Breast cancers are classified as malignant, neoplastic tumors that start in the tissue of the breast. The two most common types are ductal and lobular carcinomas, with ductal carcinomas having a higher prevalence (ACS, 2019a). Breast cancers may be invasive or noninvasive (also called *in situ*). Ductal carcinoma *in situ* (DCIS) is a condition in which abnormal cells replace the normal epithelial cells of the breast ducts and is considered a noninvasive form of breast cancer (ACS, 2019a). Lobular carcinoma *in situ* (LCIS) is considered a benign condition, although LCIS does increase the risk of invasive breast cancer (ACS, 2019a; Giuliano et al., 2018).

Most breast cancers are invasive, which means cancer cells have broken through the walls of the glands or ducts where they originated and subsequently grow into surrounding breast tissue. The prognosis of invasive breast cancer is influenced by disease stage at first diagnosis. This is determined clinically by a classification of tumor stage by the American Joint Committee on Cancer (AJCC) Tumor-Node-Metastasis (TNM) staging system (ACS, 2019a). Staging using the AJCC TNM system includes information about tumor size, spread within the breast and to adjacent tissues (T), the extent of spread to nearby lymph nodes (N), presence or absence of distant metastases (spread to distant organs) (M), receptors for estrogen (ER), progesterone (PR), human epidermal growth factor (HER2) and extra copies of the HER2 gene as well as grading how closely the microscopic appearance of the cancer resembles normal breast tissue (ACS, 2019a). Once all the factors are determined, a stage of 0, I, II, III, or IV is assigned, with stage 0 being *in situ,* stage I being early stage invasive cancer, and stage IV being the most advanced disease with distant organ metastases (Giuliano et al., 2018).

Receptors for estrogen, progesterone, and HER2 are crucial in breast cancer staging and prognosis. If tumors are positive for either or both estrogen and progesterone receptors, the term hormone receptor (HR) positive is used. The most common breast cancer with the best prognosis is HR receptor positive and HER2 negative. Tumors positive for both HR and HER2 are generally diagnosed at a higher grade and have a less positive prognosis. Tumors negative for both HR and HER2, called triple negative cancers, have a poorer prognosis than other cancers, primarily because there is a lack of effective treatments. Triple negative cancers are twice as likely to occur in non-Hispanic Black women compared to non-Hispanic White women in the United States and are also more common in premenopausal women and those with *BRCA* mutations (ACS, 2019a). Other types of breast cancer involving tissues other than lobes or ducts are less common and include inflammatory breast cancer and Paget's disease (ACS, 2019b).

Etiology: The exact cause of breast cancer is unknown, with environmental and genetic contributions.

Occurrence: Excluding cancers of the skin, breast cancer is the most common cancer among U.S. women and accounts for 30% of newly diagnosed cancers (ACS, 2021a). An estimated 281,550 cases of breast cancer were predicted among U.S. women in 2021. At the same time, 43,600 women were expected to die from breast cancer in 2021, which is second only to lung cancer deaths. In men, 2,650 new cases of breast cancer and 530 deaths were predicted in 2021 (ACS, 2021a).

Age: The median age of diagnosis of breast cancer is 62 years. Risk is positively related to increased age, placing older individuals at higher risk (ACS, 2021a).

Ethnicity: The incidence of breast cancer is highest in non-Hispanic White women, closely followed by non-Hispanic Black women. Hispanic, Native American/Alaskan Native, and Asian/Pacific Islander women have a lower incidence of breast cancer, although Hispanic women generally present at a later stage of disease (ACS, 2019a; Yedjou et al., 2019). Non-Hispanic Black women have a higher mortality rate at all ages and have a higher incidence of breast cancer under age 40 (ACS, 2019a; Yedjou et al., 2019). Disparities that

© F.A. Davis Publishing

factor into different outcomes in breast cancer include socioeconomic status (education, income, and employment), access to adequate health-care services, extent of mistrust of the health-care system, tobacco use, exposure to environmental toxins, prevalence of comorbidities (particularly obesity), nutritional and physical activity status, and rates of breastfeeding (Yedjou et al., 2019).

Contributing Factors: Female sex assigned at birth is a significant risk factor for developing breast cancer. Although family history is a strong contributing factor, most individuals with a first-degree relative with breast cancer will not develop breast cancer, and most individuals who develop breast cancer do not have a family history. Compared to women with no family history, the relative risk (RR) is 1.5 with one affected first-degree relative and the RR is 2.0 to 4.0 with two or more first-degree relatives (ACS, 2019a). The risk is increased if the affected relative developed breast cancer at an early age, in both breasts, or is male (ACS, 2019a). Another strong contributing factor is the presence of an inherited gene mutation such as *BRCA1* or *BRCA2*. In the general population, the risk of developing breast cancer by age 80 is around 10%. For individuals with *BRCA* mutations, the risk is about 70% (ACS, 2019a). In addition to *BRCA* mutations, there are about 300 identified gene mutations associated with increased breast cancer risk. A few of the more common genetic mutations are Partner and Localizer of *BRCA2* (*PALB2*), *TP53* (associated with Li-Fraumeni's syndrome), *PTEN* (Cowden's syndrome), *LKB1/STK11* (Peutz-Jeghers' syndrome), Checkpoint Kinase 2(CHEK2), *ATM*, and *CDH* (ACS, 2019a; Odle, 2017).

Dense breast tissue, present in up to one half of all women, is a contributing factor to breast cancer. Increased density identified on mammography is more common in young women and makes mammograms more difficult to read. Glandular and connective tissue are typically replaced by fatty tissue after menopause, making breasts less dense. The RR for developing breast cancer with heterogeneously or extremely dense breasts increases with age from 1.23 for those aged 40 to 49 to a RR of 1.30 for those aged 65 to 74 (Siu, 2016). At least 44 states have legislation addressing notification of patients when increased breast density is identified on mammography (Dense Breast-info, 2019).

Compared to those who were never diagnosed with breast cancer, individuals with a personal history have a 3% to 7% risk over 10 years of developing a new breast cancer. Rates of new primary breast cancers after a prior breast cancer diagnosis have decreased over the past 40 years, potentially because of an increase in hormonal therapy for HR positive cancers and an increase in bilateral mastectomy (ACS, 2019a). DCIS increases the risk of invasive breast cancer by a RR of 2.1 to 4.0. Although LCIS is a benign condition, it increases the risk of invasive breast cancer by a RR of >4. For this reason, LCIS may be surgically removed even though it is benign (ACS, 2019a). Previous chest radiation, a family history of ovarian cancer, and a personal history of ovarian or endometrial cancer increases the risk of breast cancer (ACS, 2019a). Other contributing factors include nulliparity or having the first child after age 30, early menarche, late menopause, use of postmenopausal hormones, obesity, alcohol consumption, tall height, and not breastfeeding (ACS, 2019a; American College of Obstetrics and Gynecology [ACOG], 2017). There is biological plausibility for environmental impacts. Recent immigrants from Asian countries have very low rates of breast cancer, whereas Asian Americans born in the United States have rates of breast cancer similar to non-Hispanic Whites (Yedjou et al., 2019).

Benign breast conditions are categorized into three general groups: nonproliferative lesions (overgrowth of breast tissue; little or no effect on breast cancer risk), proliferative lesions without atypia (abnormal cells; small increase in risk of breast cancer, RR of 1.5 to 2.0); and proliferative lesions with atypia (RR >4) (ACS, 2019a). Although not an independent risk factor for breast cancer, high bone mineral density in postmenopausal women has been associated with increased rates of HR positive breast cancer, potentially because of cumulative estrogen exposure (ACS, 2019a).

Signs and Symptoms: Signs and symptoms of breast cancer range from completely asymptomatic to a breast or axillary lump or mass, black or bloody nipple discharge, change in the size or shape of the breast, changes in the skin, and inversion or deviation of the nipple (ACS, 2019a).

Diagnostic Tests: For individuals at high risk or individuals who have noted a breast mass or other symptoms, history taking and clinical breast examination is the first stage of breast cancer diagnosis. A diagnostic mammogram is used to determine breast disease in those who have breast symptoms or abnormal screening mammography. This diagnostic procedure is distinguished from screening mammography. Suspicious findings on mammography must be confirmed by biopsy.

Standard setting agencies have published a number of different breast cancer screening guidelines. Although there are nuances in these different guidelines, for individuals at average risk for breast cancer or less than a 20% lifetime risk, there is consensus that screening mammograms should start by at least age 50, be performed at an interval of between one and two years, and that discontinuation be considered when life expectancy is less than 10 years (Narayan et al., 2020). Table 15-1 compares the recommendations for mammography for average risk women from various organizations.

To determine risk for breast cancer, several risk assessment tools are available (Table 15-2). Although these risk tools help identify individuals who might benefit from early or enhanced screening, they do not all include the detailed family history necessary to determine which individuals should be referred to genetic counseling or testing for *BRCA* gene mutations. Risk factors that are associated with *BRCA* gene mutations include a family history of any of the following: breast cancer prior to age 50, breast and ovarian cancer in the same family member, male breast cancer, bilateral breast cancer, multiple relatives with breast cancer or with ovarian cancer, and Ashkenazi Jewish ancestry (Smith et al., 2019). If these risk factors are present, then referral to genetic counseling should be offered. For individuals with a 20% or greater lifetime risk of breast cancer, annual magnetic resonance imaging (MRI) and mammography is recommended (Smith et al., 2019). A common screening protocol for individuals at increased risk is to alternate mammograms and MRIs every 6 months.

Breast ultrasound is used to further evaluate abnormal findings from a screening or diagnostic mammogram or from a clinical breast examination. It has been demonstrated that ultrasound detects more cancer than mammography alone in women with dense breast tissue, although it can increase the likelihood of false-positive results (ACS, 2019a; Monticciolo et al., 2018). Biopsy to obtain samples for cytology and

histology is recommended to confirm the breast cancer diagnosis (Cardoso et al., 2019)

Differential Diagnosis: The majority of breast masses are benign. Benign conditions are classified as nonproliferating lesions, proliferating lesions without atypia, and proliferating lesions with atypia (ACS, 2019a). Mastitis is not a tumor and does not increase the risk of breast cancer.

- Benign nonproliferating breast mass: Nonproliferating lesions do not seem to affect future cancer risk. These include:
  - Adenosis
  - Benign phyllodes tumor
  - Duct ectasia
  - Epithelial calcifications
  - Fat necrosis
  - Fibrosis
  - Lipomas
  - Mild hyperplasia
  - Neurofibromas
  - Single papilloma
- Proliferating lesions without atypia: Increase cancer risk by approximately one to two times over average risk. These include:
  - Ductal hyperplasia without atypia
  - Fibroadenoma
  - Multiple papillomas
  - Radial scar
  - Sclerosing adenosis
- Proliferating lesions with atypia: Increase cancer risk by four to five times, and higher if there is a family history (ACS, 2019a). These include:
  - Atypical ductal hyperplasia
  - Atypical lobular hyperplasia

Treatment: The treatment for breast cancer confirmed by biopsy is ideally determined by shared decision making with a multidisciplinary team of surgeons, medical oncologists, and genetic specialists after consideration of patient's age, menopausal status, and preferences, and cancer staging and biological characteristics along with the risks and benefits of each treatment option. A variety of multi-gene testing panels are available and genetic testing is recommended to help determine prognosis and treatment (Telli et al., 2019). Depending on the stage of disease, hormone markers, and genetics, the treatment for an initial occurrence of cancer may include breast-conserving surgery (lumpectomy or partial mastectomy), mastectomy, chemotherapy, radiation, targeted therapies, selective estrogen

© F.A. Davis Publishing

receptor modulators, aromatase inhibitors, bisphosphonates, immune modulators, and monoclonal antibodies (ACS, 2019a; Cardoso et al., 2019; Telli et al., 2019; Waks & Winer, 2019). Ovarian suppression has become a standard part of breast cancer therapy for premenopausal women (Telli et al., 2019).

Follow-Up: Follow-up of breast masses and breast cancer is based on the specific diagnosis, cancer staging, and treatment rendered.

Sequelae: Adjusting for age, mortality rates declined 40% since 1989. Decline in breast cancer mortality is attributed to improved breast cancer treatment coupled with early detection (Smith et al., 2019). These trends have not affected all populations equally. From 2011 to 2016, rates of mortality were 41% higher for non-Hispanic Black individuals as compared to non-Hispanic White individuals (Smith et al., 2019). Factors contributing to this disparity include discrepancies in insurance status, tumor size and receptor status at diagnosis, presence of comorbidities, and disparity in breast cancer treatment (Dreyer et al., 2018; Waks & Winer, 2019).

Prevention/Prophylaxis: Screening mammography remains the most effective means of breast cancer screening and recommendations were discussed previously. It is no longer recommended to teach breast self-examination due to potential overdiagnosis and overtreatment (ACOG, 2017; Siu, 2016). Rather than the regimented, every month breast self-examination that used to be taught, breast self-awareness is recommended by the ACS and ACOG. Breast self-awareness means being familiar with how breasts normally look and feel so that changes can be reported. (ACS, 2019a; ACOG, 2017). Clinical breast examinations (CBE) by a health-care provider can also lead to overdiagnosis and overtreatment. Some organizations either recommend against CBE (ACS, 2019a; Oeffinger et al., 2015; Qaseem et al., 2019) or state there is insufficient evidence to recommend (Siu, 2016). Only ACOG guidelines recommend offering a clinical breast examination every 1 to 3 years from ages 25 to 49 and then yearly starting at age 50 (ACOG, 2017).

Genetic testing is recommended for individuals with a family history suggestive of a cancer gene mutation. Early and/or enhanced screening is recommended for those with a lifetime risk of 20% or greater (Monticciolo et al., 2018; Smith et al., 2019). Carriers of *BRCA* genes can be offered prophylactic oophorectomy (if childbearing is complete) and/or prophylactic mastectomy (Carbine et al., 2018). Chemoprevention using tamoxifen or raloxifene decreases breast cancer risk and breast cancer death for individuals at high risk, particularly those with *BRCA* mutations (Samadder et al., 2019). Enhanced screening including MRIs, prophylactic surgery, and chemoprevention are not recommended for individuals with a lifetime risk of less than 20% (ACOG, 2017).

Several strategies are suggested to help reduce the risk of breast cancer, and these include avoiding weight gain and obesity, engaging in regular physical activity, minimizing alcohol intake, and minimizing exposure to menopause hormone therapy (ACS, 2019a). Breastfeeding decreases breast cancer risk by 4% for every 12 months of breastfeeding (ACS, 2019a).

Referral: All breast masses should be further evaluated for malignancy. Referrals to surgeons, oncologists, geneticists, genetic counselors, mental health services, and appropriate support groups are made as necessary. A persistent palpable breast mass with a negative mammogram warrants further evaluation, especially in young women with dense breast tissue.

Education: A comprehensive plan of education empowers patients to put breast cancer risk in perspective with other health risks, to modify risk factors that can be controlled, and to be proactive about screening. Use of risk assessment tools and a detailed personal and family history can help individuals assess their breast cancer risks. A lack of clear consensus on screening guidelines necessitates shared decision making between patient and provider about when to start screening, the frequency of mammograms, and when it is prudent to discontinue screening. Providers have a role in educating patients on self-breast awareness, that self-breast examinations are no longer recommended, and that most guidelines also suggest against CBE. Educating patients on danger signs and when to report changes along with discussing modifiable risk factors such as weight management, physical activity, and alcohol consumption is a crucial part of the plan.

ENDOMETRIAL CANCER

Signal Symptoms: Abnormal uterine bleeding, particularly postmenopausal bleeding.

