CffDNA)	A noninvasive prenatal test using maternal plasma which hold a mixture	Determines fetal sex in pregnancies at risk of sex-linked	A maternal blood sample is taken and next generation sequencing is

	of maternal and fetal DNA after 4 weeks' gestation	conditions; RhD genotyping in pregnancies at risk of hemolytic disease of the newborn and fetal chromosomal abnormalities such as Down syndrome	used to analyze the cffDNA at approximately 10 weeks' gestation.

Chapter 32 Prenatal diagnosis of congenital disorders. In *Creasy & Resnik's Maternal-fetal Medicine: Principles and practice* (8th ed., pp. 493–538). Elsevier.

Talking with families who have recently been diagnosed with a genetic disorder or who have had a child born with congenital anomalies is very difficult. Many times the nurse may be the one who has first contact with these parents and will be the one to provide follow-up care.

Genetic disorders are significant, life-changing, and possibly life-threatening situations. The information is highly technical and the field is undergoing significant technologic advances. Nurses need an understanding of who will benefit from genetic counseling and must be able to discuss the role of the genetic counselor with families. The nurse wants to ensure that families at risk are aware that genetic counseling is available before they attempt to have another baby.

Based on the results of their genetic tests, Robert and Kate are placed at moderate risk for having an infant with an autosomal recessive genetic disorder. The couple asks the nurse what all of this means. What information should the nurse provide about concepts of probability and disorder susceptibility for this couple? How can the nurse help this couple to make knowledgeable decisions concerning their reproductive future?

Nurses play an essential role in providing emotional support to the family through this challenging time. Genetics permeates all aspects of health care. Today, everyone is embracing quality and evidence-based care. Nurses who have an understanding of genetics and genomics will possess the foundation to provide quality, evidence-based care especially with follow-up counseling after the couple or family has been to the genetic specialist (Sharma et al., 2019).

TAKE NOTE!

Nurses need to be actively engaged with clients and their families and help them consider the facts, values, and context in which they are making decisions. Nurses need to be open and honest with families as they discuss these sensitive and emotionally laden choices.

The nurse is in an ideal position to help families review what has been discussed during the genetic counseling sessions and to answer any additional questions they might have. Referral to appropriate agencies, support groups, and resources, such as a social worker, a chaplain, or an ethicist, is another key role when caring for families with suspected or diagnosed genetic disorders. Couples need unique clinical care which includes screening for genetic disorders, discussion of the etiology of a potential condition, connections to social supports, and clarification of the recurrence risks and prenatal testing and treatment options. Nurses need to be involved in all aspects of this care because well-informed nurses can make valuable contributions to applications of genetic science to women's health care.

KEY CONCEPTS

- Fertilization, which takes place in the outer third of the ampulla of the fallopian tube, leads to the formation of a zygote. The zygote undergoes cleavage, eventually implanting in the endometrium about 7 to 10 days after conception.
- Three embryonic layers of cells are formed and include the ectoderm, which forms the central nervous system, special senses, skin, and glands; the mesoderm, which forms the skeletal, urinary, circulatory, and reproductive systems; and the endoderm, which forms the respiratory system, liver, pancreas, and digestive system.
- Amniotic fluid surrounds the embryo and increases in volume as the pregnancy progresses, reaching approximately 1 L in volume by term.
- At no time during pregnancy is there any direct connection between the blood of the fetus and the blood of the mother, so there is no mixing of blood. A specialized connective tissue known as Wharton jelly surrounds the three blood vessels in the umbilical cord to prevent compression, which would choke off the blood supply and nutrients to the growing life inside.
- The placenta protects the fetus from immune attack by the mother, removes waste products from the fetus, induces the mother to bring more food to the placenta and, near the time of birth, and produces hormones that mature fetal organs in preparation for life outside the uterus.
- The purpose of fetal circulation is to carry highly oxygenated blood to vital areas (heart and brain) while first shunting it away from less vital ones (lungs and liver).
- Humans have 46 paired chromosomes that are found in all cells of the body, except the ovum and sperm cells, which have just 23 chromosomes. Each person has a unique genetic constitution, or genotype.
- Research from the Human Genome Project has provided a better understanding of the genetic contribution to disease.
- Genetic disorders can result from abnormalities in patterns of inheritance or chromosomal abnormalities involving chromosomal number or structure.

- Autosomal dominant inheritance occurs when a single gene in the heterozygous state is capable of producing the phenotype. Autosomal recessive inheritance occurs when two copies of the mutant or abnormal gene in the homozygous state are necessary to produce the phenotype. X-linked inheritance disorders are those associated with altered genes present on the X chromosome. They can be dominant or recessive. Multifactorial inheritance is thought to be caused by multiple genetic and environmental factors.
- In some cases of genetic disorders, a chromosomal abnormality occurs. Chromosomal abnormalities do not follow straightforward patterns of inheritance. These abnormalities occur on autosomal as well as sex chromosomes and can result from changes in the number or structure of the chromosomes.
- Genetic counseling involves evaluation of an individual or a family. Its purpose is to confirm, diagnose, or rule out genetic conditions; identify medical management issues; calculate and communicate genetic risks to a family; discuss ethical and legal issues; and assist in providing and arranging psychosocial support.
- Legal, ethical, and social issues can arise related to genetic testing and may include the privacy and confidentiality of genetic information, who should have access to personal genetic information, psychological impact and stigmatization due to individual genetic differences, use of genetic information in reproductive decision-making and reproductive rights, and whether testing should be performed if no cure is available.
- Preconception screening and counseling can raise serious ethical and moral issues for a couple. The results of prenatal genetic testing can lead to the decision to terminate a pregnancy.
- Nurses play an important role in beginning the preconception counseling process and referring women and their partners for further genetic information when indicated. Many times the nurse is the one who has first contact with these women and will be the one to provide follow-up care.
- Nurses need to have a solid understanding of who will benefit from genetic counseling and be able to discuss the role of the

genetic counselor with families, ensuring that families at risk are aware that genetic counseling is available before they attempt to have another baby.

- Nurses play an essential role in providing emotional support and referrals to appropriate agencies, support groups, and resources when caring for families with suspected or diagnosed genetic disorders. Nurses can assist clients with their decision-making by referring them to a social worker, chaplain, or ethicist.

Unfolding Patient Stories: Brenda Patton • Part 2

Recall from Chapter 9 Brenda Patton. She is 18 years old at 24 weeks' gestation with her first child. During each prenatal visit, what questions would the nurse ask to evaluate fetal well-being? What factors can interfere with normal growth and development of the fetus? Describe the assessments the nurse performs to monitor fetal growth and development.

Care for Brenda and other patients in a realistic virtual environment: *vSim for Nursing* (**thepoint.lww.com/vSimMaternity**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. After teaching a group of students about fertilization, the instructor determines that the teaching was successful when the group identifies which as the usual site of fertilization?

   a. Fundus of the uterus
   b. Endometrium of the uterus
   c. Distal portion of fallopian tube
   d. Follicular tissue of the ovary

2. A client comes to the clinic for pregnancy testing. The nurse explains that the test detects the presence of which hormone?

   a. Human placental lactogen (hPL)
   b. Human chorionic gonadotropin (hCG)
   c. Follicle-stimulating hormone (FSH)
   d. Thyroid-stimulating hormone (TSH)

3. The nurse is counseling a couple, one of whom is affected by an autosomal dominant disorder. They express concerns about the risk of transmitting the disorder. What is the best response by the nurse regarding the risk that their baby may have for the disease?

   a. “You have a one in four (25%) chance.”
   b. “The risk is 12.5%, or a one in eight chance.”
   c. “The chance is 100%.”
   d. “Your risk is 50%, or a one in two chance.”

4. What is the first step in determining a couple's risk for a genetic disorder?

   a. Observing the client and family over time
   b. Conducting extensive psychological testing
   c. Obtaining a thorough family health history
   d. Completing an extensive exclusionary list

5. A nurse is working in a women's health clinic. Which woman would genetic counseling be most appropriate for?

   a. Had her first miscarriage at 10 weeks
   b. Is 30 years old and planning to conceive
   c. Has a history with a close relative with Down syndrome
   d. Is 18 weeks pregnant with a normal triple screen result

6. Which of the following is an example of an autosomal dominant disorder?

   a. Phenylketonuria
   b. Tay–Sachs disease
   c. Polycystic kidney disease
   d. Cystic fibrosis

7. Which of the following is the major goal of genetic counseling?

   a. Identify and determine the role of heredity
   b. Reinforce previously presented test data
   c. Emphasize good communication skills
   d. Offer referral to community support groups

CRITICAL THINKING EXERCISES

1. Mr. and Mrs. Martin wish to start a family, but they can't agree on something important. Mr. Martin wants his wife to be tested for cystic fibrosis (CF) to see if she is a carrier. Mr. Martin had a brother with CF and watched his

parents struggle with the hardship and the expense of caring for him for years, and he doesn't want to experience it in his own life. Mr. Martin has found out he is a CF carrier. Mrs. Martin doesn't want to have the test because she figures that once a baby is in their arms, they will be glad, no matter what.

a. What information/education should this couple consider before deciding whether to have the test?
b. How can you assist this couple in their decision-making process?
c. What is your role in this situation if you don't agree with their decision?

STUDY ACTIVITIES

1. Obtain the video *Miracle of Life,* which shows conception and fetal development. What are your impressions? Is the title of this video realistic?
2. Select one of the websites listed in to explore the topic of genetics. Critique the information presented. Was it understandable to a layperson? What specifically did you learn? Share your findings with your classmates during a discussion group.
3. Draw your own family pedigree, identifying inheritance patterns. Share it with your family to validate its accuracy. What did you discover about your family's past health?
4. Select one of the various prenatal screening tests (alpha-fetoprotein, amniocentesis, chorionic villus sampling, or fetal nuchal translucency) and research it in depth. Role-play with another nursing student how you would explain its purpose, the procedure, and potential findings to an expectant couple at risk for a fetal abnormality.

BRINGING IT ALL TOGETHER: A CASE STUDY

Rebecca and Jon are a couple seeking genetic counseling. Rebecca, 43 years old, is 10 weeks pregnant with their first

baby. The couple is concerned about the possibility of their child demonstrating trisomy 21 (Down syndrome).

Go to thePoint to find questions to consider about this case.

11

Maternal Adaptation During Pregnancy

WOW

WORDS OF WISDOM

When a woman discovers she is pregnant, she must remember to protect and nourish the fetus by making wise choices.

KEY TERMS

ballottement (bal-ot-mōn[h]´)
Braxton Hicks contractions
Chadwick sign
dietary reference intakes (DRIs)
Goodell sign
Hegar sign
linea nigra
physiologic anemia of pregnancy
pica
quickening
trimester

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Differentiate between subjective (presumptive), objective (probable), and diagnostic (positive) signs of pregnancy.
2. Describe maternal physiologic changes that occur during pregnancy.
3. Summarize the nutritional needs of the pregnant woman and her fetus.
4. Characterize the emotional and psychological changes that occur during pregnancy.

Marva, age 17, appeared at the health department clinic complaining that she had a stomach virus and needed to be seen right away. When the nurse asked her additional questions about her illness, Marva reported that she had been sick to her stomach and “exhausted” for days. She had stopped eating to avoid any more nausea and vomiting.

INTRODUCTION

Pregnancy is a dynamic and precisely coordinated process involving systemic and local changes in the mother that support the supply of nutrients and oxygen to the growing fetus in utero and in subsequent lactation. The success of pregnancy depends on (1) fertilization and successful implantation of the developing embryo into the endometrium; (2) development and function of the placenta; (3) adaptation of the maternal physiology to accept the fetal allograft and satisfy its nutritional, metabolic, and physical demands; (4) appropriate growth and functional development of organs and homeostatic systems in the fetus; and (5) proper timing of birth so that the fetus is mature enough to survive outside the uterus (Strauss & Barbieri, 2019).

A pregnancy is divided into three **trimesters** of 13 weeks each. Within each trimester, numerous adaptations take place that facilitate the growth of the fetus. The most obvious are physical changes to accommodate the growing fetus, but pregnant women also undergo psychological changes as they prepare for parenthood. A thorough understanding of these numerous changes and adaptations is essential for all nurses caring for women during pregnancy.

SIGNS AND SYMPTOMS OF PREGNANCY

Traditionally, signs and symptoms of pregnancy have been grouped into the following categories: presumptive, probable, and positive (Box 11.1). The only signs that can determine a pregnancy with 100% accuracy are positive signs.

> What additional information is necessary to complete the assessment of Marva, the 17-year-old with nausea and vomiting? What diagnostic tests might be done to confirm the nurse's suspicion that she is pregnant?

Subjective (Presumptive) Signs

Presumptive signs are those signs that the mother can perceive. The most obvious presumptive sign of pregnancy is the absence of menstruation. Skipping a period is not a reliable sign of pregnancy by itself, but if it is accompanied by consistent nausea, fatigue, breast tenderness, and urinary frequency, pregnancy may be likely.

Presumptive changes are the least reliable indicators of pregnancy because any one of them can be caused by conditions other than pregnancy (Napso et al., 2018). For example, amenorrhea can be caused by early menopause, endocrine dysfunction, malnutrition, anemia, diabetes mellitus, long-distance running, cancer, or stress. Nausea and vomiting can be caused by gastrointestinal disorders, food poisoning, acute infections, or eating disorders. Fatigue could be caused by anemia, stress, or viral infections. Breast tenderness may result from chronic cystic mastitis, premenstrual changes, or the use of oral contraceptives. Urinary frequency could have a variety of causes other than pregnancy, such as infection, cystocele, structural disorders, pelvic tumors, or emotional tension (Edmonds et al., 2019).

CONSIDER THIS

Jim and I decided to start our family, so I stopped taking the pill 3 months ago. One morning when I got out of bed to take the dog out, I felt queasy and light-headed. I hoped I was not coming down with the flu. By the end of the week, I was feeling really tired and started taking naps in the afternoon. In addition, I seemed to be going to the bathroom frequently, despite not drinking much fluid. When my breasts started to tingle and ache, I decided to make an appointment with my doctor to see what illness I had contracted.

After listening to my list of physical complaints, the office nurse asked me if I might be pregnant. My eyes opened wide; I had somehow missed the link between my symptoms and pregnancy. I started to think about when my last period was, and it had been 2 months ago. The office ran a pregnancy test, and much to my surprise, it was positive!

Thoughts: Many women stop contraceptives in an attempt to achieve pregnancy but miss the early signs of pregnancy. This woman was experiencing several signs of early pregnancy—urinary frequency, fatigue, morning nausea, and breast tenderness. What advice can the nurse give this woman to ease these symptoms? What additional education related to her pregnancy would be appropriate at this time?

BOX 11.1 Signs and Symptoms of Pregnancy

Presumptive (Time of Occurrence)	Probable (Time of Occurrence)	Positive (Time of Occurrence)
Fatigue (12 weeks)	Braxton Hicks contractions (16–28 weeks)	Ultrasound verification of embryo or fetus (4–6 weeks)
Breast tenderness (3–4 weeks)	Positive pregnancy test (4–12 weeks)	Fetal movement felt by experienced clinician (20 weeks)
Nausea and vomiting (4–14 weeks)	Abdominal enlargement (14 weeks)	Auscultation of fetal heart tones via Doppler (10–12 weeks)
Amenorrhea (4 weeks)	Ballottement (16–28 weeks)	
Urinary frequency (6–12 weeks)	Goodell sign (5 weeks)	
Hyperpigmentation of the skin (16 weeks)	Chadwick sign (6–8 weeks)	
Fetal movements known as **quickening** (16–20 weeks)	Hegar sign (6–12 weeks)	
Uterine enlargement (7–12 weeks)		
Breast enlargement (6 weeks)		

Norwitz, E., Miller, D., Zelop, C., & Keefe, D. (2019). *Evidence-based obstetrics and gynecology*, Wiley Blackwell; King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning; and Jordan, R. G., Farley, C. L., & Grace, T. (2019). *Prenatal and postnatal care: A woman-centered approach* (2nd ed.). Wiley Blackwell.

Objective (Probable) Signs

Physical Signs

Probable signs of pregnancy are those that can be detected on physical examination by a health care provider. Common probable signs of pregnancy include softening of the lower uterine segment or isthmus (**Hegar sign**), softening of the cervix (**Goodell sign**), and a bluish-purple coloration of the vaginal mucosa and cervix (**Chadwick sign**). Other probable signs include changes in the shape and size of the uterus, abdominal enlargement, Braxton Hicks contractions,

and **ballottement** (the examiner pushes against the woman's cervix during a pelvic examination and feels a rebound from the floating fetus).

Pregnancy Tests

Along with these physical signs, pregnancy tests are also considered a probable sign of pregnancy. In-home pregnancy testing became available in the United States in late 1977. In-home testing appealed to the general public because of convenience, cost, and confidentiality. Several pregnancy tests are available (Table 11.1). The tests vary in sensitivity, specificity, and accuracy and are influenced by the length of gestation, specimen concentration, presence of blood, and the presence of some drugs. Human chorionic gonadotropin (hCG) is detectable in the serum of approximately 5% of clients 8 days after conception and in more than 98% of clients by day 11 (Luppa & Junker, 2018). At least 25 different home pregnancy tests are currently marketed in the United States. Most of these tests claim "99% accuracy" according to a U.S. Food and Drug Administration (FDA) guideline or make other similar statements on the packaging or product insert. The 99% accuracy statement in reference to the FDA guideline is misleading in that it has no bearing on the ability of the home pregnancy test to detect early pregnancy (Luppa & Junker, 2018). The limitations of these tests must be understood so that pregnancy detection is not significantly delayed. Early pregnancy detection allows for the commencement of prenatal care, potential medication changes, and lifestyle changes to promote a healthy pregnancy.

hCG is a glycoprotein and the earliest biochemical marker for pregnancy. Many pregnancy tests are based on the recognition of hCG or a beta subunit of hCG. An hCG level lower than 5 mIU/mL is considered negative for pregnancy, and anything higher than 25 mIU/mL is considered positive for pregnancy. hCG levels in normal pregnancy usually double every 48 to 72 hours until they peak approximately 60 to 70 days after fertilization. At this point, they decrease to a plateau at 100 to 130 days of pregnancy. The hCG

doubling time has been used as a marker by clinicians to differentiate normal from abnormal gestations. Low levels are associated with an ectopic pregnancy and higher-than-normal levels may indicate a molar pregnancy or multiple-gestational pregnancies (Bastian & Brown, 2019).

TABLE 11.1 Select Pregnancy Tests

Type	Specimen	Example	Remarks
Agglutination inhibition tests (qualitative)	Urine	Pregnosticon, Gravindex	If hCG is present in urine, agglutination does not occur, which is positive for pregnancy; reliable 14–21 days after conception; 95% accurate in diagnosing pregnancy
Immunoradiometric assay	Blood serum	Neocept, Pregnosis	Measures ability of blood sample to inhibit the binding of radiolabeled hCG to receptors; reliable 6–8 days after conception; 99% accurate in diagnosing pregnancy
Enzyme-linked immunosorbent assay (ELISA)	Blood serum or urine	Over-the-counter home/office pregnancy tests; precise	Uses an enzyme to bond with hCG in the urine if present; reliable 4 days after implantation; 99% accurate if hCG-specific

Office on Women's Health. (2019). *Pregnancy tests*. Retrieved January 31, 2019, from https://www.womenshealth.gov/a-z-topics/pregnancy-tests; Luppa, P. B., & Junker, R. (2018). *Point-of-care-testing: Principles and clinical applications*. Springer Nature; and Edmonds, D. K., Lees, C., & Bourne, T. (2019). *Dewhurst's textbook of obstetrics & gynecology* (9th ed.). Wiley Blackwell.

TAKE NOTE!

This elevation of hCG corresponds to the morning sickness period of approximately 6 to 12 weeks during early pregnancy.

Although probable signs suggest pregnancy and are more reliable than presumptive signs, they still are not 100% reliable in confirming a pregnancy. For example, uterine tumors, polyps, infection, and pelvic congestion can cause changes to uterine shape, size, and consistency. And although pregnancy tests are used to establish the diagnosis of pregnancy when the physical signs are still inconclusive, they are not completely reliable, because conditions other than pregnancy (e.g., ovarian cancer, choriocarcinoma, hydatidiform mole) can also elevate hCG levels.

Positive Signs

Usually within 2 weeks after missed menses, enough subjective symptoms are present so that a woman can be reasonably sure she is pregnant. However, an experienced health care provider can confirm the woman's suspicions by identifying positive signs of pregnancy that can be directly attributed to the fetus. The positive signs of pregnancy confirm that a fetus is growing in the uterus. Visualizing the fetus by ultrasound, palpating for fetal movements, and hearing a fetal heartbeat are all signs that make the pregnancy a certainty.

If the pregnancy test is positive, the clinical visit should include an estimation of gestational age so that appropriate counseling can be provided. In addition, clients should receive information about the normal signs and symptoms of early pregnancy, and should be instructed to report any concerns to the health care provider for further evaluation. Once pregnancy has been confirmed, the health care provider will set up a schedule of prenatal visits to assess the woman and her fetus throughout the entire pregnancy. Assessment

and education begins at the first visits and continues throughout the pregnancy (see Chapter 12).

Remember Marva, who thought she had a stomach virus? Her pregnancy test was positive. During the assessment, she acknowledged missing two menstrual periods and being sexually active with her boyfriend without using protection. What is the nurse's role at this point in caring for Marva? What instructions might be given to her while she waits for her first prenatal visit?

PHYSIOLOGIC ADAPTATIONS DURING PREGNANCY

Every system of a woman's body changes during pregnancy to accommodate the needs of the growing fetus, and these changes occur with startling speed. The physical changes of pregnancy can be uncomfortable, though every woman reacts uniquely.

Reproductive System Adaptations

Significant changes occur throughout the woman's body during pregnancy to accommodate the growing human being within her. Many have a protective role for maternal homeostasis and are essential in meeting the demands of both the mother and the fetus. Many adaptations are reversible after the woman gives birth, but some persist for life.

Uterus

In pregnancy, there is a decrease in uterine vascular and muscle tone and a rise in blood flow. The uterus grows at a steady and predictable rate during pregnancy. Normally pear-shaped, the uterus expands more in length than width and exits the pelvis by 12 weeks' gestation. During the first few months of pregnancy, estrogen stimulates uterine growth, and the uterus undergoes a tremendous increase in size, weight, length, width, depth, volume, and overall capacity. The weight of the uterus increases from 70 g to about

1,100 to 1,200 g at term; its capacity increases from 10 to 5,000 mL or more at term (Steegers et al., 2019). The uterine walls thin to 1.5 cm or less; the shape changes from a pear shape to a solid globe in the first trimester and then expands to become a hollow vessel.

Uterine growth occurs as a result of both hyperplasia and hypertrophy of the myometrial cells, which do not increase much in number but do increase in size. In early pregnancy, uterine growth is due to hyperplasia of uterine smooth muscle cells within the myometrium; however, the major component of myometrial growth occurs after mid-gestation due to smooth muscle cell hypertrophy caused by mechanical stretch of uterine tissue by the growing fetus (Cunningham et al., 2018). Blood vessels elongate, enlarge, dilate, and sprout new branches to support and nourish the growing muscle tissue, and the increase in uterine weight is accompanied by a large increase in uterine blood flow, which is necessary to perfuse the uterine muscle and accommodate the growing fetus. As pregnancy progresses, 80% to 90% of uterine blood flow goes to the placenta with the remainder distributed between the endometrium and myometrium. During pregnancy, the diameter of the main uterine artery approximately doubles in size. This enlargement from a narrow to a larger-caliber vessel enhances the capacity of the uteroplacental vessels to accommodate the increased blood volume needed to supply the placenta (Kail & Cavanaugh, 2018).

Uterine contractility is enhanced as well. Spontaneous, irregular, and painless contractions called **Braxton Hicks contractions** begin during the first trimester. These contractions continue throughout pregnancy, becoming especially noticeable during the last month, when they function to thin out or efface the cervix before birth (see Chapter 12 for more information).

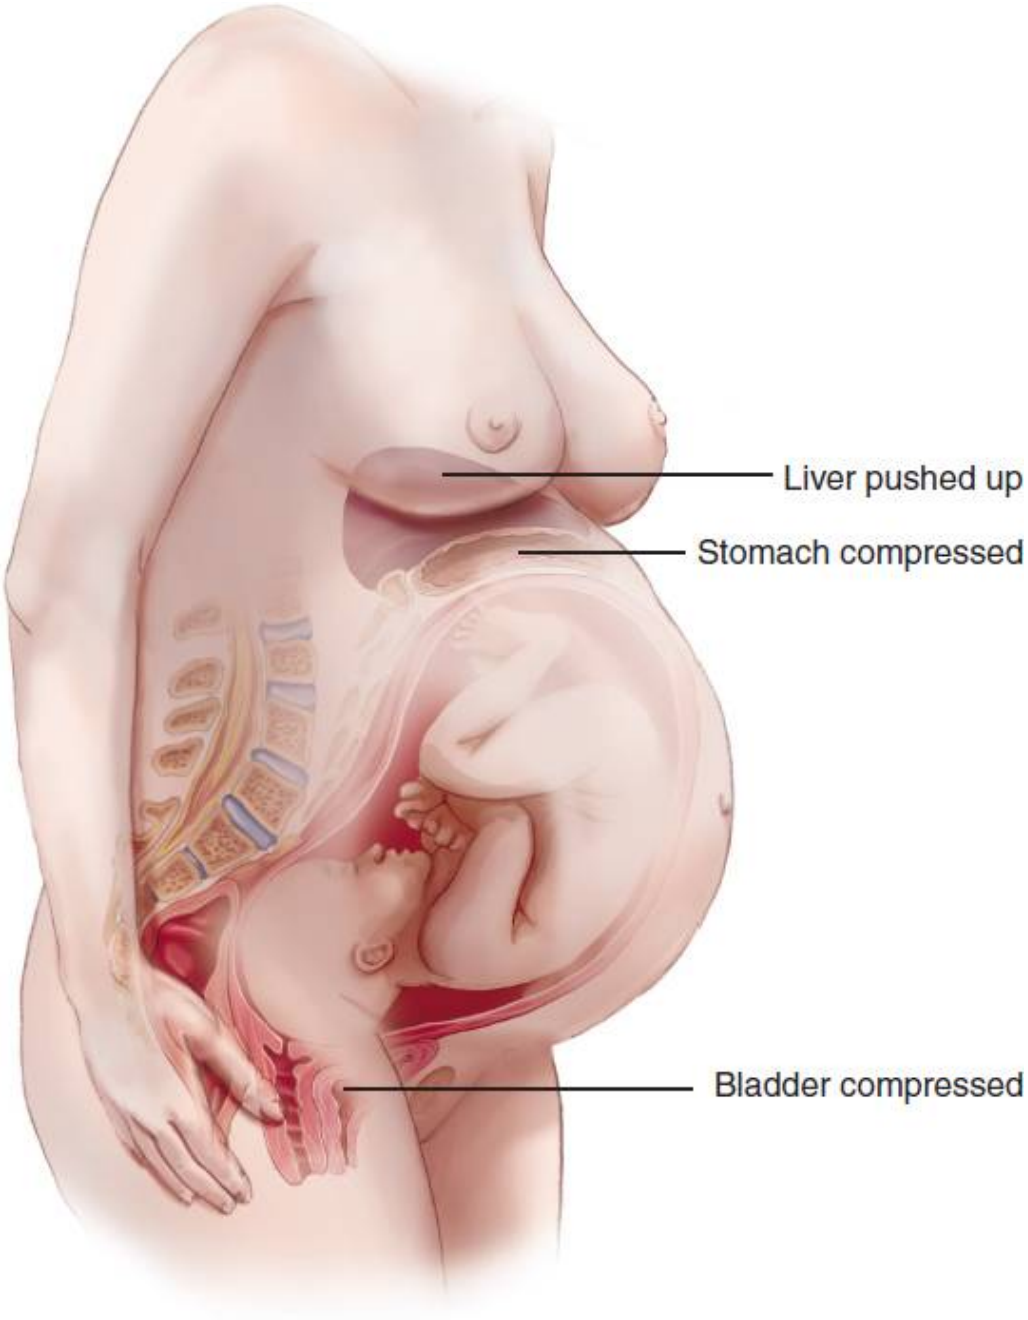

FIGURE 11.1. The growing uterus in the abdomen.

The lower portion of the uterus (the isthmus) does not undergo hypertrophy and becomes increasingly thinner as pregnancy progresses, thereby forming the lower uterine segment. Changes in the lower uterus occurring during the first 6 to 8 weeks' gestation produce some of the typical findings, including a positive Hegar sign.

This softening and compressibility of the lower uterine segment results in exaggerated uterine anteflexion during the early months of pregnancy, which adds to urinary frequency by placing pressure on the bladder (Jordan et al., 2019).

The uterus remains in the pelvic cavity for the first 3 months of pregnancy, after which it progressively ascends into the abdomen (Fig. 11.1). As the uterus grows, it presses on the urinary bladder and causes the increased frequency of urination experienced during early pregnancy. In addition, the heavy gravid uterus in the last trimester can fall back against the inferior vena cava in the supine position, resulting in vena cava compression, which reduces venous return and decreases cardiac output and blood pressure, increasing orthostatic stress. This occurs when the woman changes her position from recumbent to sitting to standing. This acute hemodynamic change, termed supine hypotensive syndrome, causes the woman to experience symptoms of weakness, light-headedness, nausea, dizziness, or syncope (Fig. 11.2). These changes are reversed when the woman is in the side-lying position, which displaces the uterus to the left and off the vena cava.

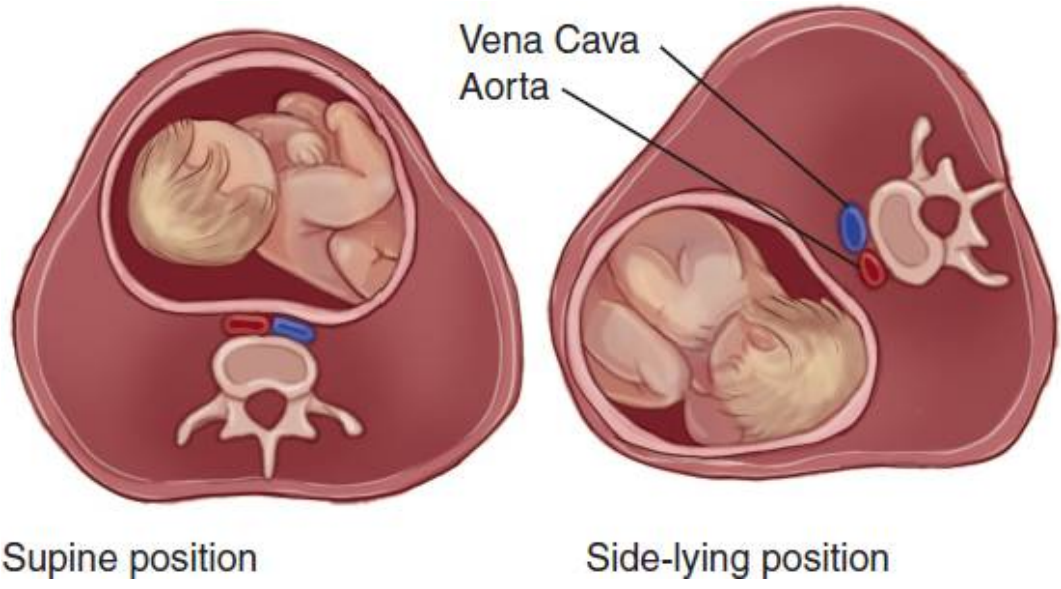

FIGURE 11.2. Supine hypotensive syndrome.

The uterus becomes ovoid as length increases over width. By 20 weeks' gestation, the fundus, or top of the uterus, is at the level of the umbilicus and measures 20 cm. A monthly measurement of the height of the top of the uterus in centimeters, which corresponds to the number of gestational weeks, is commonly used to date the pregnancy.

TAKE NOTE!

Fundal height can usually be correlated with gestational weeks most accurately between 18 and 32 weeks. Obesity, hydramnios, and uterine fibroids interfere with the accuracy of this correlation.

The fundus reaches its highest level, at the xiphoid process, at approximately 36 weeks. Between 38 and 40 weeks, fundal height drops as the fetus begins to descend and engage into the pelvis. Because it pushes against the diaphragm, many women experience shortness of breath. By 40 weeks, the fetal head begins to descend and engage in the pelvis, which is termed *lightening.* For the woman who is pregnant for the first time, lightening usually occurs approximately 2 weeks before the onset of labor; for the woman who is experiencing her second or subsequent pregnancy, it usually occurs at the onset of labor. Although breathing becomes easier because of this descent, the pressure on the urinary bladder now increases and the woman now experiences urinary frequency again, as she did in the first trimester of pregnancy.

Cervix

Between weeks 6 and 8 of pregnancy, the cervix begins to soften (Goodell sign) due to vasocongestion and the influence of estrogen. Along with the softening, the endocervical glands increase in size and number and produce more cervical mucus. Under the influence of progesterone, a thick mucus plug is formed that blocks the cervical os and protects the opening from bacterial invasion. At about the same time, increased vascularization of the cervix causes

Chadwick sign, a cyanosis or bluish purple discoloration. Cervical ripening (softening, effacement, and increased distensibility) begins about 4 weeks before birth. The connective tissues of the cervix undergo biochemical modifications in preparation for labor that result in changes to its elasticity and strength. These changes are mediated through several factors, including inflammation, cervical stretch, pressure of the fetal presenting part, and release of hormones, including oxytocin, relaxin, nitric oxide, and prostaglandins (Norwitz et al., 2019).

Vagina

During pregnancy, vascularity increases because of the influences of estrogen, resulting in pelvic congestion and hypertrophy of the vagina in preparation for the distention needed for birth. The vaginal mucosa thickens, the connective tissue begins to loosen, the smooth muscle begins to hypertrophy, and the vaginal vault begins to lengthen (Leung & Qiao, 2019). Vaginal secretions become more acidic, white, and thick. Most women experience an increase in a whitish vaginal discharge, called leukorrhea, during pregnancy. This is normal except when it is accompanied by itching and irritation, possibly suggesting *Candida albicans,* a monilial vaginitis, which is a common occurrence in this glycogen-rich environment (Norwitz et al., 2019). Symptomatic vulvovaginal candidiasis affects 15% of pregnant women (King et al., 2019). It is a benign fungal condition that is uncomfortable for the woman and can be transmitted from an infected mother to her newborn at birth. Neonates develop an oral infection known as thrush, which presents as white patches on the mucous membranes of their mouths. It is self-limiting and is treated with local antifungal agents.

Ovaries

The increased blood supply to the ovaries causes them to enlarge until approximately the 12th to 14th week of gestation. The ovaries are not palpable after that time because the uterus fills the pelvic cavity. Ovulation ceases during pregnancy because of the elevated

levels of estrogen and progesterone, which block secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary. The ovaries are active in hormone production to support the pregnancy until about weeks 6 to 7, when the corpus luteum regresses and the placenta takes over the major production of progesterone.

Breasts

The breasts increase in fullness, become tender, and grow larger throughout pregnancy under the influence of estrogen and progesterone. The breasts become highly vascular, and veins become visible under the skin. The nipples become larger and more erect. Both the nipples and the areola become deeply pigmented, and tubercles of Montgomery (sebaceous glands) become prominent. These sebaceous glands keep the nipples lubricated for breastfeeding.

Changes that occur in the connective tissue of the breasts, along with the tremendous growth, lead to striae (stretch marks) in approximately half of all pregnant women (Jordan et al., 2019). Initially they appear as pink to purple lines on the skin, but they eventually fade to a silver color. Although they become less conspicuous in time, they never completely disappear.

Creamy, yellowish breast fluid called colostrum can be expressed from the breast, if squeezed, by the third trimester. This fluid provides nourishment for the breastfeeding newborn during the first few days of life (see Chapters 15 and 16 for more information). Table 11.2 summarizes reproductive system adaptations.

General Body System Adaptations

In addition to changes in the reproductive system, the pregnant woman also experiences changes in virtually every other body system in response to the growing fetus.

Gastrointestinal System

The gastrointestinal (GI) system begins in the oral cavity and ends at the rectum. The secretory and absorptive functions of the GI system are not much affected during pregnancy, but motility is. There is displacement of the intra-abdominal portion of the esophagus into the thorax, in addition to relaxation of the lower esophageal sphincter, causing a decrease in its tone. This leads to gastroesophageal reflux disease of pregnancy (Cunningham et al., 2018). During pregnancy, the gums become hyperemic, swollen, and friable and tend to bleed easily. This change is influenced by estrogen and increased proliferation of blood vessels and circulation to the mouth. In addition, the saliva produced in the mouth becomes more acidic. Some women complain about excessive salivation, termed *ptyalism*, which may be caused by the decrease in unconscious swallowing by the woman when nauseated. Ptyalism typically resolves spontaneously, though in some women, it endures throughout the pregnancy. Some women get temporary relief from gum chewing or sucking on hard candies (Bianco, 2020). Dental plaque, calculus, and debris deposits increase during pregnancy and are all associated with gingivitis. An increased production of female hormones during pregnancy contributes to the development of gingivitis and periodontitis because vascular permeability and possible tissue edema are both increased. It is reported that as many as 50% to 70% of pregnant women will have some level of gingivitis during pregnancy as a result of hormonal changes that promote inflammation (Levine & Stillman-Lowe, 2019). Previous studies linked periodontal disease with preterm birth; preeclampsia; low-birth-weight risk; stillbirth; and early-onset neonatal sepsis. However, more recent research findings indicated no reduction in preterm births with the treatment of periodontal disease during pregnancy (Merchant et al., 2018).

TABLE 11.2 Summary of Reproductive System Adaptations

Reproductive Organ	Adaptations
Uterus	Size increases to 20 times that of nonpregnant size. Capacity increases by 2,000 times to accommodate the developing fetus. Weight increases from 2 oz to approximately 2 lb at term. Uterine growth occurs as a result of both hyperplasia and hypertrophy of the myometrial cells. Increased strength and elasticity allow uterus to contract and expel fetus during birth.
Cervix	Increases in mass, water content, and vascularization. Changes from a relatively rigid to a soft, distensible structure that allows the fetus to be expelled. Under the influence of progesterone, a thick mucus plug is formed, which blocks the cervical os and protects the developing fetus from bacterial invasion.
Vagina	Increased vascularity because of estrogen influences, results in pelvic congestion and hypertrophy. Increased thickness of mucosa, along with an increase in vaginal secretions, helps prevent bacterial infections.
Ovaries	Increased blood supply to the ovaries causes them to enlarge until approximately the 12th to 14th week of gestation. They actively produce hormones to support the pregnancy until weeks 6–7 when the placenta takes over the production of progesterone.
Breasts	Breast changes begin soon after conception; they increase in size and areolar pigmentation. The tubercles of Montgomery enlarge and become more prominent, and the nipples become more erect. The blood vessels become more prominent, and blood flow to the breast doubles.

Concept Mastery Alert

Gum Fragility in Pregnancy

Bleeding of gums during pregnancy results from increased estrogen levels that cause blood vessel proliferation. This then leads to increased blood vessels in the gums and an increased chance of bleeding.

Smooth muscle relaxation and decreased peristalsis occur related to the influence of progesterone. Elevated progesterone levels cause smooth muscle relaxation, which results in delayed gastric emptying and decreased peristalsis. Transition time of food throughout the GI tract may be so much slower that more water than normal is reabsorbed, leading to bloating and constipation. Constipation can also result from low-fiber food choices, reduced fluid intake, use of iron supplements, decreased activity level, and intestinal displacement secondary to a growing uterus. Constipation, increased venous pressure, and the pressure of the gravid uterus contribute to the formation of hemorrhoids.

The slowed gastric emptying combined with relaxation of the cardiac sphincter allows reflux, which causes heartburn. Acid indigestion or heartburn (pyrosis) seems to be a universal problem for pregnant women. It is caused by regurgitation of the stomach contents into the upper esophagus and may be associated with the generalized relaxation of the entire digestive system. Over-the-counter antacids will usually relieve the symptoms, but they should be taken only with the health care provider's knowledge and as directed.

The emptying time of the gallbladder is prolonged secondary to the smooth muscle relaxation from progesterone. Hypercholesterolemia can follow, increasing the risk of gallstone formation. Other risk factors for gallbladder disease include obesity, Hispanic ethnicity, and increasing maternal age. Laparoscopic cholecystectomy is a safe procedure in all trimesters of pregnancy if removal of the gallbladder is warranted (Brooks, 2019).

Nausea and vomiting, better known as morning sickness, can plague up to 90% of pregnant women. This condition is usually self-limiting, but the symptoms can be distressing and interfere with work, social activities, and sleep. Ginger is effective in reducing mild to

moderate nausea and vomiting of pregnancy for some women. The FDA has approved doxylamine succinate 10 mg/pyridoxine hydrochloride 10 mg (Diclegis) as a medication to specifically treat morning sickness in pregnancy. Two tablets are taken at bedtime, and this is considered safe during pregnancy (Norwitz et al., 2019). Although it occurs most often in the morning, the nauseated feeling can last all day in some women. The highest incidence of morning sickness occurs between 6 and 12 weeks. The physiologic basis for morning sickness is still debatable. It has been linked to the high levels of hCG, high levels of circulating estrogens, prostaglandins, reduced stomach acidity, advancing maternal age, slowed peristalsis, genetic factors, and the lowered tone and motility of the digestive tract (Jordan et al., 2019).

Cardiovascular System

Cardiovascular changes occur early during pregnancy to meet the demands of the enlarging uterus and the placenta for more blood and more oxygen. The changes include an increase in heart rate (25%); an increase in cardiac output by 30% to 50% and peaks at 25 to 30 weeks' gestation; reduced total peripheral resistance; increased blood volume; and increased plasma volume, which leads to physiologic anemia. Perhaps the most striking cardiac alteration occurring during pregnancy is the increase in blood volume.

BLOOD VOLUME

Blood volume increases by approximately 1,500 mL, or up to 50% above nonpregnant levels, by the 32nd week of gestation and remains more or less constant thereafter (Webster et al., 2018). The increase is made up of 1,000 mL plasma plus 450 mL red blood cells (RBCs). It is not clear how this occurs, but retention of sodium seems to be involved. It begins at weeks 10 to 12, peaks at weeks 32 to 34, and decreases slightly by week 40.

TAKE NOTE!

The rise in blood volume correlates directly with fetal weight, supporting the concept of the placenta as an arteriovenous shunt in the maternal vascular compartment.

This increase in blood volume is needed to provide adequate hydration of fetal and maternal tissues, to supply blood flow to perfuse the enlarging uterus, and to provide a reserve to compensate for blood loss at birth and during the postpartum period. The maternal blood volume expansion occurs at a larger proportion than the increase in RBC mass, which results in physiologic anemia and hemodilution. This dilution of RBCs is termed **physiologic anemia of pregnancy**. This is reflected in a lowered hematocrit and hemoglobin. These changes cannot be prevented by giving iron supplementation, and they are considered a normal adaptation of pregnancy (Blackburn, 2018). This increase is also necessary to meet the increased metabolic needs of the mother and to meet the need for increased perfusion of other organs, especially the woman's kidneys since she is excreting waste products for both herself and the fetus.

CARDIAC OUTPUT AND HEART RATE

Cardiac output, the product of stroke volume and heart rate, is a measure of the functional capacity of the heart. It increases from 30% to 50% over the nonpregnant rate by the 32nd week of pregnancy and declines to about a 20% increase at 40 weeks' gestation. The increase in cardiac output is associated with an increase in venous return and greater right ventricular output, especially in the left lateral position (Ikeda & Aoki-Kamiya, 2019). Heart rate increases by 10 to 15 bpm between 14 and 20 weeks' gestation, and this persists to term. There is slight hypertrophy or enlargement of the heart during pregnancy. This is probably to accommodate the increase in blood volume and cardiac output. The heart works harder and pumps more blood to supply the oxygen

needs of the fetus as well as those of the mother. Both heart rate and venous return are increased in pregnancy, contributing to the increase in cardiac output seen throughout gestation. A woman with preexisting heart disease may become symptomatic and begin to decompensate during the time the blood volume peaks. Close monitoring is warranted during 28 to 35 weeks' gestation.

BLOOD PRESSURE

Blood pressure, especially the diastolic pressure, declines slightly during pregnancy as a result of peripheral vasodilation caused by progesterone. It usually reaches a low point mid-pregnancy and thereafter increases to prepregnancy levels until term. During the first trimester, blood pressure typically remains at the prepregnancy level. During the second trimester, the blood pressure decreases 5 to 10 mm Hg and thereafter returns to first-trimester levels. This decrease in blood pressure begins at about 7 weeks' gestation and persists until 32 weeks' gestation, when it begins to rise to prepregnancy levels (Jordan et al., 2019). Any significant rise in blood pressure during pregnancy should be investigated to rule out gestational hypertension. Gestational hypertension is a clinical diagnosis defined by the new onset of hypertension (systolic of 140 mm Hg or higher and/or diastolic of 90 mm Hg or higher) after 20 weeks' gestation.

BLOOD COMPONENTS

The number of RBCs also increases throughout pregnancy to a level that is 20% to 30% higher than nonpregnant values, depending on the amount of iron available. This increase is necessary to transport the additional oxygen required during pregnancy. Although there is an increase in RBCs, there is a greater increase in the plasma volume as a result of hormonal factors and sodium and water retention. Because the plasma increase exceeds the increase of RBC production, normal hemoglobin and hematocrit values decrease, resulting in physiologic anemia of pregnancy. Changes in

RBC volume are due to increased circulating erythropoietin and accelerated RBC production. The rise in erythropoietin in the last two trimesters is stimulated by progesterone, prolactin, and human placental lactogen (Blackburn, 2018).

Iron requirements during pregnancy increase because of the demands of the growing fetus and the increase in maternal blood volume. The fetal tissues prevail over the mother's tissues with respect to use of iron stores. With the accelerated production of RBCs, iron is necessary for hemoglobin formation, the oxygen-carrying component of RBCs.

TAKE NOTE!

Many women enter pregnancy with insufficient iron stores and thus need supplementation to meet the extra demands of pregnancy.

Both fibrin and plasma fibrinogen levels increase along with various blood clotting factors. These factors make pregnancy a hypercoagulable state. These changes, coupled with venous stasis secondary to venous pooling, which occurs during late pregnancy after long periods of standing in the upright position with the pressure exerted by the uterus on the large pelvic veins, contribute to slowed venous return, pooling, and dependent edema. These factors also increase the woman's risk for venous thrombosis (Ikeda & Aoki-Kamiya, 2019).

Respiratory System

Pregnancy puts less stress on the respiratory system than on the cardiovascular system, but adaptations to this system do take place during pregnancy. The primary changes occur in lung volume and ventilation. Oxygen consumption reflects the uptick of maternal metabolism by increasing between 20% and 30% by the time full term is reached. During pregnancy, the amount of space available to house the lungs decreases as the uterus puts pressure on the diaphragm and causes it to shift upward by 4 cm above its usual

position. The growing uterus does change the size and shape of the thoracic cavity, but diaphragmatic excursion increases, chest circumference increases by 2 to 3 in, and the transverse diameter increases by an inch, allowing a larger tidal volume, as evidenced by deeper breathing. Tidal volume, or the volume of air inhaled, increases by 30% to 40% (from 500 to 700 mL) as the pregnancy progresses. This increase results in maternal hyperventilation and hypocapnia. As a result of these changes, the woman's breathing becomes more diaphragmatic than abdominal. Concomitant with the increase in tidal volume is a 30% to 40% increase in maternal oxygen consumption due to the increased oxygen requirements of the developing fetus, placenta, and maternal organs.

Anatomic and physiologic changes of pregnancy predispose the mother to increased morbidity and mortality and increase the risks of a less than optimal outcome for the fetus. The frequency and significance of acute and chronic respiratory conditions in pregnant women have increased in recent years. Because of these various changes, pregnant women with asthma, pneumonia, or other respiratory pathology are more susceptible to early decompensation (Namazy & Schatz, 2019).

A pregnant woman breathes faster and more deeply because she and the fetus need more oxygen. Oxygen consumption increases during pregnancy even as airway resistance and lung compliance remain unchanged. Changes in the structures of the respiratory system take place to prepare the body for the enlarging uterus and increased lung volume (Jarvis & Eckhardt, 2020). As muscles and cartilage in the thoracic region relax, the chest broadens with a conversion from abdominal breathing to thoracic breathing. This leads to a 50% increase in air volume per minute. All of these structural alterations are temporary and revert back to their prepregnant state at the end of the pregnancy.

Increased vascularity of the respiratory tract is influenced by increased estrogen levels, leading to congestion. Rising levels of sex hormones and heightened sensitivity to allergens may influence the nasal mucosa, precipitating epistaxis (nosebleed) and rhinitis. This

congestion gives rise to nasal and sinus stuffiness and changes in the tone and quality of the woman's voice (Jordan et al., 2019).

Renal/Urinary System

The renal and urinary systems undergo dramatic change in response to pregnancy. The kidneys must adapt to an increase in blood volume and increased maternal and fetal waste. Hormonal changes during pregnancy allow for increased blood flow to the kidneys. The renal system must handle the effects of increased maternal intravascular and extracellular volume and metabolic waste products as well as excretion of fetal wastes. The predominant structural change in the renal system during pregnancy is dilation of the renal pelvis and uterus. Changes in renal structure occur as a result of the hormonal influences of estrogen and progesterone, pressure from an enlarging uterus, and an increase in maternal blood volume. Dilation of the kidneys and ureters increases the potential for urinary stasis and infection. Like the heart, the kidneys work harder throughout the pregnancy. Changes in kidney function occur to accommodate a heavier workload while maintaining a stable electrolyte balance and blood pressure. As more blood flows to the kidneys, the glomerular filtration rate (GFR) increases, leading to an increase in urine flow and volume, substances delivered to the kidneys, and filtration and excretion of urea, uric acid, creatinine, water, and solutes (Webster et al., 2018).

Anatomically, the kidneys enlarge during pregnancy. Each kidney increases in length by approximately 1 to 1.5 cm and weight as a result of hormonal effects that cause increased tone and decreased motility of the smooth muscle. The renal pelvis becomes dilated. The ureters (especially the right ureter) elongate, widen, and become more curved above the pelvic rim as early as the 10th gestational week (Edmonds et al., 2019). Progesterone is thought to cause both of these changes because of its relaxing influence on smooth muscle.

Blood flow to the kidneys increases by 50% to 80% as a result of the increase in cardiac output and relaxin which causes a decrease

in both efferent and afferent resistance. This in turn leads to an increase in the GFR by as much as 40% to 60% starting during the second trimester, resulting in hyperfiltration. This elevation continues until birth. This change has important clinical implications for medication use because drugs excreted through the kidneys may require higher doses and more frequent administration for therapeutic blood levels during pregnancy (Norwitz et al., 2019).

The activity of the kidneys normally increases when a person lies down and decreases upon standing. This difference is amplified during pregnancy, which is one reason a pregnant woman feels the need to urinate frequently while trying to sleep. Late in the pregnancy, the increase in kidney activity is even greater when the woman lies on her side rather than her back. Lying on either side relieves the pressure that the enlarged uterus puts on the vena cava carrying blood from the legs. Subsequently, venous return to the heart increases, leading to increased cardiac output. Increased cardiac output results in increased renal perfusion and glomerular filtration. As a rule, all the physiologic changes maximize by the end of the second trimester and then start to return to the prepregnant level. However, changes in this anatomy take up to 3 months postpartum to subside (Jordan et al., 2019).

Musculoskeletal System

The musculoskeletal system undergoes significant changes during pregnancy and childbirth. Pregnancy represents a window of opportunity to adopt an active, healthy lifestyle, but it also places a woman at risk for musculoskeletal disorders, impairments, and other discomforts. Changes in the musculoskeletal system are progressive, resulting from the influence of hormones, fetal growth, and maternal weight gain. Pregnancy is characterized by changes in posture and gait. By the 10th to 12th week of pregnancy, the ligaments that hold the sacroiliac joints and the pubis symphysis in place begin to soften and stretch, and the articulations between the joints widen and become more movable (Santos-Rocha, 2019). The relaxation of the joints peaks by the beginning of the third trimester.

The purpose of these changes is to increase the size of the pelvic cavity and to make delivery easier.

The postural changes of pregnancy—an increased swayback and an upper spine extension to compensate for the enlarging abdomen—coupled with the loosening of the sacroiliac joints may result in lower back pain. The woman's center of gravity shifts forward, requiring a realignment of the spinal curvatures. Factors thought to contribute to these postural changes include the alteration to the center of gravity that come with pregnancy, the influence of the pregnancy-related hormone relaxin on the pelvic joints, and the increasing weight and position of the growing fetus.

An increase in the normal lumbosacral curve (lordosis) occurs and a compensatory curvature in the cervicodorsal area develops to assist her in maintaining her balance (Fig. 11.3). In addition, relaxation and increased mobility of joints occur because of the hormones progesterone and relaxin, which lead to the characteristic "waddle" gait that pregnant women demonstrate as they near term. Increased weight gain can add to this discomfort by accentuating the lumbar and dorsal curves (Santos-Rocha, 2019).

Integumentary System

The integumentary system includes skin, hair, nails, and sebaceous and sweat glands. There are a variety of integumentary changes that are associated with pregnancy including changes in pigment, vascular supply, connective skin tissue, hair growth, nail structure, and gland functions. Increased activity of the maternal adrenal and pituitary glands, along with a contribution for the developing fetal endocrine glands, increasing cortisone levels, accelerated metabolism, and enhanced production of progesterone and estrogenic hormones, are responsible for most skin changes in pregnancy (Keltz, 2019; Zaidi et al., 2019). Up to 90% of pregnant women will show signs of hyperpigmentation during pregnancy, typically generalized and mild. The skin of pregnant women undergoes hyperpigmentation primarily resulting from estrogen, progesterone, and melanocyte-stimulating hormone levels. These

changes are mainly seen on the nipples, areola, umbilicus, perineum, and axilla. Although many integumentary changes disappear after giving birth, some only fade. Many pregnant women express concern about stretch marks, skin color changes, and hair loss. Little is known about how to avoid these changes.

Complexion changes are not unusual. The increased pigmentation that occurs on the breasts and genitalia also develops on the face to form the “mask of pregnancy,” which is also called facial melasma. It occurs in up to 70% of pregnant women. There is a genetic predisposition toward melasma, which is exacerbated by the sun, and it tends to recur in subsequent pregnancies. This blotchy, brownish pigment covers the forehead and cheeks in dark-haired women. Most facial pigmentation fades as the hormones subside at the end of the pregnancy, but some may linger. The skin in the middle of the abdomen may develop a pigmented line called the **linea nigra**, which extends from the umbilicus to the pubic area (Fig. 11.4).

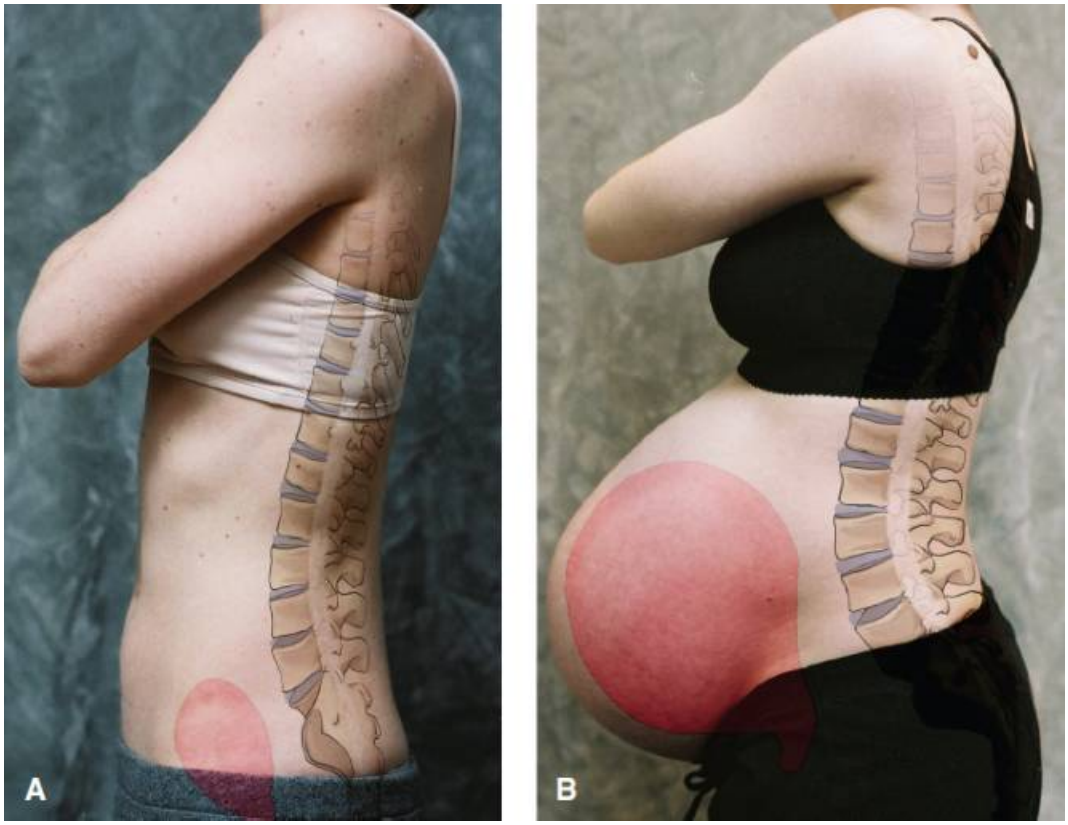

FIGURE 11.3. Postural changes during **(A)** the first trimester and **(B)** the third trimester.

FIGURE 11.4. Linea nigra.

Striae gravidarum, or stretch marks, are irregular reddish streaks that appear on the abdomen, breasts, and buttocks in up to 90% of pregnant women. Estrogen, relaxin, and adrenocorticoids contribute to these changes. Striae are most prominent by 6 to 7 months. They result from genetics, reduced connective tissue strength resulting from the elevated adrenal steroid levels, and stretching of the structures secondary to growth (Strauss & Barbieri, 2019). They are more common in younger women, women with larger infants, and women with higher body mass indices (BMIs). Non-White women and women with a history of breast or thigh striae or a family history

of striae gravidarum are also at higher risk. Several creams and lotions such as cocoa butter and olive oil have been touted as preventing striae gravidarum, but research currently does not validate these claims. Over time, many striae improve. Lasers and radiofrequency treatments hold promise as they do modify the vascularity and the collagen and perhaps the elastin, but the effect of treatment is difficult to access (Oakley & Patel, 2019).

VASCULAR-RELATED SKIN CHANGES

Vascular changes during pregnancy manifest in the integumentary system include varicosities of the legs, vulva, and perineum. Varicose veins are commonly the result of distention, instability, and poor circulation secondary to prolonged standing or sitting and the heavy gravid uterus placing pressure on the pelvic veins, preventing complete venous return. Interventions to reduce the risk of developing varicosities include:

- Elevating both legs when sitting or lying down
- Avoiding prolonged standing or sitting; changing position frequently
- Resting in the left lateral position
- Walking daily for exercise
- Avoiding tight clothing or knee-high hosiery
- Wearing support hose if varicosities are a preexisting condition to pregnancy

Another skin manifestation, believed to be secondary to vascular changes and high estrogen levels, is the appearance of small blood vessels called vascular spiders. They may appear on the neck, thorax, face, and arms. They are especially obvious in White women and typically disappear after childbirth. Palmar erythema is a well-delineated pinkish area on the palmar surface of the hands. This integumentary change is also related to elevated estrogen levels (Norwitz et al., 2019).

HAIR AND NAILS

Some women also notice a decline in hair growth during pregnancy. The hair follicles normally undergo a growing and resting phase. The resting phase is followed by a loss of hair; the hairs are then replaced by new ones. During pregnancy, fewer hair follicles go into the resting phase. After delivery, the body catches up with subsequent hair loss for several months. Nails typically grow faster during pregnancy. Pregnant women may experience increased brittleness, distal separation of the nail bed, whitish discoloration, and transverse grooves on the nails, but most of these conditions resolve in the postpartum period (Blackburn, 2018).

Endocrine System

The endocrine system undergoes many changes during pregnancy because hormonal changes are essential in meeting the needs of the growing fetus. Hormonal changes play a major role in controlling the supplies of maternal glucose, amino acids, and lipids to the fetus. Although estrogen and progesterone are the main hormones involved in pregnancy changes, other endocrine glands and hormones also change during pregnancy.

THYROID GLAND

Multiple organs undergo physiologic changes during pregnancy, and the thyroid is no exception. The thyroid gland enlarges slightly and becomes more active during pregnancy as a result of increased vascularity and hyperplasia. Increased gland activity results in an increase in thyroid hormone secretion starting during the first trimester; levels taper off within a few weeks after birth and return to normal limits. Maternal thyroid hormone is transferred to the fetus beginning soon after conception and is critical for fetal brain development, neurogenesis, and organizational processes prior to 20 weeks when fetal thyroid production is low. However, even after the fetal thyroid is producing increasing amounts of hormone, much of the thyroxin (T4) needed for development continues to be provided by the mother. Low maternal thyroid levels with thyroid insufficiency, hypothyroidism, or low or inadequate iodine intake may

compromise fetal neurologic development (Eaton, 2019). With an increase in the secretion of thyroid hormones, the basal metabolic rate (the amount of oxygen consumed by the body over a unit of time in milliliters per minute) progressively increases by 25%, along with heart rate and cardiac output (Jordan et al., 2019).

PITUITARY GLAND

During pregnancy, major endocrine and metabolic alterations occur due to the physiologic hormonal secretion from the placenta. The pituitary gland adapts to these changes and all secretory axes are affected. During pregnancy, the pituitary gland enlarges and grows by 135% of its original size. It returns to normal size after birth.

The anterior lobe of the pituitary is glandular tissue and produces multiple hormones. The release of these hormones is regulated by releasing and inhibiting hormones produced by the hypothalamus. Some of these anterior pituitary hormones induce other glands to secrete their hormones. The increase in blood levels of the hormones produced by the final target glands (e.g., the ovary or thyroid) inhibits the release of anterior pituitary hormones.

FSH and LH secretion are inhibited during pregnancy, probably as a result of hCG produced by the placenta and corpus luteum, and the increased secretion of prolactin by the anterior pituitary gland. Levels remain decreased until after delivery.

Thyroid-stimulating hormone (TSH) is reduced during the first trimester but usually returns to normal for the remainder of the pregnancy. Decreased TSH is thought to be one of the factors, along with elevated hCG levels, associated with morning sickness, nausea, and vomiting during the first trimester.

Growth hormone (GH) is an anabolic hormone that promotes protein synthesis. It stimulates most body cells to grow in size and divide, facilitating the use of fats for fuel and conserving glucose. During pregnancy, there is a decrease in the number of GH-producing cells and a corresponding decrease in GH blood levels. The action of human placental lactogen (hPL) is thought to decrease the need for and use of GH. During pregnancy, prolactin is secreted

in pulses and increases 10-fold to promote breast development and the lactation process. High levels of progesterone secreted by the placenta inhibit the direct influence of prolactin on the breast during pregnancy, thus suppressing lactation. At birth, as soon as the placenta is expelled and there is a drop in progesterone, lactogenesis can begin. Prolactin, released from the anterior pituitary gland in response to suckling by the newborn is the major hormonal signal responsible for stimulation in the breasts (Strauss & Barbieri, 2019).

Melanocyte-stimulating hormone (MSH), another anterior pituitary hormone, increases during pregnancy. For many years, its increase was thought to be responsible for many of the skin changes of pregnancy, particularly changes in skin pigmentation (e.g., darkening of the areola, melasma, and linea nigra). However, it is currently thought that the skin changes are due to estrogen (and possibly progesterone) as well as the increase in MSH.

The two hormones oxytocin and antidiuretic hormone (ADH) released by the posterior pituitary are actually synthesized in the hypothalamus. They migrate along nerve fibers to the posterior pituitary and are stored until stimulated to be released into the general circulation. Oxytocin is released by the posterior pituitary gland, and its production gradually increases as the fetus matures (King et al., 2019). Oxytocin is responsible for uterine contractions, both before and after delivery. The muscle layers of the uterus (myometrium) become more sensitive to oxytocin near term. Toward the end of a term pregnancy, levels of progesterone decline and contractions that were previously suppressed by progesterone begin to occur more frequently and with stronger intensity. This change in the hormonal levels is believed to be one of the initiators of labor.

Oxytocin is responsible for stimulating the uterine contractions that bring about delivery. Contractions lead to cervical thinning and dilation. They also exert pressure, helping the fetus to descend in the pelvis for eventual delivery. After delivery, oxytocin secretion continues, causing the myometrium to contract and helping to constrict the uterine blood vessels, decreasing the amount of vaginal bleeding after delivery. Oxytocin is also responsible for milk ejection

during breastfeeding. Stimulation of the breasts through sucking or touching stimulates the secretion of oxytocin from the posterior pituitary gland. Oxytocin causes contraction of the myoepithelial cells in the lactating mammary gland.

Women experience cramping pain and discomfort following childbirth as the uterus contracts and returns to its prepregnant size. These postpartum pains are caused by involuntary contractions and usually last for a few days after childbirth. They are more evident in women who have previously had a baby. Breastfeeding signals the release of oxytocin, which stimulates the uterus to contract and increases the severity of after birth pains.

Vasopressin, also known as ADH, functions to inhibit or prevent the formation of urine via vasoconstriction, which results in increased blood pressure. Vasopressin also exhibits an antidiuretic effect and plays an important role in the regulation of water balance (Woodmansee, 2019).

PANCREAS

The pancreas is an exocrine organ, supplying digestive enzymes and buffers, as well as an endocrine organ. The endocrine pancreas consists of the islets of Langerhans, which are groups of cells scattered throughout, each containing four cell types. One of the cell types is the beta cell, which produces insulin. Insulin lowers blood glucose by increasing the rate of glucose uptake and utilization by most body cells. The growing fetus needs significant amounts of glucose, amino acids, and lipids. Even during early pregnancy, the fetus makes demands on the maternal glucose stores. Ideally, hormonal changes of pregnancy help meet fetal needs without putting the mother's metabolism out of balance.

A woman's insulin secretion works on a supply versus demand mode. As the demand to meet the needs of pregnancy increases, more insulin is secreted. Maternal insulin does not cross the placenta, so the fetus must produce their own supply to maintain glucose control (Box 11.2).

Maternal glucose metabolism during pregnancy differs from the nongravid state to allow the mother to meet her own and the growing fetus's energy needs. During the first half of pregnancy, much of the maternal glucose is diverted to the growing fetus, and thus the mother's glucose levels are low. Human placental lactogen and other hormonal antagonists increase during the second half of pregnancy. Therefore, the mother must produce more insulin to overcome the resistance by these hormones. Insulin resistance (the inability of insulin to increase glucose uptake and utilization) in pregnancy is consequent to the physiologic adaptation necessary to provide glucose to the growing fetus. Disturbance in the maternal metabolism can induce structural and functional adaptations during fetal development (Strauss & Barbieri, 2019).

BOX 11.2 Pregnancy, Insulin, and Glucose

- During early pregnancy, maternal glucose levels decrease because of the heavy fetal demand for glucose. The fetus is also drawing amino acids and lipids from the mother, decreasing the mother's ability to synthesize glucose. Maternal glucose is diverted across the placenta to assist the growing embryo/fetus during early pregnancy, and thus levels decline in the mother. As a result, maternal glucose concentrations decline to a level that would be considered "hypoglycemic" in a nonpregnant woman.
- During early pregnancy there is also a decrease in maternal insulin production and insulin levels. The pancreas is responsible for the production of insulin, which facilitates entry of glucose into cells. Although glucose and other nutrients easily cross the placenta to the fetus, insulin does not. Therefore, the fetus must produce its own insulin to facilitate the entry of glucose into its own cells.
- After the first trimester, hPL from the placenta and steroids (cortisol) from the adrenal cortex act against insulin. hPL acts as an antagonist against maternal insulin, and thus more insulin must be secreted to counteract the increasing levels of hPL and cortisol during the last half of pregnancy.
- Prolactin, estrogen, and progesterone are also thought to oppose insulin. As a result, glucose is less likely to enter the mother's cells and is more likely to cross over the placenta to the fetus.

Cunningham, F. G., Leveno, K. J., Bloom, S. L., Dashe, J. S., Hoffman, B. L., Casey, B. M., & Spong, C. Y. (2018). *Williams obstetrics* (25th ed.). McGraw-Hill Professional Publishing; Blackburn, S. T. (2018). *Maternal, fetal, neonatal physiology: A clinical perspective*. Elsevier.

If the mother has normal beta cells of the islets of Langerhans, there is usually no problem meeting the demands for extra insulin. However, if the woman has inadequate numbers of beta cells, she may be unable to produce enough insulin and will develop glucose intolerance during pregnancy. If the woman has glucose intolerance, she is not able to meet the increasing demands and her blood glucose level increases.

ADRENAL GLANDS

Pregnancy does not cause much change in the size of the adrenal glands themselves, but there are changes in some secretions and activity. One of the key changes is the marked increase in cortisol

secretion, which regulates carbohydrate and protein metabolism and is helpful in times of stress. Although pregnancy is considered a normal condition, it is a time of stress for a woman's body. The rate of secretion of cortisol by maternal adrenals is not increased during pregnancy, but the rate of clearance is decreased. Cortisol increases in response to increased estrogen levels throughout pregnancy and returns to normal levels within 6 weeks postpartum (Blackburn, 2018). During the stress of pregnancy, cortisol:

- helps keep up the level of glucose in the plasma by breaking down noncarbohydrate sources, such as amino and fatty acids, to make glycogen. Glycogen, stored in the liver, is easily broken down to glucose when needed so that glucose is available in times of stress.
- breaks down proteins to repair tissues and manufacture enzymes.
- has antiinsulin, antiinflammatory, and antiallergic actions.
- is needed to make the precursors of adrenaline, which the adrenal medulla produces and secretes (Cunningham et al., 2018).

The amount of aldosterone, also secreted by the adrenal glands, is increased during pregnancy. It normally regulates absorption of sodium from the distal tubules of the kidney. During pregnancy, progesterone allows salt to be wasted (or lost) in the urine. Aldosterone is a key regulator of electrolyte and water homeostasis and plays a central role in blood pressure regulation. Hormonal changes during pregnancy, among them increased progesterone and aldosterone production, lead to the required plasma volume expansion of the maternal body as an accommodation mechanism for fetus growth. Aldosterone is produced in increased amounts by the adrenal glands as early as 15 weeks of pregnancy (Edmonds et al., 2019).

PROSTAGLANDIN SECRETION DURING PREGNANCY

Prostaglandins are not protein or steroid hormones; they are chemical mediators, or local hormones. Although hormones circulate in the blood to influence distant tissues, prostaglandins act locally on

adjacent cells. The fetal membranes of the amniotic sac—the amnion and chorion—are both believed to be involved in the production of prostaglandins. Various maternal and fetal tissues, as well as the amniotic fluid itself, are considered to be sources of prostaglandins, but details about their composition and sources are limited. It is widely believed that prostaglandins play a part in softening the cervix and initiating and/or maintaining labor, but the exact mechanism is unclear. What is theorized is that when progesterone levels drop at term, an increased production of prostaglandins occurs, which facilitates uterine contractions and increases myometrial sensitivity to oxytocin that is needed for the labor process (Steegers et al., 2019). Along with oxytocin, the influence of prostaglandins on the uterine myometrium predominates to promote uterine contractile activity.

PLACENTAL SECRETION

The placenta is an organ that serves to prevent the direct exchange between the blood of the fetus and the blood of the mother. The placenta is not only a transfer organ but also a factory as well. It is capable of synthesizing enzymes and proteins and manufactures fats and carbohydrates that serve as a source of stored energy. The placenta also functions as an endocrine gland, manufacturing and secreting hormones. The placenta has a feature possessed by no other endocrine organ—the ability to form protein and steroid hormones. Very early during pregnancy, the placenta begins to produce the following hormones:

- hCG
- hPL
- Relaxin
- Progesterone
- Estrogen

Table 11.3 summarizes the role of these hormones.

Immune System

The immune system is made up of organs and specialized cells with the primary purpose of defending the body from foreign substances (antigens) that may cause tissue injury or disease. The mechanisms of innate and adaptive immunity work cooperatively to prevent, control, and eradicate foreign antigens in the body.

A general enhancement of innate immunity (inflammatory response and phagocytosis) and suppression of adaptive immunity (protective response to a specific foreign antigen) take place during pregnancy. These immunologic alterations help prevent the mother's immune system from rejecting the fetus (foreign body), increase her risk of developing certain infections such as urinary tract infections, and influence the course of chronic disorders such as autoimmune diseases. Some chronic conditions worsen (diabetes) while others seem to stabilize (asthma) during pregnancy, but this is individualized and not predictable. In general, immune function in pregnant women is similar to immune function in nonpregnant women. Table 11.4 summarizes the general body systems' adaptations to pregnancy.

TABLE 11.3 Placental Hormones

Hormone	Description
Human chorionic gonadotropin (hCG)	• Responsible for maintaining the maternal corpus luteum, which secretes progesterone and estrogens with synthesis occurring before implantation • Production by fetal trophoblast cells until the placenta is developed sufficiently to take over that function • Basis for early pregnancy tests because it appears in the maternal bloodstream soon after implantation • Production peaks at 8 weeks and then gradually declines
hPL (also known as human chorionic somatomammotropin [hCS])	• Preparation of mammary glands for lactation and involved in the process of making glucose available for fetal growth by altering maternal carbohydrate, fat, and protein metabolism • Antagonist of insulin because it decreases tissue sensitivity or alters the ability to use insulin • Increase in the amount of circulating free fatty acids for maternal metabolic needs and decrease in maternal metabolism of glucose to facilitate fetal growth
Relaxin	• Secretion by the placenta as well as the corpus luteum during pregnancy • Thought to act synergistically with progesterone to maintain pregnancy • Increase in flexibility of the pubic symphysis, permitting the pelvis to expand during delivery • Dilation of the cervix, making it easier for the fetus to enter the vaginal canal; thought to suppress the release of oxytocin by the hypothalamus, thus delaying the onset of labor contractions
Progesterone	• Often called the “hormone of pregnancy” because of the critical role it plays in supporting the endometrium of the uterus • Supports the endometrium to provide an environment conducive to fetal survival • Produced by the corpus luteum during the first few weeks of pregnancy and then by the placenta until term

	• Initially, causes thickening of the uterine lining in anticipation of implantation of the fertilized ovum; from then on, it maintains the endometrium, inhibits uterine contractility, and assists in the development of the breasts for lactation
Estrogen	• Promotes enlargement of the genitals, uterus, and breasts, and increases vascularity, causing vasodilatation • Relaxation of pelvic ligaments and joints • Associated with hyperpigmentation, vascular changes in the skin, increased activity of the salivary glands, and hyperemia of the gums and nasal mucous membranes • Aids in developing the ductal system of the breasts in preparation for lactation

Marva returns for her first prenatal appointment and tells the nurse that her whole body is “out of sorts.” She is overwhelmed and feels bad. Outline the bodily changes Marva can expect each trimester to help her understand the adaptations taking place. What guidance can the nurse give Marva to help her understand the changes of pregnancy?

CHANGING NUTRITIONAL NEEDS OF PREGNANCY

Maternal body weight and diet quality, even prepregnancy, can affect the uterine environment, birth weight, and the infant’s subsequent health into adulthood. Healthy eating during pregnancy enables optimal gestational weight gain and reduces complications, both of which are associated with positive birth outcomes. During pregnancy, maternal nutritional needs change to meet the demands of the pregnancy. Healthy eating can help ensure that adequate nutrients are available for both mother and fetus.

Nutritional intake during pregnancy has a direct effect on fetal well-being and birth outcome. Inadequate nutritional intake, for example, is associated with preterm birth, low birth weight, and congenital anomalies. Excessive nutritional intake is connected with fetal macrosomia (heavier than 4,000 g), leading to a difficult birth, neonatal hypoglycemia, and continued obesity in the mother and the potential for childhood obesity with the components of metabolic syndrome (Kane & Prelack, 2019).

Since the requirements for so many nutrients increase during pregnancy, pregnant women should take a vitamin and mineral supplement daily. Prenatal vitamins are prescribed routinely as a safeguard against less-than-optimal diets. With the exception of folic acid, there is little scientific evidence to support giving vitamin supplements to healthy pregnant women, but it seems to be the standard of care today. Prenatal vitamins are prescribed in the United States almost universally (Kane & Prelack, 2019). In particular, iron and folic acid need to be supplemented because their increased requirements during pregnancy are usually too great to be met through diet alone. Iron and folic acid are needed to form new blood cells for the expanded maternal blood volume and to prevent anemia. Iron is essential for fetal growth and brain development and in the prevention of maternal anemia. An increase in folic acid is essential before pregnancy and in the early weeks of pregnancy to prevent neural tube defects in the fetus. For most pregnant women, supplements of 27 mg of ferrous iron and 400 to 800 mcg of folic acid per day are recommended as **dietary reference intakes (DRIs)** (American College of Obstetricians and Gynecologists [ACOG], 2018; Norwitz et al., 2019; U.S. Preventive Services Task Force [USPSTF], 2018). Women with previous histories of fetuses with neural tube defects are often prescribed higher doses of folic acid.

TABLE 11.4 Summary of General Body System Adaptations

System	Adaptation
Gastrointestinal system	*Mouth and pharynx:* Gums become hyperemic, swollen, and friable and tend to bleed easily. Saliva production increases. *Esophagus:* Decreased lower esophageal sphincter pressure and tone, which increases the risk of developing heartburn. *Stomach:* Decreased tone and mobility with delayed gastric emptying time, which increases the risk of gastroesophageal reflux and vomiting. Decreased gastric acidity and histamine output, which improves symptoms of peptic ulcer disease. *Intestines:* Decreased intestinal tone motility with increased transit time, which increases risk of constipation and flatulence. *Gallbladder:* Decreased tone and motility, which may increase risk of gallstone formation.
Cardiovascular system	*Blood volume:* Marked increase in plasma (50%) and RBCs (25–33%) compared to nonpregnant values. Causes hemodilution, which is reflected in a lower hematocrit and hemoglobin. *Cardiac output and heart rate:* Cardiac output increases from 30% to 50% over the nonpregnant rate by the 32nd week of pregnancy. The increase in cardiac output is associated with an increase in venous return and greater right ventricular output, especially in the left lateral position. Heart rate increases by 10–15 bpm between 14 and 20 weeks' gestation, and this increase will persist to term. *Blood pressure:* Diastolic pressure decreases typically 10–15 mm Hg to reach its lowest point by mid-pregnancy; it then gradually returns to nonpregnant baseline values by term. *Blood components:* The number of RBCs increases throughout pregnancy to a level 25–33% higher than nonpregnant values. Both fibrin and plasma fibrinogen levels increase, along with various blood clotting factors. These factors make pregnancy a hypercoagulable state.

Respiratory system	Enlargement of the uterus shifts the diaphragm up to 4 cm above its usual position. As muscles and cartilage in the thoracic region relax, the chest broadens with conversion from abdominal breathing to thoracic breathing. This leads to a 50% increase in air volume per minute. Tidal volume, or the volume of air inhaled, increases gradually by 30–40% (from 500 to 700 mL) as the pregnancy progresses.
Renal/urinary system	The renal pelvis becomes dilated. The ureters (especially the right ureter) elongate, widen, and become more curved above the pelvic rim. Bladder tone decreases and bladder capacity doubles by term. Glomerular filtration rate increases 40–60% during pregnancy. Blood flow to the kidneys increases by 50–80% as a result of the increase in cardiac output.
Musculoskeletal system	Distention of the abdomen with growth of the fetus tilts the pelvis forward, shifting the center of gravity. The woman compensates by developing an increased curvature (lordosis) of the spine. Relaxation and increased mobility of joints occur because of the hormones progesterone and relaxin, which lead to the characteristic “waddle gait” that pregnant women demonstrate toward term.
Integumentary system	Hyperpigmentation of the skin is the most common alteration during pregnancy. The most common areas include the areola, genital skin, axilla, inner aspects of the thighs, and linea nigra. Striae gravidarum, or stretch marks, are irregular reddish streaks that may appear on the abdomen, breasts, and buttocks in about half of pregnant women. The skin in the middle of the abdomen may develop a pigmented line called the linea nigra, which extends from the umbilicus to the pubic area. Melasma (“mask of pregnancy”) occurs in up to 70% of pregnant women. It is characterized by

	irregular, blotchy areas of pigmentation on the face, most commonly on the cheeks, chin, and nose.
Endocrine system	Controls the integrity and duration of gestation by maintaining the corpus luteum via hCG secretion; production of estrogen, progesterone, hPL, and other hormones and growth factors via the placenta; release of oxytocin (by the posterior pituitary gland), prolactin (by the anterior pituitary), and relaxin (by the ovary, uterus, and placenta).
Immune system	A general enhancement of innate immunity (inflammatory response and phagocytosis) and suppression of adaptive immunity (protective response to a specific foreign antigen) take place during pregnancy. These immunologic alterations help prevent the mother's immune system from rejecting the fetus (foreign body), increase her risk of developing certain infections, and influence the course of chronic disorders such as autoimmune diseases.

There is an abundance of conflicting advice about nutrition during pregnancy and what is good or bad to eat. Overall, the following guidelines are helpful:

- Increase consumption of fruits and vegetables, taking up half the plate with these.
- Replace saturated fats with unsaturated ones.
- Eat breakfast every day.
- Choose whole grains in place of refined grains.
- Choose foods with a lot of fiber to prevent constipation.
- Avoid hydrogenated or partially hydrogenated fats.
- Do not consume any alcoholic beverages.
- Limit calories from added sugars and saturated fats.
- Use reduced-fat spreads and dairy products instead of full-fat ones.
- Eat at least two servings of fish weekly, with one of them being an oily fish.
- Consume at least 3 qt of water daily (USDA, 2019).

In the months before conception, food choices are key. The foods and vitamins consumed can ensure that the woman and her fetus will have the nutrients that are essential for the very start of pregnancy.

While most women recognize the importance of healthy eating during pregnancy, some find it challenging to achieve. Many women say they have little time and energy to devote to meal planning and preparation. Another barrier to healthy eating is conflicting messages from various sources, resulting in a lack of clear, reliable, and relevant information. Moreover, many women are eating less in an effort to control their weight, putting them at greater risk of inadequate nutrient intake.