Description: Endometrial cancer is the abnormal proliferation and neoplastic transformation of endometrial tissues. It is the most common gynecological malignancy in the United States. Endometrial cancer may be confined to the lining of the uterus, may spread to the myometrium or cervix, may have local spread to the pelvic region, or metastasize to remote tissues.

Etiology: Endometrioid tumors, which are comprised of an increased number of endometrial cells and are associated with excess estrogen, either endogenous or exogenous, account for 70% of all endometrial cancer (but only 40% of the deaths). These were historically labeled type 1 tumors and are associated with obesity and metabolic syndrome (Brooks et al., 2019; Gentry-Maharaj & Karpinskyj, 2020; Lu & Broaddus, 2020; McDonald & Bender, 2019). Non-endometrioid tumors may have serous, clear cell, or carcinosarcoma histology, are not associated with excess estrogen or obesity, are more aggressive, present at a higher stage, have a higher risk of recurrence and a worse prognosis. These were historically called type 2 tumors (Brooks et al., 2019; Gentry-Maharaj & Karpinskyj, 2020; Lu & Broaddus, 2020).

Occurrence: Endometrial cancer represents 7% of all cancers in women and 4% of all cancer deaths (American Cancer Society [ACS], 2021a); it is the most common gynecological cancer in developed countries, and rates have increased about 1% per year in the past 20 years (ACS, 2021a). Because of increased rates of obesity and increased life expectancy, this trend of increasing rates is expected to continue (Gentry-Maharaj & Karpinskyj, 2020). It is estimated that in 2021 there will be approximately 66,570 cases of uterine cancer and 12,940 deaths (ACS, 2021b). The lifetime probability of developing endometrial cancer for all women in the United States is 3% (Gentry-Maharaj & Karpinskyj, 2020). Most individuals present with early-stage disease and have an excellent prognosis (Brooks et al., 2019).

Age: Advancing age is the most important risk factor for endometrial cancer; 5% of tumors occur in women younger than 40 years old. Most tumors occur after menopause, with 60 years being the average age of diagnosis (ACS, 2021b).

Ethnicity: Incidence rates in the United States are higher in non-Hispanic White women, but the mortality rate is almost twice as high in non-Hispanic Black women. This discrepancy has been associated with non-Hispanic Black women having tumors with a more aggressive profile, presenting at a higher grade and more advanced stage, and not receiving comparable treatment to non-Hispanic White women (Brooks et al., 2019; Doll et al., 2018). Lack of access to appropriate care may contribute to this disparity (Lu & Broaddus, 2020).

Contributing Factors: Endometrial cancer occurs only in individuals assigned female sex at birth. Obesity, diabetes hypertension, and exposure to endogenous or exogenous estrogen are significant risk factors for endometrial carcinoma (Brooks et al., 2019; Gentry-Maharaj & Karpinskyj, 2020; McDonald & Bender, 2019). Nulliparity, early menarche, and late menopause are all associated with an increased risk of endometrial cancer (Gentry-Maharaj & Karpinskyj, 2020). There is a high incidence of this cancer in individuals with polycystic ovarian syndrome (Gentry-Maharaj & Karpinskyj, 2020). The use of tamoxifen increases risk by a relative risk (RR) of 2.0 to 3.0 (Gentry-Maharaj & Karpinskyj, 2020). The risk of endometrial cancer in individuals with Lynch syndrome is around 50%, accounting for 3% of all endometrial cancers. Lynch syndrome is a hereditary genetic mutation that places persons affected at higher risk for developing cancer and at a younger age. In addition to endometrial cancer, persons with Lynch syndrome are at risk for colorectal cancer, as well as several others. Multiparity, breastfeeding, and combined oral contraceptives decrease the risk of endometrial cancer (Gentry-Maharaj & Karpinskyj, 2020).

Signs and Symptoms: Postmenopausal bleeding is the most common symptom associated with endometrial carcinoma, occurring in 94% of all cases (Gentry-Maharaj & Karpinskyj, 2020). A finding of endometrial cells after menopause or atypical glandular cells on Pap testing should prompt further evaluation (Passarello et al., 2019).

Diagnostic Tests: For an individual with abnormal uterine bleeding, particularly postmenopausal bleeding, a thorough history and physical examination, including a pelvic and rectal examination, is essential to rule out pelvic masses and other urogenital causes of bleeding. Transvaginal pelvic ultrasound is the most common imaging modality, and magnetic resonance imaging (MRI) may also be ordered (Faria et al., 2019; Murali et al., 2018). Diagnosis of endometrial cancer is confirmed with endometrial sampling obtained by blind biopsy, hysteroscopy, or curettage (Murali et al., 2018). Detection of early endometrial cancer by evaluating endometrial epithelial cells from the cervical opening using a cytobrush is being investigated (Yen et al., 2020). Comprehensive surgical staging is based on extent of invasion into the myometrium and/or cervix, extent of local spread to the adnexal and /or peritoneal regions, extent of spread to lymph nodes, histology, type, and grade of tumor (Murali et al., 2018). There is no screening recommended for individuals at average risk (Gentry-Maharaj & Karpinskyj, 2020). For individuals with Lynch syndrome, routine endometrial biopsy starting at age 35 and hysterectomy with bilateral salpingo-oophorectomy at age 40 or when childbearing is complete is recommended by the American Cancer Society and the National Comprehensive Cancer Network (Bercow & Eisenhauer, 2019; Bristowe et al., 2018; Gentry-Maharaj & Karpinskyj, 2020; MacKintosh & Crosbie, 2018; Passarello et al., 2019).

Differential Diagnosis:

- Infection
- Atrophy
- Polyps
- Other causes of genital tract bleeding

Treatment: Treatment decisions are made primarily on the basis of stage, extent of lymph node involvement, histology, and grade. Genomic factors are not typically used in treatment decisions at this point (Brooks et al., 2019). The primary treatment for early-stage cancer is surgery (total hysterectomy and bilateral salpingo-oophorectomy and

© F.A. Davis Publishing

assessment/removal of lymph nodes), which also allows accurate staging of the cancer (Brooks et al., 2019). In select individuals who do not have Lynch syndrome and are younger than age 50, ovarian sparing surgery might be considered (Brooks et al., 2019). Radiation therapy, often targeted to the vagina rather than the whole pelvic region, is used for individuals with intermediate or high-risk disease (Brooks et al., 2019; Passarello et al., 2019). Chemotherapy may be used in advanced disease or for serous type histologies (Brooks et al., 2019; Faria et al., 2019; Passarello et al., 2019). Progestins alone, or in combination with tamoxifen, can be used for metastatic disease (Brooks et al., 2019).

Follow-Up: For individuals with low risk of recurrence, follow-up is every 6 months for 1 to 2 years and then yearly. For individuals with a higher risk of recurrence, follow-up is every 3 months for 2 years followed by every 6 months until year 5, then annual follow-up (Passarello et al., 2019).

Sequelae: Around 75% of cancers are diagnosed at an early stage, with a 5-year survival rate of 95%, and a 10-year survival rate of 77% (Gentry-Maharaj & Karpinskyj, 2020). Various factors influence the prognosis, including histological differentiation, depth of invasion, and lymph node metastases. Histological type also influences the outcome. Sexual side effects due to postoperative vaginal shortening and vaginal scar tissue post radiation are common (Passarello et al., 2019).

Prevention/Prophylaxis: Protective factors include combined hormonal contraceptives, breastfeeding, coffee consumption of more than four cups a day, physical activity, and regular use of aspirin (Gentry-Maharaj & Karpinskyj, 2020; MacKintosh & Crosbie, 2018). The progesterone-releasing intrauterine device decreases the risk of endometrial cancer by 19% (Gentry-Maharaj & Karpinskyj, 2020; MacKintosh & Crosbie, 2018). Individuals with a uterus who are prescribed estrogen therapy post menopause must also be prescribed a progestin.

Referral: All cases of suspected endometrial cancer are referred to a gynecologist for evaluation and treatment. Routine surveillance of the endometrium and prophylactic surgery should be considered for those at high risk.

Education: Explain the significance of postmenopausal bleeding to every individual at the time of menopause, and inquire about the presence of vaginal bleeding at visits after menopause. Estrogen should not be taken without progesterone in the postmenopausal period in the presence of an intact uterus.

GENITOURINARY SYNDROME OF MENOPAUSE

Signal Symptoms: Dyspareunia vaginal dryness and pain, vulvovaginal irritation and burning, urinary frequency and dysuria, and recurrent urinary tract infections (UTI) (Shifren, 2018).

Description: The hypoestrogenic state after menopause causes chronic and progressive anatomic and physiological changes to the genital and urinary tissues that result in a variety of symptoms. Vulvovaginal atrophy with loss of lubrication and dyspareunia is the most common component of genitourinary syndrome of menopause (GSM), affecting up to 90% of individuals post menopause (Alvisi et al., 2019; Angelou et al., 2020; Mitchell & Waetjen, 2018; Shifren, 2018). GSM can have a significant negative effect on sexual health and quality of life, although it is often not addressed by either health-care providers or patients (Alvisi et al., 2019; Kagan et al., 2019; Nappi et al., 2019; Scavello at al., 2019).

Etiology: Estrogen deprivation post menopause causes GSM. The main physiological changes include drying and thinning of urogenital tissues with a loss of collagen, elasticity, and blood flow, increased pH, decreased vaginal discharge, and decreased bladder capacity and sensation (Alvisi et al., 2019; Angelou et al., 2020; Faubion et al., 2017; Manda et al., 2021; Mitchell & Waetjen, 2018; Nappi et al., 2019; Scavello et al., 2019). Decreased libido is common (Alvisi et al., 2019; Angelou et al., 2020; Scavello et al., 2019).

© F.A. Davis Publishing

Occurrence: This disorder affects all postmenopausal individuals assigned female sex at birth to some degree and depends on the length of time since menopause. More individuals report symptoms 5 years after menopause than in the first year after menopause (Angelou et al., 2020). Individuals assigned male sex at birth who have had vaginoplasty surgery in a male to female transition may have GSM symptoms. Maintaining a neovagina requires lifelong vaginal dilation and estrogen therapy (Mundluru & Larson, 2018).

Age: While GSM is most common after menopause, typically starting in the fifth decade of life, it can occur at any time if an individual has a lack of estrogen. Hypoestrogenic states are common in hypothalamic or pituitary dysfunction, after oophorectomy, and after chemotherapy or radiation therapy (Shifren, 2018).

Ethnicity: Not significant.

Contributing Factors: Menopause resulting in decreased estrogen is the main contributing factor. Any condition leading to a hypoestrogenic state can be associated with GSM. Premature ovarian insufficiency, premenopausal oophorectomy, alcohol abuse, tobacco use, sexual abstinence, physical inactivity, pelvic radiation, chemotherapy, and use of antiestrogens are all associated with GSM (Angelou et al., 2020; Scavello et al., 2019; Shifren, 2018). Individuals treated with aromatase inhibitors for breast cancer often have severe GSM symptoms related to extreme estrogen deficiency (Faubion et al., 2017; Shifren, 2018).

Signs and Symptoms: Vaginal dryness and painful intercourse are common symptoms. Other symptoms include vulvar/vaginal itching and burning and loss of libido. Urinary symptoms are less common and include dysuria, urgency, incontinence, and recurrent UTI (Angelou et al., 2020; Faubion et al., 2017; Manda et al., 2021; Mitchell & Waetjen, 2018; Nappi et al., 2019; Scavello et al., 2019). Typical physical examination signs include a loss of pubic hair; decreased subcutaneous fat; pale, dry, nonrugated vaginal walls, and loss of definition of the labia minora and labia majora. The vaginal canal is short with a narrow introitus. Estrogen deficiency can lead to loss of pelvic organ support and subsequent pelvic organ prolapse (Angelou et al., 2020; Faubion et al., 2017; Nappi et al., 2019).

Diagnostic Tests: Patient surveys can be used to evaluate symptomatology and quality of life impacts. Two common surveys are the Vulvovaginal Symptoms Questionnaire and the Day-to-Day Impact of Vaginal Aging (DIVA) Questionnaire (Angelou et al., 2020). In addition to a thorough history, a pelvic examination should be performed to rule out other conditions. There are two physical scoring systems that can be used to evaluate vaginal and vulvar health. A score less than 15 on the vaginal health index or greater than 8 on the vulvar health index indicates objective diagnosis of GSM (Alvisi et al., 2019). If urinary symptoms are present, a urinalysis and culture should be performed.

Differential Diagnosis (Scavello et al., 2019):

- Autoimmune disorders
- Chronic Vaginitis
- Dermatitis
- Diabetes related conditions such as chronic candidiasis or neuropathy
- Eczema
- Foreign bodies
- Lichen planus
- Lichen sclerosus
- Lichen simplex chronicus
- Malignancy
- Pain disorders of the vagina including vulvodynia and chronic pelvic pain
- Trauma

Treatment: Treatment includes maintaining vaginal blood flow, elasticity, lubrication, and muscle tone through vaginal activity with or without a partner that may include sexual stimulation, the use of vaginal dilators, or pelvic floor physical therapy (Angelou et al., 2020; Scavello et al., 2019; Shifren, 2018). Mild to moderate symptoms may be treated with over-the-counter lubricants and/or moisturizers (Alvisi et al., 2019; Angelou et al., 2020; Faubion et al., 2017; Scavello et al., 2019; Shifren, 2018). Regardless of other therapies, lubricants may always be needed for intercourse. Lubricants may be water-based (e.g., Astroglide or KY jelly), silicone-based (e.g., Pjur Eros), or oil-based (e.g., olive oil or coconut oil). Moisturizers (e.g., Luvena or Replens) are longer lasting and are typically applied twice a week. Severe dyspareunia, particularly in those treated for breast cancer, may be relieved with local application of 4% aqueous lidocaine solution with a cotton swab prior to intercourse (Goetsch et al., 2015).

For more severe or persistent symptoms, vaginal estrogen is the most common prescription therapy for GSM. Vaginal estrogen preparations include creams, rings, tablets, and a softgel insert. Serum levels of estrogen remain in the normal postmenopausal range with the use of vaginal estrogen, and a progestin is not required for individuals with a uterus. The exception to this is Femring, which provides systemic estrogen for treatment of vasomotor symptoms in addition to GSM. When Femring is used, a progestin must also be prescribed if a uterus is present (Angelou et al., 2020; Faubion et al., 2017; Nappi et al., 2019; Scavello et al., 2019; Shifren, 2018). Individuals using systemic estrogen for vasomotor symptoms may need supplemental vaginal estrogen to control symptoms of GSM (Faubion et al., 2017). If there is a history of an estrogen-dependent tumor such as breast cancer, vaginal estrogen products should be used with caution, and after a thorough discussion of risks and benefits in consultation with an oncologist (Angelou et al., 2020; Nappi et al., 2019). The U.S. Food and Drug Administration (FDA) requires package inserts for all estrogen products, including vaginal estrogen, to carry a warning that there is a risk of heart attacks, strokes, breast cancer, and blood clots, even though there is minimal systemic absorption of vaginal products (Kagan et al., 2019). It is helpful to give anticipatory guidance to patients about this language in the package insert before prescribing vaginal estrogen.

Other nonestrogen prescription therapies include intravaginal prasterone or DHEA, which is converted in the body to estrogen and testosterone and oral ospemifene, which is an estrogen agonist-antogonist or SERM, and the only oral agent approved for GSM. Neither prasterone nor ospemifene have

© F.A. Davis Publishing

been studied in individuals with breast cancer. All the prescription therapies can be found in Table 15-3.