Nutritional Requirements During Pregnancy

Pregnancy is a time of intense fetal growth and development as well as maternal physiologic changes. Good nutrition during pregnancy promotes these processes, while under- or overnutrition is associated with poor pregnancy outcomes. Optimal maternal health via good nutritional practices during pregnancy reduces the risk of suboptimal fetal development.

The Food and Nutrition Board of the National Research Council has made recommendations for nutrient intakes for people living in the United States. The DRIs are more comprehensive than previous nutrient guidelines issued by the Food and Nutrition Board. They have replaced previous recommendations because they are not limited to preventing deficiency diseases. Rather, the DRIs incorporate current concepts about the role of nutrients and food components in reducing the risk of chronic disease, developmental disorders, and other related problems. The DRIs can be used to plan and assess diets for healthy people (National Academies of Sciences, Engineering, & Medicine, 2019).

These dietary recommendations also include information for women who are pregnant or lactating, because growing fetal and maternal tissues require increased quantities of essential dietary components. For example, the current DRIs suggest an increase in

the pregnant woman's intake of protein from 60 to 80 g/day, iron from 18 to 27 g/day, and folic acid from 400 to 800 mcg/day, along with an increase of 300 calories/day over the recommended intake of 1,800 to 2,200 calories/day for nonpregnant women (Table 11.5) (Garner, 2019; Kane & Prelack, 2019).

Gluten-Free Diet During Pregnancy

In recent years, gluten-free foods have become popular, fueling a growing market for the food industry. However, pregnant women may be missing out on important nutrients if they adopt gluten-free diets. People who do not live with gluten intolerance may choose to not consume it because it is frequently found in many processed and unhealthy foods. However, some gluten-free foods contain more fat, including saturated, and sodium, and fewer minerals and vitamins than their equivalents with gluten (Patel & Lacy, 2018). Skipping processed foods altogether and focusing on fruits, vegetables, lean protein, and whole grains can provide a well-balanced, healthy diet.

Eating a gluten-free diet can make it hard to get the recommended amount of folate, vitamin B, iron, calcium, fiber, and grain-servings that all pregnant women need. That is why, unless there is medical reason in which gluten must be eliminated from the diet due to celiac disease or a gluten allergy, there is no scientific reason to cut out wholesome, nutrient-dense grains from the diet (Kane & Prelack, 2019).

USDA and MyPlate

For a pregnant woman to meet recommended DRIs, she should eat according to the U.S. Department of Agriculture (USDA) food guide, MyPlate (Fig. 11.5). MyPlate replaced the Food Guide Pyramid in 2011 as the government's primary food group symbol. MyPlate is an easy-to-understand visual cue to help consumers adopt healthy eating habits by encouraging them to build a healthy plate at each meal that is consistent with the *Dietary Guidelines for Americans* (USDA, 2019). These are the basis for federal nutrition policy

(USDA, 2019). MyPlate can serve as a basis for dietary instruction, and it can be tailored to meet each woman's individual needs.

TABLE 11.5 Dietary Recommendations for the Pregnant and Lactating Woman

Nutrient	Nonpregnant Women	Pregnant Woman	Lactating Woman
Calories	2,200	2,500	2,700
Protein	60 g	80 g	80 g
Water/fluids	6–8 glasses daily	8 glasses daily	8 glasses daily
Vitamin A	700 mcg	770 mcg	1,300 mcg
Vitamin C	75 mg	85 mg	120 mg
Vitamin D	5 mcg	5 mcg	5 mcg
Folate	400 mcg	600 mcg	500 mcg
Calcium	1,000 mg	1,000 mg	1,000 mg
Iodine			
Iron	18 mg	27 mg	9 mg

U.S. Department of Agriculture (USDA). (2019). *Nutritional needs during pregnancy*. (2019). *Dietary reference intakes tables and application*. Retrieved June 16, 2020, from http://nationalacademies.org/hmd/Activities/Nutrition/SummaryDRIs/DRI-Tables.aspx; and Kane, K., & Prelack, K. (2019). *Advanced medical nutrition therapy.* Jones & Bartlett Learning.

MyPlate provides guidance to help implement the dietary guidelines. The USDA has designed an interactive online diet-planning program called the MyPlate Plan for Moms that helps pregnant women personalize their dietary intake throughout their pregnancies. A summary of the new guidelines is as follows:

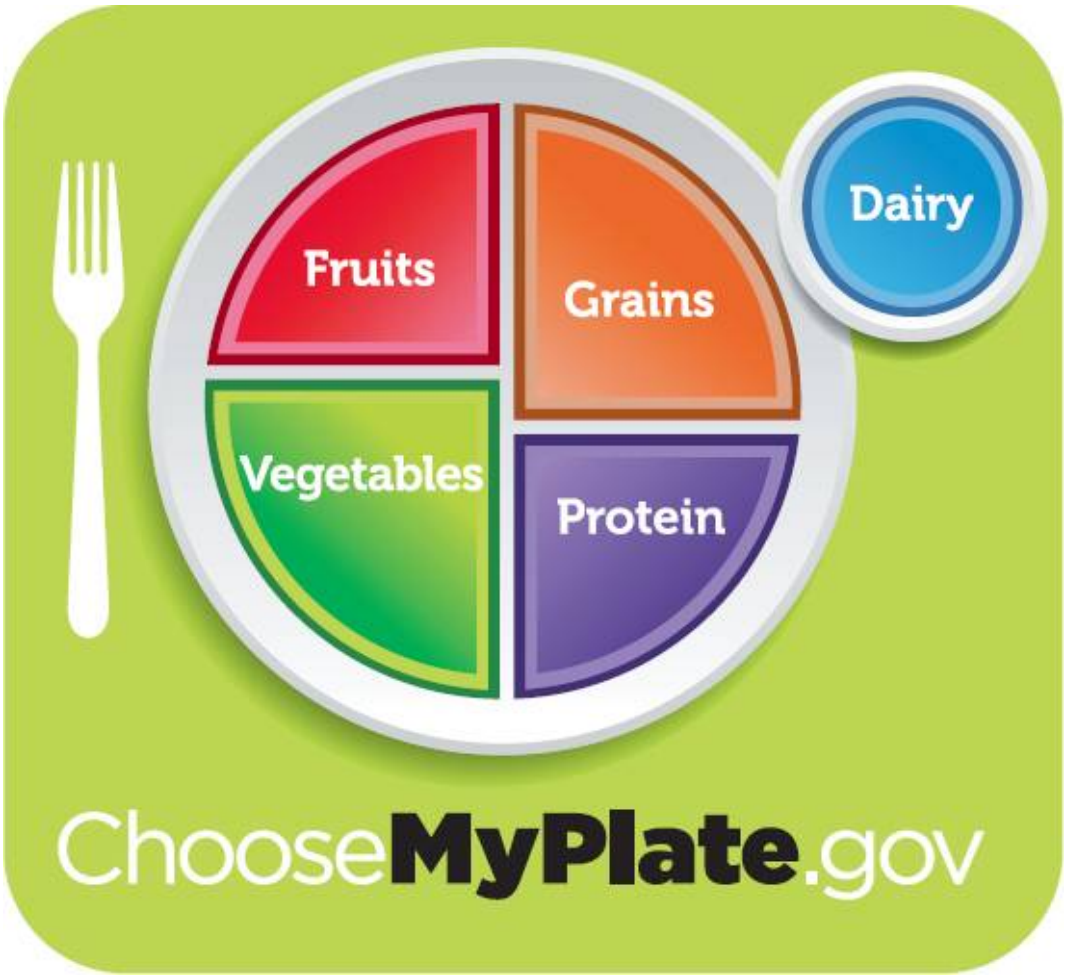

FIGURE 11.5. MyPlate.

- Eat a variety of food from all food groups using portion control.
- Increase intake of vitamins, minerals, and dietary fiber.
- Lower intake of saturated fats, trans fats, and cholesterol.
- Consume adequate synthetic folic acid from supplements or from fortified foods.
- Increase intake of fruits, vegetables, and whole grains.
- Balance calorie intake with exercise to maintain ideal healthy weight (USDA, 2019).

An eating plan that follows MyPlate should provide sufficient nutrients for a healthy pregnancy. Except for iron, folic acid, and calcium, most of the nutrients a woman needs during pregnancy can be obtained by making healthy food choices. However, a vitamin and mineral supplement is generally prescribed.

TAKE NOTE!

Good food sources of folic acid include dark green vegetables, such as broccoli, romaine lettuce, and spinach; baked beans; black-eyed peas; citrus fruits; peanuts; and liver.

Food Concerns During Pregnancy

ARTIFICIAL SWEETENERS

Few studies have investigated whether foods containing artificial sweeteners are safe during pregnancy. Artificial sweeteners or intense sweeteners are sugar substitutes that are used as an alternative to table sugar. They are many times sweeter than natural sugar and contain no calories. Extensive scientific research has demonstrated the safety of the six low-calorie sweeteners currently approved for use in foods in the United States and Europe (stevia, acesulfame-K, aspartame, neotame, saccharin, and sucralose) if taken in acceptable quantities daily. Recent evidence links nonnutritive sweeteners with higher newborn birth weights and higher rates of childhood obesity (Toews et al., 2019).

The safety of artificial sweeteners consumed during pregnancy remains controversial. Some health care providers advise their pregnant clients to avoid all nonnutritive sweeteners during pregnancy, while others suggest they can be used in moderation (Jordan et al., 2019). The debate continues on this matter until additional research can be completed.

FISH, SHELLFISH, AND LEVELS OF MERCURY

Fish and shellfish are an important part of a healthy diet because they contain high-quality protein, are low in saturated fat, and contain omega-3 fatty acids. However, nearly all fish and shellfish contain traces of mercury and some contain higher levels of mercury that may harm a developing fetus if ingested by pregnant women in large amounts. Human exposure to mercury occurs primarily through the consumption of fish contaminated through atmospheric mercury

releases. The U.S. Environmental Protection Agency (EPA) and the United Nations Environment Program have identified coal-fired power plants as the source of 50% to 75% of the atmospheric mercury pollution in the United States and worldwide. Once airborne, rainfall transfers mercury particles into waterways where it is converted to the neurotoxic methylmercury form through a microbial process. Plankton absorbs the methylmercury and as the smaller fish eat the plankton and the larger predatory fish consume the smaller fish, the methylmercury bioaccumulates up the food chain to humans. Mercury exposure in pregnancy has been associated with both pregnancy complications and developmental problems in infants. Apart from the environmental exposure, mercury is likely to arise from predatory fish consumption. All pregnant women should avoid these potential problems to minimize any risk.

All fish contain methylmercury regardless of the size or the geographic location of the waters from which the fish is caught, though these factors can influence the amounts of methylmercury. In addition, because methylmercury resides in the tissue of the fish, no method of cleaning or cooking will reduce the amount of mercury in a meal of contaminated fish (Budnik & Casteleyn, 2019). With this in mind, the FDA and the EPA advise women who may become pregnant, pregnant women, and nursing mothers to:

- avoid consumption of fish with moderate to high mercury levels (e.g., for 6 to 12 months prior to conception and throughout pregnancy).
- avoid eating shark, swordfish, king mackerel, orange roughy, ahi tuna, and tilefish because they are high in mercury levels.
- eat up to 12 oz (two average meals) weekly of fish known to have low mercury levels, such as shrimp, canned light tuna, salmon, lobster, sole, tilapia, cod, haddock, pollock, and catfish.
- check local advisories about the safety of fish caught by family and friends in local lakes, rivers, and coastal areas (USFDA, 2019a).

See Evidence-Based Practice 11.1.

LISTERIOSIS AND PREGNANCY

Another food issue concern for pregnant women is consumption of food contaminated with the Gram-positive bacillus *Listeria monocytogenes*. *Listeria* is a type of bacteria found in soil, groundwater, animals, and sometimes on plants. It is commonly found in processed and prepared foods and in raw or unpasteurized milk, and it causes listeriosis. Listeriosis is associated with high morbidity and mortality. Though *Listeria* is all around our environment, most *Listeria* infections in people result from eating contaminated foods. Listeriosis during pregnancy usually presents as an unremarkable febrile illness in the mother but can be fatal for the fetus and newborn. Reliable laboratory testing for early diagnosis is lacking. Listeriosis can be passed to an unborn baby through the placenta even if the mother is not showing signs of illness. This can lead to preterm births, miscarriages, stillbirths, and high neonatal mortality rates (Norwitz et al., 2019). Pregnant women with known or suspected listeriosis should be treated with a minimum dose of 6 g of ampicillin for at least 14 days (Presterl et al., 2019). The Food Safety and Inspection Service and the FDA (2019b) provide the following advice for pregnant women to avoid listeriosis:

EVIDENCE-BASED PRACTICE 11.1 Multiple-Micronutrient Supplementation for Women during Pregnancy

STUDY

Multiple-micronutrient deficiencies often exist among women of reproductive age. Micronutrients are vitamins and minerals that are needed by the body in small quantities but are important for normal functioning, growth, and development. Deficiencies are exacerbated during pregnancy due to the increased demands of the developing fetus, leading to adverse effects for the mother and infant. The purpose of this study was to evaluate the benefits of oral multiple-micronutrient supplementation during pregnancy on maternal, fetal, and infant health outcomes. Eligible for review were 21 trials involving 142,496 women.

Findings

Overall, it was found that pregnant women who received multiple-nutrient supplementation had fewer infants that were born too small (lighter than 2,500 g), fewer infants were smaller in size than normal for gestational age, and fewer births occurred before 37 weeks' gestation.

Nursing Implications

These findings suggest a positive impact of multiple-nutrient supplementation on several birth outcomes. It led to a reduction in low birth weight and small-for-gestational-age infants. In addition, the supplementation reduced preterm births. A balanced diet is necessary for a healthy pregnancy, but a majority of women do not consume one that provides all the micronutrients needed to support a healthy pregnancy. Nurses can be instrumental in offering advice to women on multiple-nutrient

supplementation and good nutrition to improve pregnancy outcomes.

Adapted from Keats, E. C., Haider, B. A., Tam, E., & Bhutta, Z. A., (2019). Multiple-micronutrient supplementation for women during pregnancy. Cochrane Database of Systematic Reviews. Issue 3. Art. No.: CD004905. https://doi.org/10.1002/14651858.CD004905.pub6.

- Wash hands frequently during food preparation.
- Refrigerate all perishable foods quickly to prevent harmful bacteria from proliferating.
- Avoid getting fluid from hot dog packages on other foods, utensils, and food preparation surfaces, and wash hands after handling hot dogs, luncheon meats, and deli meats.
- Do not eat soft cheeses such as feta, Brie, Camembert, and blue-veined cheeses.
- It is safe to eat hard cheeses, semi-soft cheeses such as mozzarella, pasteurized processed cheese slices and spreads, cream cheese, and cottage cheese.
- Do not eat refrigerated pâté or meat spreads.
- It is safe to eat canned or shelf-stable pâté and meat spreads.
- Do not eat refrigerated smoked seafood unless it is an ingredient in a cooked dish such as a casserole. Examples of refrigerated smoked seafood include salmon, trout, whitefish, cod, tuna, and mackerel and are most often labeled as “nova-style,” “lox,” “kippered,” “smoked,” or “jerky.” These refrigerated smoked fish are found in the refrigerated section or sold at delicatessens and deli counters of grocery stores.
- It is safe to eat canned fish such as salmon and tuna or shelf-stable smoked seafood.
- Do not drink raw (unpasteurized) milk or eat foods that contain unpasteurized milk.
- Use all refrigerated perishable items that are precooked or ready-to-eat as soon as possible.
- Use a refrigerator thermometer to make sure that the refrigerator always stays at 40° F (about 5° C) or below.

- Do not eat salads made in the store such as ham salad, chicken salad, egg salad, tuna salad, or seafood salad.
- Clean your refrigerator regularly.

Maternal Weight Gain

The amount of weight that a woman gains during pregnancy is not as important as what she eats. A woman can lose extra weight after a pregnancy, but she can never make up for poor nutritional status during the pregnancy. Earlier guidelines recommended weight gain that would be optimal for the infant, but new guidelines take into account the well-being of the mother too (Table 11.6).

TABLE 11.6 Normal Distribution of Weight Gain During Pregnancy

Component	Weight (pounds)
Infant birth weight	7.5
Blood volume increase	4
Uterus	2
Increase in breast tissue	2
Placenta	1.5
Maternal fluid volume	4
Maternal fat tissue	7
Amniotic fluid	2
Approximate total weight gain	30

Blackburn, S. T. (2018). *Maternal, fetal, neonatal physiology: A clinical perspective*. Elsevier; Jordan, R. G., Farley, C. L., & Grace, T. (2019). *Prenatal and postnatal care: A woman-centered approach* (2nd ed.). Wiley Blackwell.

Weight gain during pregnancy reflects increased maternal stores as well as those of the developing fetus and placenta. The Centers for Disease Control and Prevention (CDC, 2019a) and the Institute of

Medicine (IOM) have revised previous weight gain recommendations. Their revisions took into account that current American women (1) have more multiple pregnancies; (2) are becoming pregnant at an older age; (3) are exceeding the ideal weight gain during pregnancy; and (4) tend to be more overweight and obese when becoming pregnant. The new recommendations are based on the woman's pregnancy BMI as follows (Box 11.3):

- Underweight (BMI less than 18.5) total weight gain range = 28–40 lb
- Normal weight (BMI = 18.5–24.9) total weight gain range = 25–35 lb
- Overweight (BMI = 25–29.9) total weight gain range = 15–25 lb
- Obese (BMI = 30 or higher) total weight gain range = 11–20 lb

A woman who is underweight before pregnancy or who has a low maternal weight gain pattern should be monitored carefully because she is at risk of giving birth to a low-birth-weight infant (lighter than 2,500 g or 5.5 lb). Frequently these women simply need advice on what to eat to add weight. Encourage the woman to eat snacks that are high in calories such as nuts, peanut butter, milkshakes, cheese, fruit, yogurt, and ice cream. Any woman who has a prepregnancy BMI less than 18.5 is considered to be at high risk and should be referred to a nutritionist (CDC, 2019b).

BOX 11.3 Body Mass Index

Body mass index (BMI) provides an accurate estimate of total body fat and is considered a good method to assess overweight and obesity in people. BMI is a weight-to-height ratio calculation that can be determined by dividing an individual's weight in kilograms by the height in meters squared. BMI can also be calculated by weight in pounds divided by the height in inches squared, multiplied by 704.5.

The Centers for Disease Control and Prevention (CDC, 2019a) categorizes BMI as follows:

- Underweight: lower than 18.5
- Healthy weight: 18.5–24.9
- Overweight: 25–29.9
- Obese: 30 or higher

Use this example to calculate BMI:
Mary is 5 ft 5 in tall and weighs 150 lb.

1. Convert weight into kilograms: 150 ÷ 2.2 lb/kg = 68.18 kg
2. Convert height into meters:
   a. 5 ft 5 in = 65 in ÷ 2.54 cm/in = 165.1 cm
   b. 165.1 cm ÷ 100 cm = 1.65 m
3. Then square the height in meters: 1.65 × 1.65 = 2.72
4. Calculate BMI: 68.18 kg ÷ 2.72 = 25

Centers for Disease Control and Prevention (CDC). (2019a). *Weight gain during pregnancy*. Retrieved June 16, 2020, from https://www.cdc.gov/reproductivehealth/maternalinfanthealth/pregnancy-weight-gain.htm; Centers for Disease Control and Prevention (CDC). (2019c). *Body mass index (BMI) for adults*. Retrieved June 16, 2020, from https://www.cdc.gov/healthyweight/assessing/bmi/adult_bmi/index.html

Women who start a pregnancy while overweight (BMI greater than 25 to 29) run the risk of having a high-birth-weight infant with resulting cephalopelvic disproportion and a potential surgical birth. Over half of reproductive-age women in the United States are overweight or obese and at risk for numerous adverse pregnancy outcomes in addition to surgical birth. Some researchers have suggested that the uterine environment may influence the potential development of offspring obesity later in life (Siega-Riz et al., 2020). Dieting during pregnancy is never recommended, even for women who are obese. Severe restriction of caloric intake is associated with

a decrease in birth weight. Because of the expansion of maternal blood volume and the development of fetal and placental tissues, some weight gain is essential for a healthy pregnancy. Women who gain more than the recommended weight during pregnancy and who fail to lose this weight 6 months after giving birth are at much higher risk of being obese nearly a decade later (Stafford et al., 2019). Women who are overweight when beginning a pregnancy should gain no more than 15 to 25 lb during the pregnancy, depending on their nutritional status and degree of obesity (Riley et al., 2018).

The best way to assess whether a pregnant woman is consuming enough calories is to follow her pattern of weight gain. All pregnant women should aim for a steady rate of weight gain throughout pregnancy. If she is gaining in a steady, gradual manner, then she is taking in enough calories. However, consuming an adequate amount of calories does not guarantee that her nutrients are sufficient. It is critical to evaluate both the quantity and the quality of the foods eaten.

During the first trimester, for women whose prepregnancy weight is within the normal weight range, weight gain should be about 3.5 to 5 lb. For underweight women, weight gain should be at least 5 lb. For overweight women, weight gain should be about 2 lb. Much of the weight gained during the first trimester is caused by growth of the uterus and expansion of the blood volume.

During the second and third trimesters, the following pattern is recommended: For women whose prepregnancy weight is within the normal weight range, weight gain should be about 1 lb per week. For underweight women, weight gain should be slightly more than 1 lb per week. For overweight women, weight gain should be about 2/3 lb per week (Kane & Prelack, 2019).

Nutrition Promotion

Through education, nurses can play an important role in ensuring adequate nutrition for pregnant women. During the initial prenatal visit, health care providers conduct a thorough assessment of a woman's typical dietary practices and address any conditions that

may cause inadequate nutrition, such as nausea and vomiting or lack of access to adequate food. Assess and reinforce dietary information at every prenatal visit to promote good nutrition. A normal pregnancy and a well-balanced diet generally provide most of the recommended nutrients except iron and folate, both of which must be supplemented in the form of prenatal vitamins (Teaching Guidelines 11.1).

TEACHING GUIDELINES 11.1
Teaching to Promote Optimal Nutrition During Pregnancy

- Follow the USDA's MyPlate guide, and select a variety of foods from each group.
- Gain between 15 and 40 lb in a gradual and steady manner depending on prepregnancy weight as follows:
  - Underweight (BMI >18.5) total weight gain range = 28–40 lb
  - Normal weight (BMI = 18.5–24.0) total weight gain range = 25–35 lb
  - Overweight (BMI = 25–29) total weight gain range = 15–25 lb
  - Obese (BMI = 30 or higher) total weight gain range = 11–20 lb (HMD, 2009)
- Take your prenatal vitamin and mineral supplementation daily.
- Avoid weight reduction diets during pregnancy.
- Do not skip meals; eat three meals with one or two snacks daily.
- Limit the intake of sodas and caffeine-rich drinks.
- Avoid the use of diuretics during pregnancy.
- Do not restrict the use of salt unless instructed to do so by your health care provider.
- Engage in reasonable physical activity daily.

Special Nutritional Considerations

Many factors play an important role in shaping a person's food habits, and these factors must be taken into account if nutritional

counseling is to be realistic and appropriate. Nurses need to be aware of these factors to ensure individualized teaching and care.

Cultural Variations and Restrictions

Food is important to every cultural group. It is often part of celebrations and rituals. When working with women from various cultures, the nurse needs to adapt American nutritional guidelines to meet each woman's nutritional needs within her cultural framework. Food choices and variations for different cultures might include:

- Bread, cereal, rice, and pasta group:
  - Bolillo
  - Couscous
  - Flaxseed
  - Hau juan
- Vegetable group:
  - Agave
  - Bok choy
  - Jicama
  - Okra
  - Water chestnuts
- Protein group:
  - Bean paste
  - Blood sausage
  - Legumes
  - Shellfish
- Fruit group:
  - Catalpa
  - Kumquats
  - Plantain
  - Yucca fruit
  - Zapote
- Milk and dairy:
  - Buffalo milk
  - Buttermilk
  - Soybean milk (Academy of Nutrition and Dietetics [AND], 2019)

Lactose Intolerance

Food plays an essential role in normal cellular processes and is required for survival of all living organisms. In some individuals with allergies and food intolerances, it can trigger or worsen certain disease states. The best source of calcium is milk and dairy products, but for women with lactose intolerance, adaptations are necessary. Women with lactose intolerance lack an enzyme (lactase) needed for the breakdown of lactose into its component simple sugars, glucose, and galactose. Without adequate lactase, lactose passes through the small intestine undigested and causes abdominal discomfort, gas, and diarrhea. Lactose intolerance is especially common among women of African, Asian, and Middle Eastern descent (Kane & Prelack, 2019).

Additional or substitute sources of calcium may be necessary. These may include peanuts, almonds, sunflower seeds, broccoli, salmon, kale, and molasses (Pearlman & Akpotaire, 2019). In addition, encourage the woman to drink lactose-free dairy products or calcium-enriched orange juice or soy milk.

Vegetarians

Vegetarian diets are becoming increasingly prevalent in the United States. Well-planned vegan diets, when based on a wide variety of plant foods and excluding all animal sources, can provide adequate nutrition throughout all stages of life. People choose a vegetarian diet for various reasons including environmental, animal rights, philosophical, religious, and health beliefs. A completely plant-based diet is suitable during pregnancy and lactation, provided it is well planned (Baroni et al., 2019). Vegetarians choose not to eat meat, poultry, and fish. Their diets consist mostly of plant-based foods, such as legumes, vegetables, whole grains, nuts, and seeds. Vegetarians fall into groups defined by the types of foods they eat. Lacto-ovo-vegetarians omit red meat, fish, and poultry but eat eggs, milk, and dairy products in addition to plant-based foods. Lacto-vegetarians consume milk and dairy products along with plant-based foods; they omit eggs, meat, fish, and poultry. Vegans eliminate all

foods originating from animals, including milk, eggs, and cheese, and eat only plant-based foods (Means, 2019).

The concern with any form of vegetarianism, especially during pregnancy, is that the diet may be inadequate in nutrients. Other risks of vegetarian eating patterns during pregnancy may include low gestational weight gain, iron-deficiency anemia, compromised protein utilization, and decreased mineral absorption. Pregnant and breastfeeding vegan women should be sure to consume reliable sources of vitamin B12 and vitamin D which they may be lacking (Baroni et al., 2019). A diet can become so restrictive that a woman is not gaining weight or consistently not eating enough from one or more of the food groups. Generally, the more restrictive the diet is, the greater the chance of nutrient deficiencies.

Well-balanced vegetarian diets that include dairy products provide adequate caloric and nutrient intake and do not require special supplementation; however, vegan diets do not include any meat, eggs, or dairy products. Pregnant vegetarians must pay special attention to their intake of protein, iron, calcium, and vitamin B12. Suggestions include:

- *For protein:* Substitute soy foods, beans, lentils, nuts, grains, and seeds.
- *For iron:* Eat a variety of meat alternatives along with vitamin C–rich foods.
- *For calcium:* Substitute soy, calcium-fortified orange juice, and tofu.
- *For vitamin B12:* Eat fortified soy foods and a B12 supplement.

Research from the Academy of Nutrition and Dietetics (2019) shows that well-planned vegetarian diets can be appropriate for individuals during all stages of the life cycle, including during pregnancy, lactation, infancy, childhood, and adolescence, and for athletes.

Pica

Pica is a term used to describe the intense craving for and eating of nonfood items over a period of time of at least 1 month. Many women experience unusual food cravings during their pregnancy.

Having cravings during pregnancy is perfectly normal. Sometimes, however, some women crave substances that have no nutritional value and can even be dangerous to themselves and the fetus. Pica is the compulsive ingestion of nonfood substances. Pica is derived from the Latin term for magpie, a bird that is known to consume a variety of nonfood substances. Unlike the bird, however, pregnant women who develop pica typically have one or two specific cravings.

Many factors have been implicated in the etiology of pica, but the exact cause of pica is not known. Many theories have been advanced to explain it, but none has been proven scientifically. The incidence of pica is difficult to determine since it is underreported. It is more common in the United States among African American women compared to those of other ethnicities, but the practice of pica is not limited to any one geographic area, race, creed, or culture. In the United States, pica is also common in women from rural areas and women with a family history of it. Common substances ingested include dirt, clay, and laundry starch. Other pica cravings are burnt matches, stones, charcoal, mothballs, ice, gravel, paper, chalk, egg shells, nail polish, cornstarch, toothpaste, soap, sand, plaster, coffee grounds, paint chips, baking soda, and cigarette ashes (Jordan et al., 2019).

The three main substances consumed by women with pica are soil or clay (geophagia), ice (pagophagia), and laundry starch (amylophagia). Nutritional implications include:

- *Soil:* replaces nutritive sources and causes iron-deficiency anemia.
- *Clay:* produces constipation; can contain toxic substances and cause parasitic infection
- *Ice:* can cause iron-deficiency anemia, tooth fractures, freezer burn injuries
- *Laundry starch:* replaces iron-rich foods, leads to iron deficiencies, and replaces protein metabolism, thus depriving the fetus of amino acids needed for proper development (American Pregnancy Association [APA], 2019)

Clinical manifestations of anemia often precede the identification of pica because the health care provider rarely addresses the

behavior, and the woman does not usually volunteer such information (Treasure et al., 2020). Secrecy surrounding pica makes research and diagnosis difficult because some women fail to view their behavior as anything unusual, harmful, or worth reporting. Because of the clinical implications, pica should be discussed with all pregnant women as a preventive measure. The topic can be part of a general discussion of cravings, and the nurse should stress the harmful effects of consuming nonfood items.

A nonjudgmental, understanding, and culturally supportive environment can facilitate reporting of pica by the client. Suspect pica when the woman exhibits anemia though her dietary intake is appropriate. Ask about her usual dietary intake, and include questions about the ingestion of nonfood substances. Consider the potential negative outcomes for the pregnant woman and her fetus, and take appropriate action. The nurse's focus should be to change potentially harmful eating habits and to be supportive to the woman in making the change.

PSYCHOSOCIAL ADAPTATIONS DURING PREGNANCY

Pregnancy is a unique time in a woman's life. The transition to motherhood is characterized by physiologic, psychologic, and social changes. It is a time of dramatic alterations in the woman's body and her appearance, as well as a time of change in her social status. All of these changes occur simultaneously. Concurrent with the physiologic changes within her body systems are psychosocial changes within the mother and family members as they face significant role and lifestyle changes. Nurses should inquire at every prenatal visit about the woman's emotional well-being to assess her psychosocial adjustments throughout her pregnancy.

Maternal Emotional Responses

Motherhood, perhaps more than any role in the society, has acquired a special significance for women. Women are taught they should find fulfillment and satisfaction in the role of the “ever-bountiful, ever-giving, self-sacrificing mother.” Pregnancy and transitioning to motherhood are critical experiences in a woman’s life, stirring a whole range of powerful emotions. Many women describe pregnancy as a moody time in their lives (National Perinatal Association, 2020). With such high expectations, many pregnant women experience various emotions throughout their pregnancy. The woman’s approach to these emotions is influenced by her emotional makeup, her sociologic and cultural background, her acceptance or rejection of the pregnancy, whether the pregnancy was planned, if the father is known, and her support network (March of Dimes, 2019).

Despite the wide-ranging emotions associated with the pregnancy, many women experience similar responses. These responses commonly include ambivalence, introversion, acceptance, mood swings, and changes in body image.

Ambivalence

The realization of a pregnancy can lead to fluctuating responses, possibly at opposite ends of the spectrum. For example, regardless of whether the pregnancy was planned, the woman may feel proud and excited by the news while at the same time fearful and anxious of the implications. The reactions are influenced by several factors, including the way the woman was raised, her current family situation, the quality of the relationship with the expectant father, and her hopes for the future. Some women express concern over the timing of the pregnancy, wishing that goals and life objectives had been met before the pregnancy. Other women may question how a newborn or infant will affect their careers or their relationships with friends and family. These feelings can cause conflict and confusion about the pregnancy.

Ambivalence, or having conflicting feelings at the same time, is a universal feeling and is considered normal when preparing for a lifestyle change and new role. Pregnant women commonly

experience ambivalence during the first trimester. Usually ambivalence evolves into acceptance by the second trimester, when fetal movement is felt. The woman's personality, her ability to adapt to changing circumstances, and the reactions of her partner will affect her adjustment to being pregnant and her acceptance of impending motherhood.

Introversion

Introversion, or focusing on oneself, is common during the early part of pregnancy. The woman may withdraw and become increasingly preoccupied with herself and her fetus. As a result, she may participate less with the outside world, and she may appear passive to her family and friends.

This introspective behavior is a normal psychological adaptation to motherhood for most women. Introversion seems to heighten during the first and third trimesters, when the woman's focus is on behaviors that will ensure a safe and health pregnancy outcome. Couples need to be aware of this behavior and should be informed about measures to maintain and support the focus on the family.

Acceptance

During the second trimester, the physical changes of the growing fetus, including an enlarging abdomen and fetal movement, bring a sense of reality and validity to the pregnancy. There are many tangible signs that someone separate from herself is present. The pregnant woman feels fetal movement and may hear the heartbeat. She may see the fetal image on an ultrasound screen and feel distinct parts, recognizing independent sleep and wake patterns. She becomes able to identify the fetus as a separate individual and accepts this.

Many women will verbalize positive feelings about the pregnancy and will conceptualize the fetus. The woman may accept her new body image and talk about the new life within. Generating a discussion about the woman's feelings and offering support and validation at prenatal visits are important.

Mood Swings

Emotional lability is characteristic throughout most pregnancies. One moment a woman can feel great joy, and within a short time, she can feel shock and disbelief. Frequently, pregnant women will start to cry without any apparent cause. Some women feel as though they are riding an “emotional roller coaster.” These extremes in emotion can make it difficult for partners and family members to communicate with the pregnant woman without placing blame on themselves for their mood changes. Clear explanations about how common mood swings are during pregnancy are essential.

Change in Body Image

The way in which pregnancy affects a woman’s body image varies greatly from person to person. Some women feel as if they have never been more beautiful, while others spend their pregnancy feeling overweight and uncomfortable. For some women, pregnancy is a relief from worrying about weight, while for others it only exacerbates their fears of weight gain. Changes in body image are normal but can be stressful for the pregnant woman. Offering a thorough explanation and initiating discussion of the expected bodily changes may help the family to cope with them.

Becoming a Mother

Reva Rubin (1984) identified maternal tasks that a woman must accomplish to incorporate the maternal role into her personality. Accomplishing these tasks helps the expectant mother develop her self-concept as a mother and form a mutually gratifying relationship with her infant. These tasks are listed in Box 11.4.

BOX 11.4 Becoming a Mother

- Ensuring safe passage throughout pregnancy and birth
  - Primary focus of the woman's attention
  - First trimester: woman focuses on herself, not on the fetus
  - Second trimester: woman develops attachment of great value to her fetus
  - Third trimester: woman has concern for herself and her fetus as a unit
  - Participation in positive self-care activities related to diet, exercise, and overall well-being
- Seeking acceptance of infant by others
  - First trimester: acceptance of pregnancy by herself and others
  - Second trimester: family needs to relate to the fetus as member
  - Third trimester: unconditional acceptance without rejection
- Seeking acceptance of self in maternal role to infant ("binding in")
  - First trimester: mother accepts idea of pregnancy, but not of infant
  - Second trimester: with sensation of fetal movement (quickening), mother acknowledges fetus as a separate entity within her
  - Third trimester: mother longs to hold infant and becomes tired of being pregnant
- Learning to give of oneself
  - First trimester: identifies what must be given up to assume new role
  - Second trimester: identifies with infant, learns how to delay own desires
  - Third trimester: questions her ability to become a good mother to infant

Pregnancy and Sexuality

Sexuality is an important part of health and well-being. Sexual behavior modifies as pregnancy progresses, influenced by biologic, psychological, and social factors. The way a pregnant woman feels and experiences her body during pregnancy can affect her sexuality. The woman's changing shape, emotional status, fetal activity, changes in breast size, pressure on the bladder, and other discomforts of pregnancy result in increased physical and emotional demands. These can produce stress on the sexual relationship between the pregnant woman and her partner. As the changes of pregnancy ensue, many partners become confused, anxious, and fearful of how the relationship may be affected.

The sexual desire of pregnant women may change throughout the pregnancy. During the first trimester, the woman may be less interested in sex because of fatigue, nausea, and fear of disturbing the early embryonic development. During the second trimester, her interest may increase because of the stability of the pregnancy. During the third trimester, her enlarging size may produce discomfort during sexual activity (Edmonds et al., 2019).

Potential complications of sex during pregnancy include preterm labor, pelvic inflammatory disease, antepartum hemorrhage in placenta previa, and venous air embolism. Generally, sexual relations are considered safe in pregnancy. Abstinence is usually only recommended for women who are at risk for preterm labor or for antepartum hemorrhage because of placenta previa (King et al., 2019).

A woman's sexual health is intimately linked to her own self-image. Sexual positions to increase comfort as the pregnancy progresses as well as alternative noncoital modes of sexual expression, such as cuddling, caressing, and holding, should be discussed. Giving permission to talk about and then normalizing sexuality can help enhance the sexual experience during pregnancy and ultimately the couple's relationship. If avenues of communication are open regarding sexuality during pregnancy, any fears and myths the couple may have can be dispelled.

Pregnancy and the Partner

Nursing care related to childbirth has expanded from a narrow emphasis on the physical health needs of the mother and infant to a broader focus on family-related social and emotional needs. One prominent feature of this family-centered approach is the recent movement toward promoting the mother–infant bond. But to achieve a truly family-centered practice, nursing must make a comparable commitment to understanding and meeting the needs of the partner in the emerging family. Recent studies suggest that the partner's potential contribution to the infant's overall development has been misperceived or devalued and that the partner's ability and

willingness to assume a more active role in the infant's care may have been underestimated.

Reactions to pregnancy and to the psychological and physical changes by the woman's partner vary greatly. Some enjoy the role of being the nurturer, while others experience alienation and may seek comfort or companionship elsewhere. Some expectant fathers may view pregnancy as proof of their masculinity and assume the dominant role, while others see their role as minimal, leaving the pregnancy up to the woman entirely. Each expectant partner reacts uniquely.

Emotionally and psychologically, expectant partners may undergo fewer visible changes than women, but changes do occur and may remain unexpressed and unappreciated. Partners play a key role in pregnancy and childbirth preparedness in terms of economic and emotional support (Cheptum et al., 2019). Expectant partners also experience a multitude of adjustments and concerns. Physically, they may gain weight around the middle and experience nausea and other GI disturbances—a reaction termed *couvade syndrome* that is a sympathetic response to their partner's pregnancy. They may also experience ambivalence during early pregnancy, with extremes of emotions (e.g., pride and joy versus an overwhelming sense of impending responsibility).

During the second trimester of pregnancy, partners go through acceptance of the role as caregiver and support person. They come to accept the reality of the fetus when movement is felt, and they experience confusion when dealing with the woman's mood swings and introspection. During the third trimester, the expectant partner prepares for the reality of this new role and negotiates what the role will be during the labor and birthing process. Many express concern about being the primary support person during labor and birth and worry how they will react when faced with their loved one in pain. Expectant partners share many of the same anxieties as their pregnant partners. However, it is uncommon for them to reveal these anxieties to the pregnant partner or health care providers. Often, how the expectant partner responds during the third trimester depends on the state of the marriage or partnership. When the

marriage or partnership is struggling, the impending increase in responsibility toward the end of pregnancy may drive the expectant partner further away. It may manifest as working late, staying out late with friends, or beginning new or superficial relationships. In the stable partnership, the expectant partner who may have been struggling to find their place in the pregnancy now finds concrete tasks to do—for example, painting the nursery, assembling the car seat, or attending childbirth classes.

Pregnancy and Siblings

A sibling's reaction to pregnancy is age dependent. Some children might express excitement and anticipation, while others might have negative reactions. A young toddler might regress in toilet training or ask to drink from a bottle again. An older school-aged child may ignore the new addition to the family and engage in outside activities to avoid the new member. The introduction of an infant into the family can be the beginning of sibling rivalry, which results from the child's fear of change in the security of the relationship with their parents. An estimated 80% of children will grow up with siblings, so first children reacting to pregnancies is a common family adjustment (Jordan et al., 2019). Preparation of the siblings for the anticipated birth is imperative and must be designed according to the age and life experiences of the sibling at home. Constant reinforcement of love and caring will help reduce the older child's fear of change and worry about being replaced by the new family member.

If possible, parents should include siblings in preparation for the birth of the new baby to help them feel as if they have an important role to play (Fig. 11.6). Parents must also continue to focus on the older sibling after the birth to reduce regressive or aggressive behavior toward the newborn.

FIGURE 11.6. Parents preparing sibling for the birth of a new baby.

Pregnancy is an extremely busy time, not only in terms of the bodily changes taking place but tasks that must be done such as choosing health care providers, preparing for the new family member in a matter of months, and making lifestyle modifications to promote the best possible pregnancy outcome. We will explore this more in Chapter 12.

KEY CONCEPTS

- Pregnancy is a normal life event that involves considerable physical, psychosocial, emotional, and relationship adjustments.
- The signs and symptoms of pregnancy have been grouped into those that are subjective (presumptive) and experienced by the woman herself; those that are objective (probable) and observed by the health care provider; and those that are the positive, diagnostic signs.
- Physiologically, almost every system of a woman's body changes during pregnancy with startling rapidity to accommodate the needs of the growing fetus. A majority of the changes are influenced by hormonal changes.
- The placenta is a unique kind of endocrine gland; it has a feature possessed by no other endocrine organ—the ability to form protein and steroid hormones.
- Occurring in conjunction with the physiologic changes in the woman's body systems are psychosocial changes occurring within the mother and family members as they face significant role and lifestyle changes.
- Commonly experienced emotional responses to pregnancy in the woman include ambivalence, introversion, acceptance, mood swings, and changes in body image.
- Reactions of expectant partners to pregnancy and to the physical and psychological changes in the woman vary greatly.
- A sibling's reaction to pregnancy is age dependent. The introduction of a new infant to the family may be the beginning of sibling rivalry, which results from the established child's fear of change in security of their relationships with their parents. Therefore, preparation of the siblings for the anticipated birth is imperative.

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. What factors would change during a pregnancy if the hormone progesterone were reduced or withdrawn?
   a. The woman's gums would become red and swollen and would bleed easily.
   b. The uterus would contract more, and peristalsis would increase.
   c. Morning sickness would increase and would be prolonged.
   d. The secretion of prolactin by the pituitary gland would be inhibited.

2. Which is a presumptive sign or symptom of pregnancy?
   a. Restlessness
   b. Elevated mood
   c. Urinary frequency
   d. Low backache

3. When obtaining a blood test for pregnancy, which hormone would the nurse expect the test to measure?
   a. Human chorionic gonadotropin (hCG)
   b. Human placental lactogen (hPL)
   c. Follicle-stimulating hormone (FSH)
   d. Luteinizing hormone (LH)

4. During pregnancy, which foods should the expectant mother reduce or avoid?
   a. Raw meat or uncooked shellfish
   b. Fresh, washed fruits and vegetables
   c. Whole grains and cereals

d. Protein and iron from meat sources

5. A feeling expressed by most women upon learning they are pregnant is

a. acceptance.
b. depression.
c. jealousy.
d. ambivalence.

6. Reva Rubin identified four major tasks that the pregnant woman undertakes to form a mutually gratifying relationship with her infant. What is “binding in?”

a. Ensuring safe passage through pregnancy, labor, and birth.
b. Seeking acceptance of this infant by others.
c. Seeking acceptance of self as mother to the infant.
d. Learning to give of oneself on behalf of the infant.

7. A pregnant client close to term comes in the clinic for an exam. The woman complains about experiencing shortness of breath. The nurse knows that this may be caused by the

a. fetus needing more oxygen due to larger size.
b. fundus of the uterus pushing the diaphragm upward.
c. woman experiencing an allergic reaction because of high histamine levels.
d. oxygen partial pressure concentration becoming lower during the third trimester.

8. Which fish should be limited in a pregnant woman’s diet because of its high mercury content?

a. Salmon
b. Cod
c. Shrimp
d. Swordfish

CRITICAL THINKING EXERCISES

1. When interviewing a woman at her first prenatal visit, the nurse asks about her feelings. The woman replies, “I’m frightened and confused. I don’t know whether I want to be pregnant or not. Being pregnant means changing our whole life, and now having somebody to care for all the time. I’m not sure I would be a good mother. Plus, I’m a bit afraid of all the changes that would happen to my body. Is this normal? Am I OK?”
   a. How should the nurse answer this question?
   b. What specific information is needed to support the client during this pregnancy?
2. Sally, age 23, is 9 weeks pregnant. At her clinic visit she says, “I’m so tired I can barely make it home from work. Then once I’m home, I don’t have the energy to make dinner.” She says she is so sick in the morning that she is frequently late to work and spends much of the day in the bathroom. Sally’s current lab work is within normal limits.
   a. What explanation can the nurse offer Sally about her discomforts?
   b. What interventions can the nurse offer to Sally?
3. Bringing a new infant into the family affects the siblings. What strategies can a nurse discuss when a mother asks how to deal with this?

STUDY ACTIVITIES

1. Go to your local health department’s maternity clinic and interview several women regarding their feelings and the bodily changes that have taken place since they became pregnant. Based on your findings, place them into appropriate trimesters of their pregnancy.
2. Search the internet for information about the psychological changes that occur during pregnancy.

Share information from the websites you found with your clinical group.

3. During pregnancy, the plasma volume increases by 50% but the RBC volume increases by only 25% to 33%. This disproportion manifests as _____.
4. When a pregnant woman in her third trimester lies on her back and experiences dizziness and light-headedness, the underlying cause of this is _____.

BRINGING IT ALL TOGETHER: A CASE STUDY

A 22-year-old pregnant client presents to the maternity clinic with a 4-day history of loss of appetite, constipation, and abdominal pain. She is in the first trimester of her first pregnancy and came to this country recently from India. Her mother accompanies her and answers most of the questions for her daughter. After much questioning, the mother reveals that her daughter frequently eats dirt, which is a common practice among people from their community.

ASSESSMENT

Examination reveals a tired-looking young woman, normal vital signs, moist pale mucous membranes, and a moderately distended abdomen. Bowel sounds are slow and faint. The fetal heart rate is within normal range.

Go to thePoint to find questions to consider about this case.

preconception care

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Relate the information typically collected at the initial prenatal visit.
2. Prepare an appropriate reproductive life plan based on a couple's risk profile.
3. Select the assessments completed at follow-up prenatal visits.
4. Evaluate the tests used to assess maternal and fetal well-being, including nursing management for each.
5. Outline appropriate nursing management to promote maternal self-care and to minimize the common discomforts of pregnancy.
6. Examine the key components of perinatal education.

Linda and her husband Rob are eager to start a family within the next year. They are stable in their careers and feel financially secure. They decide to investigate a new nurse–midwife practice associated with the local hospital, and they go for a preconception appointment. They leave their appointment overwhelmed with all the information they were given about having a healthy pregnancy.

INTRODUCTION

Pregnancy is a time of many physiologic and psychological changes that can positively or negatively affect the woman, her fetus, and her family. For the approximately 9 months during which the woman carries the fetus in her uterus, both the woman, and the developing fetus can face various health risks. Misconceptions, inadequate information, and unanswered questions about pregnancy, birth, and parenthood are common. The ultimate goal of any pregnancy is the birth of a healthy newborn while maintaining the health of the mother, and nurses play a major role in helping the pregnant woman and her partner achieve this goal. Ongoing assessment and education are essential.

This chapter describes the nursing management required during pregnancy. It begins with a brief discussion of preconception care and then describes the assessment of the woman at the first prenatal visit and on follow-up visits. The chapter discusses tests commonly used to assess maternal and fetal well-being, including specific nursing management related to each test. The chapter also identifies important strategies to minimize the common discomforts of pregnancy and promote self-care. Finally, the chapter discusses perinatal education, including childbirth education, birthing options, health care provider options, preparation for breastfeeding or bottle-feeding, and final preparation for labor and birth.

PRECONCEPTION AND INTERCONCEPTION CARE

Ideally, couples thinking about having children should schedule visits with the health care provider for preconception counseling to ensure that they are in the best possible state of health before pregnancy. **Preconception care** is the promotion of the health and well-being of a woman and her partner before pregnancy. The goal of preconception care is to identify and modify biomedical, behavioral, and social risks to a woman's health or pregnancy outcome through

prevention and management interventions. The interconception period is the time between pregnancies when a woman can improve her health status, especially if the prior pregnancy experience had a poor outcome or adverse events occurred. These interventions focus on risk factors that can be modified and/or eliminated prior to conception to optimize birth outcomes (Centers for Disease Control and Prevention [CDC], 2019a).

Preconception and interconception care are both advocated throughout the world as tools for improving perinatal outcomes. Preconception and interconception care should occur any time a health care provider sees a woman of reproductive age. Primary nursing care for all women of childbearing age should include a routine assessment of the woman's reproductive goals and planning. Women who could potentially become pregnant should be assessed for preconception or interconception risks and educated about the importance of maternal health in ensuring healthy pregnancies. Women may be motivated to address modified health risks by learning about the way their present health will affect a future pregnancy. For women not intending a pregnancy soon, preconception care should focus on contraception counseling and optimizing overall health that may be aggravated by pregnancy if it occurs (Kwansa & Stewart-Moore, 2019). Personal and family history, physical examination, laboratory screening, reproductive planning, nutrition, supplements, weight, exercise, vaccinations, and injury prevention should be reviewed in all women. Encourage folic acid 400 to 800 mcg per day depending on risk profile, as well as proper diet and exercise. Women should receive the influenza vaccine if planning pregnancy during flu season; the rubella and varicella vaccines if there is no evidence of immunity to these viruses; and tetanus/diphtheria/pertussis if lacking adult vaccination. Offer specific interventions to reduce morbidity and mortality for both the baby and the woman who has been identified with chronic diseases or exposed to teratogens or illicit substances. Several interventions have been proven to effectively improve pregnancy outcomes when provided as preconception care. Recent research suggests that events that occur in the uterine decidua even before a

woman knows she is pregnant may have a significant impact on fetal growth and the outcome of pregnancy. In addition, an intact immune system optimizes placental development and function and is essential for fetal survival (Buddolla, 2019). New insights reveal that the early embryo is extremely sensitive to signals from gametes, trophoblastic tissue, and periconception maternal lifestyles. Also, environmental factors prior to and after conception have an enormous impact on the developing embryo and cause long-term health problems. There is a growing body of evidence that environmental factors, such as exposure to heavy metals during embryonic development, can cause irreversible alteration in epigenetic markers and induce various adult diseases, such as cardiovascular, neurologic, and metabolic disorders later in life (Soomro et al., 2019). With this in mind, shifting the focus on the preconception and interconception periods and the early stages of pregnancy can have significant benefits to the health of both the mother and her infant. The overall aim should be to effectively use every pregnancy as the health care opportunity of two lifetimes (Wilczynska et al., 2019).

The CDC (2019i) offers 10 guidelines for preconception care (Box 12.1).

Risk Factors for Adverse Pregnancy Outcomes

Preconception and interconception care are just as important as prenatal care in reducing adverse pregnancy outcomes such as maternal and infant mortality, preterm births, and low–birth-weight infants. Adverse pregnancy outcomes constitute a major public health challenge: 10.2% of infants are born premature; 8.28% are born with low birth weight; 3% of live births have major birth defects; and 32% of women experience pregnancy complications (CDC, 2019b). Risk factors for these adverse pregnancy outcomes are prevalent among women of reproductive age as demonstrated by the following statistics:

BOX 12.1 Guidelines for Preconception/Interconception Care

- **Recommendation 1.** Individual responsibility across the lifespan: Each woman, man, and couple should be encouraged to have a reproductive life plan.
- **Recommendation 2.** Consumer awareness: Increase public awareness of the importance of preconception health behaviors and preconception care services by using information and tools appropriate across various ages; literacy, including health literacy; and cultural/linguistic contexts.
- **Recommendation 3.** Preventive visits: As a part of primary care visits, provide risk assessment and educational and health promotion counseling to all women of childbearing age to reduce reproductive risks and improve pregnancy outcomes.
- **Recommendation 4.** Interventions for identified risks: Increase the proportion of women who receive interventions as follow-up to preconception risk screening, focusing on high-priority interventions (i.e., those with evidence of effectiveness and greatest potential impact).
- **Recommendation 5.** Interconception care: Use the interconception period to provide additional intensive interventions to women who have had a previous pregnancy that ended in an adverse outcome (i.e., infant death, fetal loss, birth defects, low birth weight, or preterm birth).
- **Recommendation 6.** Prepregnancy check-up: Offer, as a component of maternity care, one prepregnancy visit for couples and persons planning pregnancy.
- **Recommendation 7.** Health insurance coverage for women with low incomes: Increase public and private health insurance coverage for women with low incomes to improve access to preventive women's health and preconception and interconception care.
- **Recommendation 8.** Public health programs and strategies: Integrate components of preconception health into existing local public health and related programs, including emphasis on interconception interventions for women with previous adverse outcomes.
- **Recommendation 9.** Research: Increase the evidence base and promote the use of the evidence to improve preconception health.
- **Recommendation 10.** Monitoring improvements: Maximize public health surveillance and related research mechanisms to monitor preconception health.

Adapted from Centers for Disease Control and Prevention (CDC). (2019i). *Before pregnancy*. Retrieved June 16, 2020, from https://www.cdc.gov/preconception/women.html.

- 10% of women smoke during pregnancy, contributing to fetal addiction to nicotine.
- 10% consume alcohol during pregnancy, leading to fetal alcohol spectrum disorder.
- 60% of women do not take folic acid supplements, increasing the risk of neural tube defects in the newborn. Taking folic acid reduces the incidence of neural tube defects by two thirds.
- 40% of women starting a pregnancy are obese, which may increase their risk of developing hypertension, diabetes, and thromboembolic disease and may increase the need for cesarean birth.
- 3% take prescription or over-the-counter (OTC) drugs that are known teratogens (substances harmful to the developing fetus).
- 7% of women have preexisting medical conditions that can negatively affect pregnancy if unmanaged (CDC, 2019c).

All these factors pose risks to pregnancy and could be addressed with early interventions if the woman seeks preconception health care. Specific recognized risk factors for adverse pregnancy outcomes that fall into one or more of these categories are listed in Box 12.2.

The period of greatest environmental sensitivity and consequent risk for the developing embryo is between days 17 and 56 after conception. The first prenatal visit, which is usually a month or later after a missed menstrual period, may occur too late to affect reproductive outcomes associated with abnormal organogenesis secondary to poor lifestyle choices. In some cases, such as with unplanned pregnancies, women may delay seeking health care because they deny that they are pregnant. Thus, commonly used prevention practices may begin too late to avert the morbidity and mortality associated with congenital anomalies and low birth weight. A more global preventative strategy is needed to reduce the high rates of pregnancy complications in all populations. Securing international-level political priority for maternal and newborn care remains critical to accomplishing the goal of better health for all families. All couples should take on the responsibility of developing their reproductive life plan and share it with their health care

providers at office visits. A reproductive life plan is an individualized plan of reproduction with goals based on personal beliefs and values. Its purpose is to reflect future intentions regarding pregnancy and take appropriate actions to optimize health status beforehand (Jordan et al., 2019).

What is the purpose of couples like Linda and Rob going for preconception counseling? What are the goals of preconception care for this couple? What psychological support can be offered by the nurse to this couple at this stage?

Nursing Management

In the United States, rates of maternal mortality, unintended pregnancies, low birth weight, and preterm infants continue to rise, making the need for preconception care a priority for all nurses. Traditionally, women have thought that preconception care is a single visit made before getting pregnant; however, the maximum benefits are obtained when the woman and her partner receive preconception and interconception care throughout her reproductive years. The nurse's role is vital in identifying risk factors and encouraging healthier behaviors that potentially improve maternal and perinatal outcomes. Preconception care involves obtaining a complete health history and physical examination of the woman and her partner. Key areas include:

BOX 12.2 Risk Factors for Adverse Pregnancy Outcomes

- **Isotretinoins:** Use of isotretinoins (e.g., Accutane) in pregnancy to treat acne can result in serious birth defects such as cleft palate, congenital heart defects, hearing loss, and microcephaly.
- **Alcohol misuse:** No time during pregnancy is safe to drink alcohol, and harm can occur early, before a woman has realized that she is or might be pregnant. Fetal alcohol syndrome and other alcohol-related birth defects can be prevented if women cease intake of alcohol before conception.
- **Antiepileptic drugs:** Certain antiepileptic drugs are known teratogens (e.g., valproic acid). Recommendations suggest that before conception, women who are on a regimen of these drugs and who are contemplating pregnancy should be prescribed lower dosages of these drugs.
- **Diabetes (preconception):** The threefold increase in the prevalence of birth defects among infants of women with type 1 and type 2 diabetes is substantially reduced through proper management of diabetes.
- **Folic acid deficiency:** Daily use of vitamin supplements containing folic acid (400 mcg) has been demonstrated to reduce the occurrence of neural tube defects by two thirds.
- **Hepatitis B:** Vaccination is recommended for men and women who are at risk for acquiring hepatitis B virus (HBV) infection. Preventing HBV infection in women of childbearing age prevents transmission of infection to infants and eliminates risk to the woman of HBV infection and sequelae, including hepatic failure, liver carcinoma, cirrhosis, and death.
- **HIV/AIDS:** If HIV infection is identified before conception, timely antiretroviral treatment can be administered, and women (or couples) can be given additional information that can help prevent mother-to-child transmission.
- **Rubella seronegativity:** Rubella vaccination provides protective seropositivity and prevents congenital rubella syndrome.
- **Obesity:** Adverse perinatal outcomes associated with maternal obesity include neural tube defects, preterm delivery, diabetes, cesarean section, and hypertensive and thromboembolic disease. Appropriate weight loss and nutritional intake before pregnancy reduce these risks.
- **Sexually transmitted infections (STIs):** *Chlamydia trachomatis* and *Neisseria gonorrhoeae* have been strongly associated with ectopic pregnancy, infertility, and chronic pelvic pain. STIs during pregnancy might result in fetal death or substantial physical and developmental disabilities, including intellectual disability and blindness. Early screening and treatment prevent these adverse outcomes.
- **Smoking:** Preterm birth, low birth weight, and other adverse perinatal outcomes associated with maternal smoking in pregnancy can be prevented if women stop smoking before or during early pregnancy. Because only 20% of women successfully control tobacco dependency during pregnancy, cessation of smoking is recommended before pregnancy.

(2020a). *Pregnancy complications*. Retrieved June 16, 2020, from https://www.marchofdimes.org/complications/pregnancy-complications.aspx; and Jordan, R. G., Farley, C. L., & Grace, K. T. (2019). *Prenatal and postnatal care: A woman-centered approach*. (2nd ed.). Wiley Blackwell.

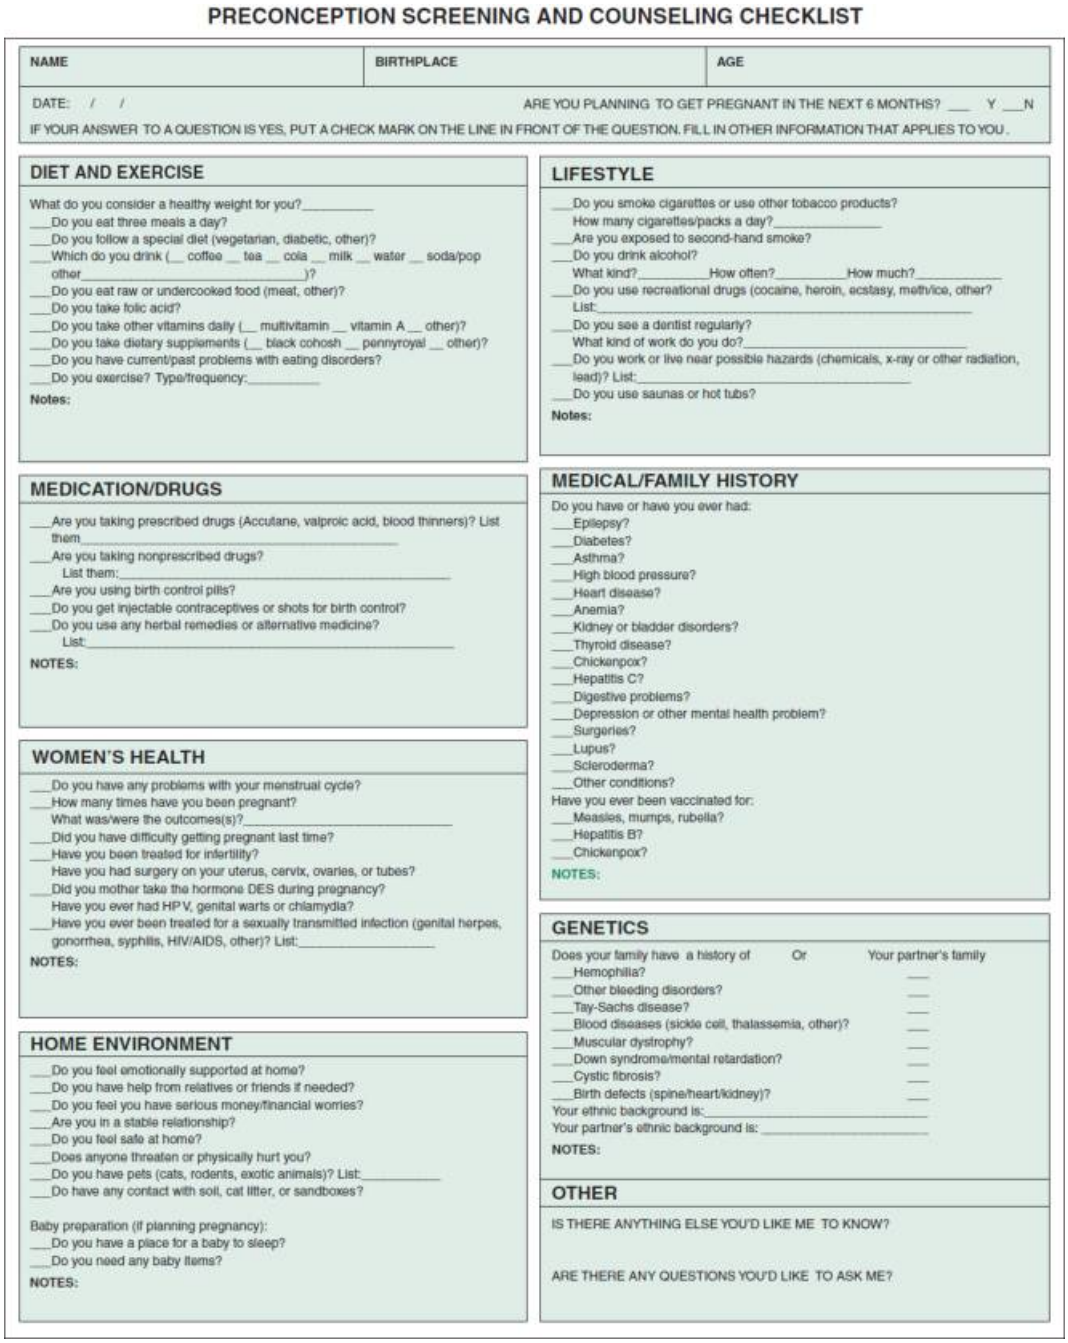
- Immunization status of the woman
- Underlying medical conditions, such as cardiovascular, metabolic conditions, and respiratory problems or genetic disorders
- Reproductive health data, such as pelvic examinations, use of contraceptives, and sexually transmitted infections (STIs)
- Sexuality and sexual practices, such as safer-sex practices and body image issues
- Nutrition history and present status
- lifestyle practices, including occupation and recreational activities
- Psychosocial issues such as levels of stress and exposure to abuse and violence
- Medication and drug use, including use of tobacco, alcohol, OTC and prescription medications, and illicit drugs
- Support system, including family, friends, and community

Figure 12.1 gives a sample preconception screening tool.

This information provides a foundation for planning health promotion activities and education. For example, to have a positive impact on the pregnancy:

- Ensure that the woman's immunizations are up to date.
- Create a reproductive life plan to address and outline reproductive needs.
- Take a thorough history of both partners to identify any medical or genetic conditions that need treatment or a referral to specialists.
- Identify history of STIs and high-risk sexual practices so they can be modified.
- Complete a dietary history combined with nutritional counseling.
- Gather information regarding exercise and lifestyle practices to encourage daily exercise for well-being and weight maintenance.
- Stress the importance of taking folic acid to prevent neural tube defects.

- Urge the woman to achieve optimal weight before a pregnancy.
- Identify work environment and any needed changes to promote health.



PRECONCEPTION SCREENING AND COUNSELING CHECKLIST

NAME | BIRTHPLACE | AGE

DATE: / /

ARE YOU PLANNING TO GET PREGNANT IN THE NEXT 6 MONTHS? ___ Y ___N

IF YOUR ANSWER TO A QUESTION IS YES, PUT A CHECK MARK ON THE LINE IN FRONT OF THE QUESTION. FILL IN OTHER INFORMATION THAT APPLIES TO YOU.

DIET AND EXERCISE

What do you consider a healthy weight for you?_____
___Do you eat three meals a day?
___Do you follow a special diet (vegetarian, diabetic, other)?
___Which do you drink (__ coffee __ tea __ cola __ milk __ water __ soda/pop other_____)?
___Do you eat raw or undercooked food (meat, other)?
___Do you take folic acid?
___Do you take other vitamins daily (__ multivitamin __ vitamin A __ other)?
___Do you take dietary supplements (__ black cohosh __ pennyroyal __ other)?
___Do you have current/past problems with eating disorders?
___Do you exercise? Type/frequency:_____
Notes:

LIFESTYLE

___Do you smoke cigarettes or use other tobacco products?
How many cigarettes/packs a day?_____
___Are you exposed to second-hand smoke?
___Do you drink alcohol?
What kind?_____How often?_____How much?_____
___Do you use recreational drugs (cocaine, heroin, ecstasy, meth/ice, other?
List:_____
___Do you see a dentist regularly?
What kind of work do you do?_____
___Do you work or live near possible hazards (chemicals, x-ray or other radiation, lead)? List:_____
___Do you use saunas or hot tubs?
Notes:

MEDICATION/DRUGS

___Are you taking prescribed drugs (Accutane, valproic acid, blood thinners)? List them_____
___Are you taking nonprescribed drugs?
List them:_____
___Are you using birth control pills?
___Do you get injectable contraceptives or shots for birth control?
___Do you use any herbal remedies or alternative medicine?
List:_____
NOTES:

MEDICAL/FAMILY HISTORY

Do you have or have you ever had:
___Epilepsy?
___Diabetes?
___Asthma?
___High blood pressure?
___Heart disease?
___Anemia?
___Kidney or bladder disorders?
___Thyroid disease?
___Chickenpox?
___Hepatitis C?
___Digestive problems?
___Depression or other mental health problem?
___Surgeries?
___Lupus?
___Scleroderma?
___Other conditions?
Have you ever been vaccinated for:
___Measles, mumps, rubella?
___Hepatitis B?
___Chickenpox?
NOTES:

WOMEN'S HEALTH

___Do you have any problems with your menstrual cycle?
___How many times have you been pregnant?
What was/were the outcomes(s)?_____
___Did you have difficulty getting pregnant last time?
___Have you been treated for infertility?
Have you had surgery on your uterus, cervix, ovaries, or tubes?
___Did you mother take the hormone DES during pregnancy?
Have you ever had HPV, genital warts or chlamydia?
___Have you ever been treated for a sexually transmitted infection (genital herpes, gonorrhea, syphilis, HIV/AIDS, other)? List:_____
NOTES:

GENETICS

Does your family have a history of	Or	Your partner's family
___Hemophilia?		___
___Other bleeding disorders?		___
___Tay-Sachs disease?		___
___Blood diseases (sickle cell, thalassemia, other)?		___
___Muscular dystrophy?		___
___Down syndrome/mental retardation?		___
___Cystic fibrosis?		___
___Birth defects (spine/heart/kidney)?		___

Your ethnic background is:_____
Your partner's ethnic background is: _____
NOTES:

HOME ENVIRONMENT

___Do you feel emotionally supported at home?
___Do you have help from relatives or friends if needed?
___Do you feel you have serious money/financial worries?
___Are you in a stable relationship?
___Do you feel safe at home?
___Does anyone threaten or physically hurt you?
___Do you have pets (cats, rodents, exotic animals)? List:_____
___Do have any contact with soil, cat litter, or sandboxes?

Baby preparation (if planning pregnancy):
___Do you have a place for a baby to sleep?
___Do you need any baby items?

ARE THERE ANY QUESTIONS YOU'D LIKE TO ASK ME?

FIGURE 12.1. Sample preconception screening tool. (Used with permission. Copyright March of Dimes.)

- Address substance use issues, including smoking and drugs.

- Identify victims of violence and assist them to get help.
- Manage chronic conditions such as diabetes and asthma.
- Educate the couple about environmental hazards, including metals and herbs.
- Offer genetic counseling to identify carriers.
- Suggest the availability of support systems, if needed (King et al., 2019; Norwitz et al., 2019).

Nurses can act as advocates and educators, creating healthy, supportive communities for women and their partners in the childbearing phases of their lives. It is important to enter into a collaborative partnership with the woman and her partner, enabling them to examine their own health and its influence on the health of their future baby. Provide information to allow the woman and her partner to make an informed decision about having a baby, but keep in mind that this decision rests solely with the couple.

TAKE NOTE!

Because all women of reproductive age, from menarche to menopause, benefit from preventive care, preconception and interconception care should be an integral part of that continuum (American College of Obstetricians and Gynecologists [ACOG], 2019a; Society for Maternal-Fetal Medicine, 2019).

Linda and Rob decide to change several aspects of their lifestyle and nutritional habits before conceiving a baby based on advice from the nurse midwife. They both want to lose weight, stop smoking, and increase their intake of fruits and vegetables. How will these lifestyle and dietary changes benefit Linda's future pregnancy? What other areas might need to be brought up to date to prepare for a future pregnancy?

THE FIRST PRENATAL VISIT

The focus of prenatal care is to reduce the risk of adverse health effects for the woman, fetus, and newborn by addressing modifiable risk factors and providing education about having a healthy pregnancy. Once a pregnancy is suspected and in some cases,

tentatively confirmed by a home pregnancy test, the woman should seek prenatal care to promote a healthy outcome. Although the most opportune window (preconception) for improving pregnancy outcomes may be missed, appropriate nursing management starting at conception and continuing throughout the pregnancy can have a positive impact on the health of pregnant women and their unborn children.

The assessment process begins at this initial prenatal visit and continues throughout the pregnancy. The initial visit is an ideal time to screen for factors that might place the woman and her fetus at risk for problems such as preterm delivery. The initial visit is also an optimal time to begin educating the client about changes that will affect her life. Recent research found that a delayed initiation of prenatal care was associated with increased rates of neonatal intensive care unit (NICU) admissions. The opportunity to improve maternal health and reduce adverse newborn outcomes was lost when prenatal care wasn't sought (Sarker et al., 2019).

Prenatal care can be delivered in one of the two methods: individually or in a group format termed *centering*. The first method is the traditional model whereby a pregnant woman sees her health care provider at specified interims throughout her pregnancy and all visits occur on a one-to-one basis. The centering pregnancy model of group prenatal care involves groups of up to a dozen women in similar gestational ages meeting with their health care provider for 10 sessions of approximately 1.5 to 2 hours each. Researchers are exploring if the centering group method produces better perinatal outcomes than traditional individually delivered prenatal care due to increased client–provider interaction, increased social support, and greater perceived empowerment (Cunningham et al., 2019). See Evidence-Based Practice 12.1.

The incidence of diabetes in pregnancy has been increasing in conjunction with high rates of obesity both in the United States and worldwide. There are 425 million people with diabetes in the world, and this figure is on track to reach more than 600 million by 2045 (Toniolo et al., 2019). Uncontrolled diabetes in pregnancy raises the risks for spontaneous abortion, fetal anomalies, preeclampsia, fetal

demise, macrosomia, neonatal hypoglycemia, and hyperbilirubinemia. The American Diabetes Association (ADA, 2020) has released the following recommendations for the management of diabetes before and in pregnancy:

- Preconception and interconception counseling should address the importance of glycemic control, ideally an A1c level lower than 6.5% to reduce the risk of congenital anomalies, preeclampsia, macrosomia, and other complications. A1c is a blood test that measures the average blood glucose level over the previous 3 months to determine glucose control and management.
- Fasting and postprandial self-monitoring of blood glucose are recommended to achieve glycemic control. Due to increased red blood cell turnover, A1c is slightly lower during pregnancy. The target A1c should be lower than 6% to 7% to prevent hypoglycemia.
- The ADA recommends targets for women with type 1 or type 2 diabetes as follows:
  - Fasting: lower than 95 mg/dL
  - 1-hour postprandial: lower than 140 mg/dL
  - 2-hour postprandial: lower than 120 mg/dL
  - Insulin is the preferred medication for treating hyperglycemia in gestational diabetes as it doesn’t cross the placenta to a measurable extent. If oral hypoglycemic agents are used, they shouldn’t be the first-line therapy since there are no safety data from long-term studies yet.

EVIDENCE-BASED PRACTICE 12.1 Using an Interprofessional Prenatal Group Care Model to Address Disparities in Pregnancy-Related Outcomes in a High-Risk Population in a Family Medicine Residency Clinic

STUDY

Maternal mortality and morbidity rates have been steadily rising in the United States. In addition, preterm birth rates remain pronounced and costly over the lifetime of the child, especially for African American women. Prior research on high-risk mothers using prenatal group care models has shown success by improving health care outcomes including reducing the risk of preterm and low birth weights; decreasing neonatal intensive care unit admissions; reducing the rates of fetal demise; increasing breastfeeding rates; increasing the likelihood of vaginal versus surgical birth; and increasing the use of postpartum family planning when compared to individual prenatal care. The purpose of this study was to determine if an interprofessional prenatal group prenatal model is better than a traditional individual pregnancy care in minimizing pregnancy-related disparities. A quasi-experimental group of 64 women between the ages of 18 and 30 from low-income households were studied.

Findings

The study found significant relationships between attending interprofessional prenatal group visits and beneficial pregnancy-related outcomes (e.g., higher attendance at prenatal and postpartum visits; higher pregnancy knowledge/confidence, lower depressive and anxiety symptoms, higher satisfaction with providers, and lower prevalence of smoking). In addition, women

reported that the prenatal group made them feel supported, understood, listened to, and helped them try new health behaviors (e.g., breastfeeding, stress reduction techniques).

Nursing Implications

This study supports the group prenatal model to change health behaviors and become more confident in their pregnancy and postpartum decisions. The additional education exposure taught by two nurses and two residents within a group produced positive pregnancy and postpartum outcomes. Nurses can encourage participation in group prenatal care, if offered, by reporting the positive aspects related to it.

Using an interprofessional prenatal group care model to address disparities in pregnancy-related outcomes in a high-risk population in a family medicine residency clinic. Journal of Interprofessional Education and Practice. https://doi.org/10.1016/j.xjep.2019.100300

Given our society's poor food choices, sedentary tendencies, obesity, increasing life stresses, and the increasing immigration of high-risk populations, the incidence of gestational diabetes is growing. ACOG, the ADA, and the World Health Organization (WHO) have all recommended screening at the first prenatal visit for women who are over 25 years old, overweight, have polycystic ovary syndrome, history of gestational diabetes, and a positive family history of diabetes (Kwansa et al., 2019). Global guidelines for screening, diagnosis, and classification have been established and offer the potential to stop the cycle of diabetes and obesity caused by hyperglycemia in pregnancy. Normoglycemia is the goal in all aspects of pregnancy and offers the benefits of decreased short- and long-term complications of diabetes. See Evidence-Based Practice 12.2.

EVIDENCE-BASED PRACTICE 12.2 Neonatal Outcomes in Gestational Diabetes Managed with Insulin Versus Glyburide Therapy: A Cost-Effective Analysis

STUDY

The purpose of this study was to compare neonatal outcomes and assess the cost-effectiveness of insulin therapy versus glyburide therapy in women with gestational diabetes in the context of most recent randomized controlled studies. A cost-effectiveness model using TreeAge software was designed to compare neonatal outcomes following insulin and glyburide management of gestational diabetes. A cohort of 195,000 women were studied. Outcomes included treatment method, mode of childbirth, shoulder dystocia, permanent brachial plexus, respiratory distress syndrome, neonatal hypoglycemia, macrosomia (larger than 4,000 g), and neonatal hyperbilirubinemia. Cost-effectiveness was assessed by comparing cost of assessed outcomes to maternal and neonatal quality of life.

Findings

Insulin was cost-effective in the management of women with gestational diabetes compared to glyburide. Insulin therapy resulted in 2,295 fewer cases of macrosomia, 386 fewer cases of surgical births, 12 fewer cases of shoulder dystocia, and 7,235 fewer cases of neonatal hypoglycemia.

Nursing Implications

Nurses can utilize the study results to educate their pregnant clients about using insulin versus oral hypoglycemic medications

for better glucose control, which equates into fewer neonatal complications. Providing instruction on how to inject insulin is essential to increase acceptance of injections versus oral taking oral medications. Stressing the better neonatal outcomes with the insulin injections will be the nurse's role to provide better overall outcomes for this dyad.

Neonatal outcomes in gestational diabetes managed with insulin vs. glyburide therapy: A cost- effectiveness analysis. American Journal of Obstetrics & Gynecology, 220(1), S330. https://doi.org/10.1016/j.ajog.2018.11.514.

Counseling and education of the pregnant woman and her partner are critical to ensure healthy outcomes for mother and her infant. Pregnant women and their partners frequently have questions, misinformation, or misconceptions about what to eat, weight gain, physical discomforts, drug and alcohol use, sexuality, and the birthing process. The nurse needs to allow time to answer questions and provide anticipatory guidance during the pregnancy and to make appropriate community referrals to meet the needs of these clients. To address these issues and foster the overall well-being of pregnant women and their fetuses, specific national health goals have been established (*Healthy People 2030* 12.1).

HEALTHY PEOPLE 2030 • 12.1

Objective	Nursing Significance
MICH-2030-08 10 Increase the proportion of pregnant women who receive early and adequate prenatal.	Will contribute to reduced rates of perinatal illness, disability, and death by helping identify possible risk factors and implementing measures to lessen these factors that contribute to poor outcomes
MICH-2030-12 Increase the proportion of women of childbearing age who have optimal red blood cell folate concentrations.	Risk of maternal and infant mortality and pregnancy-related complications can be reduced by educating women to take folic acid prenatally and throughout pregnancy to reduce the risk of neural tube birth defects; will enhance healthy birth outcomes and early identification and treatment of health
MICH-2030-13 Increase the proportion of women delivering a live birth who had a healthy weight prior to pregnancy.	Will reduce the risks associated with overweight and/or obesity for better perinatal outcomes for mother and infant

Comprehensive Health History

During the initial visit, the woman should feel supported by a skilled, knowledgeable, and well-prepared nurse. A comprehensive health history is obtained, including age, menstrual history, prior obstetric history, past medical and surgical history, psychological screening, family history, genetic screening, dietary habits, lifestyle and health practices, medication or drug use, and history of exposure to STIs (Lindsay et al., 2018). Often, use of a prenatal history form (Fig. 12.2) is the best way to document the data collected.

The initial health history typically includes questions about three major areas: the reason for seeking care; the client's past medical, surgical, and personal history, including that of the family and her partner; and the client's reproductive history. During the history-

taking process, the nurse and client establish the foundation of a trusting relationship and jointly develop a plan of care for the pregnancy. They tailor this plan to the client's lifestyle as much as possible and focus primarily on education for overall wellness during the pregnancy. The ultimate goal for the first prenatal visit is to collect baseline data about the woman and her partner and to detect any risk factors that need to be addressed to facilitate a healthy pregnancy (King et al., 2019).

Reason for Seeking Care

The woman commonly comes for prenatal care based on the suspicion that she is pregnant. She may report that she has missed her menstrual period or has had a positive result on a home pregnancy test. Ask the woman for the date of her last normal menstrual period (LMP). Also ask about any presumptive or probable signs of pregnancy that she might be experiencing. Typically, a urine or blood test to check for evidence of human chorionic gonadotropin (hCG) is done to confirm the pregnancy.

Past History

Ask about the woman's past medical and surgical history. This information is important because conditions that the woman experienced in the past (e.g., urinary tract infections) may recur or be exacerbated during pregnancy. Also, chronic illnesses, such as diabetes or heart disease, can increase the risk for complications during pregnancy for the woman and her fetus. Ask about any history of allergies to medications, foods, or environmental substances. Ask about any mental health problems, such as depression or anxiety. Gather similar information about the woman's family and her partner.

The woman's personal history is also important. Ask about her occupation, possible exposure to teratogens, exercise and activity level, recreational patterns (including the use of substances such as alcohol, tobacco, and drugs), use of alternative and complementary therapies, sleep patterns, nutritional habits, and general lifestyle.

Each of these may have an impact on the outcome of the pregnancy. For example, if the woman smokes during pregnancy, nicotine in the cigarettes causes vasoconstriction in the mother, leading to reduced placental perfusion. As a result, the newborn may be small for gestational age. The newborn will also go through nicotine withdrawal soon after birth. In addition, no safe level of alcohol ingestion in pregnancy has been determined. Many fetuses exposed to heavy alcohol levels during pregnancy develop fetal alcohol spectrum disorder, a collection of deformities and disabilities.

Reproductive History

The woman's reproductive history includes a menstrual, obstetric, and gynecologic history. Typically, this history begins with a description of the woman's menstrual cycle, including her age at

menarche, number of days in her cycle, typical flow characteristics, and any discomfort experienced. The use of contraception is also important, including when the woman last used it.

Establishing an accurate due date is one of the most important assessments for a pregnant woman, one that has both social and medical significance. For women and their families, this estimated due date (EDD) represents the long-awaited birthday of their child and is a time frame around which many economic and social activities are planned. This end point date provides guidance for the timing of specific maternal and fetal testing throughout pregnancy, gauges fetal growth parameters, and provides well-established timelines for specific interventions in the management of prenatal complications. In fact, critical decisions, such as preterm labor management, timing of postdate induction of labor, and identification of fetal growth restriction (FGR), are all based on the presumed gestational age of the fetus, which is calculated backward from the EDD (Jordan et al., 2019).

Ask the woman the date of her LMP to determine the estimated or EDD. Several methods may be used to estimate the date of birth. Nagele's rule can be used to establish the EDD (Box 12.3). Using this rule, subtract 3 months from the month of her LMP and then add 7 days to the first day of the LMP. Then correct the year by adding 1 to it where necessary. An alternative way is to add 7 days and then add 9 months = year where needed. This date has a margin of error of plus or minus 2 weeks. For instance, if a woman reports that her LMP was October 14, 2020, you would subtract 3 months (July) and add 7 days (21), then add 1 year (2021). The woman's EDD is July 21, 2021.