Vaginal laser therapy and radiofrequency treatments are under investigation for treatment of GSM (Angelou et al., 2020; Faubion et al., 2017; Shifren, 2018). Complementary treatments such as vitamin D, vaginal vitamin E, probiotics, vaginal testosterone, and phytoestrogens such as soy do not have sufficient evidence to recommend them for symptom relief (Angelou et al., 2020).

Follow-Up: Expected response to prescribed therapy is quick, with resolution of symptoms within 2 to 3 months. Many individuals stop using a prescribed treatment prior to this time due to issues related to the vaginal mode of delivery or concerns over safety of treatment. A 3-month follow-up is recommended, and if symptoms are not resolved, adherence to therapy should be assessed (Faubion et al., 2017). If adherence is not an issue, then a re-evaluation for other causes should be considered (Faubion et al., 2017).

Sequelae: Untreated GSM is a progressive condition. The physical changes related to GSM can result in an inability to participate in painless and satisfying sexual activity. Elevated vaginal pH can lead to an increased susceptibility to vaginal infection, and UTI can become chronic.

Prevention/Prophylaxis: The most important prevention is to screen perimenopausal and postmenopausal individuals for GSM and to offer treatment. Recognition of early signs and symptoms of GSM can lead to prevention of symptoms, continued sexual functioning, and improved quality of life.

Referral: Gynecology referral is appropriate for those who do not respond to treatment or have vaginal bleeding. Referral for pelvic floor physical therapy can help maintain blood flow and elasticity of tissues.

Education: All individuals post menopause should be counseled that symptoms of GSM are common and progressive without treatment, and that treatments are available to improve symptoms and quality of life (Faubion et al., 2017). Selection of a treatment is based on goals of therapy and patient preference. Use water-soluble lubricants for patients with atrophic vaginitis. Counsel regarding the benefits of regular sexual activity. Identify age-related difficulty associated with intravaginal application of prescription therapies and address these needs with sensitivity. If a vaginal estrogen is prescribed, inform the individual that the package insert will contain language about risks related to systemic estrogen, even though there is minimal systemic absorption with vaginal estrogen.

TABLE 15-3 Prescription Therapies for Genitourinary Syndrome of Menopause

TREATMENT OPTION	BRAND NAME	DOSE	COMMENTS
Estradiol hemihydrate vaginal tablets	Vagifem and generics	Initial treatment: 1 tablet intravaginally q.h.s. × 14 days followed by maintenance of 1 tablet twice a week	Preloaded on individual applicators. Easy to insert.
17β estradiol cream	Estrace and generics	Initial treatment: 0.5–1.0 g intravaginally q.h.s. followed by maintenance of 0.5–1.0 g one to three times a week	Most common reason for discontinuation is messiness.
Conjugated estrogen cream	Premarin (no generic available)	Initial treatment: 0.5–1.0 g intravaginally q.h.s. followed by maintenance of 0.5–1.0 g one to three times a week	Most common reason for discontinuation is messiness.
17β estradiol vaginal ring	Estring	Change the ring every 90 days	Estring is local estrogen with minimal systemic absorption.
Estradiol acetate vaginal ring—systemic	Femring	Change the ring every 90 days	Femring is a systemic product approved for relief of vasomotor symptoms. It must be used with a progestin if a uterus is present.
17β estradiol vaginal softgel insert	Imvexxy	Initial treatment: 1 insert intravaginally q.h.s. × 14 days followed by maintenance of 1 insert twice a week	Comes in 2 strengths: 4 mcg and 10 mcg. Does not need an applicator.
Prasterone (DHEA) vaginal tablet	Intrarosa	Insert a vaginal tablet q.h.s.	Does not have same package insert warnings as estrogen. Has not been studied in individuals with a history of breast cancer.
Ospemifene oral tablet	Osphena	Oral	Good option if individual unable or unwilling to use a vaginal product. Most common side effect is hot flashes. Has not been studied in individuals with a history of breast cancer.
4% Lidocaine Hydrochloride Topical Solution	Xylocaine and generics	Apply a small amount with a cotton swab to the vaginal introitus prior to intercourse	Effective relief of dyspareunia for individuals who are not able to use estrogen products.

LICHEN SCLEROSUS (VULVAR)

Signal Symptoms: Pruritis, dyspareunia, and pain, although may be asymptomatic (Krapf et al., 2020; Ringel & Iglesia, 2020).

Description: An autoimmune skin disorder affecting the vulva and anogenital tissues. Epithelial thinning and inflammation cause whitened plaques involving the labia minora, labia majora, clitoral region, or anogenital area. If untreated, lichen sclerosus (LS) can result in changes in the architecture of the external genital structures and scarring (Krapf et al., 2020; Ringel & Iglesia, 2020). Decreased sexual interest and activity and pain with sexual activity is common (Krapf et al., 2020).

Etiology: Although LS is considered an autoimmune disease and there are genetic predispositions, the exact etiology is unknown (ACOG, 2020; Fergus et al., 2020; Krapf et al., 2020).

Occurrence: LS occurs in individuals assigned female or male sex at birth. The ratio of female to male is estimated at 3:1 to 10:1 (Fergus et al., 2020). Exact incidence is difficult to assess because many are asymptomatic and LS may be unrecognized by both patients and clinicians (ACOG, 2020). One frequently cited estimate is an incidence of 1.7% of the general population, but this is probably an underestimate (Ringel & Iglesia, 2020). In the setting of long-term care facilities, it is estimated that 1 in 32 individuals may have LS (ACOG, 2020).

Age: Can occur at any age but is more common in older adults. A bimodal distribution of LS occurring most commonly in those before puberty and then after menopause has historically been reported, but newer information suggests that LS is underdiagnosed and underreported in the ages between puberty and menopause (Krapf et al., 2020). The mean age at diagnosis is between ages 52 and 60 (Chamli & Souisi, 2021).

Ethnicity: Not significant.

Contributing Factors: A family history of LS is a contributing factor, as there is a known genetic component to the disease (Fergus et al., 2020). Those with incontinence may develop LS as there is evidence that chronic exposure of the genital tissues to urine is associated with LS (Fergus et al., 2020). Other contributing factors may include genital piercings, higher body mass index, diabetes, hyperlipidemia, tobacco use, hypertension, and coronary artery disease (Fergus et al., 2020).

Signs and Symptoms: When symptoms are present, they commonly include genital itching, burning, and pain. Itching is typically the predominant symptom, and it is worse at night (Chamli & Souissi, 2021). Dyspareunia is common (Krapf et al., 2020). Many individuals experience no symptoms, even with advanced disease (Krapf et al., 2020). On physical examination, the genital epithelium is thin and may be wrinkled with hypopigmented or white patches. The typical presentation is for the whitened areas to be in a "keyhole" pattern around the clitoris and the perineal area (Chamli & Souissi, 2021). In advanced cases, there may be changes to the genital architecture, with narrowing of the vaginal introitus and resorption of the labia (Krapf et al., 2020).

Diagnostic Tests: LS is usually diagnosed by clinical presentation (ACOG, 2020; Chamli & Souissi, 2021; Krapf et al., 2020). Biopsy of the lesion is recommended if the presentation is atypical, not responsive to treatment, or cancer is suspected (ACOG, 2020; Chamli & Souissi, 2021; Fergus et al., 2020). There are no other specific diagnostic tests for LS.

Differential Diagnosis (ACOG, 2020; Chamli & Souissi, 2021):

- Atopic and contact dermatitis
- Crohn's disease
- Eczema
- Genitourinary syndrome of menopause
- Herpes infection

© F.A. Davis Publishing

- Hidradenitis suppurativa
- Infestation of scabies or pediculosis
- Lichen planus
- Lichen simplex chronicus
- Morphea
- Nerve compression or injury
- Neuroma
- Paget disease
- Post-chemotherapy or post-radiation pain
- Postherpetic neuralgia
- Psoriasis
- Tinea cruris
- Trauma
- Vitiligo
- Vulvar precancerous or cancerous lesions
- Vulvovaginal candidiasis

Treatment: Standard treatment for LS is clobetasol 0.05%. Ointment is preferred over cream. Dosing regimens vary, but there is general agreement to apply to the affected area one to two times a day for 4 weeks, followed by a tapering of dose over the next 2 months (ACOG, 2020; Fergus et al., 2020; Krapf et al., 2020; Ringel & Iglesia, 2020). Treatment of asymptomatic LS is recommended to stop progression of the disease (Fergus et al., 2020). If clobetasol is ineffective, treatment with a topical calcineurin inhibitor such as tacrolimus or pimecrolimus can be considered (Fergus et al., 2020; Krapf et al., 2020; Ringel & Iglesia, 2020). Photodynamic therapy, high-frequency ultrasound, and fractional carbon dioxide laser have been studied in the treatment for LS, but more evidence is needed before these are considered first-line therapies (Krapf et al., 2020). Other less common therapies include injection of triamcinolone acetonide into the lesion, with a maximum total dose of 40 mg, and oral treatments such as retinoids, methotrexate, and hydroxyurea (Ringel & Iglesia, 2020). Surgical treatment is reserved for treatment of cancer or release of adhesions and correction of vaginal introital stenosis (ACOG, 2020; Krapf et al., 2020).

Follow-Up: Initial follow-up should occur 3 to 6 months after initiation of treatment. If there is a lack of response to treatment, ability to adhere to the treatment regimen and confirmation of the diagnosis with biopsy should be considered (ACOG, 2020; Ringel & Iglesia, 2020). Long-term follow-up should continue every 6 months, and when remission is achieved, an individualized plan for long-term steroid therapy should be developed (ACOG, 2020; Ringel & Iglesia, 2020). Any new or worsening symptoms should prompt reevaluation (ACOG, 2020).

Sequelae: Untreated LS may lead to scarring, narrowing of the vaginal introitus, resorption of the labia, impaired sexual functioning, and vulvar cancer (Krapf et al., 2020). Risk of progression to vulvar cancer is approximately 5% (ACOG, 2020; Fergus et al., 2020; Ringel & Iglesia, 2020).

Prevention/Prophylaxis: Although there is no known prevention for LS, addressing incontinence and preventing chronic contact of urine with genital tissues is recommended. Early diagnosis and treatment, particularly for those with a family history, will help maintain sexual function and prevent progression.

Referral: Referral to a vulvar dermatoses specialist may be indicated when there is no response to treatment and other causes have been excluded (ACOG, 2020).

Education: Periodic self-inspection of the vulva, particularly for those with a family history, can identify early LS. The rationale for long-term therapy and follow-up should be explained. Discontinuation of therapy is one reason for a lack of response to treatment, and may result in loss of sexual functioning and an increased risk of vulvar cancer (ACOG, 2020; Chamli & Souissi, 2021).

OVARIAN CANCER

Signal Symptoms: None; most women are asymptomatic until the disease is in an advanced stage.

Description: Cancer of the ovary is the most lethal of pelvic malignancies in women. Cancerous processes in the ovary and fallopian tube and primary adenocarcinoma of the peritoneum share the same clinical presentation, and all are managed as a single disease process of ovarian cancer (Orr & Edwards, 2018). Many ovarian cancers actually start in the

© F.A. Davis Publishing

fallopian tube (Stewart et al., 2019). Histologically, epithelial ovarian cancer predominates, accounting for approximately 90% to 95% of all tumors (American Cancer Society [ACS], 2021; Lheureux et al., 2019). Germ cell and sex cord stromal histological types account for the other tumors. Within the broader category of epithelial tumors, there are four main subtypes: serous, endometroid, mucinous, and clear cell. The rest are undifferentiated and mixed epithelial carcinomas (Stewart et al., 2019). Serous carcinoma is categorized as high grade (HGSC) or low grade (LGSC), and 70% to 80% of all serous carcinomas are HGSC, which has a poorer prognosis than LGSC (Stewart et al., 2019). The World Health Organization categorizes ovarian tumors as type 1, which present clinically as a large mass, progress slowly, and have a good prognosis. These are typically LGSC, clear cell, mucinous, or transitional cell types (Lisio et al., 2019). Type 2, the majority of tumors, are high-grade lesions with few known risk factors, a rapid spread, and a poor prognosis (ACS, 2021; Lisio et al., 2019).

Etiology: Unknown.

Occurrence: Ovarian cancer only occurs in individuals assigned female sex at birth. It is estimated that in 2021, 21,410 women will be diagnosed with ovarian cancer, and 13,770 will die of the disease (ACS, 2021). Late diagnosis is the primary reason for the poor prognosis. Less than 20% of cancers are detected at an early stage (ACS, 2021; Chandra et al., 2019). For women in the United States, the lifetime risk for developing ovarian cancer is 1.3%, and for those with *BRCA* gene mutations the lifetime risk is 45% (ACS, 2018b; Menon et al., 2018).

Age: The median age at diagnosis is 63, and the peak incidence of epithelial ovarian cancer is for individuals in their 70s (ACS, 2018b; Lisio et al., 2019). Germ cell tumors occur most commonly in adolescents and younger individuals, whereas sex cord stromal tumors occur most often in individuals in their 50s (ACS, 2018b).

Ethnicity: The incidence of ovarian cancer is highest in northern and central Eastern Europe, with lowest rates in Asia and Africa (Lisio et al., 2019). In the United States, ovarian cancer incidence is highest in non-Hispanic White women followed by American Indian or Alaskan Native, Hispanic, Asian and Pacific Islander, with the lowest incidence in non-Hispanic Black women (ACS, 2018a; Lisio et al., 2019). Those of Ashkenazi Jewish descent have an increased risk, primarily because of an increase in *BRCA* gene mutations in that population (Menon et al., 2018). Despite the fact that non-Hispanic Black women in the United States have lower rates of cancer incidence, they have mortality rates second only to non-Hispanic White women. In addition to a higher stage at diagnosis and an increased incidence of comorbidities, Black women are less likely to receive guideline-based treatment and are more likely to have treatment delayed or to not receive treatment at all (ACS, 2018b; Lheureux et al., 2019).

Contributing Factors: Increasing age and family history are the most important risk factors for ovarian cancer (ACS, 2018b, 2021). With a first-degree relative with ovarian cancer, the relative risk (RR) is 4.0, and with a second-degree affected relative, the RR is 2.0 (ACS, 2018b). Risk increases by 70% if there is a first-degree relative with a history of breast cancer (ACS, 2018b). If there is a *BRCA1* or *BRCA2* gene mutation or Lynch syndrome family history, there is an increased risk for breast and ovarian cancer (Lheureux et al., 2019). Approximately 20% of all ovarian cancer is related to a *BRCA* gene mutation (ACS, 2018b). Other risk factors include a personal history of breast cancer, endometriosis, pelvic inflammatory disease, the use of postmenopausal hormone therapy, late menopause, early menarche, nulliparity or having the first child after age 30, obesity, and tall height (ACS, 2021; Lheureux et al., 2019; Lisio et al., 2019; Menon et al., 2018). Rare mucinous tumors are associated with tobacco use (ACS, 2021). Preventive factors include having the first child before age 30 and multiparity, breastfeeding, tubal ligation or salpingectomy, use of an intrauterine device, and use of oral contraceptives (ACS, 2021; Lheureux et al., 2019; Lisio et al., 2019; Menon et al., 2018). There is some evidence that regular use of aspirin or nonsteroidal anti-inflammatory medications might be protective (Lheureux et al., 2019; Menon et al., 2018). There is no reliable evidence that the use of talcum powder is associated with a risk of ovarian cancer (ACS, 2021). Risk reduction for individuals at high risk includes bilateral salpingo-oophorectomy. Salpingectomy with delayed oophorectomy can be considered if childbearing is desired (Menon et al., 2018).