BOX 12.3 Nagele's Rule for Calculating the Estimated Due Date (EDD)

1. Use the first day of the last normal menstrual period.	10/14/20
2. Subtract 3 from the number of months.	7/14/20
3. Add 7 to the number of days.	7/21/20
4. Adjust the year by adding 1 year.	7/21/21
5. Estimated due date (+ or − 2 weeks) = July 21, 2020.	

Because of the normal variations in women's menstrual cycles, differences in the normal length of gestation among ethnic groups, and errors in dating methods, there is no such thing as an exact due date. In general, a birth 2 weeks before or 2 weeks after the EDD is considered normal. Nagele's rule is less accurate if the woman's menstrual cycles are irregular; and if the woman conceives while breastfeeding or before her regular menstrual cycle is established after childbirth; if she is ovulating though she experiences amenorrhea. A second trimester fetal head circumference measurement via ultrasound can also be used to predict EDD (Kessler et al., 2019).

A gestational or birth calculator or wheel can also be used to calculate the due date (Fig. 12.3). Some practitioners use ultrasound to more accurately determine the gestational age and date the pregnancy. Ultrasound is typically the most accurate method of dating a pregnancy.

Typically, an obstetric history provides information about the woman's past pregnancies, including any problems encountered during the pregnancy, labor, birth, and postpartum. Such information can provide clues to problems that might develop in the current pregnancy. Some common terms used to describe and document an obstetric history include **gravid**, gravida, gravida I (primigravida), gravida II (secundigravida), multigravida, and **para** (Table 12.1).

Other systems may be used to document a woman's obstetric history. These systems often break down the category of para more specifically (Box 12.4).

Information about the woman's gynecologic history is important. Ask about any reproductive tract surgeries the woman has undergone. For example, surgery on the uterus may affect its ability to contract effectively during labor. A history of tubal pregnancy increases the woman's risk for another tubal pregnancy. Also ask about safe-sex practices and any history of STIs.

Physical Examination

The next step in the assessment process is the physical examination, which detects any physical problems that may affect the pregnancy outcome. The initial physical examination provides the baseline for evaluating changes during future visits.

Preparation

Instruct the client to undress and put on a gown. Also ask her to empty her bladder, and when doing so, to collect a urine specimen. Typically, this specimen is a clean-catch urine specimen that is sent to the laboratory for a urinalysis to detect possible urinary tract infections.

Begin the physical examination by obtaining vital signs, including blood pressure, respiratory rate, temperature, and pulse. Also measure the client's height and weight. Abnormalities such as an elevated blood pressure may suggest pregestational hypertension, requiring further evaluation. Abnormalities in pulse rate and respiration require further investigation for possible cardiac or respiratory disease. If the woman weighs less than 100 lb or more than 200 lb or there has been a sudden weight gain, report these findings to the primary care provider; medical treatment or nutritional counseling may be necessary.

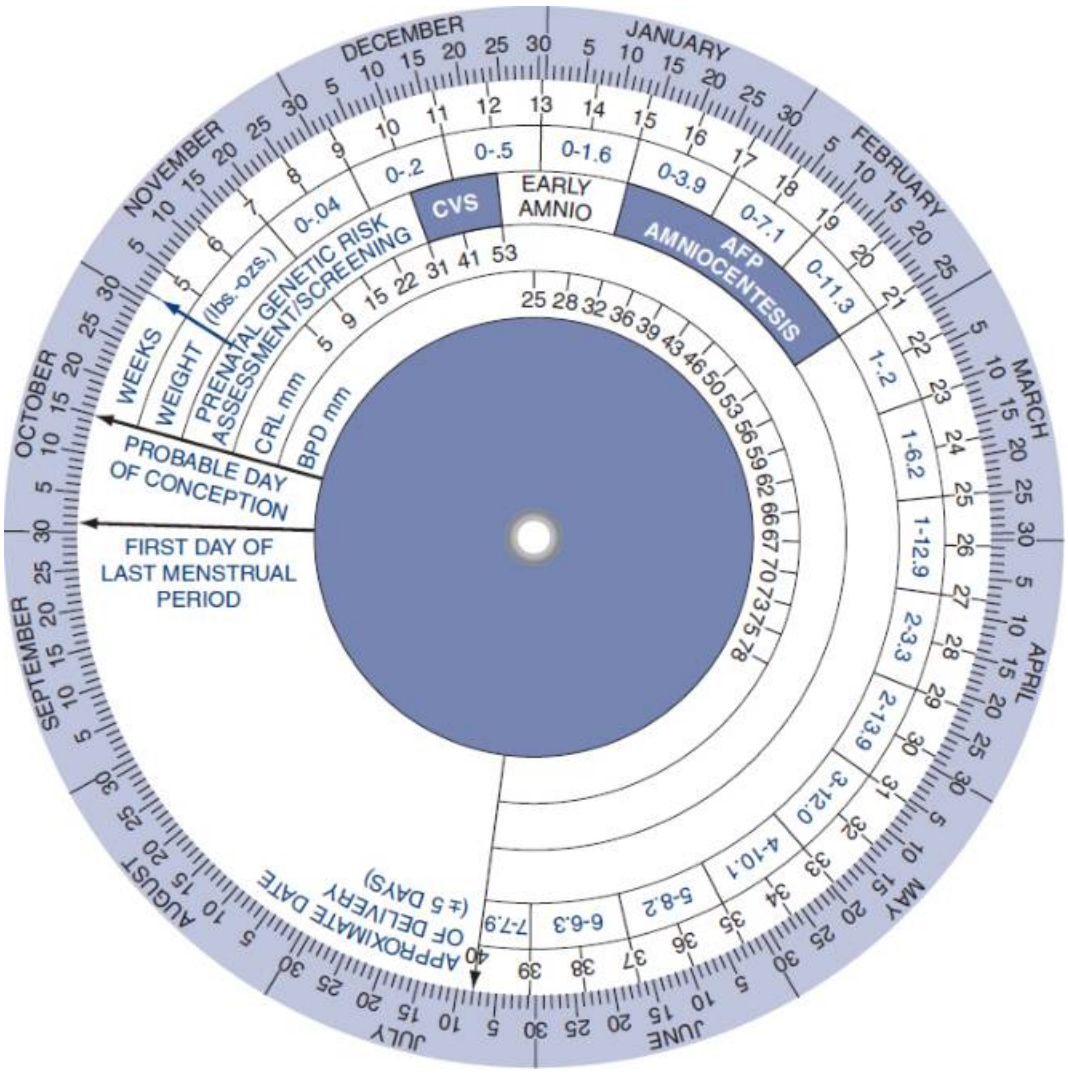

FIGURE 12.3. EDD using a birth wheel. The first day of the woman's last normal menstrual period was October 1. Using the birth wheel, her EDD would be approximately July 8 of the following year. (Used with permission. Copyright March of Dimes, 2015.)

TABLE 12.1 Pregnancy Terms

Term	Definition
Gravid	The state of being pregnant
Gravida/Gravidity	The total number of times a woman has been pregnant, regardless of whether the pregnancy resulted in a termination or if multiple infants were born from a pregnancy
Nulligravida	A woman who has never experienced pregnancy
Primigravida	A woman pregnant for the first time
Secundigravida	A woman pregnant for the second time
Multigravida	A woman pregnant for at least the third time
Para	The number of times a woman has given birth to a fetus of at least 20 gestational weeks (viable or not), counting multiple births as one birth event
Parity	Refers to the number of pregnancies, not the number of fetuses, carried to the point of viability, regardless of the outcome
Nullipara (para 0)	A woman who has not produced a viable offspring
Primipara	A woman who has given birth once after a pregnancy of at least 20 weeks, commonly referred to as a “primip” in clinical practice
Multipara	A woman who has had two or more pregnancies of at least 20 weeks’ gestation resulting in viable offspring, commonly referred to as a “multip”

BOX 12.4 Obstetric History Terms: GTPAL or TPAL

G, gravida; T, term births; P, preterm births; A, abortions; L, living children

- G—the current pregnancy to be included in count
- T—the number of term gestations delivering between 38 and 42 weeks
- P—the number of preterm pregnancies ending >20 weeks or viability but before completion of 37 weeks
- A—the number of pregnancies ending before 20 weeks or viability
- L—the number of children currently living

Consider this example:

Mary Johnson is pregnant for the fourth time. She had one abortion at 8 weeks' gestation. She has a daughter who was born at 40 weeks' gestation and a son born at 34 weeks. Mary's obstetric history would be documented as follows:

- Using the gravida/para method: gravida 4, para 2
- Using the TPAL method: 1112 (T = 1 [daughter born at 40 weeks]; P = 1 [son born at 34 weeks]; A = 1 [abortion at 8 weeks]; L = 2 [two living children])

Head-to-Toe Assessment

A complete head-to-toe assessment is usually performed by the health care provider. Every body system is assessed. Some of the major areas are discussed here. Throughout the assessment, be sure to drape the client appropriately to ensure privacy and prevent chilling.

HEAD AND NECK

Assess the head and neck area for any previous injuries and sequelae. Evaluate for any limitations in range of motion. Palpate for any enlarged lymph nodes or swelling. Note any edema of the nasal mucosa or hypertrophy of gingival tissue in the mouth; these are typical responses to increased estrogen levels in pregnancy. Palpate the thyroid gland for enlargement. Slight enlargement is normal, but marked enlargement may indicate hyperthyroidism, requiring further investigation.

CHEST

Auscultate heart sounds, noting any abnormalities. A soft systolic murmur caused by the increase in blood volume may be noted. Anticipate an increase in heart rate by 10 to 15 beats per minute (bpm) (starting between 14 and 20 weeks of pregnancy) secondary to increases in cardiac output and blood volume. The body adapts to the increase in blood volume with peripheral dilation to maintain blood pressure. Progesterone causes peripheral dilation.

Auscultate the chest for breath sounds, which should be clear. Also note symmetry of chest movement and thoracic breathing patterns. Estrogen promotes relaxation of the ligaments and joints of the ribs with a resulting increase in the anteroposterior chest diameter. Expect a slight increase in respiratory rate to accommodate the increase in tidal volume and oxygen consumption.

Inspect and palpate the breasts and nipples for symmetry and color. Increases in estrogen and progesterone and blood supply make the breasts feel full and more nodular with increased sensitivity to touch. Blood vessels become more visible and there is an increase in breast size. Striae gravidarum (stretch marks) may be visible in women with large breasts. Darker pigmentation of the nipple and areola is present, along with enlargement of Montgomery glands. Colostrum (yellowish secretion that precedes mature breast milk) is excreted typically in the third trimester.

TAKE NOTE!

Use this opportunity to reinforce and teach breast self-examination if the woman has a high-risk history.

ABDOMEN

The appearance of the abdomen depends on the number of weeks of gestation. The abdomen enlarges progressively as the fetus grows. Inspect the abdomen for striae, scars, shape, and size. Inspection may reveal striae gravidarum and the **linea nigra**, a thin brownish black pigmented line running from the umbilicus to the symphysis pubis, depending on the duration of the pregnancy.

Palpate the abdomen, which should be rounded and nontender. A decrease in muscle tone may be noted due to the influence of progesterone.

Typically, the height of the fundus is measured when the uterus arises out of the pelvis to evaluate fetal growth. At 12 weeks' gestation, the fundus can be palpated at the symphysis pubis. At 16 weeks' gestation, the fundus is midway between the symphysis and the umbilicus. At 20 weeks, the fundus can be palpated at the umbilicus and measures approximately 20 cm from the symphysis pubis. By 36 weeks, the fundus is just below the xiphoid process and measures approximately 36 cm. The uterus maintains a globular/ovoid shape throughout pregnancy (Jarvis, 2020).

EXTREMITIES

Inspect and palpate both legs for dependent edema, pulses, and varicose veins. If edema is present in early pregnancy, further evaluation may be needed to rule out gestational hypertension. During the third trimester, dependent edema is a normal finding. Ask the woman if she has any pain in her calf that increases when she ambulates. This might indicate a deep vein thrombosis (DVT). High levels of estrogen during pregnancy place women at higher risk for DVT.

Pelvic Examination

The pelvic examination provides information about the internal and external reproductive organs. In addition, it aids in assessing some of the presumptive and probable signs of pregnancy and allows for determination of pelvic adequacy. During the pelvic examination, remain in the examining room to assist the health care provider with any specimen collection, fixation, and labeling. Also provide comfort and emotional support for the woman, who might be anxious. Throughout the examination, explain what is happening and why, and answer any questions as necessary.

EXTERNAL GENITALIA

After the client is placed in the lithotomy position and draped appropriately, the external genitalia are inspected visually. They should be free from lesions, discharge, hematomas, varicosities, and inflammation upon inspection. A culture for STIs may be collected at this time.

INTERNAL GENITALIA

Next, the internal genitalia are examined via a speculum. The cervix should be smooth, long, thick, and closed. Because of increased pelvic congestion, the cervix will be softened (Goodell sign), the uterine isthmus will be softened (Hegar sign), and there will be a bluish coloration of the cervix and vaginal mucosa (Chadwick sign).

The uterus is typically pear shaped and mobile with a smooth surface. It will undergo cell hypertrophy and hyperplasia so that it enlarges throughout the pregnancy to accommodate the growing fetus.

During the pelvic examination, a Papanicolaou (Pap) smear may be obtained. Additional cultures, such as for gonorrhea and chlamydia screening, may also be obtained. Ensure that all specimens obtained are labeled correctly and sent to the laboratory for evaluation. A rectal examination is done last to assess for lesions, masses, prolapse, or hemorrhoids.

Once the examination of the internal genitalia is completed and the speculum is removed, a bimanual examination is performed to estimate the size of the uterus to confirm dates and to palpate the ovaries. The ovaries should be small and nontender without masses. At the conclusion of the bimanual examination, the health care provider reinserts the index finger into the vagina and the middle finger into the rectum to assess the strength and regularity of the posterior vaginal wall.

PELVIC SIZE, SHAPE, AND MEASUREMENTS

The size and shape of the women's pelvis can affect her ability to deliver vaginally. Pelvic shape is typically classified as one of the four types: gynecoid, android, anthropoid, and platypelloid. Refer to Chapter 13 for an in-depth discussion of pelvic size and shape.

Taking internal pelvic measurements determines the actual diameters of the inlet and outlet through which the fetus will pass. This is extremely important if the woman has never given birth vaginally. Taking pelvic measurements is unnecessary for the woman who has given birth vaginally before (unless she has experienced some type of trauma to the area) because vaginal delivery demonstrates that the pelvis is adequate for the passage of the fetus.

Three measurements are assessed: diagonal conjugate, true conjugate, and ischial tuberosity (Fig. 12.4).The diagonal conjugate is the distance between the anterior surface of the sacral prominence and the anterior surface of the inferior margin of the symphysis pubis (Jarvis, 2020). This measurement, usually 12.5 cm or greater, represents the anteroposterior diameter of the pelvic inlet through which the fetal head passes first. The diagonal conjugate is the most useful measurement for estimating pelvic size because a misfit with the fetal head occurs if it is too small.

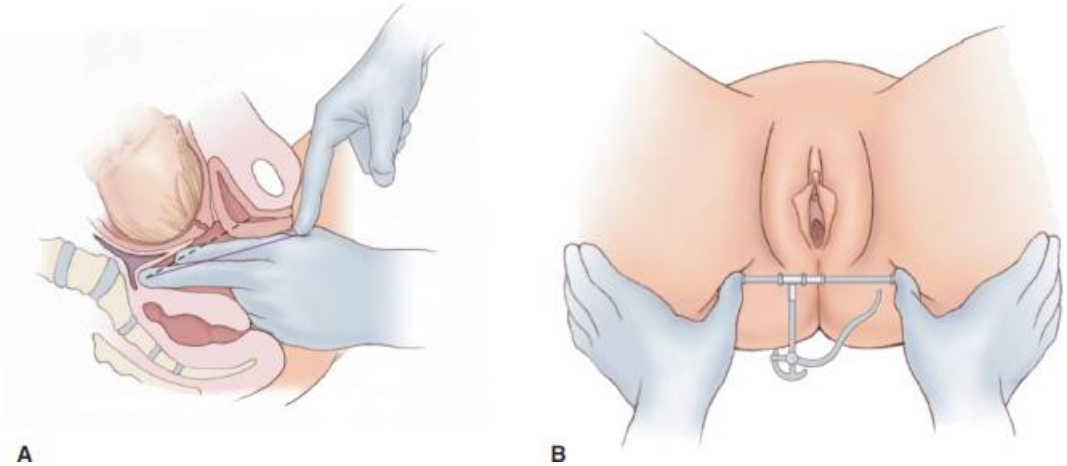

FIGURE 12.4. Pelvic measurements. **A.** Diagonal conjugate (*solid line*) and true conjugate (*dotted line*). **B.** Ischial tuberosity diameter.

The true conjugate, also called the obstetric conjugate, is the measurement from the anterior surface of the sacral prominence to the posterior surface of the inferior margin of the symphysis pubis. This diameter cannot be measured directly; rather, it is estimated by subtracting 1 to 2 cm from the diagonal conjugate measurement. The average true conjugate diameter is at least 11.5 cm (Cunningham et al., 2018). This measurement is important because it is the smallest front-to-back diameter through which the fetal head must pass when moving through the pelvic inlet.

The ischial tuberosity diameter is the transverse diameter of the pelvic outlet. This measurement is made outside the pelvis at the lowest aspect of the ischial tuberosities. A diameter of 10.5 cm or more is considered adequate for passage of the fetal head (Jordan et al., 2019).

Laboratory Tests

A series of tests is generally ordered during the initial visit so that baseline data can be obtained, allowing for early detection and prompt intervention if any problems occur. Tests that are generally conducted for all pregnant women include urinalysis and blood studies. The urine is analyzed for albumin, glucose, ketones, and bacteria casts. Blood studies usually include a complete blood count (CBC) (hemoglobin, hematocrit, red and white blood cell counts, and platelets), blood typing and Rh factor, glucose screening for high-risk women, a rubella titer, hepatitis B surface antibody antigen, HIV, venereal disease research laboratory (VDRL) or rapid plasma reagin (RPR) tests, and cervical smears to detect STIs (Common Laboratory and Diagnostic Tests 12.1). In addition, most offices and clinics have ultrasound equipment available to validate an intrauterine pregnancy and assess early fetal growth.

The need for additional laboratory studies is determined by a woman's history, physical examination findings, current health status, and risk factors identified in the initial interview. Additional tests can be offered (e.g., screening for genetic diseases, blood lead screening, rubeola, and so on), but ultimately the woman and her

partner make the decision about undergoing them. Educate the client and her partner about the tests, including the rationale. In addition, support the client and her partner in their decision-making process, regardless of whether you agree with the couple's decisions. The couple's decisions about their health care are based on the ethical principle of autonomy, which allows an individual the right to make decisions about their own body.

COMMON LABORATORY AND DIAGNOSIS TESTS 12.1

Test	Explanation
Complete blood cell count (CBC)	Evaluates hemoglobin (12–14 g) and hematocrit (42% ± 5%) levels and red blood cell count (4.2–5.4 million/mm^3) to detect the presence of anemia; identifies white blood cell level (5,000–10,000 mm^{-3}), which if elevated, may indicate an infection; determines platelet count (150,000–450,000 mL^3) to assess clotting ability
Blood typing	Determines woman's blood type and Rh status to rule out any blood incompatibility issues early; Rh-negative mother would likely receive RhoGAM (at 28 weeks' gestation) and again within 72 hours after childbirth if she is Rh-sensitive
Rubella titer	Detects antibodies for the virus that causes German measles; if titer is 1:8 or less, the woman is not immune; requires immunization after birth, and the woman is advised to avoid people with undiagnosed rashes
Hepatitis B	Determines if the mother has hepatitis B by detecting presence of hepatitis antibody surface antigen (HbsAg) in her blood
HIV testing	Detects HIV antibodies and if positive, requires more specific testing, counseling, and treatment during pregnancy with antiretroviral medications to prevent transmission to fetus
STI screening: venereal disease research laboratory	Detects STIs (such as syphilis, herpes, HPV, gonorrhea) so that treatment can be initiated early to prevent transmission to fetus

(VDRL) or rapid plasma reagin (RPR) serologic tests or by cervical smears, cultures, or visual identification of suspicious lesions	
Cervical smears	Detects abnormalities such as cervical cancer (Pap test) or infections such as gonorrhea, chlamydia, or group B streptococcus so that treatment can be initiated if positive

(2019). *Therapeutics in pregnancy and lactation*. Routledge; and Norwitz, E., Zelop, C., Miller, D., & Keefe, D. (2019). *Evidence-based obstetrics and gynecology.* Wiley Blackwell.

Remember Linda and Rob, the couple who want to start a family? Ten months after the preconception appointment, Linda calls to make a first prenatal appointment. What key areas will be addressed at this first prenatal visit? What interventions might be suggested for Linda to implement in order to ensure a healthy newborn? What emotional support might Linda need during her first trimester of pregnancy?

FOLLOW-UP VISITS

Continuous prenatal care is important for a successful pregnancy outcome. The recommended follow-up visit schedule for a healthy pregnant woman is:

- Every 4 weeks up to 28 weeks (7 months)
- Every 2 weeks from 29 to 36 weeks
- Every week from 37 weeks to birth

At each subsequent prenatal visit, the following assessments are completed:

- Weight and blood pressure, which are compared with baseline values
- Urine testing for protein, glucose, ketones, and nitrites
- Fundal height measurement to assess fetal growth
- Assessment for quickening/fetal movement to determine fetal well-being
- Assessment of fetal heart rate (should be 110 to 160 bpm)

At each follow-up visit, answer questions, provide anticipatory guidance and education, review nutritional guidelines, and evaluate the client for adherence to prenatal vitamin therapy. Throughout the pregnancy, encourage the woman's partner to participate if possible.

Follow-Up Visit Intervals and Assessments

Up to 28 weeks' gestation, follow-up visits involve assessment of the client's blood pressure and weight. The urine is tested for protein and glucose. Fundal height and fetal heart rate are assessed at every office visit.

The best procedure for screening and diagnosing gestational diabetes remains controversial. All strategies involve an oral glucose test, but there remains disagreement about how many grams of glucose (50, 75, or 100) the woman ingests and how long afterward her blood sample is drawn. A recent release of *Standards of Medical Care in Diabetes – 2020* by the ADA (2020) concluded that there was insufficient evidence to determine which assessment test is the best method to use to identify women who have gestational diabetes. Screening for gestational diabetes is best done between 24 and 28 weeks' gestation, unless screening is warranted in the first trimester for high-risk reasons (obesity, older age, family history of diabetes, history of gestational diabetes, or woman is of Hispanic, Native Americans, Asian, or African American descent) (ADA, 2020). Between weeks 24 and 28, a blood glucose level is obtained using an oral 50-g glucose load followed by a 1-hour plasma glucose

determination. If the result is more than to 140 mg/dL, further testing, such as a 3-hour 100-g glucose tolerance test, is warranted to determine whether gestational diabetes is present (ADA, 2020). Because insulin resistance increases as pregnancy advances, testing at this gestational point yields a higher rate of abnormal test results.

During this time, review the common discomforts of pregnancy, evaluate any client complaints, and answer questions. Reinforce the importance of good nutrition and use of prenatal vitamins, along with daily exercise.

Between 29 and 36 weeks' gestation, all the assessments of previous visits are completed, along with assessment for edema. Special attention is focused on the presence and location of edema during the last trimester. Pregnant women commonly experience dependent edema of the lower extremities from constriction of blood vessels secondary to the heavy gravid uterus. Periorbital edema around the eyes, edema of the hands, and pretibial edema (edema on the front, or shin part of the leg) are abnormal and could be signs of gestational hypertension. Inspecting and palpating both extremities, listening for complaints about rings becoming too tight on the fingers, and observing for swelling around the eyes are important assessments. Abnormal findings in any of these areas need to be reported.

If the mother is Rh-negative, her antibody titer is evaluated. RhoGAM is given if indicated. RhoGAM is used to prevent development of antibodies to Rh-positive red cells whenever fetal cells are known or suspected of entering the maternal circulation such as after a spontaneous abortion or amniocentesis. It is also recommended for prophylaxis at 28 weeks' gestation and following birth if the infant is Rh-positive (King et al., 2019). The client is also evaluated for risk of preterm labor. At each visit, ask if she is experiencing any common signs or symptoms of preterm labor (e.g., uterine contractions, dull backache, feeling of pressure in the pelvic area or thighs, increased vaginal discharge, menstrual-like cramps, vaginal bleeding). If the woman has had a previous preterm birth, she is at risk for another, and close monitoring is warranted. An initial

preterm labor evaluation if the woman reports signs and symptoms of preterm labor includes: review of prenatal record for risk factors; evaluation of reported symptoms (uterine contractions, vital signs, fetal heart rate, pelvic exam for cervical dilation and effacement assessment, and status of fetal membranes); and a urine culture to diagnose asymptomatic bacteriuria (Jordan et al., 2019). If positive for preterm labor, the woman may be requested to rest, and medications to stop contractions may be in order.

Counsel the woman about choosing a health care provider for the newborn if she has not selected one yet. Along with completion of a breast assessment, the nurse should discuss and educate the client about the choice of breastfeeding versus bottle-feeding. The American Academy of Pediatrics (AAP) does encourage all mothers to breastfeed their offspring, but the decision to do so is ultimately the woman's. The nurse can refer the client to the Nursing Mothers and La Leche League websites for further information to assist her in making that decision. Reinforce the importance of daily fetal movement monitoring as an indicator of fetal well-being. Reevaluate hemoglobin and hematocrit levels to assess for anemia.

Between 37 and 40 weeks' gestation, the same assessments are done as for the previous weeks. In addition, screening for group B streptococcus, gonorrhea, and chlamydia is done. Fetal presentation and position (via Leopold maneuvers) are assessed. Review the signs and symptoms of labor, and forward a copy of the prenatal record to the hospital labor department for future reference. Review the client's desire for family planning after birth as well as her decision to breastfeed or bottle-feed. Remind the client that an infant car seat is required by law and must be used to drive the newborn home from the hospital or birthing center.

Fundal Height Measurement

Fundal height is the distance (in centimeters) measured with a tape measure from the top of the pubic bone to the top of the uterus (fundus) with the client lying on her back with her knees slightly flexed (Fig. 12.5). Measurement in this way is termed the McDonald

method. Fundal height typically increases as the pregnancy progresses; it reflects fetal growth and provides a gross estimate of the duration of the pregnancy.

FIGURE 12.5. Fundal height measurement.

Between 12 and 14 weeks' gestation, the fundus can be palpated above the symphysis pubis. The fundus reaches the level of the umbilicus at approximately 20 weeks and measures 20 cm. Fundal measurement should approximately equal the number of weeks of gestation until week 36. For example, a fundal height of 24 cm suggests a fetus at 24 weeks' gestation. After 36 weeks, the fundal height then drops due to lightening and may no longer correspond with the week of gestation.

It is expected that the fundal height will increase progressively throughout the pregnancy, reflecting fetal growth. However, if the growth curve flattens or stays stable, it may indicate the presence of FGR. If the fundal height measurement is greater than 4 cm from the estimated gestational age, further evaluation is warranted if a

multifetal gestation has not been diagnosed or hydramnios has not been ruled out (Jarvis, 2020).

Fetal Movement Determination

Perception of fetal movement typically begins in the second trimester and occurs earlier in multiparous women than in nulliparous women. The mother's first perception of fetal movement, termed "quickening," is commonly described as a gentle fluttering. This perceived fetal movement is most often related to trunk and limb motion and rollovers, or flips (Norwitz et al., 2019). Maternal perception of fetal movement is an important screening method for fetal well-being, because decreased fetal movement is associated with a range of pregnancy pathologies and poor pregnancy outcomes. Decreased fetal movement may indicate asphyxia and FGR. If compromised, the fetus decreases its oxygen requirements by decreasing activity. Reduced fetal movement is thought to represent fetal compensation in a chronic hypoxic environment due to inadequacies in the placental supply of oxygen and nutrients (Fretts, 2019). A decrease in fetal movement may also be related to other factors as well, such as maternal use of central nervous system depressants, fetal sleep cycles, hydrocephalus, bilateral renal agenesis, stillbirth, placental dysfunction, and bilateral hip dislocation (Fretts, 2019).

Fetal movement counting is a method used by the mother to quantify her fetus's movement. However, the optimal number of movements and the ideal duration of counting them remain controversial. Many variations for determining fetal movement, also called fetal movement counts, have been developed, but the one most common method is described as follows. Determining fetal movement is a noninvasive method of screening and can be easily taught to all pregnant women. Any technique used requires client participation and cooperation.

Instruct the client about how to count fetal movements, the reasons for doing so, and the significance of decreased fetal movements. Urge the client to perform the counts in a relaxed

environment and a comfortable position, such as semi-Fowler or side-lying. Provide the client with detailed information concerning fetal movement counts, and stress the need for consistency in monitoring (at approximately the same time each day) and the importance of informing the health care provider promptly of any reduced movements. Providing clients with “fetal kick count” charts to record movement helps promote adherence to instructions. No values for fetal movement have been established that indicate fetal well-being, so the woman needs to be aware of a decrease in the number of movements when last assessed. The most common method used is “Count to 10,” with which a woman focuses her attention on her fetus’s movement and records how long it takes to document 10 movements. If it takes longer than 2 hours, the woman should contact her health care provider for further evaluation. Fetal kick counting in current prenatal care appears to be underutilized, and nurses need to educate women about this assessment in their pregnancy care.

Fetal Heart Rate Measurement

Fetal heart rate measurement is integral to fetal surveillance throughout the pregnancy. Auscultating the fetal heart rate with a handheld Doppler at each prenatal visit helps confirm that the intrauterine environment is still supportive to the growing fetus. The purpose of assessing fetal heart rate is to determine the rate and rhythm. The normal fetal heart rate range is 110 to 160 bpm. Nursing Procedure 12.1 lists the steps for measuring fetal heart rate.

Teaching about the Danger Signs during Pregnancy

It is important to educate the client about danger signs during pregnancy that require further evaluation. Explain that she should contact her health care provider immediately if she experiences any of the following:

- *During the first trimester:* spotting or bleeding (miscarriage), painful urination (infection), severe persistent vomiting (hyperemesis gravidarum), fever higher than 100°F (37.7°C; indicative of infection), and lower abdominal pain with dizziness and accompanied by shoulder pain (indicative of ruptured ectopic pregnancy).
- *During the second trimester:* regular uterine contractions (preterm labor); pain in calf, often increased with foot flexion (indicative of DVT); sudden gush or leakage of fluid from vagina (prelabor rupture of membranes); and absence of fetal movement for more than 12 hours (indicative of possible fetal distress or demise).
- *During the third trimester:* sudden weight gain; periorbital or facial edema, severe upper abdominal pain, or headache with visual changes (indicative of gestational hypertension and/or preeclampsia); and a decrease in fetal daily movement for more than 24 hours (indicative of possible demise).

NURSING PROCEDURE 12.1 Measuring Fetal Heart Rate

Purpose: To Assess Fetal Well-Being

1. Assist the woman onto the examining table and have her lie down.
2. Cover her with a sheet to ensure privacy, and then expose her abdomen.
3. Palpate the abdomen to determine the fetal lie, position, and presentation.
4. Locate the back of the fetus (the ideal position to hear the heart rate).
5. Apply lubricant gel to abdomen in the area where the back has been located.
6. Turn on the handheld Doppler device, and place it on the spot over the fetal back.
7. Listen for the sound of the amplified heart rate, moving the device slightly from side to side as necessary to obtain the loudest sound. Assess the woman's pulse rate and compare it to the amplified sound. If the rates appear the same, reposition the Doppler device.
8. Once the fetal heart rate has been identified, count the number of beats in 1 minute and record the results.
9. Remove the Doppler device and wipe off any remaining gel from the woman's abdomen and the device.
0. Record the heart rate on the woman's medical record; normal range is 110 to 160 bpm.
1. Provide information to the woman regarding fetal well-being based on findings.

Any of the first- and second-trimester warning signs and symptoms can also be present in the last trimester (March of Dimes, 2019a).

Early Contractions

One of the warning signs that should be emphasized is early contractions, which can lead to preterm birth. The woman should not confuse these early preterm contractions with Braxton Hicks contractions, which are not true labor pains because they go away when walking around or resting. They often go away when the woman goes to sleep. Braxton Hicks contractions are usually felt in the abdomen rather than in the lower back with true preterm labor contractions. Signs of preterm labor that a woman may experience include contractions every 10 minutes or more frequently, change in vaginal discharge, pelvic pressure, low, dull backache, pelvic cramps, and diarrhea (Cunningham et al., 2018).

All pregnant women need to be able to recognize early signs of contractions to prevent preterm labor, which is a major public health problem in the United States. Approximately 12% of all live births—or one out of nine infants—are born too soon. The U.S. rate of preterm births has increased by 38% over the last 25 years. Worldwide, 15 million infants are born too soon each year (CDC, 2019d). These preterm infants (born earlier than 37 weeks' gestation) can suffer lifelong health consequences such as intellectual disability, chronic lung disease, cerebral palsy, seizure disorders, and blindness (March of Dimes, 2020b). Preterm labor can happen to any pregnant women at any time. In many cases, it can be stopped with medications if it is recognized early, before significant cervical dilation has taken place. If the woman experiences menstrual-like cramps occurring every 10 minutes accompanied by a low, dull backache, she should stop what she is doing and lie down on her left side for 1 hour and drink two or three glasses of water. If the symptoms worsen or do not subside after 1 hour, she should contact her health care provider.

ASSESSMENT OF FETAL WELL-BEING

During the antepartum period, several tests are routinely performed to monitor fetal well-being and to detect possible problems. When a high-risk pregnancy is identified, additional antepartum testing can

be initiated to promote positive maternal, fetal, and neonatal outcomes. **High-risk pregnancies** include those that are complicated by maternal or fetal conditions (coincidental with or unique to pregnancy) that jeopardize the health status of the mother and put the fetus at risk for uteroplacental insufficiency, hypoxia, and death (CDC, 2019e). However, additional antepartum fetal testing should take place only when the results obtained will guide future care, whether it is reassurance, more frequent testing, admission to the hospital, or the need for immediate delivery (Marcondes et al., 2019).

Ultrasonography

Since its introduction in the late 1950s, ultrasonography has become a useful diagnostic tool in obstetrics. Diagnostic ultrasound is employed in a variety of circumstances during pregnancy such as concerns regarding fetal growth and after maternal complications. Real-time scanners can produce a continuous picture of the fetus on a monitor screen. A transducer that emits high-frequency sound waves is placed on the mother's abdomen and moved to visualize the fetus (Fig. 12.6). The fetal heartbeat and any malformations in the fetus can be assessed, and measurements can be made accurately from the picture on the monitor screen.

Obstetric ultrasound is a standard component of prenatal care used to identify pregnancy complications and establish an accurate gestational age in order to improve pregnancy outcomes. Because the ultrasound procedure is noninvasive, it is a safe practice for low-risk women and an accurate and cost-effective tool. It provides important information about fetal activity, growth, and gestational age; assesses fetal well-being; and determines the need for invasive intrauterine tests (WHO, 2019).

There are no hard-and-fast rules as to the number of ultrasounds a woman should have during her pregnancy. A low-risk woman does not necessarily require any, but most practices do them as part of the prenatal care routine. A transvaginal ultrasound may be performed in the first trimester to confirm pregnancy, exclude ectopic

(in which a fertilized egg implants somewhere other than the main cavity of the uterus) or molar (hydatidiform mole, a benign tumor that develops in the uterus) pregnancies, and confirm cardiac pulsation. A second abdominal scan may be performed at about 18 to 20 weeks to look for congenital malformations, exclude multifetal pregnancies, and verify dates and growth. A third abdominal scan may be done at around 34 weeks to evaluate fetal size, assess fetal growth, and verify placental position (Crum et al., 2019). An ultrasound is used to confirm placental location during amniocentesis and to provide visualization during chorionic villus sampling (CVS). An ultrasound is also ordered whenever an abnormality is suspected.

FIGURE 12.6. Ultrasound. **A.** Ultrasound device being applied to client's abdomen. **B.** View of monitor.

During the past several years, ultrasound technology has advanced significantly. Now available for expecting parents is 3D/4D ultrasound imaging. Unlike traditional 2D imaging, which takes a look at the developing fetus from one angle (thus creating the "flat" image), 3D imaging takes a view of the fetus from three different angles. Software then takes these three images and merges them to produce a 3D image. Because the fourth dimension is time and movement, with 4D, parents are able to watch the live movements of their fetus in 3D.

Nursing management during the ultrasound procedure focuses on educating the woman about the ultrasound test and reassuring her that she will not experience any sensation from the sound waves

during the test. No special client preparation is needed before performing the ultrasound, although in early pregnancy, the woman may need to have a full bladder. Inform her that she may experience some discomfort from the pressure on the full bladder during the scan, but it will last only a short time. Tell the client that the conducting gel used on the abdomen during the scan may feel cold initially.

Doppler Flow Studies

Doppler ultrasonography is the use of sound waves to examine the flow of blood in blood vessels. Comprehensive assessment of fetal well-being involves monitoring of fetal growth, placental function, central venous pressure, and cardiac function. Ultrasound evaluation of the fetus using 2D, color Doppler, and pulse-wave Doppler techniques forms the foundation of prenatal diagnosis of structural anomalies, rhythm abnormalities, and altered fetal circulation (Cunningham et al., 2018). Doppler flow studies can be used to measure the velocity of blood flow via ultrasound. Doppler flow studies can detect fetal compromise in high-risk pregnancies. The test is noninvasive and has no contraindications. The color images produced help to identify abnormalities in diastolic flow within the umbilical vessels. The velocity of the fetal red blood cells can be determined by measuring the change in the frequency of the sound wave reflected off the cells. Thus, Doppler flow studies can detect the movement of red blood cells in vessels to investigate fetal hemodynamics to use these findings for fetal surveillance (Maulik, 2020). In pregnancies complicated by hypertension or FGR, diastolic blood flow may be absent or even reversed (King et al., 2019). Doppler flow studies can also be used to evaluate the blood flow through other fetal blood vessels, such as the aorta and those in the brain. Research continues to determine the indications for Doppler flow studies to improve pregnancy outcomes. Nursing management of the woman undergoing Doppler flow studies is similar to that described for an ultrasound.

Alpha-Fetoprotein Analysis

Alpha-fetoprotein (AFP) is a glycoprotein produced initially by the yolk sac and fetal gut, and later predominantly by the fetal liver. In a fetus, the serum AFP level increases until approximately 14 to 15 weeks and then falls progressively. In normal pregnancies, AFP from fetal serum enters the amniotic fluid (in microgram quantities) through fetal urination, fetal gastrointestinal secretions, and transudation across fetal membranes (amnion and placenta). About 30 years ago, elevated levels of maternal serum AFP or amniotic fluid AFP were first linked to the occurrence of fetal neural tube defects. This biomarker screening test is now recommended for all pregnant women along with other prenatal screening tests depending on risk profile (ACOG, 2019b; Crum et al., 2019).

AFP is present in amniotic fluid in low concentrations between 10 and 14 weeks' gestation and can be detected in maternal serum beginning at approximately 12 to 14 weeks' gestation (Jordan et al., 2019). If a developmental defect is present, such as failure of the neural tube to close, more AFP escapes into amniotic fluid from the fetus. AFP then enters the maternal circulation by crossing the placenta, and the level in maternal serum can be measured. The optimal time for AFP screening is 16 to 18 weeks' gestation. Currently, ACOG recommends offering screening and diagnostic tests to all pregnant women, regardless of age or risk factors present (2019b). Correct information about gestational dating, maternal weight, race, number of fetuses, and insulin dependency is necessary to ensure the accuracy of this screening test. If incorrect maternal information is submitted or the blood specimen is not drawn during the appropriate time frame, false-positive results may occur, increasing the woman's anxiety. Subsequently, further testing might be ordered based on an inaccurate interpretation, resulting in additional financial and emotional costs to the woman.

A variety of situations can lead to elevation of maternal serum AFP, including open neural tube defects, underestimation of gestational age, the presence of multiple fetuses, gastrointestinal defects, low birth weight, oligohydramnios, maternal age, diabetes,

and decreased maternal weight (King et al., 2019). Lower-than-expected maternal serum AFP levels are seen when fetal gestational age is overestimated or in cases of fetal death, hydatidiform mole, increased maternal weight, maternal type 1 diabetes, and fetal trisomy 21 (Down syndrome) or trisomy 18 (Edward syndrome) (Adigun & Bhimji, 2019).

Measurement of maternal serum AFP is minimally invasive, requiring only a venipuncture for a blood sample. AFP has now been combined with other biomarker screening tests (triple, quad, or penta screens) to determine the risk of neural tube defects and Down syndrome.

Nursing management for AFP testing consists of preparing the woman for this screening test by gathering accurate information about the date of her LMP, weight, race, and gestational dating. Accurately determining the window of 16 to 18 weeks' gestation will help ensure that the test results are correct. Also explain that the test involves obtaining a blood specimen.