Signs and Symptoms: Ovarian cancer is typically asymptomatic until there is spread outside of the ovary. Once there is dissemination of cancer cells into the peritoneum, the individual may experience a variety of symptoms based on site of implantation including pelvic or abdominal pain or pressure, vaginal discharge or bleeding, gas/bloating, early satiety, constipation, or urinary symptoms such as frequency or urgency. Pain is not usually a symptom of early disease (Orr & Edwards, 2018). Because many of these symptoms are nonspecific and occur with other health conditions, they are frequently overlooked by patient and health-care professional alike (Lheureux et al., 2019). A number of tools have been developed to aid in the earlier detection of ovarian cancer. Some tools use symptom questions alone and some are combined with laboratory testing. To date, no one tool has enough sensitivity or specificity to recommend it for screening, and there is not yet evidence on outcomes related to prediction tools (Funston et al., 2020). Common physical findings include abdominal distention, lower leg edema, and abnormal pelvic examination findings such as an adnexal mass (Orr & Edwards, 2018).

Diagnostic Tests: For individuals with symptoms, a complete history and physical examination, including a pelvic examination and imaging with transvaginal ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI), should be considered. Although a number of models using tumor characteristics on imaging and other factors have been proposed to confirm the diagnosis of ovarian cancer, none have so far shown to be superior to pattern recognition of tumor characteristics and vascular flow by experienced ultrasonographers (Shetty, 2019a). A complete blood count (CBC), cancer antigen 125 (CA-125) and other tumor markers, chest x-ray, and liver function tests (LFTs) are also part of the initial evaluation (Armstrong et al., 2021; Orr & Edwards, 2018).

There are currently no screening tests for individuals at average risk (Lheureux et al., 2019). Routine bimanual pelvic examinations are no longer recommended (American College

© F.A. Davis Publishing

of Obstetricians and Gynecologists [ACOG], 2018; U.S. Preventive Services Task Force [USPSTF], 2017). For individuals at high risk, regular pelvic examinations in combination with a transvaginal ultrasound and CA-125 can be considered, but these tests have not decreased mortality related to ovarian cancer and are associated with a high rate of false positives (ACS, 2021).

Differential Diagnosis (Shetty, 2019b):

- Benign ovarian mass including ovarian and paraovarian cysts
- Broad ligament fibroid
- Distended bladder
- Diverticular abscess
- Fallopian tube abnormalities
- Irritable bowel syndrome
- Pelvic inflammatory disease
- Pelvic kidney
- Peritoneal tuberculosis
- Stool-filled sigmoid colon
- Tubo-ovarian abscess

Treatment: All patients with a diagnosis of ovarian cancer should have an evaluation by a gynecologist oncologist (Orr & Edwards, 2018). Treatment is based on the individual's age, overall health status and comorbidities, and stage and genetic features of the cancer. Unless the cancer is at an advanced stage or the individual is not a surgical candidate, the first treatment is **s**urgical excision, usually a staging laparotomy, with total abdominal hysterectomy and bilateral salpingo-oopherectomy (ACS, 2021; Armstrong et al., 2021; Orr & Edwards, 2018). Neoadjunctive chemotherapy may be used prior to surgery. Early-stage disease may be treated with surgery alone (Orr & Edwards, 2018). For cancers staged II or III, debulking of the tumor is done followed by 3 to 6 months of a platinum- and taxane-based chemotherapy. Chemotherapy may be delivered systemically or into the peritoneum (ACS, 2021; Orr & Edwards, 2018). Targeted therapy with bevacizumab may be used in addition to chemotherapy, especially for recurrent cancer (Lheureux et al., 2019; Orr & Edwards, 2018). Poly (ADP-ribose) polymerase (PARP) inhibitors can be used as maintenance therapy or as an additional treatment for those with *BRCA* gene mutations or who have become resistant to platinum-based chemotherapy (Armstrong et al., 2021; Lheureux et al., 2019).

Follow-Up: Surveillance guidelines include physical and pelvic examinations and CA-125 measurements (if initially elevated) every 2 to 4 months for the first 2 years, every 3 to 6 months for the next 2 years, and annually starting at year 5. If genetic counseling and/or testing was not done previously, it should be done postoperatively. Imaging is scheduled as indicated (Armstrong et al., 2021).

Sequelae: The average 5-year survival rate for all stages is 48% (ACS, 2018a). If the disease is localized, the 5-year survival rate is 93%, but only 16% of new cases are localized to the ovary (ACS, 2021). Although 80% to 90% of ovarian cancers will initially respond to chemotherapy, most will recur over time, and the 5-year survival for metastatic cancer is 29%. Most cancers return within 1 to 4 years (ACS, 2018a; Kossaï et al., 2018; Lheureux et al., 2019). Tumors associated with *BRCA* gene mutations respond more positively to chemotherapy and have a better prognosis than those not associated with *BRCA* gene mutations (Kossaï et al., 2018). Individuals younger than age 65 have twice the survival rate of individuals older than 65 (ACS, 2021).

Prevention/Prophylaxis: In women who are high risk due to genetic mutations (*BRCA1* or *BRCA2*), a risk-reducing bilateral salpingo-oophorectomy (RRSO) may be considered (ACS, 2021), ideally at the age of 35 to 40 years, on completion of childbearing (Armstrong et al., 2021). However, after this surgery is performed, these women are at higher risk for cardiovascular events and osteoporosis due to premature menopause. Combined hormonal contraceptive pills for at least 2 years is a preventive strategy, and high-risk individuals could consider aspirin therapy (Lheureux et al., 2019; Menon et al., 2018).

Referral: Individuals with a significant family history of ovarian or breast cancer should be referred for genetic counseling. All individuals with a diagnosis of ovarian cancer should be referred to a gynecological oncologist. Because of the lethality of the disease, referrals for psychological, social, and spiritual support should be considered as well as referrals for palliative care for advanced disease (Stewart et al., 2019).

Education: Routine screening for women without a family history of ovarian cancer is not currently recommended. Individuals should be encouraged to report the vague persistent symptoms that are associated with ovarian cancer.

PELVIC ORGAN PROLAPSE

Signal Symptoms: Vaginal bulge, pelvic pressure, urinary incontinence or retention, fecal incontinence or retention, sexual dysfunction (American College of Obstetricians and Gynecologists [ACOG], 2019).

Description: Pelvic organ prolapse (POP) is caused by a weakening of the connective tissues of the pelvic floor, resulting in a relaxation of the anterior vaginal wall, the posterior vaginal wall, and/or the ligaments supporting the uterus (Fig. 15-1). This relaxation causes herniation of organs into the vagina: cystocele or urethrocele if the anterior wall is involved, rectocele if the posterior wall is involved, and uterine descensus if uterine ligaments are involved (ACOG, 2019; Weintraub et al., 2020). Relaxation of the apex of the vagina after hysterectomy can cause herniation of bowel into the vagina, called an enterocele (ACOG, 2019). The symptoms of POP are related to negative body image, depression, decreased quality of life, and difficulty achieving activities of daily living (Bugge et al., 2020; Lawson & Sacks, 2018).

Etiology: It is known that there is a genetic component to POP, although no specific cause has been identified (Good & Solomon, 2019; Weintraub et al., 2020). Any condition that results in weakening of the pelvic floor or increased abdominal pressure on the pelvic region can contribute to the development of POP (Good & Solomon, 2019; Weintraub et al., 2020).

Occurrence: POP is most common in those identified female sex at birth. It is estimated that 3% of U.S. women report vaginal symptoms of prolapse; however, because most prolapse is asymptomatic, up to 50% of women have some degree of prolapse identified on examination (ACOG, 2019). It is estimated that 1.5 to 1.8 in 1,000 women per year have surgery for POP (ACOG, 2019). POP in those identified male sex at birth may occur, and primarily involves rectal prolapse. Men are underrepresented in studies on POP, and information on incidence is unknown (Giagio et al., 2021). POP can occur in those with a neovagina after male to female transition surgery, but the incidence is unknown (Manrique et al., 2019; Roslan et al., 2019).

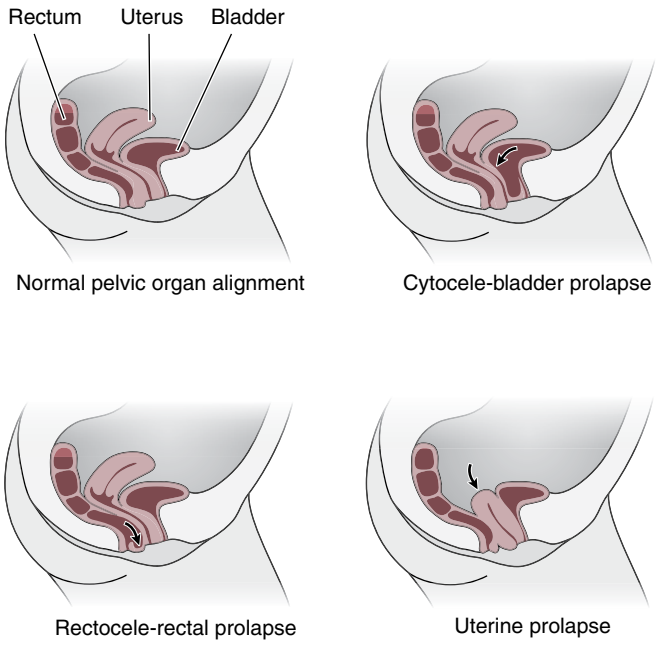

FIGURE 15-1 Types of pelvic organ prolapse. (Adapted from Irion, J. M., and Irion, G. L. (Eds.). *Women's health in physical therapy*. Lippincott Williams & Wilkins, Philadelphia, 2010, p 119.)

Age: POP can occur at any age, but the risk increases with age. Peak incidence is in those ages 70 to 79 (ACOG, 2019; Weintraub et al., 2020).

Ethnicity: Not significant

Contributing Factors: Increasing age is a main contributing factor (Weintraub et al., 2020). Pelvic floor laxity is associated with genetic factors, increased parity, particularly with vaginal births, obesity, chronic constipation, heavy lifting, connective tissue disorders, and menopausal status (ACOG, 2019; Bugge et al., 2020; Good & Solomon, 2019; Weintraub et al., 2020). Evidence on hysterectomy and strenuous exercise as risk factors for POP is mixed (ACOG, 2019; Bø & Nygaard, 2020). There is a risk of recurrence after surgery for POP, which is increased by having a more significant prolapse before surgery, family history of POP, obesity, and having surgery before age 60 (ACOG, 2019; Friedman et al., 2018).

Signs and Symptoms: Symptoms include feeling something bulging from the vagina, pelvic pressure, backache, urinary incontinence or retention, fecal incontinence or retention, dyspareunia, decreased libido, and avoidance of sex due to embarrassment (ACOG, 2019; Bugge et al., 2020; Good & Solomon, 2019; Lawson & Sacks, 2018; Rantell, 2019). On physical examination, the prolapse may be visible on inspection either with or without the aid of separation of the vulvar tissues and the use of a speculum (ACOG, 2019).

Diagnostic Tests: Evaluation includes a complete history, particularly of symptom severity, and a physical examination. Assessing whether POP is affecting urination, defecation, sexual functioning, or activities of daily living in addition to ascertaining if symptoms are worsening is crucial (ACOG, 2019). The physical examination should include an abdominal examination to assess for masses. The pelvic examination should include inspection for the degree of atrophy of external tissues, assessment of pelvic floor muscle tone, and to identify whether any prolapse is visible without the aid of a speculum. The speculum examination is performed with the lower half of a bivalve speculum. The half speculum is placed in the posterior vagina to evaluate for relaxation of the anterior vaginal wall and apex of the vagina and the half speculum is then rotated to retract the anterior vaginal wall to evaluate the posterior vaginal wall and perineal body. It can be helpful to have the patient perform a Valsalva maneuver or cough during the examination to evaluate the extent of prolapse (ACOG, 2019). A complete history and physical examination are usually sufficient for diagnosis of POP. Standard scoring of the extent of prolapse with the International Continence Society Pelvic Organ Prolapse Quantification (POP-Q) tool is recommended, particularly if surgery is anticipated. The POP-Q tool assesses nine points in the vagina, using the hymen as the reference point or zero value. At each of the nine points, structures are evaluated as being above or below the hymen in centimeters

© F.A. Davis Publishing

TABLE 15-4 Stages of Pelvic Organ Prolapse

STAGE	DESCRIPTION OF THE MOST DISTAL PROLAPSE
0	No prolapse. All structures are 3 cm or more above the hymen
I	More than 1 cm above the hymen
II	Between 1 cm above and 1 cm below the hymen
III	Between 1 cm and 2 cm below the hymen
IV	At least 2 cm below the hymen

Source: *ACOG and the American Urogynecologic Society, 2019*

(Good & Solomon, 2019). POP can be staged based on the system in Table 15-4. Urodynamics or other testing may be indicated based on symptoms (ACOG, 2019).

Differential Diagnosis:

- Benign or malignant growth or tumor
- Chronic constipation
- Hemorrhoids
- Stress urinary incontinence
- Urge urinary incontinence

Treatment: Some degree of POP is a common finding on examination, and treatment is indicated only if the individual is symptomatic (ACOG, 2019). The most common initial treatment includes pelvic floor muscle therapy and use of a pessary (Good & Solomon, 2019). Pessaries (Fig. 15-2) are polyvinyl chloride (PVC), latex, or silicon devices inserted into the vagina that provide passive support to the pelvic structures (Bugge et al., 2020; Good & Solomon, 2019; Rantell, 2019). The type and size of pessary is determined by symptoms and pelvic anatomy. The two types of pessaries are support (e.g., ring) and space filling (e.g., gelhorn). Compared to space-filling pessaries, support pessaries are compatible with intercourse and are easier to insert and remove (Bugge et al., 2020; Rantell, 2019). Pessaries need to be removed, cleaned, and reinserted on a regular basis. This may be done by individuals themselves, if possible, on a daily or weekly basis, or by the health-care provider every 3 to 4 months (ACOG, 2019). Two pessaries that must be removed and cleaned daily are the cube and inflatoball pessaries. Failure to remove and clean these daily can result in ulceration and infection of the vagina. These two pessaries are not recommended for those who are not able to perform self-management (Rantell, 2019). Although pessaries have been recommended as first-line treatment for decades, a Cochrane review reported that in four small randomized control trials, pessaries were not effective by themselves, but they may be effective in combination with pelvic floor physical therapy (Bugge et al., 2020). The review recommended more robust research to evaluate pessaries as a treatment option (Bugge et al., 2020). Surgical treatment is indicated for bothersome symptoms when first-line therapies are ineffective or declined (ACOG & The American Urogynecologic Society, 2019). For individuals with significant comorbidities who no longer desire preservation of the vagina or vaginal sexual activity, a minimal surgical procedure to eliminate the vaginal opening (colpocleisis) done under local or regional anesthesia can be a safe and effective treatment option (ACOG & The American Urogynecologic Society, 2019).

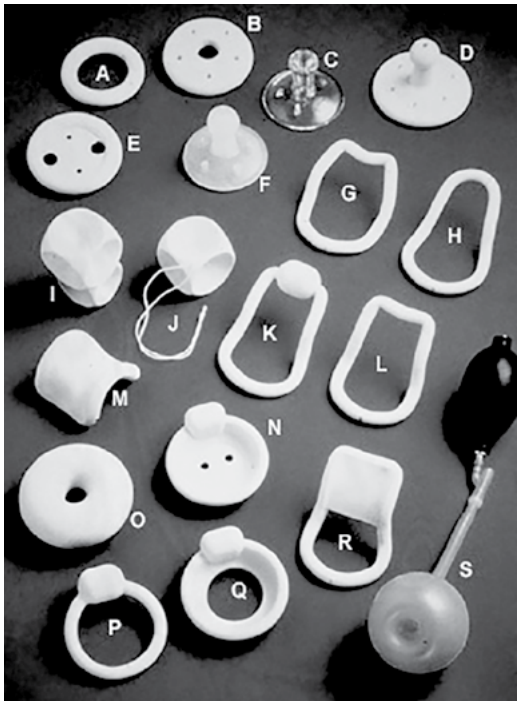

FIGURE 15-2 Types of pessaries. (A) Ring, (B) Shaatz, (C) Gellhorn, (D) Gellhorn, (E) Ring with support, (F) Gellhorn, (G) Risser, (H) Smith, (I) Tandem cube, (J) Cube, (K) Hodge with knob, (L) Hodge, (M) Gehrung, (N) Incontinence dish with support, (O) Donut, (P) Incontinence ring, (Q) Incontinence dish, (R) Hodge with support, (S) Inflatoball (latex).

Follow-Up: If a pessary is in place, and the patient is not maintaining it, then a visit every 3 to 4 months is indicated. If the patient is performing self-maintenance, then a yearly examination is indicated (ACOG & The American Urogynecologic Society, 2019).

Sequelae: Untreated POP often progresses slowly, if at all, so treatment is reserved for POP that is symptomatic (ACOG & The American Urogynecologic Society, 2019). Use of a pessary can result in vaginal erosion, and fistula is a rare complication (ACOG & The American Urogynecologic Society, 2019). If surgery is performed, postoperative sequelae may include bleeding, infection, and temporary urinary dysfunction (ACOG & The American Urogynecologic Society, 2019).

Prevention/Prophylaxis: Performing pelvic floor strengthening exercises, particularly after childbirth, and avoiding constipation can decrease the risk of POP (Good & Solomon, 2019).

Referral: If nonsurgical options are ineffective or not indicated, or if the physical examination findings do not concur with symptomatology, referral to a gynecologist or urogynecologist is indicated (ACOG & The American Urogynecologic Society, 2019). Referral to physical therapy for pelvic floor muscle training is often an initial treatment step.

Education: Educating patients on correct technique for pelvic floor strengthening exercises can help reduce the risk for POP. If there is a risk for chronic constipation, relief measures should be discussed. Assessing for POP and providing patients with resources if they are symptomatic can help patients regain or maintain quality of life (Good & Solomon, 2019; Hage-Fransen et al., 2021).

CASE STUDY

A 72-year-old patient (she/her) presents to the outpatient office with a report of a new onset of urinary incontinence with exertion, particularly coughing, and a feeling of lower pelvic pressure. The patient is widowed, and not in a sexual relationship. Her gynecological history includes five normal spontaneous vaginal births, menopause at age 52 with no menopausal issues, and no use of hormone therapy. There is no surgical history, and the patient has an intact uterus and ovaries. Her medical history includes hypertension, which is well controlled with Lisinopril 20 mg orally daily and a history of intermittent bouts of chronic bronchitis treated with antibiotics and benzonatate (Tessalon perles) for cough. The patient presents regularly for care, and her last comprehensive physical examination was 6 months ago.

Vital signs: T 97.6°F, HR 98, RR 22, BP 130/82, BMI 35

Chief Complaint: New-onset urinary incontinence and pelvic pressure

1. What additional subjective information will you be asking the patient?
2. What additional objective findings would you be examining the patient for?
3. What are the differential diagnoses that you are considering?
4. What laboratory tests will help you rule out some of the differential diagnoses?
5. What screening tools will you select to use on this patient?
6. What is your plan of care?
7. What additional patient teaching may be needed?
8. Will you be looking for a consult?

CHAPTER 16

Musculoskeletal Disorders

Laurie Kennedy-Malone

ASSESSMENT

To make an accurate assessment of the musculoskeletal system in the older adult, the nurse practitioner needs to be familiar with changes in the musculoskeletal system caused by aging. For example, aging often brings about a decrease in height, resulting from a decrease in the length of the trunk with respect to the length of the extremities. An older person may tilt the head backward to compensate for the bend in the thoracic spine, producing the typical posture of those in this age-group. Because of the loss of subcutaneous fat caused by aging, bony prominences became more noticeable. Some absolute loss of muscle mass occurs, with some muscles diminishing and others atrophying, resulting in sarcopenia (Strasser, 2020). With lean muscle loss there is commonly an increase in body fat, resulting in sarcopenia obesity (Kemp et al., 2018). Without continued use, muscles stiffen, and range of motion (ROM) becomes impaired as an older person ages (Manini et al., 2016).

Often when an older person experiences a limitation in functional ability resulting from pain, weakness, or physical impairment, they seek medical attention. A goal of the nurse practitioner in gathering the subjective information from the older adult is to try to determine whether there is a pattern of symptoms (Browne & Merrill, 2015).

To obtain an accurate history of musculoskeletal problems, ask the patient these questions:

- Is there any pain, swelling, stiffness, change in temperature perception (hot or cold), limitation of movement, weakness, body deformity, or paralysis?
- Are the symptoms constant or intermittent?
- What was the sequence of events that triggered the onset of each symptom and what are the precipitating factors? (Browne & Merrill, 2015)
- Is the muscle, joint, and/or periarticular signs and symptoms related to an accident, illness, or prior trauma?
- What time of day do the symptoms begin and for how long?
- Is there a family history of chronic musculoskeletal conditions?
- Review occupational and hobby history to determine an underlying contributing factor to pain and gross deformities.
- Is there a history of obesity?
- Is there a trigger to the complaint such as lack of mobility, temperature, or position (as in sleeping)? Often the patient complains of one or more of these symptoms; however, the condition may actually be a neurological condition (e.g., Parkinson's disease) or a systemic disorder (e.g., thyroid disease). Additionally, patients may be experiencing a new musculoskeletal condition concomitant with an existing condition, such as a new onset of gout with pre-existing osteoarthritis (OA) of the interphalangeal joints.

In addition, the nurse practitioner should:

- Determine whether the condition has been triggered by medications such as statins, with the known side effect of myalgias (Pedro-Botet et al., 2019), or steroids, which can contribute to bone loss.
- Briefly review dietary history to determine pattern on calcium intake.
- Be alert for other symptoms the patient may describe; for example, constitutional symptoms of fever and malaise may be clustered to form a differential diagnosis (Resnick, 2022).
- Review prior therapy and results, determining what the patient has used in the past to alleviate symptoms to include herbal products such as chondroitin, use of complementary or alternative treatments such as heat or cold, massage, ultrasound, and/or acupuncture or pressure.

Pain or Stiffness

Initially, the nurse practitioner will need to determine whether the presenting symptoms arise from the joint, tendons, muscles, or periarticular structures, such as bursae (Hawker, 2017). Further questioning needs to help distinguish whether the condition is acute or chronic, to include an exacerbation of a former condition that had been deemed in remission or resolved. Is the patient experiencing an inflammatory or noninflammatory condition? It is important to remember that both can coexist in patients. Most importantly, determine how the pain and stiffness is affecting function and quality of life (Browne & Merrill, 2015).

When a patient complains of pain or stiffness with movement, the history of the complaint should be discerned. Ask

© F.A. Davis Publishing

whether the patient has experienced any severe trauma in the past that may be now manifesting itself as an articular degeneration. Because patients who have had a structural deformity or amputation typically place excessive strain on the joints for years, older individuals may experience degeneration of the bone and surrounding musculature. An overextension or a recent increase in activity may lead to muscle soreness, followed by disuse, atrophy, and chronic pain. Adhesive capsulitis or frozen shoulder is a common condition in patients experiencing pain in the shoulder and, in turn, limiting their ROM. Knowing the history of the presenting symptom may help you distinguish between a local inflammation and a systemic problem. Questioning the patient about the time of day when the symptoms of pain and stiffness occur is essential data to support the differential diagnosis. Rheumatic disease, for example, is associated with pain on waking, whereas osteoarthritic pain and stiffness worsen as the day progresses. It is important to remember that within the current cohort of older adults a stoic attitude toward pain may be displayed despite the presence of an acute or chronic musculoskeletal condition.

Weakness and Paralysis

Patients with musculoskeletal problems often complain of weakness and paralysis. Determine whether the disability is local or generalized, constant or intermittent. Local weakness or paralysis may be due to disuse because of pain, trauma, or a neurological problem. Generalized weakness may indicate a systemic disorder or recent deconditioning related to extensive immobility or frailty, as in the case of patients with sarcopenia (Dhillon & Hasni, 2017). Patients with an underlying thyroid disorder may have constant weakness, whereas those with rheumatoid arthritis (RA) may experience weakness intermittently (Resnick, 2022).

Muscular weakness should always be differentiated from subjective fatigue. Generally, proximal weakness results from a myopathy and distal weakness from a neuropathy (Larson & Wilbur, 2020). The patient should be asked about their ability to carry out certain activities of daily living (ADLs), such as:

- Does the patient have difficulty combing their hair?
- Can they lift objects?
- Does the patient have any trouble standing up after sitting in a chair?

Patients with a proximal weakness of the upper extremities may have difficulty grooming the hair or lifting objects. Those with a proximal weakness of a lower extremity may have trouble crossing the legs at the knees or walking. If a patient reports difficulty fastening buttons or turning doorknobs, a neuropathy involving the upper extremity is likely.

Nodularity

Another common complaint in patients with a musculoskeletal disorder is nodularity or deformity. In obtaining the history from a patient with a deformity, the examiner needs to know how long the patient has noticed the deformity:

- Did it occur suddenly?
- Was it the result of trauma?
- Has there been any change in the deformity since its onset, such as a new onset of pain, swelling, or erythema?
- Is there a family history of similar nodularity?

Physical Examination

Focus of the physical examination of the musculoskeletal system includes inspection, palpation, ROM, and joint special maneuvers. Observe for any noted asymmetry, atrophy, wasting, masses, and erythema of the muscles. Examine the skin specifically for any lesions or change in color that may be related to an acute or chronic musculoskeletal condition. Ecchymosis in the area of a joint may be indicative of tendon rupture. Joints and surrounding structures should be examined to determine presence of any deformities, nodularity, subluxation, abnormal angulation, limitation of movement, stability, and malalignment. Palpation may reveal swelling, change in temperature, tenderness, and crepitus (Suneja et al., 2020). Engage the patient in active ROM of joints necessitated by the specific complaint. Specific provocative maneuvers related to pathology occurring in that affected joint(s) is warranted during a focused examination.

GAIT

The initial physical examination of the musculoskeletal system can begin with observing the patient's gait. Overall assessment of gait includes an extensive examination of the lower extremities to include podiatric issues (examining patient's feet). Any gait abnormalities or problems in maintaining balance should be noted. Assessment of gait needs to consider the patient's stance and arm swing (Pirker & Katzenschlager, 2017). Observe for any limping or asymmetrical leg movement or noted deformities. An abnormal stance is referred to as an antalgic gait, often resulting from chronic hip pain and muscle atrophy. Note whether the patient is having difficulty in shifting weight from one leg to the other and instead relies on shoulder movement from side to side. This abnormality in arm swing is referred to as a lurch (Pirker & Katzenschlager, 2017).

Another important aspect of the gait examination is to note the patient's ability to sit in and rise from a chair. If a patient relies on a rocking motion and/or arm strength to stand, consider quadriceps weakness. More sophisticated testing is warranted if the patient demonstrates difficulty in performing this task because they could be at a high risk for falling (Pirker & Katzenschlager, 2017).

POSTURE

Note the patient's posture for any abnormalities of the trunk and spine. Examine the patient while the patient is standing erect to note any changes in the spinal curvature such as scoliosis. In older adults, kyphosis of the thoracic spine is accentuated. While looking at the older person from the side, the examiner may note that the spine appears to form the number 3. If the curve appears more to be a sharp angle, this is called a gibbus. A gibbus deformity of the spine resulting from a vertebral compression fracture may be the first evidence of osteoporosis (Williams, 2009).

RANGE OF MOTION

Patients presenting with a functional limitation should be asked to demonstrate active ROM, which should be performed smoothly and effortlessly. Remember that joint movements include flexion, extension, abduction, adduction, and external rotation. If the patient has limited active ROM, passive ROM should be performed. If the passive range exceeds the active range, the limitation is due to a muscle weakness.

© F.A. Davis Publishing

Patients may resist passive ROM because of fear, a neurological disorder, or a joint abnormality.

JOINT PAIN

When patients complain of joint-related pain, the practitioner needs to determine whether the underlying condition is articular, periarticular, or both. When examining the patient's joints, the joints should be inspected in a relaxed position and then in flexion and in extension. Abnormalities of the position or carrying angle, joint deformity, erythema, swellings, nodulation, and muscle changes should be assessed. In an older patient with muscle changes, the limb or portion of the body will appear thinner, which indicates atrophy. To determine whether bone structure changes have occurred, appearance and symmetry should be observed. Enlargement, excessive curvature, and irregularity may indicate sequelae of childhood rickets, osteoporotic fractures, Paget's disease, OA, tophaceous gout, or bone tumors. Crepitation or a crackling noise may be heard when the joints are put through ROM. Crepitation is produced by the rubbing together of bone or irregular cartilage surfaces (Suneja et al., 2020).

JOINT SWELLING AND NODULARITY

Specific questions about the duration of any swelling, presence of pain, limitation of movement, evidence of erythema, and locking or buckling of the joint are important to assess. Erythema is usually associated with active inflammation and accompanied by swelling. Examples of joint nodulation are the nodules found in the interphalangeal joints in patients with RA and OA. Heberden nodes are nodules of the distal interphalangeal (DIP) joints; Bouchard's nodes are nodules of the proximal joints. Both are found in patients with OA (Suneja et al., 2020). In RA, the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints and wrist of both hands are commonly involved (Mohammed et al., 2021). Common nodularity/deformity in RA is swan neck deformity, which involves the hyperextension of the PIP joint and flexion of DIP joint, and boutonnière deformity, which is flexion of the PIP joint and hyperextension of the DIP joint (Fox & Chang, 2018).

Rheumatoid nodules are described as firm, nontender nodules often found on the dorsum of the wrist, elbow, or MCP joint (Cabling, 2020). Haygarth's nodes are spindle-shaped enlargements of the middle interphalangeal joints that occur in RA (Suneja et al., 2020). Patients presenting with "sausage-like" digits known as dactylitis may have reactive or psoriatic arthritis (Girolimetto et al., 2021).

Any joint deformity should be palpated to determine whether it fluctuates because of fluid or is firm because of a thickening or enlargement. If there is fluid, the cause may be recent trauma, inflammation, or joint infection. An articular enlargement of RA is usually soft, whereas a joint deformity found in OA is usually firm. Erythema may also be indicative of septic arthritis. If the joint swelling persists for more than 3 days, this may indicate an arthritic condition. Also examine the bursal areas around the joints, palpating for swelling, tenderness, ganglions, and presence of nodules. Tophaceous gout appears as salmon-colored nodules that do not transilluminate, as is possible when examining a superficial inflamed bursa (Williams, 2009). A ganglion is usually a soft cyst-like swelling, often found near joints. Swelling of the bursa is usually tender on palpation. All masses should be measured across their greatest diameter (Suneja et al., 2020).