Marker Screening Tests

Using maternal serum is an effective, noninvasive method for identifying fetal risk for aneuploidy (trisomies 13, 18, and 21) and neural tube defects. Prenatal screening for Down syndrome in the early second trimester with multiple maternal serum markers has been available for more than 15 years. Abnormalities in maternal serum marker levels and fetal measurements obtained during the first trimester screening can be markers for not only certain chromosomal disorders and anomalies in the fetus, but also for specific pregnancy complications. Pregnancy-associated plasma protein A (PAPP-A) is a key regulator of insulin-like growth factor essential for normal fetal development. In maternal blood, this protein increases with gestational age. It is routinely used for Down syndrome screening in the first trimester. A low maternal serum PAPP-A at 11 to 13 weeks' gestation is associated with stillbirth, infant death, preterm birth, preeclampsia, and chromosomal abnormalities (Hill, 2019; Fetal Medicine Foundation, 2020).

Multiple blood screening tests may be used to determine the risk of open neural tube defects and Down syndrome: the triple-marker screen measures three hormones (AFP, hCG, and unconjugated estriol) or the quad screen, which includes the triple screening tests with the addition of a fourth marker, inhibin A (glycoprotein secreted by the placenta). The quad screen is used to enhance the accuracy of screening for Down syndrome in women younger than 35 years of age. Low inhibin A levels indicate the possibility of Down syndrome (Norwitz et al., 2019). The penta screen includes AFP, hCG, unconjugated estrogen, dimeric inhibin A (DIA), and hyperglycosylated hCG (h-hCG). This screening test is not widely available. These biomarkers are merely screening tests and identify women who need further definitive procedures (i.e., ultrasound, amniocentesis, and genetic counseling) to make a diagnosis of neural tube defects (anencephaly, spina bifida, and encephalocele) or Down syndrome in the fetus. Most screening tests are performed between 15 and 22 weeks' gestation (16 to 18 weeks is ideal), except for the cell-free fetal DNA (cffDNA) test which can be performed around 9 to 10 weeks' gestation. The cffDNA test offers clinical benefits over existing prenatal screening tests by detecting the presence of trisomy 21 with high sensitivity (99.9%) and specificity (98%) at an earlier time frame (Palomaki et al., 2019).

Low maternal serum AFP (MSAFP), unconjugated estriol levels, and a high hCG level suggest the possibility of Down syndrome. Elevated levels of MSAFP are associated with open neural tube defects, ventral wall defects, some renal abnormalities, multiple gestation, certain skin disorders, fetal demise, and placental abnormality. The multiple marker combination with the highest screening performance currently available is AFP, unconjugated estriol, hCG, and inhibin A, together with maternal age (the so-called quad marker test). With this combination, a detection rate of 81% at a 5% false-positive rate is achieved (Jordan et al., 2019).

A number of factors influence the interpretation of an MSAFP value. The most important is the accuracy of the gestational age determination. A variation of 2 weeks can be misleading and lead to a wrong interpretation. Maternal weight (over 250 lb), ethnicity,

maternal smoking habits, fetal gender, gravidity, para status, and insulin-dependent diabetes may also alter the levels of MSAFP and need to be taken into consideration when interpreting the results (Palomaki et al., 2019). Recent research studies indicate prenatal testing with the use of cffDNA has significantly lower false positives and high positive predictive values for detection of trisomies than standard testing (di Renzo et al., 2019).

Accurate test interpretation and risk determination are dependent on accurate pregnancy dating and reporting of relevant maternal characteristics. This is why it is so important, if an abnormal test result is reported, for nurses to confirm pregnancy dating and report any significant maternal factors relevant to test accuracy. In addition, nurses have a prominent role in providing education about the tests to the couples. Prenatal screening has become standard in prenatal care. However, for many couples, it remains confusing, emotionally charged, and filled with uncertain risks. Offer a thorough explanation of the test, reinforcing the information given by the health care professional. Provide couples with a description of the risks and benefits of performing these screens, emphasizing that these tests are for screening purposes only. Remind the couple that a definitive diagnosis is not made without further tests such as an amniocentesis. Answer any questions about these prenatal screening tests and respect the couple's decision if they choose not to have them done. Many couples may choose not to know because they would not consider having an abortion regardless of the test results. Prenatal tests are expanding rapidly and will continue to provide families more reproductive choices but at the same time create ethical challenges for them.

Nuchal Translucency Screening

Nuchal translucency screening (ultrasound) is also done in the first trimester between 11 and 14 weeks. This allows for early detection and diagnosis of some fetal chromosomal and structural abnormalities. Over the years, it has become clear that increased nuchal translucency is a marker for chromosomal abnormalities and

is also associated with a wide spectrum of structural anomalies, genetic syndromes, and high risk of abortion and fetal death (Levy, 2019). Ultrasound is used to identify an increase in nuchal translucency, which is due to the subcutaneous accumulation of fluid behind the fetal neck. Increased nuchal translucency is associated with chromosomal abnormalities such as trisomies 21, 18, and 13. Infants with trisomies tend to have more collagen and elastic connective tissue, allowing for accumulation. In addition, diaphragmatic hernias, cardiac defects, and fetal skeletal and neurologic abnormalities have been associated with increased nuchal translucency measurements (Leung & Qiao, 2019). See Chapter 10 for more information.

Amniocentesis

Amniocentesis involves a transabdominal puncture of the amniotic sac to obtain a sample of amniotic fluid for analysis. The fluid contains fetal cells that are examined to detect chromosomal abnormalities and several hereditary metabolic defects in the fetus before birth. In addition, amniocentesis is used to confirm a fetal abnormality when other screening tests detect a possible problem.

Amniocentesis is performed in the second trimester, usually between 15 and 20 weeks' gestation. At this age, the amount of fluid is adequate (approximately 150 mL), and the ratio of viable to nonviable cells is the greatest. About 20 mL is removed for a sample to be tested (March of Dimes, 2020c). More than 40 different chromosomal abnormalities, inborn errors of metabolism, and neural tube defects can be diagnosed with amniocentesis. It can replace a genetic probability with a diagnostic certainty, allowing the woman and her partner to make an informed decision about the option of therapeutic abortion.

Amniocentesis can be performed in any of the three trimesters of pregnancy. An early amniocentesis (performed between weeks 11 and 14) is done to detect genetic anomalies. However, early amniocentesis has been associated with a high risk of spontaneous

miscarriage and postprocedural amniotic fluid leakage compared with transabdominal chorionic villus screening (King et al., 2019).

In the second trimester, the procedure is performed between 15 and 20 weeks to detect chromosomal abnormalities, evaluate the fetal condition when the woman is sensitized to the Rh-positive blood, diagnose intrauterine infections, and investigate amniotic fluid AFP when the MSAFP level is elevated (March of Dimes, 2020c).

In the third trimester, amniocentesis is most commonly indicated to determine fetal lung maturity after the 35th week of gestation via analysis of lecithin-to-sphingomyelin ratios and to evaluate the fetal condition with Rh isoimmunization. Table 12.2 lists amniotic fluid analysis findings and their implications.

Procedure

Amniocentesis is performed after an ultrasound examination identifies an adequate pocket of amniotic fluid free of fetal parts, the umbilical cord, or the placenta (Fig. 12.7). The health care provider inserts a long pudendal or spinal needle, a 22-gauge, 5-in needle, into the amniotic cavity and aspirates amniotic fluid, which is placed in an amber or foil-covered test tube to protect it from light. When the desired amount of fluid has been withdrawn (about 20 mL), the needle is removed and slight pressure is applied to the site. If there is no evidence of bleeding, a sterile bandage is applied to the needle site. The specimens are then sent to the laboratory immediately for the cytologist to evaluate.

Examining a sample of fetal cells directly produces a definitive diagnosis rather than a “best guess” diagnosis based on indirect screening tests. It is an invaluable diagnostic tool, but the risks include lower abdominal discomfort and cramping that may last up to 48 hours after the procedure, spontaneous abortion (one in 300 to 500), maternal or fetal infection, postamniocentesis chorioamnionitis that has an insidious onset, fetal–maternal hemorrhage, leakage of amniotic fluid in 2% to 3% of women after the procedure, and higher rates of fetal loss in earlier amniocentesis procedures (earlier than 15 weeks’ gestation) versus later ones (Ghidini, 2019). Obtaining the

test results may take up to 3 weeks. Women today are choosing noninvasive prenatal testing rather than undergoing invasive testing such as amniocentesis despite those tests not being 100% correct. Women with reassuring noninvasive results and normal ultrasound findings seem satisfied over the risk of procedure-related pregnancy loss (Norwitz et al., 2019). The number of invasive procedures has declined since the availability of noninvasive prenatal testing, and it is predicted that they will replace the more invasive procedures in the future.

Nursing Management

When preparing the woman for an amniocentesis, explain the procedure and its potential complications, and encourage her to empty her bladder just before the procedure to avoid the risk of bladder puncture. Inform her that a 20-minute electronic fetal monitoring strip is usually obtained to evaluate fetal well-being and obtain a baseline to compare after the procedure is completed. Obtain and record maternal vital signs.

TABLE 12.2 Amniotic Fluid Analysis and Implications

Test Component	Normal Findings	Fetal Implications of Abnormal Findings
Color	Clear with white flecks of vernix caseosa in a mature fetus	Blood of maternal origin is usually harmless. “Port wine” fluid may indicate abruptio placentae. Fetal blood may indicate damage to the fetal, placental, or umbilical cord vessels.
Bilirubin	Absent at term	High levels indicate hemolytic disease of the neonate in isoimmunized pregnancy.
Meconium	Absent (except in breech presentation)	Presence indicates fetal hypotension or distress.
Creatinine	>2 mg/dL in a mature fetus	Decrease may indicate immature fetus (<37 weeks).
Lecithin-to-sphingomyelin ratio (L/S ratio)	>2 generally indicates fetal pulmonary maturity	A ratio of <2 indicates pulmonary immaturity and subsequent respiratory distress syndrome.
Phosphatidylglycerol	Present	Absence indicates pulmonary immaturity.
Glucose	<45 mg/dL	Excessive increases at term or near term indicate hypertrophied fetal pancreas and subsequent neonatal hypoglycemia.
Alpha-fetoprotein	Variable, depending on gestation age and laboratory technique; highest concentration (about 18.5 ng/mL) occurs at 13–14 weeks	Inappropriate increases indicate neural tube defects such as spina bifida or anencephaly, impending fetal death, congenital nephrosis, or contamination of fetal blood.
Bacteria	Absent	Presence indicates

		chorioamnionitis.
Chromosomes	Normal karyotype	Abnormal karyotype may indicate fetal sex and chromosome disorders.
Acetylcholinesterase	Absent	Presence may indicate neural tube defects, exomphalos, or other serious malformations.

FIGURE 12.7. Technique for amniocentesis: inserting needle.

After the procedure, assist the woman into a position of comfort and administer RhoGAM intramuscularly if the woman is Rh-negative to prevent potential sensitization to fetal blood. Assess maternal vital signs and fetal heart rate every 15 minutes for an hour after the procedure. Observe the puncture site for bleeding or drainage. Instruct the client to rest after returning home and remind her to report fever, leaking amniotic fluid, vaginal bleeding, or uterine contractions or any changes in fetal activity (increased or decreased) to the health care provider.

When the test results come back, be available to offer support, especially if a fetal abnormality is found. Also prepare the woman and her partner for the need for genetic counseling. Trained genetic counselors can provide accurate medical information and help couples interpret the results of the amniocentesis so they can make the decisions that are right for them as a family.

Chorionic Villus Sampling

Chorionic villus sampling (CVS) is an invasive procedure involving an 18-gauge needlestick through the abdomen or passage of a suction catheter through the cervix under ultrasound guidance. This test is used to obtain a sample of the chorionic villi from the placenta for prenatal evaluation of chromosomal disorders such as Down syndrome or cystic fibrosis, enzyme deficiencies, and fetal gender determination and to identify sex-linked disorders such as hemophilia, sickle cell anemia, and Tay–Sachs disease (Levy, 2019). Chorionic villi are fingerlike projections that cover the embryo and anchor it to the uterine lining before the placenta is developed. Because they are of embryonic origin, sampling provides information about the developing fetus. CVS can be used to detect numerous genetic disorders with the exception of neural tube defects (Leung & Qiao, 2019).

There has been an impetus to develop earlier prenatal diagnostic procedures so that couples can make an early decision to terminate the pregnancy if an anomaly is confirmed. Early prenatal diagnosis by CVS has been proposed as an alternative to routine amniocentesis, which carries fewer risks if done later in the pregnancy. In addition, results of CVS testing are available sooner than those of amniocentesis, usually within 48 hours.

Procedure

CVS is generally performed 10 to 13 weeks after the LMP. Earlier, chorionic villi may not be sufficiently developed for adequate tissue sampling and the risk of limb defects is increased (Ng, 2019). First,

an ultrasound is done to confirm gestational age and viability. Then, under continuous ultrasound guidance, CVS is performed using either a transcervical or transabdominal approach. With the transcervical approach, the woman is placed in the lithotomy position and a sterile catheter is introduced through the cervix and inserted in the placenta, where a sample of chorionic villi is aspirated. This approach requires the client to have a full bladder to push the uterus and placenta into a position that is more accessible to the catheter. A full bladder also helps in better visualization of the structures. With the transabdominal approach, an 18-gauge spinal needle is inserted through the abdominal wall into the placental tissue and a sample of chorionic villi is aspirated. Regardless of the approach used, the sample is sent to the cytogenetics laboratory for analysis.

Potential complications of CVS include postprocedure vaginal bleeding and cramping (most common), hematomas, spontaneous abortion, limb abnormalities, rupture of membranes, infection, chorioamnionitis, and fetal–maternal hemorrhage (March of Dimes, 2020d). The pregnancy loss rate or procedure-related miscarriage rate is approximately 0.5% to 1.0%, which is the same rate for amniocentesis. In addition, women who are Rh-negative should receive immune globulin (RhoGAM) to avoid isoimmunization (Jordan et al., 2019).

Nursing Management

Explain to the woman that the procedure will last about 15 minutes. An ultrasound will be done first to locate the embryo, and a baseline set of vital signs will be taken before starting. Make sure she is informed of the risks related to the procedure, including their incidence. If a transabdominal CVS procedure is planned, advise her to fill her bladder by drinking increased amounts of water. Inform her that a needle will be inserted through her abdominal wall and samples will be collected. Once the samples are collected, the needle will be withdrawn and the samples will be sent to the genetics laboratory for evaluation.

For transcervical CVS, inform the women that a speculum will be placed into the vagina under ultrasound guidance. Then the vagina is cleaned and a small catheter is inserted through the cervix. The samples obtained through the catheter are then sent to a laboratory.

After either procedure, assist the woman into a position of comfort and clean any excess lubricant or secretions from the area. Instruct her about signs to watch for and report, such as fever, cramping, and vaginal bleeding. Urge her not to engage in any strenuous activity for the next 48 hours. Assess the fetal heart rate for changes and administer RhoGAM to an unsensitized Rh-negative woman after the procedure.

Nonstress Test

The nonstress test (NST) is the most common method of prenatal testing used in practice today. The NST provides an indirect measurement of uteroplacental function. Unlike the fetal movement counting done by the mother alone, this procedure requires specialized equipment and trained personnel. The basis for the NST is that the normal fetus produces characteristic fetal heart rate patterns in response to fetal movements. In the healthy fetus, there is an acceleration of the fetal heart rate with fetal movement. Currently, an NST is recommended twice weekly (after 28 weeks' gestation) for clients with diabetes and other high-risk conditions, such as intrauterine growth restriction (IUGR), preeclampsia, post-term pregnancy, renal disease, and multifetal pregnancies (Cunningham et al., 2018). NST is a noninvasive test that requires no initiation of contractions. It is quick to perform and there are no known side effects.

Procedure

Before the procedure, the client eats a meal to stimulate fetal activity. Then she is placed in the left lateral recumbent position to avoid supine hypotension syndrome. An external electronic fetal monitoring device is applied to her abdomen. The device consists of

two belts, each with a sensor. One of the sensors records uterine activity, while the second sensor records fetal heart rate. The client is handed an “event marker” with a button that she pushes every time she perceives fetal movement. When the button is pushed, the fetal monitor strip is marked to identify that fetal movement has occurred. The procedure usually lasts 20 to 30 minutes.

Nursing Management

Prior to the NST, explain the testing procedure and have the woman empty her bladder. Position her in a semi-Fowler position and apply the two external monitor belts. Document the date and time the test is started, client information, the reason for the test, and the maternal vital signs. Obtain a baseline fetal monitor strip over 15 to 30 minutes.

During the test, observe for signs of fetal activity with a concurrent acceleration of the fetal heart rate. Interpret the NST as reactive or nonreactive. A reactive NST includes at least two fetal heart rate accelerations from the baseline of at least 15 bpm for at least 15 seconds within the 20-minute recording period. If the test does not meet these criteria after 40 minutes, it is considered nonreactive. A nonreactive NST is characterized by the absence of two fetal heart rate accelerations using the 15-by-15 criterion in a 20-minute time frame. A nonreactive test has been correlated with a higher incidence of fetal distress during labor, fetal mortality, and IUGR. Additional testing, such as a biophysical profile, should be considered (King et al., 2019).

After the NST procedure, assist the woman off the table, provide her with fluids, and allow her to use the restroom. Typically, the health care provider discusses the results with the woman at this time. Provide teaching about signs and symptoms to report. If serial NSTs are being done, schedule the next testing session.

Biophysical Profile

A **biophysical profile (BPP)** uses a real-time ultrasound and NST to allow assessment of various parameters of fetal well-being that are sensitive to hypoxia. A BPP includes ultrasound monitoring of fetal movements, fetal tone, and fetal breathing as well as ultrasound assessment of amniotic fluid volume with or without assessment of the fetal heart rate. A BPP is performed in an effort to identify infants who may be at risk of poor pregnancy outcome, so that additional assessments of well-being may be performed or labor may be induced or a cesarean section performed to expedite birth. The primary objectives of the BPP are to reduce stillbirth and to detect hypoxia early enough to allow delivery in time to avoid permanent fetal damage resulting from fetal asphyxia. These parameters, together with the NST, constitute the BPP. Each parameter is controlled by a different structure in the fetal brain: fetal tone by the cortex; fetal movements by the cortex and motor nuclei; fetal breathing movements by the centers close to the fourth ventricle; and the NST by the posterior hypothalamus and medulla. The amniotic fluid is the result of fetal urine volume. Some facilities do not perform an NST unless other parameters of the profile are abnormal (King et al., 2019). The BPP is based on the concept that a fetus that experiences hypoxia loses certain behavioral parameters in the reverse order in which they were acquired during fetal development (normal order of development: tone at 8 weeks; movement at 9 weeks; breathing at 20 weeks; and fetal heart rate reactivity at 24 weeks).

Scoring and Interpretation

The BPP is a scored test with five components, each worth two points if present. A total score of 10 is possible if the NST is used. Thirty minutes are allotted for testing, though less than 10 minutes are usually needed. The following criteria must be met to obtain a score of 2; anything less is scored as 0 (Blackburn, 2018):

- *Body movements:* three or more discrete limb or trunk movements
- *Fetal tone:* one or more instances of full extension and flexion of a limb or trunk

- *Fetal breathing:* one or more fetal breathing movements of more than 30 seconds
- *Amniotic fluid volume:* one or more pockets of fluid measuring 2 cm
- *NST:* normal NST = 2 points; abnormal NST = 0 points

Interpretation of the BPP score can be complicated, depending on several fetal and maternal variables. Because it is indicated as a result of a nonreassuring finding from previous fetal surveillance tests, this test can be used to quantify the interpretation, and intervention can be initiated if appropriate. A maximum score of 10 can be achieved and the test is complete once all of the variables have been observed. For the test to be judged abnormal and a score of zero awarded for the absence of fetal movement, fetal tone, or fetal breathing movements, a period of not less than 30 minutes must have elapsed. Because of the excellent sensitivity of fetal NST for fetal acidemia, it has been proposed that this acute marker alone may be used for fetal assessment in combination with the amniotic fluid volume assessment, a chronic marker. This combination, also known as the modified BPP, has been shown to have excellent false-negative rates that compare with those of the complete BPP. In addition, a recent study reported that BPP scores correlates fairly closely with the Apgar scores obtained after birth (Manning, 2019).

One of the important factors is the amniotic fluid volume, taken in conjunction with the results of the NST. Amniotic fluid is largely composed of fetal urine. As placental function decreases, perfusion of fetal organs, such as kidneys, decreases, and this can lead to a reduction of amniotic fluid. If oligohydramnios or decreased amniotic fluid is present, the potential exists for antepartum or intrapartum fetal compromise (Crum et al., 2019).

Overall, a score of 8 to 10 is considered normal if the amniotic fluid volume is adequate. A score of 6 or below is suspicious, possibly indicating a compromised fetus; further investigation of fetal well-being is needed.

Because the BPP is an ultrasonographic assessment of fetal behavior, it requires more extensive equipment and more highly trained personnel than other testing modalities. The cost is much

greater than those of less sophisticated tests. It permits conservative therapy and prevents premature or unnecessary intervention. There are fewer false-positive results than with the NST alone (Norwitz et al., 2019).

Nursing Management

Nursing management focuses primarily on offering the client support and answering her questions. Expect to complete the NST before scheduling the BPP, and explain why further testing might be needed. Tell the woman that the ultrasound will be done in the diagnostic imaging department.

NURSING MANAGEMENT FOR THE COMMON DISCOMFORTS OF PREGNANCY

Most women experience common discomforts during pregnancy and ask a nurse's advice about ways to minimize them. However, other women will not bring up their concerns unless asked. Therefore, the nurse needs to address the common discomforts that occur in each trimester at each prenatal visit and provide realistic measures to help the client deal with them (Teaching Guidelines 12.1). Nursing Care Plan 12.1 applies the nursing process to the care of a woman experiencing some discomforts of pregnancy.

TEACHING GUIDELINES 12.1

Managing the Discomforts of Pregnancy

Urinary Frequency or Incontinence

- Try pelvic floor exercises to increase control over leakage.
- Empty your bladder when you first feel a full sensation.
- Avoid caffeinated drinks, which stimulate voiding.
- Reduce your fluid intake after dinner to reduce nighttime urination.

Fatigue

- Attempt to get a full night's sleep without interruptions.
  - Eat a healthy balanced diet.
  - Schedule a nap in the early afternoon daily.
  - When feeling tired, pause and rest.

Nausea and Vomiting

- Avoid an empty stomach at all times.
  - Eat dry crackers/toast in bed before arising.
  - Eat several small meals throughout the day.
  - Avoid brushing teeth immediately after eating to avoid gag reflex.
  - Acupressure wristbands can be worn daily.
  - Drink fluids between meals rather than with meals.
  - Avoid greasy, fried foods or ones with a strong odor, such as cabbage or Brussels sprouts.

Backache

- Avoid standing or sitting in one position for long periods.
  - Apply heating pad (low setting) to the small of your back.
  - Support your lower back with pillows when sitting.
  - Use proper body mechanics for lifting anything.
  - Avoid excessive bending, lifting, or walking without rest periods.
  - Wear supportive low-heeled shoes; avoid high heels.
  - Stand with your shoulders back to maintain correct posture.

Leg Cramps

- Elevate legs above heart level frequently throughout the day.

- If you get a cramp, straighten both legs and flex your feet toward your body.
- Ask your health care provider about taking additional calcium supplements, which may reduce leg spasms.

Varicosities

- Walk daily to improve circulation to extremities.
- Elevate both legs above heart level while resting.
- Avoid standing in one position for long periods of time.
- Don’t wear constrictive stockings and socks.
- Don’t cross the legs when sitting for long periods.
- Wear support stockings to promote better circulation.

Hemorrhoids

- Establish a regular time for daily bowel elimination.
- Avoid constipation and straining during defecation.
- Prevent straining by drinking plenty of fluids and eating fiber-rich foods and exercising daily.
- Use warm sitz baths and cool witch hazel compresses for comfort.

Constipation

- Increase your intake of foods high in fiber and drink at least eight 8-oz glasses of fluid daily.

NURSING CARE PLAN 12.1 Overview of the Woman Experiencing Common Discomforts of Pregnancy

Alicia, a 32-year-old, G1 P0, at 10 weeks' gestation, comes to the clinic for a visit. During the interview she tells you, "I'm running to the bathroom to urinate it seems like all the time, and I'm so nauseous that I'm having trouble eating." She denies any burning or pain on urination. Vital signs are within acceptable limits.

NURSING ANALYSIS: Altered urinary elimination related to frequency secondary to physiologic changes of pregnancy

OUTCOME IDENTIFICATION AND EVALUATION

The client will report a decrease in urinary complaints as evidenced by a decrease in the number of times she uses the bathroom to void, reports that she feels her bladder is empty after voiding, and use of Kegel exercises.

INTERVENTIONS: *Promoting Normal Urinary Elimination Patterns*

- Assess client's usual bladder elimination patterns *to establish a baseline for comparison*.
- Obtain a urine specimen for analysis *to rule out infection or glucosuria*.
- Review with client the physiologic basis for the increased frequency during pregnancy; inform client that frequency should abate during the second trimester and that it most likely will return during her third trimester. *This will promote understanding of the problem*.
- Encourage the client to empty her bladder when first feeling a sensation of fullness *to minimize risk of urinary retention*.
- Suggest client avoid caffeinated drinks, *which can stimulate the need to void*.
- Encourage client to drink adequate amounts of fluid throughout the day; however, have client reduce her fluid intake before bedtime *to reduce nighttime urination*.
- Urge client to keep perineal area clean and dry *to prevent irritation and excoriation from any leakage*.
- Instruct client in Kegel exercises *to increase perineal muscle tone and control over leakage*.
- Teach client about the signs and symptoms of urinary tract infection and urge her to report them should they occur *to ensure early detection and prompt intervention*.

NURSING ANALYSIS: Malnutrition risk related to nausea and vomiting

OUTCOME IDENTIFICATION AND EVALUATION

The client will ingest adequate amounts of nutrients for maternal and fetal well-being as evidenced by acceptable weight gain pattern and statements indicating an increase in food intake with a decrease in the number of episodes of nausea and vomiting.

INTERVENTIONS: ***Promoting Adequate Nutrition***

- Obtain weight and compare to baseline *to determine effects of nausea and vomiting on nutritional intake*.
- Review client's typical dietary intake over 24 hours *to determine nutritional intake and patterns so that suggestions can be individualized*.
- Encourage client to eat five or six small frequent meals throughout the day *to prevent her stomach from becoming empty*.
- Suggest that she munch on dry crackers, toast, cereal, or cheese, or drink a small amount of lemonade before arising *to minimize nausea*.
- Encourage client to arise slowly from bed in the morning and avoid sudden movements *to reduce stimulation of the vomiting center*.
- Advise client to drink fluids between meals rather than with meals *to avoid overdistention of the abdomen and subsequent increase in abdominal pressure*.
- Encourage her to increase her intake of foods high in vitamin B6 such as meat, poultry, bananas, fish, green leafy vegetables, peanuts, raisins, walnuts, and whole grains, as tolerated, *to ensure adequate nutrient intake*.
- Advise the client to avoid greasy, fried, or highly spiced foods and to avoid strong odors, including foods such as cabbage, *to minimize gastrointestinal upset*.
- Encourage the client to avoid wearing tight or restrictive clothes *to minimize pressure on the expanding abdomen*.
- Arrange for consultation with nutritionist as necessary *to assist with diet planning*.

- Ingest prunes or prune juice which are natural laxatives.
- Consume warm liquids (e.g., tea) upon rising to stimulate peristalsis.
- Exercise each day (brisk walking) to promote movement through the intestine.
- Reduce the amount of cheese consumed.

Heartburn/Indigestion

- Avoid spicy or greasy foods and eat small frequent meals.
- Sleep on several pillows so that your head is elevated 30 degrees.
- Stop smoking and avoid caffeinated drinks to reduce stimulation.
- Avoid lying down for at least 3 hours after meals.
- Try drinking sips of water to reduce burning sensation.
- Avoid foods that trigger symptoms—fried foods, citrus, soda, chocolate.
- Take antacids sparingly if burning sensation is severe.

Braxton Hicks Contractions

- Keep in mind that these contractions are a normal sensation. Try changing your position or engaging in mild exercise to help reduce the sensation.
- Drink more fluids if possible.

First-Trimester Discomforts

During the first 3 months of pregnancy, the woman's body is undergoing numerous changes. Some women experience many discomforts, but others have few. These discomforts are caused by the changes taking place within the body and they pass as the pregnancy progresses.

Urinary Frequency or Incontinence

Urinary frequency or incontinence is common in the first trimester because the growing uterus compresses the bladder. This is also a common complaint during the third trimester, especially when the

fetal head settles into the pelvis. However, the discomfort tends to improve in the second trimester, when the uterus becomes an abdominal organ and moves away from the bladder region.

After infection and gestational diabetes have been ruled out as causative factors of increased urinary frequency, suggest that the woman decrease her fluid intake 2 to 3 hours before bedtime and limit her intake of caffeinated beverages. Increased voiding is normal, but encourage the client to report any pain or burning during urination. Also explain that increased urinary frequency may subside as she enters her second trimester, only to recur in the third trimester. Teach the client to perform pelvic floor muscle training exercises, also called Kegel exercises, to increase support of the uterus, bladder, small intestine, and rectum throughout the day to help strengthen perineal muscle tone, thereby enhancing urinary control and decreasing the possibility of incontinence.

Fatigue

Fatigue plagues all pregnant women, primarily in the first and third trimesters (the highest-energy levels typically occur during the second trimester), even if they get their normal amount of sleep at night. First-trimester fatigue is most often related to the many physical changes (e.g., increased oxygen consumption, increased levels of progesterone and relaxin, increased metabolic demands) and psychosocial changes (e.g., mood swings, multiple role demands) of pregnancy. Third-trimester fatigue can be caused by sleep disturbances from increased weight (many women cannot find comfortable sleeping positions due to the enlarging abdomen), physical discomforts such as heartburn, and insomnia due to mood swings, multiple role anxiety, and a decrease in exercise (Blackburn, 2018).

Once anemia, infection, and blood dyscrasias have been ruled out as contributing to the client's fatigue, advise her to arrange work, child care, and other demands in her life to permit additional rest periods. Work with the client to devise a realistic schedule for rest. Using pillows for support in the left-side–lying position relieves

pressure on major blood vessels that supply oxygen and nutrients to the fetus when resting (Fig. 12.8). Also recommend the use of relaxation techniques, providing instructions as necessary, and suggest she increase her daily exercise level.

FIGURE 12.8. Using pillows for support in the side-lying position.

Nausea and Vomiting

It is estimated that somewhere between 70% and 90% of pregnant women experience nausea and vomiting. In the United States, this translates to approximately 4 million women. It is found more often in Western countries and urban populations and is rare among Africans, Native Americans, Eskimos, and most Asian populations (Jordan et al., 2019). The problem is generally time-limited, with the onset about the 5th week after the last menstrual period, a peak at 8 to 12 weeks, and resolution by 16 to 18 weeks. Despite popular use of the term *morning sickness*, nausea and vomiting of pregnancy may persist throughout the day in the majority of affected women and has been found to be limited to the morning in less than 2% of women (Smith et al., 2020). The physiologic changes that cause

nausea and vomiting are unknown, but research suggests that unusually high levels of estrogen, progesterone, and hCG, and a vitamin B6 deficiency may be contributing factors. Symptoms generally last until the second trimester and are generally associated with positive pregnancy outcomes, in terms of lower rates of miscarriages, congenital malformations, and preterm births (Cunningham et al., 2018). In summary, the etiology of nausea and vomiting in pregnancy is physiologic, thus assessment of the condition focuses on severity, and the management is largely supportive.

Nausea and vomiting of pregnancy can take a physical and psychological toll on the pregnant woman, and may have an adverse effect on her partner, family members, and even coworkers. The burden it places on the woman is usually minimized, as it is considered a normal part of pregnancy, thus it may not be worthy of evaluation, diagnosis, management, and emotional support. As a result, it may not be taken seriously because it is so common and time-limited, leading some women to feel frustrated and feel guilty that they are even complaining about their symptoms. Nurses need to pick up on this, address it, and provide support for her.

The goal of treatment is to improve symptoms while minimizing risks to mother and fetus. Treatment management ranges from simple dietary modifications to drug therapy. To help alleviate nausea and vomiting, advise the woman to eat small, frequent meals that are bland and low in fat (five or six times a day) to prevent her stomach from becoming completely empty. Other helpful suggestions include eating dry crackers, Cheerios, or cheese or drinking lemonade before getting out of bed in the morning and increasing her intake of foods high in vitamin B6, such as meat, poultry, bananas, fish, green leafy vegetables, peanuts, raisins, walnuts, and whole grains, or making sure she is receiving enough vitamin B6 by taking her prescribed prenatal vitamins.

Pharmacologic treatment of nausea and vomiting in pregnancy is limited. The Food and Drug Administration (FDA) has approved vitamin B6 (pyridoxine) alone or in combination with doxylamine–pyridoxine (Diclegis) therapy for use during pregnancy, which seems

to work fairly well based on the current reviews (ACOG, 2018). Other pharmacotherapies that might be considered may include diphenhydramine (e.g., Benadryl); dimenhydrinate (e.g., Dramamine); meclinine (e.g., Antivert); prochlorperazine (e.g., Compazine); promethazine (e.g., Phenergan); or ondansetron (e.g., Zofran).

Other helpful tips to deal with nausea and vomiting include:

- Get out of bed in the morning slowly.
- Avoid sudden movements.
- Avoid triggers that stimulate or exacerbate nausea—strong food odors.
- Eat a high-protein snack before retiring at night to prevent an empty stomach.
- Take ginger (up to 1 g in divided doses daily; 250-mg capsules QID), which increases tone and peristalsis in the gastrointestinal tract.
- Open a window to remove odors of food being cooked.
- Eat more protein than carbohydrates and take in more liquids than solids.
- Limit intake of fluids or soups during meals (drink them between meals).
- Avoid fried foods and foods cooked with grease, oils, or fatty meats, because they tend to upset the stomach.
- Increase periods of rest.
- Suck on popsicles throughout the day.
- Avoid highly seasoned foods such as those cooked with garlic, onions, peppers, and chili.
- Drink a small amount of caffeine-free carbonated beverage (ginger ale) if nauseated.
- Trying acupressure using a wristband has been FDA-approved for nausea.
- Avoid wearing tight or restricting clothes, which might place increased pressure on the expanding abdomen.
- Avoid stress (Jordan et al., 2019; Kellerman & Rakel, 2019; King et al., 2019).

Breast Tenderness

As a result of increased estrogen and progesterone levels, which cause the fat layer of breasts to thicken and the number of milk ducts and glands to increase during the first trimester, many women experience breast tenderness. Offering a thorough explanation to the woman about the reasons for the breast discomfort is important. Wearing a larger bra with good support can help alleviate this discomfort. Advise her to wear a supportive bra, even while sleeping. As her breasts increase in size, advise her to change her bra size to ensure adequate support.

Constipation

Constipation affects up to 38% of pregnancies (Yikar & Nazik, 2019). Increasing levels of progesterone during pregnancy lead to decreased contractility of the gastrointestinal tract, slowed movement of substances through the colon, and a resulting increase in water absorption. All of these factors lead to constipation. Lack of exercise or too little fiber or fluids in the diet can also promote constipation. In addition, the large bowel is mechanically compressed by the enlarging uterus, adding to this discomfort. The iron and calcium in prenatal vitamins can also contribute to constipation during the first and third trimesters.

Explain how pregnancy exacerbates the symptoms of constipation and offer the following suggestions:

- Eat fresh or dried fruit daily.
- Eat more raw fruits and vegetables, including their skins.
- Eat whole-grain cereals and breads such as raisin bran or bran flakes.
- Participate in physical activity every day.
- Engage in pelvic floor exercises, stretching exercises, and yoga daily.
- Eat meals at regular intervals.
- Establish a time of day to defecate, and elevate feet on a stool to avoid straining.
- Drink six to eight glasses of water daily.

- Decrease intake of refined carbohydrates.
- Drink warm fluids upon arising to stimulate bowel motility.
- Decrease consumption of sugary sodas.
- Avoid eating large amounts of cheese.

If the suggestions above are ineffective, suggest that the woman use a bulk-forming laxative such as Metamucil.

Nasal Stuffiness, Bleeding Gums, and Epistaxis (Nosebleeds)

Increased levels of estrogen cause edema of the mucous membranes of the nasal and oral cavities. Advise the woman to drink extra water for hydration of the mucous membranes or to use a cool mist humidifier in her bedroom at night. If she needs to blow her nose to relieve nasal stuffiness, advise her to blow gently, one nostril at a time. Advise her to avoid the use of nasal decongestants and sprays.

If a nosebleed occurs, advise the woman to loosen the clothing around her neck, sit with her head tilted forward, pinch her nostrils with her thumb and forefinger for 10 to 15 minutes, and apply an ice pack to the bridge of her nose.

If the woman has bleeding gums, encourage her to practice good oral hygiene by using a soft toothbrush and flossing daily. Warm saline mouthwashes can relieve discomfort. If the gum problem persists, instruct her to see her dentist.

Cravings

Food craving refers to an intense desire to consume a specific food. Desires for certain foods and beverages are likely to begin during the first trimester but do not appear to reflect any physiologic need. Foods with a high sodium or sugar content are often the ones craved. At times, some women crave nonfood substances such as clay, cornstarch, laundry detergent, baking soda, soap, paint chips, dirt, ice, or wax. As explained in Chapter 11, this craving for nonfood substances, termed “pica,” may indicate a severe dietary deficiency

of minerals or vitamins, or it may have cultural roots (Kane & Prelack, 2019).

Leukorrhea

Increased vaginal discharge begins during the first trimester and continues throughout pregnancy. The physiologic changes behind leukorrhea arise from the high levels of estrogen, which cause increased vascularity and hypertrophy of cervical glands as well as vaginal cells (Cunningham et al., 2018). The result is progressively increasing vaginal secretions throughout pregnancy.

Advise the woman to keep the perineal area clean and dry, washing the area with mild soap and water during her daily shower. Also recommend that she avoid wearing pantyhose and other tight-fitting nylon clothes that prevent air from circulating to the genital area. Encourage the use of cotton underwear and suggest wearing a nightgown rather than pajamas to allow for increased airflow. Also instruct the woman to avoid douching and tampon use.

Second-Trimester Discomforts

A sense of well-being typically characterizes the second trimester for most women. By this time, the fatigue, nausea, and vomiting have subsided and the uncomfortable changes of the third trimester are a few months away. Not every woman experiences the same discomforts during this time, so nursing assessments and interventions must be individualized.

Backache

Musculoskeletal pain is a common occurrence during pregnancy and the postpartum period. Up to 75% of women report having back pain at some point during pregnancy. This can seriously impact the quality of life of women and have socioeconomic impacts from lost days at work. The pain can be lumbar or sacroiliac. The pain may also be present only at night. Back pain is thought to be due to multiple factors, which include shifting of the center of gravity caused

by the enlarging uterus, increased joint laxity due to an increase in relaxin, stretching of the ligaments (which are pain-sensitive structures), and pregnancy-related circulatory changes.

Treatment includes heat and ice, acetaminophen, massage, proper posturing, good support shoes, and a good exercise program for strength and conditioning. Pregnant women may also relieve back pain by placing one foot on a stool when standing for long periods of time and placing a pillow between the legs when lying down (Jordan et al., 2019). After ruling out other potential causes such as uterine contractions, urinary tract infection, ulcers, or musculoskeletal back disorders, the following instructions may be helpful:

- Maintain correct posture with head up and shoulders back.
- Wear low-heeled shoes with good arch support.
- Get daily exercise to strengthen back muscles.
- Swimming or aquatic therapy relieves joint and muscle pressure.
- Consider investing in a firm mattress for better back support.
- When standing for long periods, place one foot on a stool or box.
- Use good body mechanics when lifting objects.
- Sleep on one side with a pillow between the legs for support.
- When sitting, use foot supports and pillows behind the back.
- Try pelvic tilt or rocking exercises to strengthen the back (ACOG, 2019c).

The pelvic tilt or pelvic rock is used to alleviate pressure on the lower back during pregnancy by stretching the core lower back muscles. It can be done sitting, standing, or on all fours. To do it on all fours, the hands are positioned directly under the shoulders and the knees under the hips. The back should be in a neutral position with the head and neck aligned with the straight back. The woman then presses up with the lower back and holds this position for a few seconds, then relaxes to a neutral position. This action of pressing upward is repeated frequently throughout the day to prevent a sore back (Kellerman & Rakel, 2019).

Leg Cramps

Many women experience leg cramps in pregnancy, especially in the last trimester. They become more common as pregnancy progresses and are especially troublesome at night. They occur primarily in the second and third trimesters and could be related to the pressure of the gravid uterus on pelvic nerves and blood vessels. During pregnancy, up to 50% of women can be affected by leg cramps, and up to 25% can be affected by restless legs syndrome (King et al., 2019). Along with lack of exercise, diet can also be a contributing factor if the woman is not consuming enough of certain minerals, such as calcium and magnesium. The sudden stretching of leg muscles may also play a role in causing leg cramps (Office on Women's Health, 2019).

Encourage the woman to gently stretch the muscle by dorsiflexing the foot up toward the body. Wrapping a warm, moist towel around the leg muscle can also help the muscle relax. Advise the client to avoid stretching her legs, pointing her toes, and walking excessively. Stress the importance of wearing low-heeled shoes and support hose and arising slowly from a sitting position. If the leg cramps are due to deficiencies in minerals, the condition can be remedied by eating more foods rich in these nutrients. Also instruct the woman on calf-stretching exercises: have her stand 3 ft from the wall and lean toward it, resting her lower arms against it while keeping her heels on the floor. This may help reduce cramping if it is done before going to bed.