MUSCLE WEAKNESS

For the patient complaining of muscle weakness, inspect for evidence of muscle atrophy and palpate the muscles during contraction and rest (Larson & Wilbur, 2020). Any fluttering or fasciculations of the muscles should be noted. To determine whether a patient is having true muscle weakness, the patient should perform against the examiner's resistance. One side should be compared with the other and a numerical value for tested muscle strength recorded. Flexor and extensor muscles should be tested for strength (Suneja et al., 2020). Testing of handgrip strength has been found to correlate with lean body mass (Kemp et al., 2018).

BURSITIS, TENDINITIS, AND SOFT TISSUE SYNDROMES

Signal Symptoms: Pain, inflammation, and/or swelling in the structures and tissues surrounding a joint including the bursa, ligaments, tendons and/or muscles

Description: Bursitis is irritation or inflammation of a bursa, a fluid-filled pad that protects soft tissues (such as muscles and tendons) from underlying bony prominences. Tendinitis is irritation or inflammation of the tendon, which is the fibrous connective tissue that attaches muscle to bone. Tenosynovitis is tendinitis that incorporates the tendon sheath lining. Enthesitis is inflammation or pain at the insertion site of tendons, ligaments, fascia, or joint capsules to the bone; it can be mistaken for tendinitis. Myofascial pain is firm knotted muscle pain often of the neck, shoulders, and back. Carpal tunnel syndrome is nerve pain caused by compression of the medial nerve within the wrist. Plantar fasciitis is inflammation and pain of the thickened fibrous aponeurosis that runs from the heel to the toes forming the arch of the foot (Biundo, 2020a; Hubbard et al., 2018; Kushner, 2020).

Etiology: Bursitis is commonly idiopathic or a result of trauma from injury or overuse. Bursitis can also occur with infection most often of the prepatellar and olecranon bursae, which also happens to be the most common locations for hemorrhagic bursitis. Tendinitis is frequently caused by overuse related to tasks such as work, sports/hobbies, and repeated microtrauma. Lateral epicondylitis (tennis elbow) is more common than medial epicondylitis (golfer's elbow) with the former occurring from repetitive forced extension and/or rotation of the wrist/hand and the latter occurring from repetitive clenching of the fingers, such as with golf. Myofascial pain can be the result of poor posture, strain, minor injury, or from degenerative arthritis. Carpal tunnel syndrome can occur from multiple causes including inflammatory arthritis, infection, and overuse/poor positioning. Plantar fasciitis can be caused by pes planus, standing for long periods, running, change in typical shoe height, or heel spurs (Biundo, 2020a; Hubbard et al., 2018; Kushner, 2020).

© F.A. Davis Publishing

Occurrence: Prevalence varies by population and can occur at any time, but these syndromes are most commonly associated with manual labor and athletics (Hubbard et al., 2018). There typically is no clear trend in the incidence of soft tissue syndromes between men and women other than the prevalence related to the underlying cause such as higher incidence of gout in men and inflammatory arthritis in women (Loiacono et al., 2019). Morton's neuroma, however, occurs five times more frequently in women than men (Santiago et al., 2018).

Age: Other than inflammatory arthritis, which affects a younger population; incidence increases with each decade of life after 40 years of age (Loiacono et al., 2019).

Ethnicity: No clear trend related to ethnicity other than incidence within specific populations of underlying cause.

Bursitis and tendinitis can occur secondary to an inflammatory arthritis such as gout or rheumatoid arthritis (RA). Tenosynovitis is often caused by inflammatory arthritis, particularly RA, and can occur with infection. Enthesitis is seen in the spondyloarthropathies, specifically psoriatic arthritis (Biundo, 2020b; Hubbard et al., 2018; Kushner, 2020). Inflammation and risk of tendon rupture, particularly of the Achilles, can occur with fluoroquinolones, more so when administered in conjunction with glucocorticoids and when given to an athletic person (Morales et al., 2019). Metabolic diseases, including diabetes, hyperlipidemia, obesity, and thyroid disease, contribute to tendon and ligament disorders. Carpal tunnel syndrome is commonly affected by metabolic disorders and in younger women, pregnancy (Loiacono et al., 2019).

Signs and Symptoms: Patients presenting with soft tissue syndromes experience pain of varying degrees with movement of the affected area. Acute bursitis is painful especially with motion when the bursa is stretched or compressed. Swelling is common with superficial bursitis such as of the olecranon or prepatellar bursa. Infectious and crystalline bursitis is frequently erythematous, painful, warm and can include pitting edema. Tendinitis pain presents with movement or resistance to movement of the affected tendon. Swelling can occur of the tendon sheath with inflammatory arthritis or infection, and is tender to palpation (Biundo, 2020b; Hubbard et al., 2018).

In assessing a patient, it is important not only to obtain a complete history of present illness, but review past medical history including recent procedures, medications, family history, and social history including occupation and hobbies/athletic activity. Pain associated with inflammatory arthritis will be more pronounced with rest and in the morning and improve with activity. In addition to determining timing and quality of pain, it is important to assess precipitating and alleviating factors.

Signs and symptoms will depend on the location of the area affected. Myofascial pain is associated with the trigger points of the neck, shoulders, and back. Shoulder pain could be subacromial bursitis, supraspinatus tendinitis, or rotator cuff tendinitis and impingement syndrome, which all affect the upper shoulder and the upper third of the arm; or bicipital tendinitis, which also causes shoulder pain but travels down the arm to the elbow and forearm. Elbow pain can include olecranon bursitis, which tends to affect the tip of the elbow; lateral epicondylitis, with pain on the outside of the elbow; or medial epicondylitis, with pain on the inside of the elbow at the respective locations of tendon attachment. Enthesitis of the lateral epicondyle can be difficult to differentiate from epicondylitis; however, enthesitis tends to include a painful nodule at the attachment site (Kaeley et al., 2018). The wrists and hands tend to be affected by de Quervain's tendinitis, which affects the wrist on the side of the thumb and is common after pregnancy; volar flexor tenosynovitis, which affects the volar aspect of the thumb or other fingers, radiates distally, and can lead to trigger finger; Dupuytren's contracture, which is abnormal thickening of skin at the base of the volar aspect of fingers and leads to contracture of the palm of the hand; and carpal tunnel syndrome, which can cause pain, numbness, and weakness of the first three fingers and the medial side of the fourth finger. Discreet swelling commonly of the wrist or hand may be a ganglion cyst; they tend to be painless and idiopathic (Biundo, 2020b; Hubbard et al., 2018).

Lateral hip pain is typically trochanteric bursitis and is noticed particularly with side sleeping or getting up from a deep chair or out of a car. Gluteus medius tendinitis often accompanies trochanteric bursitis, causing pain of the buttocks (typically while climbing stairs). Ischial bursitis causes pain of the buttocks that travels to the posterior thigh and occurs with long sitting on hard surfaces. Knee pain from bursitis is most commonly of the prepatellar bursa and includes swelling of the front of the knee; less often is infrapatellar bursitis from long kneeling with pain just below the knee; pes anserine bursitis occurs of the proximal anterior medial tibia and is noted with knee-to-knee contact with side sleeping, often with osteoarthritis (OA) of the knee, and with jogging. Enthesitis can occur of the medial femoral condyles of the distal femur but again can be difficult to differentiate from other musculoskeletal disorders. Painful, mostly discreet, posterior swelling of the knee may be a Baker's cyst secondary to OA. Ankle and foot soft tissue syndromes include retrocalcaneal bursitis of the posterior heel (often from ill-fitting shoes), calcaneal bursitis of the sole of the heel (often noted with heel spurs), and Achilles' tendinitis with pain, swelling, and ankle stiffness noted when pushing from the ball of the foot. Achilles' enthesitis tends to include a painful nodule at the attachment site. A Morton's neuroma is a painful nerve entrapment neuropathy and nodule most frequently of the third or second plantar intermetatarsal web space (Santiago et al., 2018). Patients may also present with tarsal tunnel syndrome affecting the medial nerve of the ankle, causing pain or burning of the sole of the foot and toes, or plantar fasciitis with pain of the sole of the foot, particularly with walking (Biundo, 2020b; Hubbard et al., 2018).

Diagnostic Tests: Diagnosis of soft tissue syndromes is primarily based on physical examination utilizing inspection, palpation, passive range of motion (ROM), active ROM, and special orthopedic maneuvers. X-rays are not useful with soft tissue syndromes except to identify bone spurs, calcifications, or to rule out another pathology such as a fracture or pseudogout. Ultrasound can be especially useful to assess deep bursae, cysts, tendon tears, and/or inflammation. Power (or color) Doppler can identify neovascularization of a pathological tendon (Loiacono et al., 2019). Magnetic resonance imaging (MRI) can be beneficial to assess inflammation and tendon pathologies as well as rule out other musculoskeletal disorders.

© F.A. Davis Publishing

Laboratory testing should be considered with concern for infection or a crystalline arthropathy, specifically aspiration of a bursa with analysis to include cell count, Gram stain, culture, and microscopy to identify crystals. Blood tests are not typically necessary—a complete blood count (CBC) could help assess for infection, a uric acid is best drawn when a patient is not having a gout flare, and inflammatory markers such as a C-reactive protein (CRP) and an erythrocyte sedimentation rate (ESR) should be reserved for when there is a high suspicion of an inflammatory or infectious process present (Ramakrishnan et al., 2015).

Differential Diagnosis:

- Soft tissue syndromes (bursitis, tendinitis, tenosynovitis, enthesitis, myofascial pain, carpal tunnel syndrome, plantar fasciitis, neuroma)
- Degenerative joint disease
- Infection (cellulitis, infected bursitis, septic joint)
- Inflammatory arthritis (e.g., gout, pseudogout, rheumatoid or psoriatic arthritis)
- Injury (strain, sprain, contusion, tendon rupture, fracture)
- Joint effusion

Treatment: Initial treatment of soft tissue syndromes should include rest and/or short-term immobilization (splint or brace) and use of intermittent heat or cold, respectively for chronic or acute inflammation. As pain and inflammation improve, gentle ROM and exercise should be started as tolerated and gradually increased. This is important to maintain good ROM and avoid contractures, which can develop of the elbow and shoulder in a short period, especially with chronic conditions. Physical therapy (PT) and therapeutic exercise are the cornerstone of treatment for soft tissue syndromes, particularly tendinopathy (Loiacono et al., 2019).

Pharmacological treatment options include addressing infection, inflammation, and the underlying cause. Empiric antibiotics for suspected infection should be initiated until Gram stain and culture results are available; then change accordingly if needed. Crystalline disease should be treated based on current recommendations. NSAIDs can be useful with inflammation and are typically given for 7 to 10 days. With any NSAIDs it is important to consider patient-specific contraindications, including kidney disease, cardiovascular risks, gastrointestinal considerations, and possible adverse medication interactions such as with anticoagulants. The challenge with NSAIDs, particularly with tendinopathies, is that tendons are not well vascularized; thus, there is not good bioavailability where needed. Short-term oral corticosteroids can be useful to reduce inflammation and associated pain without the renal risk; however, there is increased risk of infection and elevation of blood glucose, and they can be contributory to tendon rupture when given with fluoroquinolone antibiotics. Additionally, some studies indicate both NSAIDs and corticosteroids can negatively affect the regenerative processes of tissues (Loiacono et al., 2019).

In the absence of infection, soft tissue corticosteroid injection can be effective when other treatments fail. Indications for corticosteroid injection for soft tissue conditions include bursitis, tendinitis, trigger points, ganglion cyst, nerve entrapment syndromes, and plantar fasciitis. Injections for tendinitis should only be into the tendon sheath and never into the tendon as that can weaken it and increase risk of rupture. As with any injection, there is a risk of infection, and corticosteroid injections can also cause changes in pigmentation, fat atrophy, and elevate blood glucose (Biundo, 2020a).

Alternate treatment options include acupuncture, extracorporeal shock wave therapy, pulsed electromagnetic fields, intratissue percutaneous electrolysis, dry needling, and platelet-enriched plasma; however, studies often are limited and not all show definitive evidence of efficacy. Similarly hyaluronic acid injection studies are limited; however, there appears to be evidence to support anti-inflammatory properties as well as positive effects on collagen synthesis and cell proliferation. Insurance does not always cover these alternative therapies due to lack of evidence and/or efficacy (Loiacono et al., 2019).

Follow-Up: These syndromes are generally acute concerns that will resolve with a combination of nonpharmacological and pharmacological therapies; however, it is important for patients to follow-up if needed. Prescribed medications or antibiotics, arthrocentesis and joint injection, or referral may be necessary.

Sequelae: Soft tissue syndromes left untreated or suboptimally treated can become chronic, leading to degenerative changes and bone spurs/calcifications, and can negatively affect joint ROM. Chronic bursitis leads to bursal adhesions, villi formation, thickening of the bursa wall with proliferation of the synovial lining, and chalky deposits. Tendinopathy typically is a result of degenerative changes, which can include calcium deposits, or repetitive tearing from poor ergonomics and highly repetitive movements (Biundo, 2020a; Loiacono et al., 2019).

Prevention/Prophylaxis: Prevention of soft tissue syndromes requires modifying or avoiding activities that exacerbate the problem. This includes avoiding improper technique and poor positioning in sports and work; and avoiding overuse and repetitive movements for long periods. When soft tissue syndromes are secondary to another condition such as an inflammatory arthritis, it is important to address that to avoid these complications.

Referral: Referral to PT, occupational therapy (OT), or orthopedics may be necessary to further address the current problem or to provide education regarding necessary modifications.

Education: In addition to preventive measures, patients should be educated to maintain a good level of fitness with good strength and flexibility, ease into new exercise routines, use good, properly fitting equipment and shoes, and (when needed) utilize splints, braces, and orthotics. It is important to educate patients to not overwork tendons with overloading and/or repeated stretching because this can initiate the degenerative process by breaking down the collagen fibers (Loiacono et al., 2019). Patients with a history of tendinitis or those on corticosteroids should be educated on the possible adverse effects of fluroquinolones and tendon rupture.

FRACTURES

Signal Symptoms: Soft tissue swelling, dislocation, altered range of motion (ROM), ecchymosis, local tenderness, pain with any motion.

Description: Fractures are a common cause of disability in older adults. Hip fractures and wrist fractures are among the two most common types of fractures in older adults. Specifically, in patients aged older than 65 years, distal radius fractures are the second most common fractures after hip fractures (Luokkala et al., 2020).

Etiology: Advanced age has been identified as a risk factor for fracture. The World Health Organization predicts that between 2000 and 2050, the proportion of those aged older than 60 will double in numbers from 11% to 22% or 605 million to 2 billion people (Downey et al., 2019). This increase in the older adult population will most certainly see an increase in the numbers of fractures seen in health care.

Occurrence: In the United States, osteoporosis accounts for over 1.5 million fractures annually. By 2050, the costs associated with osteoporotic fractures are expected to exceed $130 billion (Bartl & Bartl, 2019). Hip fractures can be particularly disabling. More than 250,000 hip fractures occur in the United States each year. Estimates show that 30% of people aged 65 years and older fall each year; in that group, 5% of those falls result in fractures. Hip fractures are increasing with excess of 6 million per year predicted in 2050 (Downey et al., 2019).

Age: Our nationwide data indicate the prevalence of hip fractures in older adults is generally on the rise, and the female occupies a higher proportion. Age (especially aged 80 years and older), race (mainly non-Hispanic white), smoking, drinking alcohol, living alone, combined with diabetes and osteoporosis may be closely linked to the occurrence of hip fractures in older adults (Zhang et al., 2021). Patients meeting any of the above criterion need to be screened for potential fall hazards/risks at any point when they enter the health-care system.

Ethnicity: In a sample of Medicare data from 2010 to 2016, Black women with postmenopausal osteoporosis had significantly higher rates of mortality, debility, and destitution after fracture than White women. These Black women had a larger prevalence of femur and hip fractures and a lower prevalence of radius/ulna and clinical vertebral fractures compared with White women (Wright et al., 2020). This racial disparity is important to remember when a Black woman has met criteria for postmenopausal osteoporosis and steps should be taken to prevent falls/fractures.

Contributing Factors: Smokers have an increased risk of fracture and experience more complications with delayed bone healing, even if they have already stopped smoking, because some adverse effects persist for a prolonged period. The patient should also be warned that using e-cigarettes or other tobaccos does not appear to reduce adverse effects on health (Hernigou & Schuind, 2019). Although lifestyle choices can have an effect on bone health, certain genetic health conditions can have equally damaging effects. One study found osteoporosis is more prevalent in people with neurological conditions, such as multiple sclerosis and Parkinson's disease (Kelly et al., 2020). Patients with these neurological conditions should receive appropriate bone health screening.

Signs and Symptoms: Symptoms include soft tissue swelling, ecchymosis, abrasions, edema, skin discoloration, local tenderness, and pain with any motion. Fractures often are a result of injury to the affected area. It is important to palpate the area of maximum tenderness to determine whether more than one bone may be involved (Eiff & Hatch, 2017).

© F.A. Davis Publishing

Neurovascular status should be obtained with any extremity fracture, especially with significant swelling due to the risk of compartment syndrome. Extremity compartment syndrome (ECS) most often develops in the context of severe trauma, especially—nearly 75% of all cases—in long bone fractures, such as tibial and forearm fractures and crush injuries. However, it may also develop from both minor traumas, when treated with tight bandage or constrictive cast, or in nontraumatic cases. ECS represents a surgical emergency: time limit for fasciotomy is within 8 hours from the diagnosis of acute ECS (Coccolini et al., 2020).

Diagnostic Tests: Recommend ordering radiographs of the affected area/injury to rule out and identify the area and type of fracture. Radiographs of the affected area are needed in two and three views (Eiff & Hatch, 2017).

Differential Diagnosis:

- An infectious process/osteomyelitis
- Neoplastic process/multiple myeloma
- Osteoporosis
- Sprain/strain

Treatment: For the pain related to the fracture, narcotic analgesics and/or short-term NSAIDs, if not prohibited, are helpful. Depending on the site of the fracture, casting, walking boot, elastic wrapping, splints, immobilization, traction, or surgical intervention may be used (Eiff & Hatch, 2017). The most common surgical intervention for a fractured hip is the open reduction with internal fixation, especially for fractures of the intertrochanteric or subtrochanteric region. The most common surgical intervention for a distal radius fracture is an open reduction and internal fixation using a volar positioned plate. Nonoperative treatment can be considered the gold standard, but shared decision making between the patient and the treating physician is warranted (Luokkala et al., 2020).

Follow-Up: Adequate nutrition and wound care are important for proper healing. It is common in skilled nursing facilities to start patients on zinc and vitamin C supplements; however, no study is conclusive in this treatment modality. Patients should be questioned about any muscle weakness or paresthesia after the incident. Patients may have return appointments with an orthopedist, physical therapist, or both. The function of the affected area should be evaluated. Determine what impact the injury had on the patient's activities of daily living (ADLs) and instrumental ADLs (IADLs) (Eiff & Hatch, 2017).

Sequelae: To an older adult, a hip fracture can be a life-changing or life-ending event. A large proportion of functionally independent patients are not able to ambulate independently after hip fracture or experience functional loss related to impaired balance and mobility. Morbidity after a hip fracture is not just physical; there is a high incidence of depression and cognitive impairment (both temporary and permanent). The recovery after a fracture is lengthy, and a relatively high number of patients do not manage to achieve preinjury levels of independence or even survive (Reyes et al., 2020). One complication after distal radius fracture is delayed carpal tunnel syndrome. This condition can result from scar tissue invading the carpal tunnel and pressing on the median nerve or from fractures allowed to heal malaligned. Careful follow-up should be performed because delayed carpal tunnel syndrome may occur within 6 months after injury (Watanabe & Ota, 2019). A recent publication describes a 1-year mortality rate post hip fracture of 21% (Downey et al., 2019). Studies have found that 25% of patients die within 1 year of experiencing a hip fracture (Wright et al., 2020).

Prevention/Prophylaxis: Calcium and vitamin D are often recommended by clinicians to boost bone health. One study found vitamin D alone (11 randomized clinical trials with 34,243 participants) showed no significant association with risk of any fracture or of hip fracture. In contrast, daily supplementation with both vitamin D and calcium (6 randomized clinical trials with 49,282 participants) was associated with a 16% reduced risk of hip fracture. (Yao et al., 2019).

Referral: Rehabilitation needs will likely include an orthopedic specialist for complex casting and surgical needs. Physical therapy/occupational therapy (PT/OT) referrals to further evaluate and treat functional physical impairments and to improve ADLs are in order to provide as much independent living as possible. Keep in mind that older patients may be hesitant to resume previous normal activities due to falls. This hesitancy may be justified as one meta-analyses have shown that individuals who have sustained a fracture are at approximately double the risk of sustaining subsequent fractures, as compared to their fracture-free peers (Harvey et al., 2017). This may be resolved by the involvement of a rehabilitation team.

GOUT

Signal Symptoms: Monoarticular inflammatory arthritis, podagra (first metatarsophalangeal [MTP] joint), tophi

Description: Gout is the most common inflammatory arthritis in the United States. This chronic disease is caused by hyperuricemia, defined as serum urate or uric acid level >6.8 mg/dL. Gout commonly causes recurrent acute flares and chronic arthritis. The initial gout attack is often podagra—occurring in the first MTP joint (Mandell, 2020). Gout occurs when monosodium urate (MSU) crystals precipitate into the joint space, soft tissues, and periarticular structures, producing an inflammatory response (Golenbiewski & Keenan, 2019). Longstanding disease can result in MSU crystal deposits in larger joints, in cutaneous tissue known as tophi, and the parenchymal of the organs—for example, the kidneys (Mandell, 2020). Clinically, patients can have asymptomatic hyperuricemia or different presentations of gout such as acute gouty arthritis, intercritical periods, or chronic tophoceous gout (Chen-Xu et al., 2019).

Etiology: Urate is the ionized form (salt) of uric acid and is the by-product of purine breakdown in the body (Golenbiewski & Keenan, 2019; Ragab et al., 2017). Uric acid occurs both endogenously by purine metabolism in the liver and exogenously through dietary intake of purine-rich foods. The human body lacks the ability to breakdown uric acid, and the threshold at which serum uric acid (SUA) becomes pathological is 6.8 mg/dL (Maiuolo et al., 2016; Ragab et al., 2017). The higher the SUA and the longer an individual has been hyperuricemic, the greater the chances of developing gout.

Elevated SUA levels can occur in multiple ways, the most common is decreased excretion. The kidneys excrete two-thirds of uric acid and the gastrointestinal (GI) tract one-third. Decreased excretion can occur when there is decreased glomerular function causing decreased renal excretion, use of diuretics, decreased GI tract excretion, the effects of alcohol catabolism on the kidneys, and/or a genetic predisposition. Uric acid levels can be elevated with increased production; however, this scenario is much less likely. Increased SUA due to increased production can occur with hematological conditions such as leukemia and lymphoma, with cytotoxic cancer therapy and radiation therapy where increased cell proliferation and cell death occurs, with obesity due to adipose tissue contributing to production, and as a genetic and/or an enzyme abnormality (Mandell, 2020). Although most purine synthesis occurs within the liver, dietary purine intake can contribute to elevated SUA, particularly in the setting of decreased excretion (Golenbiewski & Keenan, 2019).

Occurrence: Worldwide, gout typically occurs in 1% to 4% of the population, although in some Oceanic countries prevalence is >10% (Golenbiewski & Keenan, 2019). According to the National Health and Nutrition Examination Survey (NHANES), the prevalence of hyperuricemia and gout doubled between the 1960s and the 1990s in the United States and continued to increase into the early 2000s. In recent years the prevalence of gout in the United States is 3.9% or approximately 9.2 million adults (Chen-Xu et al., 2019). Gout is highest among men with a three or four to one male-to-female ratio; however, this discrepancy narrows with age. It is estimated approximately 5.2% of men (5.9 million) and 2.7% of women (3.3 million) have gout (Golenbiewski & Keenan, 2019). There is a higher incidence of gout in postmenopausal women than in premenopausal women (Singh & Gaffo, 2020).

Age: The incidence and prevalence of gout increases with each decade of life. The lowest prevalence is in individuals 20 to 39 years old at 0.7%, and the highest is in individuals 80 years and older at 8.7% (Chen-Xu et al., 2019).

Ethnicity: Some ethnic groups have a higher prevalence of gout, including Blacks, the New Zealand Maori, the Han Chinese, and some Polynesian people. For example, the relative risk of gout in Black men is 1.69 (confidence interval [CI] 95%, 1.02–2.80) compared to White men. Higher incidence of hypertension in Black men is felt to be a contributing factor in higher rates of gout (Singh & Gaffo, 2020).

Contributing Factors: In addition to sex, genetics, and obesity, there is a strong correlation between gout and hypertension, diabetes, kidney disease, heart disease, metabolic syndrome, and hyperlipidemia (Chen-Xu et al., 2019; Singh & Gaffo, 2020). Gout can also be triggered by a medical stressor such as acute dehydration, surgery, infection, or an injury/trauma. Both loop and thiazide diuretics can cause gout attacks as well as urate-lowering therapy (ULT) as it mobilizes urate upon initiation. Purine-rich foods, such as red meats, organ meats, meat gravies and broth, certain seafoods and shellfish, alcohol (particularly beer), and sugary foods and drinks can contribute to elevated SUA (Mandell, 2020).

Signs and Symptoms: Initial gout attacks typically occur nocturnally in the first MTP, with pain peaking within 24 hours and gradually resolving in 1 to 2 weeks (Towiwat et al., 2019). This can sometimes be precipitated by alcohol consumption or a purine-rich meal. Pain is often described as rapidly progressing from severe to excruciating, tender even to very light touch and accompanied by swelling, erythema, and the skin may have a tight shiny appearance. Systemic symptoms of fever/ chills, malaise, and tachycardia are possible. As the disease progresses, flares last longer—up to 3 weeks—and multiple joints can be affected at the same time or sequentially with little to no rest between attacks (Mandell, 2020). Gout can affect the instep, ankle, knee, elbow, and wrist; rarely the cervical spine, shoulder, or hip (Pillinger & Mandell, 2020).

Suboptimally treated patients can develop tophi, firm white-yellow nodules of the interphalangeal and/or MCP joints, wrists, feet, ears, and near the olecranon and Achilles' tendon. Normally painless, tophi can drain chalky white urate crystals and can become inflamed with minimal injury or infected due to ulceration. Tophi contribute to joint erosions and deformity (Mandell, 2020).

Diagnostic Tests: Arthrocentesis with synovial fluid analysis should be completed at initial presentation if gout is suspected; this will also enable ruling out infection. The analysis during a flare should show 2,000 to 100,000 white blood cells (WBCs)/mcL with >80% polymorphonuclear WBCs. Gram stain and culture are important as well because infectious arthritis can

© F.A. Davis Publishing

have similar WBC counts (Mandell, 2020). The gold standard for diagnosis of gout is identification of MSU crystals in synovial fluid using microscopy (Ragab et al., 2017). Joint aspiration is not necessary for recurrent flares unless presentation or symptoms differ (Mandell, 2020).

The diagnosis of gout is supported by an elevated serum uric acid; however, approximately 30% of patients will have a normal SUA during an acute flare. SUA is neither sensitive nor specific enough to solely make the diagnosis, although it is useful to have a baseline level drawn between flares to quantify the hyperuricemia and recheck intermittently or when adjusting urate-lowering medications. Measurement of urinary uric acid is not recommended because it is a poor indicator of therapeutic response (Mandell, 2020). Laboratory testing should include assessing renal function and a complete blood count (CBC) to check for leukocytosis if septic arthritis is a consideration.

Imaging modalities utilized in the diagnosis and treatment of gout include conventional radiography and computerized tomography (CT), dual-energy CT, ultrasound, magnetic resonance imaging (MRI), positron emission tomography (PET), and nuclear scintigraphy (Ragab et al., 2017). Plain x-rays are inexpensive and help to assess the degree of bony erosions and tophi in advanced gout; they may also help to identify chondrocalcinosis, particularly of large joints such as the knees. Bone erosions appear as punched-out lesions of the subchondral bone but must be >5 mm to be visible. Typically, joint space is preserved until late stage of the disease course. Ultrasound is especially useful in identifying subclinical tophi and MSU crystals. Dual-energy CT is unique and clinically relevant because it color codes crystals to differentiate between urate and calcium, which is invaluable with atypical presentation or when arthrocentesis is not possible or inconclusive (Mandell, 2020).

Differential Diagnosis: (Mandell, 2020)

- Chondrocalcinosis/calcium pyrophosphate dihydrate (CPPD)/pseudogout–synovial fluid analysis would reveal calcium pyrophosphate crystals; under microscopy CPPD appear weakly positive birefringent, and MSU appear negative birefringent
- Injury/Trauma—history and imaging
- Inflammatory arthritis (for example, rheumatoid arthritis [RA] or psoriatic arthritis)—serology and distinguishing accompanying symptoms
- Infection/septic arthritis—Gram stain and culture from arthrocentesis
- Cellulitis—similar superficial symptoms without involvement of the joint
- Osteoarthritis—radiographs, narrowing of joint space without hallmark erosions
- Reactive Arthritis—history and serology

Treatment: Treatment of gout involves management of acute flares and treatment of established gout. Acute flares require one or more anti-inflammatory medications (NSAIDs, corticosteroids, and/or colchicine) and are best treated within the first 24 hours of symptoms. Treatment with these medicines should be part of an individualized plan of care weighing the risks and benefits to the patient, taking into consideration other comorbidities, such as renal insufficiency and GI conditions, and requisite laboratory monitoring.

Choice of a NSAID is guided by health-care provider preference, concern for possible adverse effects (such as central nervous system [CNS] intolerance with indomethacin), preferable safety profiles (such as with cyclooxygenase type 2 [COX-2] inhibitors), and to what medicines the patient has previously responded. Any NSAID choice will likely require higher doses, and it is important to sufficiently treat the patient (typically 3–5 days), while at the same time avoiding a rebound attack if discontinued too soon. Careful considerations in this drug choice include chronic kidney disease (CKD), hypertension, heart failure, anticoagulation/thrombocytopenia, and GI conditions (Pillinger & Mandell, 2020). Also, NSAIDs are included in the American Geriatrics Society Beers list of potentially inappropriate medications in older adults.

Corticosteroids offer about the same efficacy as NSAIDs and likewise should be used for the shortest duration possible while avoiding a rebound attack. There are two strategies that appear to be equally efficacious in prescribing corticosteroids (Pillinger & Mandell, 2020). Both use the American College of Rheumatology 2012 guideline recommending an initial dose of 0.5 mg/kg of prednisone or equivalent. Corticosteroids do not require renal impairment dose adjustments; however, they can have significant cardiovascular (CV), GI, CNS, and endocrine effects and can increase risk of infection even when given for short periods. Corticosteroids can be alternatively administered intra-articularly or intramuscularly (FitzGerald et al., 2020; Pillinger & Mandell, 2020).