Elevating the legs throughout the day will help relieve pressure and minimize strain. Wearing support hose and avoiding curling the toes may help relieve leg discomfort. Also instruct the client to avoid standing in one spot for a prolonged period or crossing her legs. If she must stand for prolonged periods, suggest that she change her position at least every 2 hours by walking or sitting to reduce the risk of leg cramps. Encourage her to drink eight 8-oz glasses of fluid throughout the day to ensure adequate hydration. Taking daily walks can also help reduce leg cramping because ambulation improves circulation to the muscles.

Varicosities of the Vulva and Legs

Varicose veins are abnormally enlarged superficial veins due to vasodilation caused by progesterone's effects on the vessel walls and valves. Varicosities of the vulva and legs are associated with the increased venous stasis caused by the pressure of the gravid uterus on pelvic vessels. Progesterone relaxes the vein walls, making it difficult for blood to return to the heart from the extremities; pooling can result. Genetic predisposition, inactivity, obesity, and poor muscle tone are also contributing factors.

Exercise may prevent varicose veins if started early in the pregnancy. Encourage the client to wear support hose that have gradient pressure in them, and teach her how to apply them properly. Advise her to elevate her legs above her heart while lying on her back for 10 minutes before she gets out of bed in the morning, thus promoting venous return before she applies the hose. Instruct the client to avoid crossing her legs and avoid wearing knee-high stockings. They cause constriction of leg vessels and muscles and contribute to venous stasis. Also encourage the client to elevate both legs above the level of the heart for 5 to 10 minutes at least twice a day (Fig. 12.9); to wear low-heeled shoes; and to avoid long periods of standing or sitting, frequently changing her position. If the client has vulvar varicosities, suggest she apply ice packs to the area when she is lying down.

Hemorrhoids

Hemorrhoids are varicosities of the rectum and may be external (outside the anal sphincter) or internal (above the sphincter) (Kellerman & Rakel, 2019). They occur as a result of progesterone-induced vasodilation and from pressure of the enlarged uterus on the lower intestine and rectum. Hemorrhoids are more common in women with constipation, a low-fiber diet, poor fluid intake or poor dietary habits, smokers, sedentary lifestyle or those with a previous history of hemorrhoids (Sandler & Peery, 2019).

FIGURE 12.9. Woman elevating her legs while working.

Instruct the client in measures to prevent constipation, including increasing fiber intake and drinking at least 2 L of fluid per day. Recommend the use of topical anesthetics (e.g., Preparation H, Anusol, witch hazel compresses such as Tucks) to reduce pain, itching, and swelling, if permitted by the health care provider. Teach the client about local comfort measures such as warm sitz baths, witch hazel compresses, or cold compresses. To minimize her risk of straining while defecating, suggest that she elevates her feet on a stool. Also encourage her to avoid prolonged sitting or standing (Yikar & Nazik, 2019).

Flatulence with Bloating

Flatulence and gas pain are another result of decreased gastrointestinal motility. The physiologic changes that result in

constipation (reduced gastrointestinal motility and dilation secondary to progesterone's influence) may also result in increased flatulence. As the enlarging uterus compresses the bowel, it delays the passage of food through the intestines, thus allowing more time for gas to be formed by bacteria in the colon. The woman usually reports increased passage of rectal gas, abdominal bloating, or belching. Instruct the woman to avoid gas-forming foods, such as beans, cabbage, and onions, as well as foods that have a high content of white sugar. Adding more fiber to the diet, increasing fluid intake, and increasing physical exercise are also helpful in reducing flatus. In addition, reducing the amount of swallowed air, if chewing gum, will reduce gas buildup. The knee–chest position may also help with discomfort from unexpelled gas. Consuming six smaller meals a day will help avoid digestive system overload. Eating slowly can reduce air swallowing, and taking a brisk walk after meals will help mobilize gas for expulsion. Reducing the intake of carbonated beverages and cheese and eating mints can also help reduce flatulence during pregnancy. OTC mediations, such as Gas-X or Beano, may also help (Hubbard & Rizzolo, 2019).

Third-Trimester Discomforts

As women enter the third trimester, many experience a return of the first-trimester discomforts of fatigue, urinary frequency, leukorrhea, and constipation. These discomforts are secondary to the enlarging uterus compressing adjacent structures, increasing hormone levels, and the metabolic demands of the fetus. In addition to these discomforts, many women experience shortness of breath, heartburn and indigestion, swelling, and Braxton Hicks contractions.

Shortness of Breath and Dyspnea

Dyspnea is a common complaint in pregnant women during the first and third semesters. Physiologic and hemodynamic changes can result in significant dyspnea in such cases. In some women, dyspnea in normal daily activities can be a sign of heart and lung

disease and may be associated with poor perinatal and cardiac outcomes in which early detection can prevent adverse events. The increasing growth of the uterus prevents complete lung expansion late in pregnancy. As the uterus enlarges upward in the second and third trimesters, the expansion of the diaphragm is limited. Dyspnea can occur when the woman lies on her back and the pressure of the gravid uterus against the vena cava reduces venous return to the heart (Jordan et al., 2019).

Reassure the woman that dyspnea is normal and will improve when the fetus drops into the pelvis (lightening). Instruct her to adjust her body position to allow for maximum expansion of the chest and to avoid large meals, which increase abdominal pressure. Raising the head of the bed on blocks or placing pillows behind the back can be helpful too. Under normal circumstances, resting with the head elevated while taking slow, deep breaths reduces shortness of breath. In addition, emphasize that lying on the left side will displace the uterus off the vena cava and improve breathing. Having the woman periodically stand up and stretch her arms above her head and take a deep breath is helpful with relieving dyspnea. Also, advise the woman to avoid exercise that precipitates dyspnea, to rest after exercise, and to avoid overheating in warm climates. If she still smokes, encourage her to stop.

Heartburn and Indigestion

Heartburn, also termed gastroesophageal reflux, is common during pregnancy. Heartburn and indigestion result when high progesterone levels cause relaxation of the cardiac sphincter, allowing food and digestive juices to flow backward from the stomach into the esophagus. Irritation of the esophageal lining occurs, causing the burning sensation known as heartburn. It occurs in up to 80% of women at some point during pregnancy with an increased frequency seen in the third trimester (King et al., 2019). The pain may radiate to the neck and throat. It worsens when the woman lies down, bends over after eating, or wears tight clothes. Indigestion (vague abdominal discomfort after meals) results from eating too much or

too fast; from eating when tense, tired, or emotionally upset; from eating food that is too fatty or spicy; and from eating heavy food or food that has been badly cooked or processed (Lee et al., 2019). In addition, the stomach is displaced upward and compressed by the large uterus in the third trimester, thus limiting the stomach's capacity to empty quickly. Food sits, causing heartburn and indigestion.

Review the client's usual dietary intake and suggest that she limit or avoid gas-producing or fatty foods and large meals. Instruct the woman to pay attention to the timing of the discomfort. Usually it is heartburn when the pain occurs 30 to 45 minutes after a meal. Encourage the client to maintain proper posture and remain in the sitting position for 1 to 3 hours after eating to prevent reflux of gastric acids into the esophagus by gravity. Urge the client to consume small, frequent meals and eat slowly, chewing her food thoroughly to prevent excessive swallowing of air, which can lead to increased gastric pressure. Instruct the client to avoid foods that act as triggers such as caffeinated drinks; greasy, gas-forming foods; citrus; spiced foods; chocolate; coffee; alcohol; and spearmint or peppermint. These items stimulate the release of gastric digestive acids, which may cause reflux into the esophagus. She should avoid late-night or large meals and gum chewing and avoid lying down within 3 hours after eating. Finally, elevating the head of the bed by 10 to 30 degrees may help.

Dependent Edema

Total body fluids increase by 6 to 8 L during pregnancy, most of which is extracellular. Swelling is the result of increased capillary permeability caused by elevated hormone levels and increased blood volume. Sodium and water are retained, and thirst increases. Edema occurs most often in dependent areas such as the legs and feet throughout the day due to gravity; it improves after a night's sleep. Warm weather or prolonged standing or sitting may increase edema. Generalized edema appearing in the face, hands, and feet can signal preeclampsia if accompanied by dizziness, blurred vision,

headaches, upper quadrant pain, or nausea (Norwitz et al., 2019). This edema should be reported to the health care provider. Appropriate suggestions to minimize dependent edema include:

- Elevate your feet and legs above the level of the heart periodically throughout the day.
- Wear compression stockings when standing or sitting for long periods.
- Change position frequently throughout the day.
- Walk at a sensible pace to help contract leg muscles to promote venous return.
- When taking a long car ride, stop to walk around every 2 hours.
- When standing, rock from the ball of the foot to the toes to stimulate circulation.
- Lie on your left side to keep the gravid uterus off the vena cava to return blood to the heart.
- Avoid foods high in sodium, such as lunch meats, potato chips, and bacon.
- Avoid wearing knee-high stockings.
- Drink six to eight glasses of water daily to replace fluids lost through perspiration.
- Avoid high intake of sugar and fats because they cause water retention.

Braxton Hicks Contractions

Braxton Hicks contractions are irregular, painless contractions that occur without cervical dilation. Typically, they intensify in the third trimester in preparation for labor. In reality, they have been present since early in the pregnancy but may have gone unnoticed. They are thought to increase the tone of uterine muscles for labor purposes (Jordan et al., 2019).

CONSIDER THIS

One has to wonder sometimes why women go through what they do. During my first pregnancy, I was sick for the first 2 months. I would experience waves of nausea from the moment I got out of bed until midmorning. Needless to say, I wasn't the happiest. After the 3rd month, my life seemed to settle down, and I was beginning to think that being pregnant wasn't too bad after all. For the moment, I was fooled. Then, during my last 2 months, another wave of discomfort struck—heartburn and constipation—a double whammy! I now feared eating anything that might trigger acid indigestion and also might remain in my body too long. I literally had to become the "fiber queen" to combat these two challenges. However, my suffering was well worth our bright-eyed baby girl in the end.

Thoughts: Despite the various discomforts associated with pregnancy, most women wouldn't change the end result. Do most women experience these discomforts? What suggestions could be made to reduce them?

Reassure the client that these contractions are normal. Instruct the client in how to differentiate between Braxton Hicks and labor contractions. Explain that true labor contractions usually grow longer, stronger, and closer together and occur at regular intervals. Walking usually strengthens true labor contractions, while Braxton Hicks contractions tend to decrease in intensity and taper off. Advise the client to keep herself well hydrated and to rest in a left-side–lying position to help relieve the discomfort. Suggest that she use breathing techniques to ease the discomfort.

NURSING MANAGEMENT TO PROMOTE SELF-CARE

Pregnancy is a natural event for many women and should be considered a time of health, not illness. Health promotion and maintenance activities are essential to promoting an optimal

outcome for the woman and her fetus. Studies have shown that improvement in maternal awareness and self-care activities during pregnancy encourages women to practice such care and subsequently reduce pregnancy complications (Solhi et al., 2019). Pregnant women commonly have many questions about the changes occurring during pregnancy: how these changes affect usual routines, such as working, traveling, exercising, or engaging in sexual activity; how the changes influence typical self-care activities, such as bathing, perineal care, or dental care; and whether these changes are signs of a problem.

TAKE NOTE!

Women may have heard stories about or been told by many others what to do and what not to do during pregnancy, leading to many misconceptions and much misinformation.

Nurses can play a major role in providing anticipatory guidance and teaching to foster the woman's responsibility for self-care, helping to clarify misconceptions and correct any misinformation. Educating the client to identify threats to safety posed by her lifestyle or environment and proposing ways to modify them to avoid a negative outcome are important. Counseling should also include healthy ways to prepare food, advice to avoid medications unless they are prescribed for her, and advice on identifying teratogens within her environment or at work and how to reduce her risk from exposure. The pregnant client can better care for herself and the fetus if her concerns are anticipated and identified by the nurse and are incorporated into teaching sessions at each prenatal visit.

Personal Hygiene

Hygiene is a necessity for the maintenance of good health. Cleansing the skin removes dirt, bacteria, sweat, dead skin cells, and body secretions. Counsel women to wash their hands and under

their fingernails frequently throughout the day in order to lower the bacterial count on both. During pregnancy, a woman's sebaceous (sweat) glands become more active under the influence of hormones, and sweating is more profuse. This increase may make it necessary to use a stronger deodorant and shower more frequently. The cervical and vaginal glands also produce more secretions during pregnancy. Frequent showering helps keep the area dry and promotes better hygiene. Encourage the use of cotton underwear to allow greater air circulation. Taking a tub bath in early pregnancy is permitted, but closer to term, when the woman's center of gravity shifts, it is safer to shower to prevent the risk of slipping.

Hot Tubs and Saunas

Caution pregnant women to avoid using hot tubs, saunas, whirlpools, and tanning beds during pregnancy. The heat may cause fetal tachycardia as well as raise the maternal temperature. Exposure to bacteria in hot tubs that have not been cleaned sufficiently is another reason to avoid them during pregnancy.

Perineal Care

The glands in the cervical and vaginal areas become more active during pregnancy secondary to hormonal influences. This increase in activity will produce more vaginal secretions, especially in the last trimester. Advise pregnant women to shower frequently and wear all-cotton underwear to minimize the effects of these secretions. Caution pregnant women not to douche, because douching can increase the risk of infection, and not to wear panty liners, which block air circulation and promote moisture. Explain that they should also avoid perfumed soaps, lotions, perineal sprays, and harsh laundry detergents to help prevent irritation and potential infection.

Dental Care

Oral health is integral to systemic health and has profound effects during pregnancy. Physiologic changes that occur in pregnant

women, however, can adversely affect oral health. Elevations in estrogen and progesterone enhance the inflammatory response and consequently alter gingival tissue. During pregnancy, the incidence of gingivitis and periodontitis increases (Marchi et al, 2019). Pregnancy is a time when a woman can be receptive to health messaging. Pregnancy is no longer a contraindication for dental treatment; it is also a time when nurses can help clients understand that good oral health is important to a healthy pregnancy and can decrease the risk of dental caries in their children. When women see oral health as a priority for themselves, they are more likely to place a high priority on their children's oral health.

Periodontal disease is a contributing factor to systemic conditions, such as heart disease, respiratory diseases, diabetes mellitus, adverse pregnancy outcomes (preterm births, low–birth-weight infants, and small-for-gestational-age infants), anemia, and stroke (Komine-Aizawa et al., 2019). Research has established that the elevated levels of estrogen and progesterone during pregnancy cause women to be more sensitive to the effects of bacterial dental plaque, which can cause gingivitis, an oral infection characterized by swollen and bleeding gums (Jordan et al., 2019). Brushing and flossing teeth twice daily will help reduce bacteria in the mouth. Advise the woman to visit her dentist early in the pregnancy to address any dental caries and have a thorough cleaning to prevent possible infection later in the pregnancy. Advise her to avoid exposure to x-rays by informing the hygienist of the pregnancy. If x-rays are necessary, the abdomen should be shielded with a lead apron.

Researchers have reported an association between prematurity and periodontitis, an oral infection that spreads beyond the gum tissues to invade the supporting structures of the teeth. Periodontitis is characterized by bleeding gums, loss of tooth attachment, loss of supporting bone, and bad breath due to pus formation. Unfortunately, because this infection is chronic and often painless, women frequently do not realize they have it, and preterm birth, FGR, low birth weight, preeclampsia, and/or gestational diabetes can result. During pregnancy, gingivitis occurs in 35% to 100% of women

and periodontitis can lead to loss of teeth (Komine-Aizawa et al., 2019). Nurses should assess all pregnant women's oral health status by taking oral health histories; checking their mouths for swollen or bleeding gums, untreated dental decay, mucosal lesions, and signs of infection; and document findings in the prenatal record. Oral health care and dental interventions should be completed before conception to prevent adverse pregnancy outcomes.

Additional guidelines that the nurse should stress regarding maintaining dental health include:

- Seek professional dental care before conception or during the first trimester for assessment and care.
- Be reassured that typical medications used in dental procedures are safe for the fetus.
- Be sure that lead aprons are used if dental x-rays are taken to protect the fetus.
- Be reassured that oral health care is safe during pregnancy in any trimester.
- Obtain treatment for dental pain and infection promptly during pregnancy.
- Brush twice daily for 2 minutes, especially before bed, with fluoridated toothpaste and rinse well. Use a soft-bristled toothbrush and be sure to brush at the gum line to remove food debris and plaque to keep gums healthy.
- Floss teeth daily with dental floss, and rinse well afterward with plain water.
- Eat healthy foods, especially those high in vitamins A, C, and D, and calcium.
- Avoid sugary snacks.
- Chew sugar-free gum for 10 minutes after a meal if brushing is not possible.
- After vomiting, rinse your mouth immediately with baking soda (1/4 tsp) and warm water (1 c) to neutralize the acid (Jordan et al., 2019).

Breast Care

Because the breasts enlarge significantly and become heavier throughout pregnancy, stress the need to wear a firm, supportive bra with wide straps to balance the weight of the breasts. Instruct the woman to anticipate buying a larger-sized bra about halfway through her pregnancy because of the increasing size of the breasts. Advise her to avoid using soap on the nipple area because it can be drying. Encourage her to rinse the nipple area with plain water while bathing to keep it clean. The Montgomery glands (located in the areolar part of the nipple) secrete a lubricating substance that keeps the nipples moist and discourages growth of bacteria, so there is no need to use alcohol or other antiseptics on the nipples.

If the mother has chosen to breastfeed, nipple preparation is unnecessary unless her nipples are inverted and do not become erect when stimulated. Breast shells can be worn during the last 2 months to address this issue (Lee et al., 2019).

Around week 16 of pregnancy, colostrum secretion begins, which the woman may notice as moisture in her bra. Advise the woman to place breast pads or a cotton cloth in her bra and change them frequently to prevent buildup, which may lead to excoriation.

Clothing

Many clothes are loose-fitting and layered, so the woman may not need to buy an entirely new wardrobe to accommodate her pregnancy. Some pregnant women may continue to wear tight clothes. Point out that loose clothing may be more comfortable for the client and her expanding waistline.

Advise pregnant women to avoid wearing constricting clothes and girdles that compress the growing abdomen. Urge the woman to avoid knee-high pantyhose, which might impede lower-extremity circulation and increase the risk of developing DVT. Low-heeled shoes will minimize pelvic tilt and possible backache. Wearing layered clothing that can be removed as the temperatures fluctuate may be more comfortable, especially toward term, when the woman may feel overheated.

Exercise

Regular physical exercise improves cardiovascular health, reduces obesity and associated medical comorbidities, and improves longevity. A physically inactive lifestyle is associated with an increase in chronic diseases such as cardiovascular disease, type 2 diabetes, osteoporosis, and cancer. The proportion of pregnant women who are overweight or obese is increasing globally, so exercise is essential to reduce these risks and promote a healthy pregnancy. Exercise is well tolerated by a healthy woman during pregnancy. It promotes a feeling of well-being; improves circulation; helps reduce constipation, bloating, and swelling; may help prevent or treat gestational diabetes; promotes muscle tone, strength, and endurance; may improve the woman's ability to cope with labor; increases energy level; improves posture; helps sleep and promotes relaxation and rest; and relieves the lower back discomfort that often arises as the pregnancy progresses (Santos-Rocha, 2019). However, the duration and difficulty of exercise should be modified throughout pregnancy because of a decrease in performance efficiency with gestational age. At least 30 minutes of moderate-intense physical activity daily is recommended. Some women continue to push themselves to maintain their prior level of exercise, but most find that as their shape changes and their abdominal area enlarges, they must modify their exercise routines. Modification also helps to reduce the risk of injury caused by laxity of the joints and connective tissue due to the hormonal effects (Santos-Rocha, 2019). Exercise during pregnancy is contraindicated in women with preterm labor, poor weight gain, anemia, facial and hand edema, pain, hypertension, threatened abortion, dizziness, shortness of breath, multiple gestation, decreased fetal activity, ruptured membranes, severe anemia, restrictive lung disease, cardiac disease, and palpitations (Norwitz et al., 2019).

Federal physical activity guidelines recommend at least 150 minutes of moderate-intensity exercise per week during pregnancy (Fig. 12.10) (King et al., 2019). It is believed that pregnancy is a unique time for behavior modification and that healthy behaviors

maintained or adopted during pregnancy may improve the woman's health for the rest of her life. The excess weight gained in pregnancy, which some women never lose, contributes to a major public health problem (Santos-Rocha, 2019). Exercise helps the woman avoid gaining excess weight during pregnancy.

FIGURE 12.10. Exercising during pregnancy.

Exercise during pregnancy helps return a woman's body to good health after the baby is born. The long-term benefits of exercise that begin in early pregnancy include improved posture, weight control, and improved muscle tone. Exercise also aids in the prevention of osteoporosis after menopause, reduces the risk of hypertension and diabetes, and assists in keeping the birth weight of the fetus within the normal range (Davies & Artal, 2019). Teaching Guidelines 12.2 highlights recommendations for exercise during pregnancy.

TEACHING GUIDELINES 12.2

Promoting Exercise during Pregnancy

- Consume liquids before, during, and after exercising.
- Consult with your health care provider before you start a new exercise routine.
- Avoid exercising in hot, humid weather or when you have a fever.
- Stop exercising if you experience vaginal bleeding, dizziness, chest pain, headache, muscle weakness, calf pain or swelling, uterine contractions, decreased fetal movement, or fluid leaking from the vagina.
- Exercise three or four times each week, not sporadically.
- Engage in brisk walking, swimming, biking, or low-impact aerobics; these are considered ideal activities.
- Avoid getting overheated during exercise.
- Wear comfortable exercise footwear that gives strong ankle and arch support.
- Contact sports should be avoided during pregnancy.
- Include relaxation and stretching before and after your exercise program.
- Reduce the intensity of workouts in late pregnancy.
- Avoid jerky, bouncy, or high-impact movements.
- Avoid lying flat (supine) after the 4th month because of hypotensive effect.
- Use pelvic tilt and pelvic rocking to relieve backache.
- Start with 5 to 10 minutes of stretching exercises.
- Rise slowly following an exercise session to avoid dizziness.
- Avoid activities such as skiing, surfing, scuba diving, and ice hockey.
- Never exercise to the point of exhaustion.

Davies, G., & Artal, R. (2019). It's time to treat exercise in pregnancy as therapy. British Journal of Sports Medicine, 53(2), 81. http://dx.doi.org/10.1136/bjsports-2018-100360; Santos-Rocha, R. (2019). *Exercise and sporting activity during pregnancy: Evidence-based guidelines*. Springer International Publishing; and King, T. L., Brucker, M. C., Jevitt, C., & Osborne, K. (2019). *Varney's midwifery* (6th ed.). Jones & Bartlett Learning.

Sleep and Rest

Getting enough sleep helps a person feel better and promotes optimal performance levels during the day. The body releases its greatest concentration of growth hormone during sleep, helping the body repair damaged tissue and grow. Also, with the increased metabolic demands during pregnancy, fatigue is a constant challenge to many pregnant women, especially during the first and third trimesters. The following tips can help promote adequate sleep:

- Stay on a regular schedule by going to bed and waking up at the same times.
- Eat regular meals at regular times to keep external body cues consistent.
- Take time to unwind and relax before bedtime.
- Avoid alcohol and nicotine because both disrupt sleep.
- Establish a bedtime routine or pattern and follow it.
- Avoid any electronic screen use for at least 1 hour prior to bedtime.
- Create a proper sleep environment by reducing the light and lowering the room temperature.
- Go to bed when you feel tired; if sleep does not occur, read a book until you are sleepy.
- Reduce caffeine intake later in the day.
- Limit fluid intake after dinner to minimize trips to the bathroom.
- Exercise daily to improve circulation and well-being.
- Use a modified Sims position to improve circulation in the lower extremities.
- Avoid lying on your back after the 4th month, which may compromise circulation to the uterus.
- Avoid sharply bending your knees, which promotes venous stasis below the knees.
- Keep anxieties and worries out of the bedroom. Set aside a specific area in the home or time of day for them.

Sexual Activity and Sexuality

Sexuality is an important part of health and well-being. Pregnancy is characterized by intense biologic, psychological, and social changes.

These changes have direct and indirect, conscious and unconscious effects on a woman's sexuality. The woman experiences dramatic alterations in her physiology, her appearance, and her body, as well as her relationships. The only contraindications to sexual intercourse during pregnancy include unexplained vaginal bleeding, placenta previa, ruptured membranes, and preterm contractions. A woman's sexual responses during pregnancy vary widely. Common symptoms such as fatigue, nausea, vomiting, breast soreness, and urinary frequency may reduce her desire for sexual intimacy. However, many women report enhanced sexual desire due to increasing levels of estrogen. Usually, sexual satisfaction does not change in pregnancy compared with the prepregnancy patterns despite a decline of sexual activity during the third trimester. A discussion of expected changes in sexuality should be routinely done in order to improve a couple's perception of possible sexual modifications induced by pregnancy. It is clear that despite some difficulties related to sexual activity during pregnancy, its need and importance are recognized for both participants.

TAKE NOTE!

Fluctuations in sexual desire are normal and a highly individualized response throughout pregnancy.

The physical and emotional adjustments of pregnancy can cause changes in body image, fatigue, mood swings, and sexual activity. The woman's changing shape, emotional status, fetal activity, changes in breast size, pressure on the bladder, and other common discomforts of pregnancy result in increased physical and emotional demands. These can produce stress on the sexual relationship of the pregnant woman and her partner. However, most women adjust well to the alterations and experience a satisfying sexual relationship. Research indicates that sexual intercourse is safe in the absence of ruptured membranes, bleeding, or placenta previa, but

pregnant women engage in sex less often as the pregnancy progresses (Jordan et al., 2019).

Often, pregnant women ask whether sexual intercourse is allowed during pregnancy or whether there are specific times when they should refrain from having sex. This is a good opportunity to educate clients about sexual behavior during pregnancy and also to ask about their expectations and individual experience related to sexuality and possible changes. It is also a good time for nurses to address the impact of the changes associated with pregnancy on sexual desire and behavior. Couples may enjoy sexual activity more because there is no fear of pregnancy and no need to disrupt spontaneity by using birth control. An increase in pelvic congestion and lubrication secondary to estrogen influence may heighten orgasm for many women. Some women have a decrease in desire because of a negative body image, fear of harming the fetus by engaging in intercourse, and fatigue, nausea, and vomiting (Jordan et al., 2019). Condom use can be recommended to decrease the release of prostaglandins in the semen that may stimulate contractions. A couple may need assistance to adjust to the various changes brought about by pregnancy.

Reassure the woman and her partner that sexual activity is permissible during pregnancy unless there is a history of:

- vaginal bleeding.
- placenta previa.
- risk of preterm labor.
- premature cervical dilation.
- premature rupture of membranes.
- presence of infection (Gunasekaran & Khan, 2019).

Inform the couple that the fetus will not be injured by intercourse. Suggest that alternative positions may be more comfortable (e.g., woman on top, side-lying), especially during the later stages of pregnancy. Some of the physical changes in pregnancy, which can affect a couple’s relationship, for example, halitosis which can result from dehydration, can still be alleviated, in this case with extra fluids and better oral hygiene. Women can have breast tenderness and

skin changes that can cause them to feel unattractive to the partner during pregnancy. In addition, they can be worried about increases in vaginal discharge and need to know what is normal and what can be a sign of infection. Nurses should make women feel comfortable talking about their fears, encouraging them to find acceptance of their changing bodies.

Women will experience a myriad symptoms, feelings, and physical sensations during pregnancy. Having a satisfying sexual relationship during pregnancy is certainly possible, but it requires honest communication between partners to determine what works best for them and a good relationship with the health care provider to ensure safety (Gunasekaran & Khan, 2019).

Employment

Nearly three quarters of pregnant women in the United States will continue to work outside the home until the last month of pregnancy (Jordan et al., 2019). For the most part, women can continue working until giving birth if they have no complications during pregnancy and the workplace does not present any special hazards. Hazardous occupations include health care workers, daycare providers, laboratory technicians, chemists, painters, hairstylists, veterinary workers, and carpenters (ACOG, 2019d). Jobs requiring strenuous work such as heavy lifting, climbing, carrying heavy objects, and standing for prolonged periods place a pregnant woman at risk if modifications are not instituted.

Assess for environmental and occupational factors that place the pregnant women and her fetus at risk for injury. Interview the woman about her employment environment. Ask about possible exposure to teratogens (substances with the potential to alter the fetus permanently in form or function) and the physical demands of employment: Is she exposed to temperature extremes? Does she need to stand for prolonged periods in a fixed position? A description of the work environment is important in providing anticipatory guidance to the woman. Stress the importance of taking rest periods throughout the day, because constant physically intensive workloads

increase the likelihood of low birth weight and preterm labor and birth (Cunningham et al., 2018).

Because of the numerous physiologic and psychosocial changes that women experience during their pregnancies, the employer may need to make special accommodations to reduce the pregnant woman's risk of hazardous exposures and heavy workloads. The employer may need to provide adequate coverage so that the woman can take rest breaks; remove the woman from any areas where she might be exposed to toxic substances; and avoid work assignments that require heavy lifting, hard physical labor, continuous standing, or constant moving. Some recommendations for working while pregnant are provided in Teaching Guidelines 12.3.

TEACHING GUIDELINES 12.3
Teaching for the Pregnant Working Woman

- Plan to take two 10- to 15-minute breaks within an 8-hour work day.
- Be sure there is a place available for you to rest, preferably in the side-lying position, with a restroom readily available.
- Avoid jobs that require strenuous workloads; if this is not possible, then request a modification of work duties (lighter tasks) to reduce your workload.
- Change your position from standing to sitting or vice versa at least every 2 hours.
- Ensure that you are allowed time off without penalty, if necessary, to ensure a healthy outcome for you and your fetus.
- Make sure the work environment is free of toxic substances.
- Ensure the work environment is smoke-free so passive smoke inhalation is not a concern.
- Minimize heavy lifting if associated with bending.

Travel

Pregnancy does not curtail a woman's ability to travel in a car or in a plane. However, women should follow a few safety guidelines to minimize risk to themselves and their fetuses. According to ACOG (2019d), pregnant women can travel safely throughout pregnancy, although the second trimester is perhaps the best time to travel because there is the least chance of complications. Pregnant women considering international travel should evaluate the problems that could occur during the journey as well as the quality of medical care available at the destination.

A woman in the third trimester should be advised to defer overseas travel because of concerns about access to medical care in case of problems such as hypertension; Zika virus and malaria infection from mosquito bites; phlebitis; or premature labor (CDC, 2019f). Pregnant women should be advised to consult with their health care providers before making any travel decisions.

TAKE NOTE!

Clinical manifestations that indicate the need for immediate medical attention while traveling are vaginal bleeding, passing tissue or clots, abdominal pain or cramps, contractions, ruptured membranes, excessive leg swelling or pain, headaches, or visual problems (King et al., 2019).

Advise pregnant women to be aware of the potential for injuries and traumas related to traveling, and teach women ways to prevent these from occurring. Teaching Guidelines 12.4 offers tips for safe travel on planes and to foreign areas.

TEACHING GUIDELINES 12.4

Promoting Safe Travel on Planes and in Foreign Countries

- Bring along a copy of the prenatal record if your travel will be prolonged in case there is a medical emergency away from home.
- When traveling abroad, carry a foreign dictionary that includes words or phrases for the most common pregnancy emergencies.
- Travel with at least one companion at all times for personal safety.
- Check with your health care provider before receiving any immunizations necessary for foreign travel; some may be harmful to the fetus.
- When in a foreign country, avoid fresh fruit, vegetables, and local water.
- Avoid any milk that is not pasteurized.
- Eat only meat that is well cooked to avoid exposure to toxoplasmosis.
- Request an aisle seat and walk about the airplane every 2 hours.
- While sitting on long flights, practice calf-tensing exercises to improve circulation to the lower extremities.
- Be aware of typical problems encountered by pregnant travelers, such as fatigue, heartburn, indigestion, constipation, vaginal discharge, leg cramps, urinary frequency, and hemorrhoids.
- Always wear support hose while flying to prevent the development of blood clots.
- Drink plenty of water to keep well hydrated throughout the flight.
- Postpone travel if risks outweigh benefits.

Centers for Disease Control and Prevention (CDC). (2020f). *Pregnant travelers*. Retrieved June 16, 2020, from https://wwwnc.cdc.gov/travel/page/pregnant-travelers; American College of Obstetricians and Gynecologists (ACOG). (2019f). *ACOG Committee Opinion 443: Air travel during pregnancy*. Retrieved June 16, 2020, from https://www.acog.org/Clinical-Guidance-and-Publications/Committee-Opinions/Committee-on-Obstetric-Practice/Air-Travel-During-Pregnancy?IsMobileSet=false.

When traveling by car, the major risk is a car accident. Motor vehicle accidents account for more than 50% of all traumas during

pregnancy and a large percentage of fetal deaths occurring during these accidents (Norwitz et al., 2019). The impact and momentum can lead to traumatic separation of the placenta from the wall of the uterus. Shock and massive hemorrhage might result. Tips that nurses can offer to promote safety during ground travel include:

- Always wear a three-point seat belt, no matter how short the trip, to prevent ejection or serious injury from collision.
- Apply a nonpadded shoulder strap properly; it should cross between the breasts and over the upper abdomen, above the uterus (Fig. 12.11).
- If no seat belts are available (buses or vans), ride in the back seat of the vehicle.
- Use a lap belt that crosses over the pelvis below the uterus.
- Deactivate the airbag if possible. If you cannot, move the seat as far back from the dashboard as possible to minimize impact on the abdomen.
- Never use a cellular phone while driving to prevent distraction.
- Avoid driving when fatigued and in the first and third trimesters.
- Avoid late-night driving when visibility might be compromised.
- Direct a tilting steering wheel away from the abdomen (CDC, 2019f).

Immunizations and Medications

Vaccines are among the greatest public health achievements of the 21st century, credited with significant reduction of morbidity and mortality from many diseases caused by bacteria and viruses (Sverrisdottir et al., 2019). Ideally, clients should receive all childhood immunizations before conception to protect the fetus from any risk of congenital anomalies. If the client comes for a preconception visit, discuss immunizations such as measles, mumps, and rubella (MMR), hepatitis B, and diphtheria/tetanus (every 10 years); administer them at this time if needed.

FIGURE 12.11. Proper application of a seat belt during pregnancy.

The risk to a developing fetus from vaccination of the mother during pregnancy is primarily theoretical. Routine immunizations are not usually indicated during pregnancy. However, no evidence exists of risk from vaccinating pregnant women with inactivated virus or bacterial vaccines or toxoids. A number of other vaccines have not been adequately studied, and thus theoretical risks of vaccination must be weighed against the risks of the disease to mother and fetus (CDC, 2019g).

TAKE NOTE!

Advise pregnant women to avoid live virus vaccines (MMR and varicella) and to avoid becoming pregnant within 1 month of having received one of these vaccines because of the theoretical risk of transmission to the fetus (CDC, 2019g).

CDC guidelines for vaccine administration are outlined in Box 12.5.

BOX 12.5 CDC Guidelines for Vaccine Administration during Pregnancy

Vaccines That Should Be Considered Unless Contraindicated

- Hepatitis B
- Influenza (inactivated) injection
- Tetanus/diphtheria (Tdap)
- Rabies

Vaccines Contraindicated during Pregnancy

- Influenza (live, attenuated vaccine) nasal spray
- Measles
- Mumps
- Rubella
- Varicella
- BCG (tuberculosis)
- Typhoid

Medication use is common during pregnancy, with prevalence estimates generally exceeding 65% and increasing over the years. Pregnant women use a wide variety of both prescription and OTC medications for both pregnancy-related conditions and conditions unrelated to pregnancy conditions (van Gelder et al., 2019). Little is

known about the effects of taking most medications during pregnancy. Less than 10% of medications approved by the FDA since 1980 have enough information to determine their risk for birth defects (CDC, 2019h). Based on this lack of evidence, it is best for pregnant women to not take any medications during their pregnancy. At the very least, encourage them to discuss with the health care provider their current medications and any herbal remedies they take so that they can learn about any potential risks should they continue to take them during pregnancy. In general, if the woman is taking medicine for seizures, high blood pressure, asthma, or depression, the benefits of continuing the medicine during pregnancy outweigh the risks to the fetus. The safety profile of some medications may change according to the gestational age of the fetus. Embryogenesis is completed by the end of the first trimester, when all fetal organs are complete. Thus, to cause a malformation, fetal drug exposure must occur in the first 12 weeks' gestation (March of Dimes, 2020e).

The FDA has developed a system of ranking drugs that appears on drug labels and package inserts. These risk categories are summarized in Box 12.6. Always advise women to check with their health care providers for guidance.

A common concern of many pregnant women involves the use of OTC medications and herbal agents. Many women consider these products benign simply because they are available without a prescription (King et al., 2019). Although herbal medications are commonly thought of as "natural" alternatives to other medicines, they can be just as potent as some prescription medications. A major concern about herbal medicine is the lack of consistent potency in the active ingredients in any given batch of product, making it difficult to know the exact strength by reading the label. Also, many herbs contain chemicals that cross the placenta and may cause harm to the fetus.

BOX 12.6 FDA Pregnancy Risk Classification of Drugs

- The “Pregnancy” subsection of each drug’s information will provide information relevant to the use of the drug in pregnant women, such as dosing and potential risks to the developing fetus, and will require information about whether there is a registry that collects and maintains data on how pregnant women are affected when they use the drug or biologic product. Information in drug labeling about the existence of any pregnancy registries has been previously recommended but not required until now. This subsection includes labor and birth.
- The “Lactation” subsection will provide information about using the drug while breastfeeding, such as the amount of drug in breast milk and potential effects on the breastfed child.
- The “Females and Males of Reproductive Potential” subsection will include information about pregnancy testing, contraception, and infertility as it relates to the drug. This information has been included in labeling, but there was no consistent placement for it until now.

USFDA. (2019). *Pregnancy and lactation labeling (Drugs)*. Retrieved March 2, 2020, from https://www.fda.gov/Drugs/DevelopmentApprovalProcess/DevelopmentResources/Labeling/ucm093307.htm.

Nurses are often asked about the safety of OTC medicines and herbal agents. Unfortunately, many drugs have not been evaluated in controlled studies, and it is difficult to make general recommendations for these products. Therefore, encourage pregnant women to check with their health care providers before taking anything. Questions about the use of OTC and herbal products are part of the initial prenatal interview.

NURSING MANAGEMENT TO PREPARE THE WOMAN AND HER PARTNER FOR LABOR, BIRTH, AND PARENTHOOD

Pregnancy and birth are unique to every woman. Women and families hold different expectations during childbearing based on their knowledge, experiences, belief systems, culture, and social and family backgrounds. These differences should be understood and

respected by the nurse, and care for them adapted to meet the individual needs of the women and families. Knowing a woman's needs, values, cultural background, preferences, and expectations during childbirth helps nurses provide high-quality care to them. Childbirth today is a different experience from childbirth in past generations. In the past, women were literally "put to sleep" with anesthetics, and they woke up with a baby. Most women never remembered the details and had a passive role in childbirth as the physician delivered the newborn. In the 1950s, consumers began to insist on taking a more active role in their health care, and couples desired to be together during the extraordinary event of childbirth. Compared to the past, there is a greater push for partners to play a greater role in the pregnancy and childbirth. Partners today want to be seen as individuals who are part of the childbirth experience. If they are left out, they tend to feel helpless; this can result in a feeling of panic and anxiety which can put support for the mother at risk (Woolston, 2020).

Health beliefs related to pregnancy and childbirth exist in various cultures. A woman's perception of her own status is critical to her decision-making process, because her personal behaviors can significantly alter her pregnancy-related risks. Pregnant women of diverse cultures hold a number of beliefs related to diet, behavior related to prenatal care, and the use of herbs during pregnancy and after birth. Nurses need to be aware of these cultural beliefs so as to incorporate these into their practices while respectfully discouraging the use of those posing any health risks (Giger & Haddad, 2020).

Childbirth education began because women demanded to become more involved in their birthing experience rather than simply turning control over to a health care provider. Nurses played a pivotal role in bringing about this change by providing information and supporting clients and their families, fostering a more active role in preparing for the upcoming birth.

Traditional childbirth education classes focused on developing and practicing techniques for use in managing pain and facilitating the progress of labor. Recently, the focus of this education has broadened; it now encompasses not only preparation for childbirth

but also preparation for breastfeeding, infant care, transition to parenthood, relationship skills, family health promotion, and sexuality (Brooks & Wilson, 2019). The term used to describe this broad range of topics is **perinatal education**. Subjects commonly addressed in perinatal education include:

- Anatomy and physiology of reproduction
- Fetal growth and development
- Prenatal maternal exercise
- Physiologic and emotional changes during pregnancy
- Sex during pregnancy
- Infant growth and development
- Nutrition and healthy eating habits during pregnancy
- Teratogens and their impact on the fetus
- Signs and symptoms of labor
- Preparation for labor and birth (for parents, siblings, and other family members)
- Options for birth
- Infant nutrition, including preparation for breastfeeding
- Infant care, including safety, cardiopulmonary resuscitation, and first aid
- Family planning (March of Dimes, 2020f)

Childbirth Education Classes

Childbirth education classes teach pregnant women and their support people about pregnancy, birth, and parenting. The classes are offered in local communities or online and are usually taught by certified childbirth educators. Many childbirth classes support the concept of **natural childbirth** (a birth without pain-relieving medications) so that the woman can be in control throughout the experience as much as she chooses. The classes differ in their approach to specific comfort techniques and breathing patterns. The three most common childbirth methods are the Lamaze (psychoprophylactic) method, the Bradley (partner-coached childbirth) method, and the Dick-Read (natural childbirth) method.

Lamaze Method

Lamaze is a psychoprophylactic ("mind prevention") method of preparing for labor and birth that promotes the use of specific breathing and relaxation techniques. Dr. Fernand Lamaze, a French obstetrician, popularized this method of childbirth preparation in the 1960s. Lamaze believed that conquering fear through knowledge and support was important. He also believed women needed to alter the perception of suffering during childbirth. This perception change would come about by learning conditioned reflexes that, instead of signaling pain, would signal the work of producing a child, and thus would carry the woman through labor awake, aware, and in control of her own body (Lamaze International, 2020). Lamaze felt strongly that all women have the right to deliver their babies with minimal or no medication while maintaining their dignity, minimizing their pain, maximizing their self-esteem, and enjoying the miracle of birth.

Lamaze classes include information on toning exercises, relaxation exercises and techniques, and breathing methods for labor. The breathing techniques are used in labor to enhance relaxation and to reduce the woman's perception of pain. The goal is for women to become aware of their own comfortable rate of breathing in order to maintain relaxation and adequate oxygenation of the fetus. The following breathing techniques are an effective attention-focusing strategy to reduce pain:

- *Paced breathing* involves breathing techniques used to decrease stress responses and therefore decrease pain. This type of breathing implies self-regulation by the woman. The woman starts off by taking a cleansing breath at the onset and end of each contraction. This cleansing breath symbolizes freeing her mind from worries and concerns. This breath enhances oxygenation and puts the woman in a relaxed state.
- *Slow-paced breathing* is associated with relaxation and should be half the normal breathing rate (six to nine breaths per minute). This type of breathing is the most relaxed pattern and is recommended throughout labor. Abdominal or chest breathing may be used. It is generally best to breathe in through the nose and breathe out

either through the nose or mouth, whichever is more comfortable for the woman.

- *Modified-paced breathing* can be used for increased work or stress during labor to increase alertness or focus attention or when slow-paced breathing is no longer effective in keeping the woman relaxed. The woman's respiratory rate increases, but it does not exceed twice her normal rate. Modified-paced breathing is a quiet upper chest breath that is increased or decreased according to the intensity of the contraction. The inhalation and the exhalation are equal. This breathing technique should be practiced during pregnancy for optimal use during labor.
- *Patterned-paced breathing* is similar to modified-paced breathing but with a rhythmic pattern. It uses a variety of patterns, with an emphasis on the exhalation breath at regular intervals. Different patterns can be used, such as 4/1, 6/1, 4/1. A 4/1 rhythm is four upper chest breaths followed by an exhalation (a sighing out of air, like blowing out a candle). Random patterns can be chosen for use as long as the basic principles of rate and relaxation are met.

Couples practice these breathing patterns typically during the last few months of the pregnancy until they feel comfortable using them. Focal points (visual fixation on a designated object), effleurage (light abdominal massage by woman or partner), massage, and imagery (journey of the mind to a relaxing place) are also added to aid in relaxation. From the nurse's perspective, encourage the woman to breathe at a level of comfort that allows her to cope. Always remain quiet during the woman's periods of imagery and focal point visualization to avoid breaking her concentration.

Bradley (Partner-Coached) Method

The Bradley method uses various exercises and slow, controlled abdominal breathing to accomplish relaxation. Dr. Robert Bradley, a Denver-based obstetrician, advocated a completely unmedicated labor and birth experience. The Bradley method emphasizes the pleasurable sensations of childbirth, teaching women to concentrate on these sensations while "tuning in" to their own bodies (Bradley

Method, 2019). In 1965, Bradley wrote *Husband-Coached Childbirth,* which advocated for the active participation of the partner as labor coach.

A woman is conditioned to work in harmony with her body using breath control and deep abdominopelvic breathing to promote general body relaxation during labor. This method stresses that childbirth is a joyful, natural process and emphasizes the partner's involvement during pregnancy, labor, birth, and the early newborn period. Thus, the training techniques are directed toward the coach, not the mother. The coach is educated in massage and comfort techniques to use on the mother throughout the labor and birth process.

Dick-Read Method

In 1944, Grantly Dick-Read, a British obstetrician, wrote *Childbirth Without Fear.* He believed that the attitude of a woman toward her birthing process had a considerable influence on the ease of her labor, and he believed that fear is the primary pain-producing agent in an otherwise normal labor. He proposed that fear builds a state of tension, creating an antagonistic effect on the laboring muscles of the uterus, which results in pain. A private, undisturbed, and dark environment, where the woman can feel safe, can promote the release of oxytocin, the hormone responsible for uterine contractions thought to promote the release of the pain-relieving hormones endorphins. When this is not achieved, women can experience fear–tension–pain syndrome, impeding labor progress and causing increased levels of pain (Jordan et al., 2019). Dick-Read sought to interrupt the circular pattern of fear, tension, and pain during the labor and birthing process. He promoted the belief that the degree of fear could be diminished with increased understanding of the normal physiologic responses to labor (King et al., 2019).

Dick-Read believed that prenatal instruction was essential for pain relief and that emotional factors during labor interfered with the normal labor progression. The woman achieves relaxation and

reduces pain by arming herself with the knowledge of normal childbirth and using abdominal breathing during contractions.

Nursing Management and Childbirth Education

Childbirth education is less about methods than about mastery. The overall aim of any method is to promote an internal locus of control that will enable each woman to yield her body to the process of birth. As the woman gains success and tangible benefits from the exercises she is taught, she begins to reframe her beliefs and gains practical knowledge, and the impetus will be there for her to engage in the conscious use of the techniques (Fig. 12.12). Nurses play a key role in supporting and encouraging each couple's use of the techniques taught in childbirth education classes.

Every woman's labor is unique, and it is important for nurses not to generalize or stereotype women. The most effective support a nurse can offer a couple using prepared childbirth methods is encouragement and presence. These nursing measures must be adapted to each individual throughout the labor process. Offering encouraging phrases such as "great job" or "you can do it" helps reinforce their efforts and at the same time empowers them to continue. Using eye contact to engage the woman's total attention is important if she appears overwhelmed or appears to lose control during the transition phase of labor.

Nurses play a significant role in enhancing the couple's relationship by respecting the involvement of the partner and demonstrating concern for their needs throughout labor. Offering to stay with the woman to give the partner a break periodically allows them to meet their needs while at the same time still actively participating. Offer anticipatory guidance to the couple and assist during critical times in labor. Demonstrate many of the coping techniques to the partner and praise their successful use to increase self-esteem. Focus on strengths and the positive elements of the labor experience. Congratulating the couple for a job well done is paramount.

Throughout the labor experience, demonstrate personal warmth and project a friendly attitude. Frequently, a nurse's touch may help prevent a crisis by reassuring the mother she is doing well.

FIGURE 12.12. A couple practicing the techniques taught in a childbirth education class.

Options for Birth Settings and Care Providers

From the moment a woman discovers she is pregnant, numerous decisions await her—where the infant will be born, which birth setting is best, and who will assist with the birth. The majority of women are well and healthy and can consider the full range of birth settings—hospital, birth center, or home setting—and care providers. They should be given information about each to ensure the most informed decision.

Birth Settings

HOSPITALS

Hospitals are the most common site for birth in the United States. If the woman has a serious medical condition or is at high risk for developing one, she will probably need to plan to give birth in a hospital setting under the care of an obstetrician. Giving birth in a hospital is advantageous for several reasons. Hospitals are best equipped to diagnose and treat women and newborns with complications; trained personnel are available if necessary; and no

transportation is needed if a complication should arise during labor or birth. Disadvantages include the clinical atmosphere; strict policies and restrictions that might limit who can be with the woman; and the medical model of care.

Within the hospital setting, however, choices do exist regarding birth environments. The conventional delivery room resembles an operating room, where the health care professional delivers the newborn from the woman, who is positioned in stirrups. The woman is then transferred to the recovery area on a stretcher and then again to the postpartum unit. The birthing suite is the other option within the hospital setting. In the birthing suite, the woman and her partner remain in one place for labor, birth, and recovery. The birthing suite is a private room decorated to look as home-like as possible. For example, the bed converts to allow for various birthing positions, and there may be a rocking chair or an easy chair for the woman's partner. Despite the homey atmosphere, the room is still equipped with emergency resuscitative obstetric equipment and electronic fetal monitors in case they are needed quickly (Fig. 12.13A). Such settings provide a more personal childbirth experience in a less formal and intimidating atmosphere compared to the traditional delivery room.

FIGURE 12.13. **A.** Birthing suite in hospital setting. **B.** Childbirth room in birthing center.

FREESTANDING BIRTH CENTERS

A freestanding birth center offers women a comfortable setting where they can receive maternity care with appropriate levels of intervention. A freestanding birth center (Fig. 12.13B) can be a good choice for a woman who wants more personalized care than that of a hospital, but does not feel comfortable with a home birth. In contrast to the institutional environment in hospitals, most freestanding birth centers have a home-like atmosphere, and many are located in converted homes. Some are located on hospital property and are affiliated with the hospitals. Birth centers are designed to provide maternity care to women judged to be at low risk for obstetric complications. Women are allowed and encouraged to give birth in the position most comfortable for them. Care in birth centers is often provided by midwives and is more relaxed, with no routine intravenous lines, fetal monitoring, and restrictive protocols. A disadvantage of the birth center is the need to transport the woman to a hospital quickly if an emergency arises because emergency equipment is not readily available. In a research study comparing home-like to conventional institutional settings, the author concluded that there appeared to be some benefits from home-like settings for childbirth, though increased support from caregivers may be more important to the woman (Phillippi et al., 2018).

HOME BIRTHS

Rates of planned home births have been increasing since the 1970s. Most women who choose a home birth believe that birth is a natural process that requires little medical intervention (Kline, 2019). Research has shown that women believe that planned home births increase privacy, comfort, and convenience; are associated with reduced rates of medical interventions; and they facilitate family involvement in a relaxed, peaceful atmosphere (King et al., 2019).

The safety of home births is an ongoing debate in the United States. The American College of Nurse Midwives (ACNM), the American Public Health Association (APHA), and WHO state that planned home birth is safe as long as the woman and the pregnancy meet certain criteria, such as a low-risk pregnancy, singleton fetus,

cephalic fetus at term, and the absence of preexisting conditions (Grunebaum et al., 2019). Home births can be safe if there are qualified, experienced attendants and an emergency transfer system in place in case of complications. Many women choose the home setting out of a strong desire to control birth and to give birth surrounded by family members. Most home birth caregivers are midwives who have provided continuous care to the woman throughout the pregnancy. Disadvantages include the need to transport the woman to the hospital during or after labor if a problem arises and the limited pain management available in the home setting.

Care Providers

While most women in the United States still receive pregnancy care from an obstetrician, an increasing number are choosing midwives for their care. The difference is a matter of degrees. Obstetricians must finish a 4-year residency in obstetrics and gynecology in addition to medical school. Certified nurse-midwives are registered nurses who have graduated from a nurse midwifery education program accredited by the Accreditation Commission for Midwifery Education (ACME) and have passed a national certification examination to receive the professional designation of certified nurse midwife. As of 2010, a graduate degree is required for entry into midwifery practice in the United States. Midwives usually care for low-risk women in a variety of settings. They are able to write prescriptions, provide prenatal care, childbirth care, postpartum care, newborn care, and well-woman care throughout the lifespan. Family practice doctors also provide maternity, woman's care, and well-baby care. Many deliver their clients' newborns in hospitals or birthing centers. Obstetricians can handle high-risk pregnancies and delivery emergencies; can administer or order pain-relief drugs; and are assisted by support staff in the hospital setting. Midwives work in hospitals, birthing centers, and home settings to deliver care. They believe in normalizing birth and tolerate wide variations of what is considered normal during labor, which leads to fewer interventions

applied during the process. Midwives attend approximately 9.1% of total United States births (American College of Nurse Midwives, 2020). Midwives do handle high-risk and emergency births, but because many are not always predictable, they typically have an obstetrician as backup when they do occur to assist them.

In addition to the woman's primary health care provider, some women hire a doula to be with them during the childbearing process. "Doula" is a Greek word that means "woman's servant." A doula is a laywoman trained to provide women and their families with encouragement, emotional and physical support, and information through late pregnancy, labor, birth, and postpartum. Doulas provide women with continuous support throughout labor but do not perform any clinical procedures.

Preparation for Breastfeeding or Bottle-Feeding

Pregnant women are faced with a decision about which method of feeding to choose. Educate the pregnant client about the advantages and disadvantages of each method, allowing the woman and her partner to make an informed decision about the best method for their situation. Providing the client and her partner with this information will increase the likelihood of a successful experience regardless of the method of feeding chosen. As part of health promotion and evidence-based interventions, nurses should be encouraging and educating all women about breastfeeding while respecting the parents' ultimate decision.

Breastfeeding

Substantial scientific evidence documents the health benefits of breastfeeding for newborns. Current evidence cited by the AAP showed improved outcomes for breastfed infants with regard to otitis media, lower respiratory infections, gastroenteritis, atopic dermatitis, childhood asthma, childhood obesity, type 1 and type 2 diabetes, childhood leukemia, sudden infant death syndrome, and cognitive development, and for their mothers with regard to breast cancer,

ovarian cancer, and type 2 diabetes. The AAP recommends that infants be breastfed exclusively until the age of 6 months and continue to be breastfed for a year and/or for as long as it is mutually desired (2019). In addition, a lack of breastfeeding contributes to a negative impact on the health care system by increasing the number of client visits, hospital admissions, rate of obesity, and health care costs. Most researchers agree that the duration of breastfeeding is inversely associated with overweight risk. Breastfeeding is a cost-effective, natural, and effective prevention strategy for reducing childhood obesity.

Human milk provides an ideal balance of nutrients for newborns (ACOG, 2019e). Breastfeeding is advantageous for the following reasons:

- Human milk is digestible and economical and requires no preparation.
- Bonding between mother and child is promoted.
- Cost is less than purchasing formula.
- Ovulation is suppressed (however, this is not a reliable birth control method).
- The risk of ovarian cancer and the incidence of premenopausal breast cancer are reduced for the woman.
- Extra calories are used, which promotes weight loss gradually without dieting.
- Oxytocin is released to promote more rapid uterine involution with less bleeding.
- Sucking helps to develop the muscles in the infant's jaw.
- Absorption of lactose and minerals in the newborn is improved.
- The immunologic properties of breast milk help prevent infections in the baby.
- The composition of breast milk adapts to meet the infant's changing needs as they grow.
- Constipation in the baby is not a problem with adequate intake.
- Food allergies are less likely to develop in the breastfed baby.
- The incidence of otitis media and upper respiratory infections in the infant is reduced.
- Breastfed babies are less likely to be overfed, thus reducing the risk of adult obesity.

- Breastfed newborns are less prone to vomiting (AAP, 2019; ACOG, 2019e; American Academy of Family Physicians, 2019; U.S. Preventive Services Task Force [USPSTF], 2019).

One could say that lactation and breastfeeding are so natural that they should just happen on their own accord, but this is not always the case. Learning to breastfeed takes practice, requires support from the partner, and requires dedication and patience on the part of the mother; it may be necessary to work closely with a lactation consultant to be successful and comfortable when breastfeeding. Figure 12.14 shows the different positions that may be used for breastfeeding. Nurses can encourage breastfeeding for all mothers except those who are HIV-positive and are untreated, have active tuberculosis, use illicit drugs, or take prescribed cancer chemotherapeutic agents. Nurses can also advise new mothers who breastfeed their infants that the use of pacifiers does not interfere with breastfeeding success (La Leche League International, 2020a).

However, breastfeeding has some uncomfortable side effects for the mother. These include breast discomfort, sore nipples, mastitis, engorgement, breast abscess, milk stasis, flat or inverted nipples, vaginal dryness, and decreased libido (Jordan et al., 2019). The most common cause of nipple pain is an improper latch, and such discomfort is usually piercing, immediate, and short-lived, typically occurring as soon as the baby starts nursing and gradually subsiding during the feeding. Some mothers feel it is inconvenient or embarrassing, limits other activities, limits partner involvement, increases their dependency by being tied to the infant all the time, and restricts their use of alcohol or drugs. Nurses can help mothers cope with their fear of dependency and feelings of obligation by emphasizing the positive aspects of breastfeeding and encouraging bonding experiences. Nurses can be instrumental in helping mothers prepare and continue to breastfeed after they return to work.

PREPARATION FOR BREASTFEEDING

Nipple preparation is not necessary during the prenatal period unless the nipples are inverted and do not become erect when stimulated.

Assess for this by placing the forefinger and thumb above and below the areola and compressing behind the nipple. If it flattens or inverts, advise the client to wear breast shields during the last 2 months of pregnancy. Breast shields exert a continuous pressure around the areola, pushing the nipple through a central opening in the inner shield (La Leche League International, 2020b). The shields are worn inside the bra. Initially the shields are worn for 1 hour, and then the woman progressively increases the wearing time up to 8 hours daily. The client maintains this schedule until after childbirth, and then she wears the shield 24 hours a day until the infant latches on easily (La Leche League International, 2020b). In addition, suggest that the woman wear a supportive nursing bra 24 hours a day.

Encourage the woman to request a certified lactation specialist (CLS) at the hospital, if giving birth there. Lactation specialists are health care providers who specialize in the clinical management of breastfeeding. Some run their own breastfeeding support groups as well. In addition, suggest that the woman attends a breastfeeding support group (e.g., La Leche League), provide her with sources of information about infant feeding, and suggest she reads a good reference book about lactation. All of these activities will help in her decision-making process and will be invaluable to her should she choose to breastfeed her newborn. Women returning to work can pump their breasts and store the milk in the freezer for future use.

Bottle-Feeding

Once the placenta no longer provides nutrition, a newborn's survival depends on the ability to consume nutrients. Recent research indicates that infants who are fed formula within the first 6 months do have an increased incidence of otitis media, diabetes, asthma, atopic dermatitis, reflux, diarrhea, colic, constipation, and lower respiratory infections (Wells, 2019). It is important to inform mothers and their partners of this.

Bottle-feeding an infant is not just a matter of "open, pour, and feed." Parents need information on types of formulas, preparation and storage of formula, equipment, and feeding positions. It is

recommended that normal full-term infants receive conventional cow's milk-based formulas; the physician should direct this choice. If the infant has a reaction (diarrhea, vomiting, abdominal pain, excessive gas) to the first formula, another formula should be tried. Sometimes a soy-based formula is substituted. In terms of preparation of formula and its use, the following guidelines should be stressed:

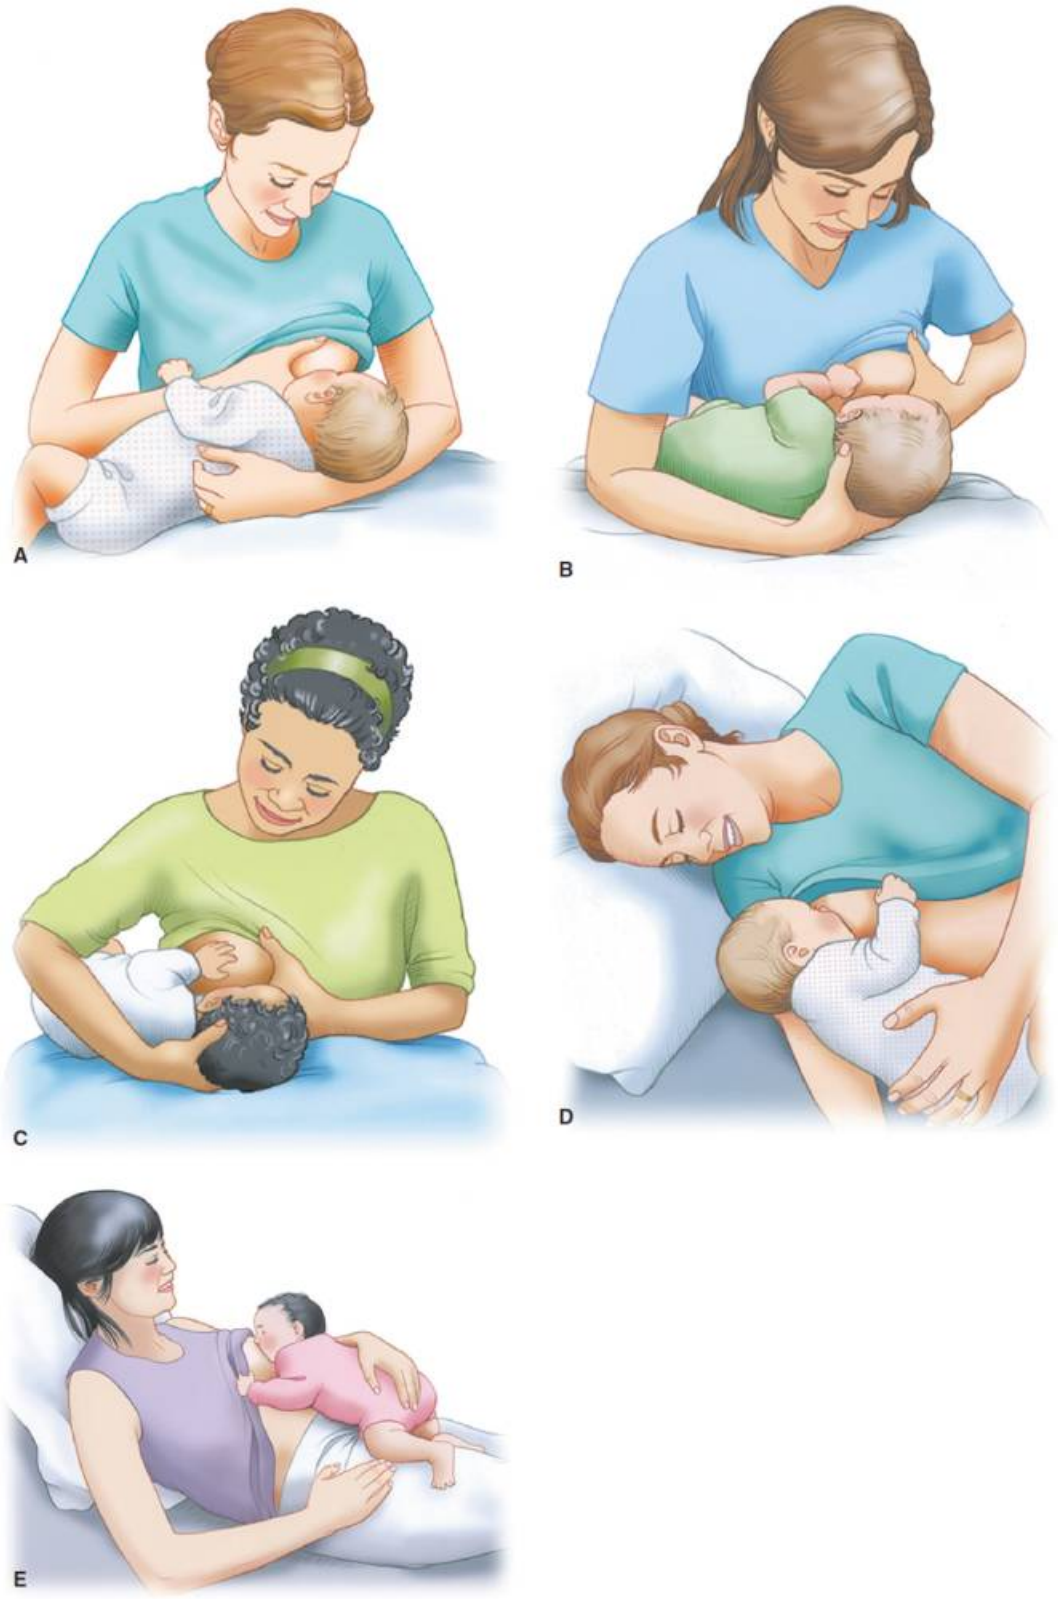

FIGURE 12.14. Positions for breastfeeding. **A.** Cradle hold—infant's head is held in the mother's forearm to nurse. **B.** Cross cradle or

transitional hold—infant is held along the opposite arm from the breast. **C.** Clutch or football hold—infant is held on mother's side hip almost under the mother's arm. **D.** Side-lying position—infant lies parallel to mother's side-lying position to nurse. **E.** Prone or laid-back position—infant lies stomach-to-stomach on top of mother to nurse. (From the Office on Women's Health, U.S. Department of Health and Human Services, 2018. Retrieved August 28, 2018, from https://www.womenshealth.gov/breastfeeding/learning-breastfeed/getting-good-latch/#4)

- Obtain adequate equipment (six 4-oz bottles, eight 8-oz bottles, and nipples).
- Consistency is important. Stay with a nipple that is comfortable to the infant.
- Frequently assess nipples for any loose pieces of rubber at the opening.
- Correct formula preparation is critical to the health and development of the infant. Formula is available in three forms: ready-to-feed, concentrate, and powder.
- Read the formula label thoroughly before mixing.
- Correct formula dilution is important to avoid fluid imbalances. For ready-to-use formula, use as is without dilution. For concentrated formulas, dilute with equal parts of water. For powdered formulas, mix one scoop of powder with 2 oz of water.
- If the water supply is safe, sterilization is not necessary.
- If the water supply is questionable, water should be boiled for 5 minutes before use.
- Bottles and nipples should be washed in hot, sudsy water using a bottle brush.
- Formula should be served at room temperature.
- Formula should not be heated in a microwave oven, because it is heated unevenly.
- Formula can be prepared 24 hours ahead of time and stored in the refrigerator.

Teach the woman and other caregivers to feed the infant in a semi-upright position using the cradle hold in the arms. This position allows for face-to-face contact between the infant and caregiver.

Advise the caregiver to hold the bottle so that the nipple is kept full of formula to prevent excessive air swallowing. Instruct the caregiver to feed the infant every 3 to 4 hours and adapt the feeding times to the infant's needs. Frequent burping of the infant (every ounce) helps prevent gas from building up in the stomach. Caution the caregiver not to prop the bottle; doing so can cause choking.

Bottle-feeding should mirror breastfeeding as closely as possible. While nutrition is important, so are the emotional and interactive components of feeding. Encourage the caregiver to cuddle the infant closely and position the infant so that their head is in a comfortable position. Also encourage communication with the infant during feedings. Nurses should know the different types of formulas available to provide advice to mothers who have made the informed choice not to breastfeed or to stop breastfeeding.

TAKE NOTE!

Warn the caregiver about the danger of putting the infant to bed with a bottle. This can lead to "baby bottle tooth decay" (nursing caries) because sugars in the formula stay in contact with the infant's developing teeth for prolonged periods.

Final Preparation for Labor and Birth

The nurse has played a supportive and education role for the couple throughout the pregnancy and now needs to assist in preparing them for their "big event" by making sure they have made informed decisions and completed the following checklist:

- Attended childbirth preparation classes and practiced breathing techniques
- Selected a birth setting and made arrangements there
- Know what to expect during labor and birth
- Toured the birthing facility
- Packed a suitcase to take to the birthing facility when labor starts
- Made arrangements to have siblings and/or pets taken care of during labor

- Been instructed regarding signs and symptoms of labor and what to do
- Know what to do if membranes rupture prior to going into labor
- Know how to reach the health care provider when labor starts
- Communicated their needs and desires concerning pain management
- Discussed the possibility of a cesarean birth if complications occur
- Discussed possible names for the newborn
- Selected a feeding method (breast or bottle) with which they feel comfortable
- Made a decision regarding circumcision if they have a boy
- Purchased an infant safety car seat in which to bring their newborn home
- Decided on a pediatrician
- Have items needed to prepare for the newborn's homecoming:
  - Infant clothes in several sizes
  - Nursing bras
  - Infant crib with spaces between the slats that are 2 in or less apart
  - Diapers (cloth or disposable)
  - Feeding supplies (bottles and nipples if bottle-feeding)
  - Infant thermometer
- Selected a family planning method to use after the birth

At each prenatal visit, the nurse has had the opportunity to discuss and reinforce the importance of being prepared for the birth of the child with the parents. It is now up to the parents to use the nurse's guidance and put it into action to be ready for the upcoming birth.

A national survey entitled *Listening to Mothers III: Pregnancy and Birth* revealed concerns about overuse of maternity care practices and women's readiness to make informed decisions. Key findings pointed to the need for quality improvement, consumer engagement, and shared decision-making (Kair et al. 2019). These findings present a challenge for all nurses caring for maternity clients to thoroughly explain all procedures, along with their rationales, and truly listen to what the woman desires to make her childbirth experience outcome a positive one for her.

All nurses have the responsibility to impart their knowledge to all women and their families—and that starts with teaching themselves first. The evidence is clear that women have better outcomes when nurses intervene only when needed in the childbirth process. Nurses need to personalize their care to every woman based on her needs, her desires, and her state of health. Nurses must focus on teaching women and their families to understand the value of birth and its long-lasting effects on the family. In addition, nurses must provide information about birth settings that are safe, whether in the hospital, birth center, or at home. Any birth setting should provide continuous support in labor, allow women the freedom to move and assume positions of choice, offer nourishment of the woman's body and spirit, use nonpharmacologic pain-relief modalities whenever possible, and ensure seamless, collaborative teamwork. Continuous labor support is a nonpharmacologic, evidence-based strategy associated with reduced cesarean rates (King et al., 2019).

KEY CONCEPTS

- Preconception and interconception care include promotion of the health and well-being of a woman and her partner before and between pregnancies. The goal of preconception and interconception care is to identify any areas such as health problems, lifestyle habits, or social concerns that might unfavorably affect pregnancy.
- A thorough history and physical examination are performed on the initial prenatal visit.
- A primary aspect of nursing management during the antepartum period is counseling and educating the pregnant women and her partner to promote healthy outcomes for all involved.
- Nagele's rule can be used to establish the estimated date of birth. Using this rule, subtract 3 months from the month of the LMP, add 7 days to the first day of the LMP, then correct the year by adding 1 to it. This date is within plus or minus 2 weeks (the margin of error).
- Pelvic shape is typically classified as one of the four types: gynecoid, android, anthropoid, and platypelloid. The gynecoid type is the typical female pelvis and offers the best shape for a vaginal delivery.
- Continuous prenatal care is important for a successful outcome. The recommended schedule is every 4 weeks up to 28 weeks (7 months); every 2 weeks from 29 to 36 weeks; and every week from 37 weeks to birth.
- The height of the fundus is measured when the uterus arises out of the pelvis to evaluate fetal growth.
- The fundus reaches the level of the umbilicus at approximately 20 weeks and measures 20 cm. The fundal measurement should approximately equal the number of weeks of gestation until week 36.
- At each visit, the woman is asked whether she is having any common signs or symptoms of preterm labor, which might include uterine contractions, dull backache, pressure in the pelvic area or thighs, increased vaginal discharge, menstrual-like cramps, and vaginal bleeding.
- Prenatal screening has become standard in prenatal care to detect neural tube defects and genetic abnormalities.

- The nurse should matter-of-factly address common discomforts that occur in each trimester at all prenatal visits and should provide realistic measures to help the client deal with them effectively.
- The pregnant client can better care for herself and the fetus if her concerns are anticipated by the nurse and incorporated into guidance sessions at each prenatal visit.
- Iron and folic acid need to be supplemented because their increased requirements during pregnancy are usually too great to be met through diet alone.
- Throughout pregnancy, a well-balanced diet is critical for a healthy baby.
- Perinatal education has broadened its focus to include preparation for pregnancy and family adaptation to the new parenting roles. Childbirth education began because of increasing pressure from consumers who wanted to become more involved in their birthing experience.
- Three common childbirth education methods are Lamaze (psychoprophylactic), Bradley (partner-coached childbirth), and Dick-Read (natural childbirth).
- Most of women in the United States are well and healthy and can consider the full range of birth settings: hospital, birth center, or home.
- All pregnant women need to be able to recognize early signs of contractions to prevent preterm labor.

Unfolding Patient Stories: Amelia Sung • Part 1

Amelia Sung is 36 years old and 8 weeks pregnant with her second child. She tells the nurse that she is considering an amniocentesis due to her age. What information would the nurse include when providing education on an amniocentesis? (Amelia Sung's story continues in Chapter 20.)

Care for Amelia and other patients in a realistic virtual environment: (**thepoint.lww.com/vSimMaternity**). Practice documenting these patients' care in DocuCare (**thepoint.lww.com/DocuCareEHR**).

DEVELOPING CLINICAL JUDGMENT

PRACTICING FOR NCLEX

1. Which biophysical profile finding indicates poor oxygenation to the fetus?

   a. Two pockets of amniotic fluid
   b. Well-flexed arms and legs
   c. Nonreactive fetal heart rate
   d. Fetal breathing movements noted

2. The nurse teaches the pregnant client how to perform Kegel exercises as a way to accomplish which action?

   a. Prevent perineal lacerations
   b. Stimulate labor contractions
   c. Increase pelvic muscle tone
   d. Lose pregnancy weight quickly

3. During a clinic visit, a pregnant client at 30 weeks' gestation tells the nurse, "I've had some mild cramps that are pretty irregular. What does this mean?" The cramps are probably

   a. the beginning of labor in the very early stages.
   b. an ominous finding indicating that the client is about to have a miscarriage.
   c. related to overhydration of the woman.
   d. Braxton Hicks contractions, which occur throughout pregnancy.

4. The nurse is preparing her teaching plan for a woman who has just had her pregnancy confirmed. Which information should be included in it? Select all that apply.

   a. Prevent constipation by taking a daily laxative.

b. Balance your dietary intake by increasing your calories by 300 daily.
c. Continue your daily walking routine just as you did before this pregnancy.
d. Tetanus, measles, mumps, and rubella vaccines will be given to you now.
e. Avoid tub baths now that you are pregnant to prevent vaginal infections.
f. Sexual activity is permitted as long as your membranes are intact.
g. Increase your consumption of milk to meet your iron needs.

5. A pregnant client's LMP was on August 10. Using Nagele's rule, the nurse calculates that her EDD will be when?

a. June 23
b. July 10
c. July 30
d. May 17

6. Which is not true about breastfeeding?

a. Breastfed infants experience more obesity and allergies.
b. Breast milk is perfectly suited to the infant's nutritional needs.
c. Breast milk contains maternal antibodies to stimulate infant's immunity.
d. Breastfeeding enhances maternal bonding and attachment.

7. Practicing good oral hygiene is important for all women throughout pregnancy. As a nurse providing anticipatory guidance for pregnant women, what condition can result from periodontal disease if good dental care isn't practiced?

a. Postdated pregnancy
b. Large-for-gestational-age infant
c. Advanced reproductive cancer
d. Preterm or low–birth-weight infant

8. What anticipatory guidance regarding sexual activity during pregnancy will be included in client teaching? Select all that apply.

a. Sexual activity is contraindicated throughout pregnancy.
b. Most women don't desire intimacy after the first trimester.
c. Sexual activity may continue up until the end of the second trimester.
d. Sexual intercourse is prohibited if a history of preterm labor exists.
e. Women's sexual desire may change throughout the pregnancy.
f. Couples can try a variety of positions of comfort during pregnancy.

9. Which would be considered risk factors for psychological well-being during pregnancy? Select all that apply.

a. Limited support system and network of friends and family
b. Introverted personality at any point in the pregnancy
c. Ambivalence any time during the pregnancy
d. High levels of stress due to family discord
e. History of previous high-risk pregnancy with complications
f. Depression prior to pregnancy and on medication

10. Which is the best time for the genetic assessment of an alpha-fetoprotein (AFP) screening test?

a. 12 to 14 weeks' gestation
b. 16 to 18 weeks' gestation

c. 22 to 24 weeks' gestation
d. 28 to 30 weeks' gestation

11. A 25-year-old woman presents to the clinic with complaints of nausea, vomiting, and urinary frequency. Based on this information, the nurse knows these are most indicative of what type of signs?

a. Presumptive signs of pregnancy
b. Positive signs of pregnancy
c. Probable signs of pregnancy
d. Signs of a urinary tract infection

CRITICAL THINKING EXERCISES

1. Mary Jones comes to the Women's Health Center, where you work as a nurse. She is in her first trimester of pregnancy and tells you her main complaints are nausea and fatigue, to the point that she wants to sleep most of the time and eats one meal daily. She appears pale and tired. Her mucous membranes are pale. She reports that she gets 8 to 9 hours of sleep each night but still can't seem to stay awake and alert at work. She tells you she knows that she is not eating as she should, but she isn't hungry. Her hemoglobin and hematocrit are low.

a. What subjective and objective data do you have to make your assessment?
b. What is your impression of this woman?
c. What nursing interventions would be appropriate for this client?
d. How will you evaluate the effectiveness of your interventions?

2. Monica, a 16-year-old high school student, is here for her first prenatal visit. Her LMP was 2 months ago, and she states she has been "sick ever since." She is 5 ft, 6 in tall and weighs 110 lb. In completing her dietary assessment,

the nurse asks about her intake of milk and dairy products. Monica reports that she doesn't like "that stuff" and doesn't want to put on too much weight because it "might ruin my figure."

a. In addition to the routine obstetric assessments, which additional ones might be warranted for this client?
b. What dietary instruction should be provided to this client based on her history?
c. What follow-up monitoring should be included in subsequent prenatal visits?

3. Maria, a 27-year-old woman in her last trimester of pregnancy (34 weeks), complains to the clinic nurse that she is constipated and feels miserable most of the time. She reports that she has started taking laxatives, but they don't help much. When questioned about her dietary habits, she replies that she eats beans and rice and drinks tea with most meals. She says she has tried to limit her fluid intake so she doesn't have to go to the bathroom so often.

a. What additional information would the nurse need to assess her complaint?
b. What interventions would be appropriate for Maria?
c. What adaptations will Maria need to make to alleviate her constipation?

STUDY ACTIVITIES

1. Visit a freestanding birth center and compare it to a traditional hospital setting in terms of restrictions, type of pain management available, and costs.
2. Arrange to shadow a nurse midwife for a day to see her role in working with the childbearing family.
3. Visit the student resources on thePoint and select two of the supplied websites that correspond to this chapter. Note their target audience, the validity of information

offered, and their appeal to expectant couples. Present your findings.

4. Request permission to attend a childbirth education class in your local area and help a woman without a partner practice the paced breathing exercises. Present the information you learned and think about how you can apply it while taking care of a woman during labor.
5. A laywoman with a specialized education and experience in assisting women during labor is a _____.

BRINGING IT ALL TOGETHER: A CASE STUDY

A 19-year-old female comes to the public health clinic. This is her first prenatal visit, although she is 8 months pregnant. Her explanation as to why she had not been there before was: “It was summer and everything was fine until my back starting hurting 2 days ago.”

ASSESSMENT

Her vital signs are within normal range. Weight is 175 lb. On physical exam, the back area is normal without tenderness when palpated. Fundal height is 36 cm; fetal heart rate is 150 bpm; urinalysis is negative for blood, glucose, or leukocytes. The pelvic exam showed the cervix to be long, thick, and closed. Missed routine prenatal lab work is done since this is her first visit. When questioned further about when her back seems to cause her the most discomfort, she stated that she waits tables and when she finishes her shifts, she can barely walk home.

Go to thePoint to find questions to consider about this case.

LEARNING OBJECTIVES

Upon completion of the chapter, you will be able to:

1. Identify premonitory signs of labor.
2. Compare and contrast true versus false labor.
3. Categorize the critical factors affecting labor and birth.
4. Analyze the cardinal movements of labor.
5. Evaluate the maternal and fetal responses to labor and birth.
6. Examine the concept of pain as it relates to the woman in labor.
7. Classify the stages of labor and the critical events in each stage.
8. Characterize the normal physiologic/psychological changes occurring during all four stages of labor.

Kathy and Chuck have been eagerly awaiting the birth of their first child for what seems to them an eternity. When Kathy finally feels contractions in her abdomen, she and Chuck rush to the birthing center. After the obstetric nurse finishes a complete history and physical assessment, she informs Kathy and her husband that she must have experienced “false labor” and that they should return home until she starts true labor.

INTRODUCTION

Labor and birth are physiologic processes that can often proceed with support, monitoring, and education from nurses without extensive medical intervention. The process of labor and birth involves more than the birth of a newborn. Numerous physiologic and psychological events occur that ultimately result in the birth of a newborn and the creation or expansion of the family. This chapter describes labor and birth as a process. It addresses initiation of labor, the premonitory signs of labor, including true and false labor, critical factors affecting labor and birth, maternal and fetal response to the laboring process, and the four stages of labor. The chapter also identifies critical factors related to each stage of labor: the “10 Ps of labor.”

INITIATION OF LABOR

Initiation of labor involves a complex interplay of maternal, fetal, and genetic factors as well as endocrine signaling. Labor involves a sequential and integrated set of changes within the myometrium, decidua, and cervix that occurs gradually over a period of days to weeks in order to expel the fetus from the uterus. It is difficult to determine exactly why labor begins and what initiates it. Although several theories have been proposed to explain the onset and maintenance of labor, none of these has been scientifically proved. It is widely believed that labor is influenced by a cascade of events,

including uterine stretch from the fetus and amniotic fluid volume, progesterone withdrawal to estrogen dominance, increased oxytocin sensitivity, and increased release of prostaglandins.