Colchicine is quite effective in the treatment of gout flares and can be useful as adjuvant therapy at lower doses to prevent attacks. Caution must be exercised with colchicine in patients with CKD as well as in those taking medications that utilize the CYP3A4 pathway, such as clarithromycin, diltiazem, verapamil, statins, and several antifungal and antiretroviral drugs (Pillinger & Mandell, 2020). Updated standards recommend low-dose over high-dose colchicine for acute flares to minimize adverse effects while having similar efficacy (FitzGerald et al., 2020).

While these medicines work to resolve flares, they do not treat the hyperuricemia. Therefore, it is essential to initiate ULT to control gout; to only treat attacks with anti-inflammatory agents allows occult MSU crystal deposition, which can lead to treatment-resistant gout and more systemic disease (Khanna et al., 2020; Pillinger & Mandell, 2020). Typically, ULT is not initiated during an acute flare; conversely, ULT should not be stopped during a flare. Treatment with ULT should be individualized, in part based on renal impairment, GI sensitivity, and cardiovascular risk; some patients may also have a better response depending on the mechanism of action. Allopurinol and febuxostat, xanthine oxidase inhibitors, block urate production and reduce hyperuricemia caused by GI or renal underexcretion or from metabolic overproduction (Pillinger & Mandell, 2020). Allopurinol is the preferred first-line treatment choice; however, careful consideration needs to be given when initiating this medication with Asian and Black patients. It is recommended to check for the genetic marker HLA B*5801 in these populations to avoid serious cutaneous complications, including Stevens-Johnson syndrome. Febuxostat currently has a black box warning for risk of increased cardiac death in cardiovascular patients compared to allopurinol. Probenecid, a uricosuric drug, increases urate excretion. Probenecid is contraindicated for patients who have had renal stones and is less effective with

© F.A. Davis Publishing

renal insufficiency. ULTs are indicated for the treatment of patients with frequent flares (more than 2 flares/year), symptomatic SUA >9.0 mg/dL even with infrequent flares, tophaceous deposits, urolithiasis, and other comorbidities that preclude the use of medications for acute flares, such as CKD or peptic ulcer disease (Mandell, 2020).

Follow-Up: Patients being treated for gout require routine laboratory monitoring particularly for kidney function, liver function, and serum uric acid levels. It is not only important to stay below the saturation threshold of 6.8 mg/dL, but if tophi are present the target level should be <6 mg/dL. If tophaceous deposits contribute to marked disability, it is reasonable to lower the target level to 5 mg/dL to dissolve tophi more rapidly. For patients who do not tolerate higher doses of allopurinol or febuxostat, probenecid can be given in combination for better control or as a monotherapy when the former is contraindicated. Pegloticase is an infusion and reserved for refractory gout; it converts urate into allantoin, which is a water-soluble metabolite of uric acid (Mandell, 2020). Unfortunately, studies indicate health-care providers are not aggressive enough in prescribing urate-lowering therapy and frequently fail to reach proper uric acid levels, thus resulting in poor disease control (Golenbiewski & Keenan, 2019).

Sequelae: Recurrent painful attacks and chronic inflammation affect quality of life, work productivity, and increase health-care utilization (Chen-Xu et al., 2019). Inadequately treated, gout can be a severe, debilitating disease leading to joint destruction and impaired joint function. Progressive renal dysfunction, often in the setting of coexisting hypertension, diabetes and/or nephropathy, further accelerates urate deposits due to decreased excretion. Renal obstruction and infection can be a complication of gout with secondary tubulointerstitial disease. Approximately 10% of kidney stones are from urate precipitates (Mandell, 2020).

Prevention/Prophylaxis: In addition to utilization of ULT, it is important to encourage lifestyle modification in patients with hyperuricemia, including weight loss and reduction in alcohol, fructose, and purine-rich foods. However, it is more important to avoid shaming patients or creating intolerable dietary restrictions because this can contribute to noncompliance and a strict low-purine diet only decreases SUA by about 1 mg/dL (Mandell, 2020; Pillinger & Mandell, 2020). When feasible, switching from a thiazide diuretic to a different antihypertensive is recommended to help reduce the incidence of flares. Although evidence shows low-dose aspirin can contribute to hyperuricemia, generally the benefits of CV risk reduction outweigh this risk. However, moderate to higher doses of aspirin should be avoided. Conversely, both losartan and fenofibrate have shown uricosuric effects; therefore, in patients with relevant comorbidities these medicines can help reduce SUA (FitzGerald et al., 2020; Mandell, 2020).

Referral: A referral to rheumatology may be necessary for arthrocentesis and/or intra-articular injections, complicated cases of gout that are refractory to treatment, or patients who have an unusual presentation of disease. A referral to a dietitian may be beneficial for patients who do not well tolerate ULT or who need further assistance in following a low-purine diet.

Education: Patients should be educated on the first signs of a gout flare and the importance of timely treatment. Abortive therapy initiated within the first 12 to 24 hours is the most effective and can greatly decrease the duration of a flare. This is often accomplished with a dose of colchicine 1.2 mg followed by a dose of 0.6 mg 1 hour later. It is important, for both the provider and the patient, to keep track of flares as often ULT needs to be initiated to avoid future complications. Patients need to be educated that initiation of an ULT or dose increases can cause acute flares; this is to be expected and should be managed with NSAIDs or daily colchicine for up to 6 months (Mandell, 2020).

Clinical Recommendation	Evidence Rating	References
Initiating urate-lowering therapy (ULT) is strongly recommended for patients with gout who have any of the following: ≥1 subcutaneous tophi; evidence of radiographic damage (any modality) attributable to gout; or frequent gout flares (≥2 annually).	A	FitzGerald et al., 2020
Initiating ULT is conditionally recommended for patients who have previously experienced >1 flare but have infrequent flares (<2/year).	B	FitzGerald et al., 2020
Initiating ULT is conditionally recommended for patients with moderate to severe CKD (stage ≥3), SUA concentration >9 mg/dL, or urolithiasis.	C	FitzGerald et al., 2020
Allopurinol as the preferred first-line treatment choice, over all other ULT, is strongly recommended for all patients, including those with moderate-to-severe CKD (stage ≥3).	A	FitzGerald et al., 2020
The choice of either allopurinol or febuxostat over probenecid is strongly recommended for patients with moderate-to-severe CKD (stage ≥3).	A	FitzGerald et al., 2020
Starting treatment with low-dose allopurinol (≤100 mg/day and lower in patients with CKD [stage ≥3]) and febuxostat (≤40 mg/day) with subsequent dose titration over starting at a higher dose is strongly recommended.	A	FitzGerald et al., 2020
Administering concomitant anti-inflammatory prophylaxis therapy (e.g., colchicine, NSAIDs, corticosteroids) over no anti-inflammatory prophylaxis therapy is strongly recommended.

Clinical Recommendation	Evidence Rating	References
Continuing concomitant anti-inflammatory prophylaxis therapy for 3–6 months over <3 months, with ongoing evaluation and continued prophylaxis as needed if the patient continues to experience gout flares, is strongly recommended	A	FitzGerald et al., 2020
A treat-to-target management strategy that includes ULT dose titration and subsequent dosing guided by SUA measurements to achieve a target SUA, over a fixed-dose ULT strategy, is strongly recommended for all patients receiving ULT.	A	FitzGerald et al., 2020
Achieving and maintaining an SUA target of <6 mg/dL over the use of no target is strongly recommended for all patients receiving ULT	A	FitzGerald et al., 2020
Continuing ULT indefinitely over stopping ULT is conditionally recommended.	C	FitzGerald et al., 2020
Switching to an alternative oral ULT agent, if available and consistent with other recommendations, is conditionally recommended for patients taking febuxostat with a history of cardiovascular disease (CVD) or a new CVD-related event.	C	FitzGerald et al., 2020
Switching to pegloticase over continuing current ULT is strongly recommended for patients with gout for whom xanthine oxidase inhibitor treatment, uricosurics, and other interventions have failed to achieve the SUA target, and who continue to have frequent gout flares (≥2 flares/year) or who have unresolving subcutaneous tophi.	A	FitzGerald et al., 2020
Limiting alcohol, purine, and high-fructose corn syrup intake is conditionally recommended for patients with gout, regardless of disease activity.	B	FitzGerald et al., 2020
Weight loss is conditionally recommended for those patients with gout who are overweight/obese, regardless of disease activity.	B	FitzGerald et al., 2020

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. For information about the SORT evidence rating system, go to https://www.aafp.org/afp/2004/0201/p548.html.

INFLAMMATORY ARTHRITIS (SPONDYLOARTHROPATHY)

Signal Symptoms: Inflammatory arthritic conditions may manifest with rashes, ulcerations, joint nodularity, fatigue, swelling, erythema, joint stiffness, limited range of motion (Pujalte & Albano-Aluquin, 2015).

Description: Spondyloarthropathy encompasses a spectrum of inflammatory arthritic disorders, including ankylosing spondylitis, non-radiographic axial spondyloarthropathy, reactive arthritis, psoriatic arthritis, and enteropathic arthritis associated with Crohn's or ulcerative colitis. All of these types of arthritis can have similar features and often overlap in signs and symptoms. This section addresses psoriatic arthritis, ankylosing spondylitis and non-radiographic axial spondyloarthropathy. The presentation of late-onset psoriatic arthritis and ankylosing spondylitis is highlighted.

PSORIATIC ARTHRITIS

Description: Psoriatic arthritis is a heterogenous disease that can affect the skin, nails, and peripheral and axil joints (Raychaudhuri et al., 2017). The condition may begin as an asymmetric oligoarticular type of psoriatic arthritis that involves different joints on each side of the body; later though most patients will have polyarticular arthritis (Tiwari & Brent, 2021). Ninety-five percent of patients will have peripheral joint disease as evidenced by synovitis and/or tenosynovitis. Enthesitis (where extensors tendons insert to bone) and dactylitis (tendon sheath swelling in the digit giving it a sausage type appearance) are common findings. About 5% of patients will have axial involvement. There is a predominant distal interphalangeal (DIP) joint involvement in the hands, which can help differentiate it from rheumatoid arthritis (RA), as well as axial involvement, which is not typically seen in RA. Psoriatic arthritis can affect up to 30% of all patients with psoriasis (Ogdie & Gelfand, 2015). Typically, a diagnosis of psoriasis will precede the arthritis by 8 to 10 years (70%). In a small subset of patients, the inflammatory arthritis will occur first (Napolitano et al., 2016).

Etiology: Both genetic and environmental factors play a role in the development of psoriatic arthritis, although the exact etiology is unknown. Just as with RA, it is a cytokine-mediated disease. Evidence suggests that trauma and infection may play a role (Ogdie & Gelfand, 2015).

Occurrence: The prevalence of psoriatic arthritis is 1.9% to 2.7% per 100 in the United States (Tiwari & Brent, 2021). Women and men are equally affected (Caso et al., 2019).

Ethnicity: Whites are affected two times more often than other ethnicities.

© F.A. Davis Publishing

Age: Psoriatic arthritis generally has its onset around the fourth to fifth decade, and the age of onset shows a peak age around 50 years, whereas late-onset psoriatic arthritis begins in patients aged 60 and older (Caso et al., 2019).

Contributing Factors: Family history and genetic predisposition tend to be contributing factors to the development of psoriatic arthritis in younger adults (Caso et al., 2019). There have been some studies implying in older adults with late-onset psoriatic arthritis that obesity contribute to the development of psoriatic arthritis; however, it may be more related to the misdiagnosis of psoriatic arthritis as osteoarthritis (OA). Smoking has been shown to contribute to the development of psoriatic arthritis in older adults (Caso et al., 2019). Environmental factors have been suggested with the development of psoriatic arthritis, especially situations that lead to trauma or mechanical stressor (Ogdie & Gelfand, 2015; Tiwari & Brent, 2021). Patients with severe psoriasis and those with psoriatic nails tend to be at a higher risk of developing psoriatic arthritis than patients who do not have severe disease (Ogdie & Gelfand, 2015).

Signs and Symptoms: When questioning the patient about signs of symptoms of an inflammatory arthritis, inquire about the onset and the progression of joint involvement, any constitutional symptoms, exposure to environmental factors, past traumas, and impact if any of functional ability. Note presence of swelling, erythema, and nodularity, counting the number of joints affected (Pujalte & Albano-Aluquin, 2015). The articular and periarticular presentation of psoriatic arthritis includes a peripheral arthritis that maybe oligoarticular then progresses to polyarticular. Specific joint signs include enthesitis and dactylitis. There may be axial joint involvement, including the sacroiliac joint (Tiwari & Brent, 2021); however, studies have shown that there tends to be less of this type of involvement. Joints may be swollen and tender to the touch. Additionally, the patient may have psoriatic skin manifestation, onycholysis, and pitting of the nails. Uveitis may occur bilaterally as a chronic eye condition (Tiwari & Brent, 2021). In older adults with psoriatic arthritis, the progression of the disease tends to have a more acute onset with more severe effect on joints than in younger patients. One study showed that erosions that occurred in the hand and feet tend to be more extensive in older adults than in younger patients with psoriatic arthritis (Punzi et al., 1999). In one study comparing younger and older patients diagnosed with psoriatic arthritis, the older patients were found to be predominately female, have higher body mass index (BMI) and more severe joint damage (Polachek et al., 2019).

Differential Diagnosis: Other inflammatory anthric conditions can mimic psoriatic arthritis.

- Diffuse idiopathic skeletal hyperostosis (DISH): Patients generally do not have spinal symptoms and can be diagnosed via x-ray.
- Polymyalgia rheumatica (PMR): A response to NSAIDs occurs in patients presenting with psoriatic arthritis, whereas steroids are used in the treatment of PMR.
- RA: Generally, the negative rheumatoid factor (RF), the DIP involvement, and the axial involvement are not characteristic of RA.
- Reactive arthritis: Onset is triggered by an infection.
- Ankylosis spondylitis: No cutaneous manifestations and symmetric sacroiliitis

(Angelopoulou, et al., 2020; Caso et al. 2019; Napolitano et al., 2016; Tiwari & Brent, 2021).

Diagnostic Tests: There are no specific laboratory tests for psoriatic arthritis. Erythrocyte sedimentation rates and C-reactive protein (CRP) may be elevated as with other inflammatory arthropathies. Normal rates for a patient's age do not discount the diagnosis (Tiwari & Brent, 2021). For patients with late-onset psoriatic arthritis, elevated synovial concentration of proinflammatory cytokines have been found (Caso et al., 2019). For patients with suspected psoriatic arthritis, if ordered to rule out RA, generally the RF is negative. Anemia can also occur. HLA-B27 will be positive in 25% of patients. Ultrasound and/or magnetic resonance imaging (MRI) can help to identify enthesitis and dactylitis. X-rays can show erosions and ankylosis of the DIP and proximal interphalangeal (PIP) joints as well as a pencil-in-cup deformity at the DIPs. Osteolysis of the bones can occur in more aggressive disease (arthritis mutilans). Sacroiliitis can be present on x-ray and/or MRI (Tiwari & Brent, 2021).

Treatment: The approach is to focus on a target considering the disease severity (Tiwari & Brent, 2021). For patients with psoriatic arthritis the treatment goals should focus on clinical remission, preserving or improving the patients' quality of life, and inhibiting structural damage that can result from joint erosion (Napolitano et al., 2016). Patients with very mild oligoarticular disease might be managed with intra-articular steroids and NSAIDs. For older adults, the transition to using disease-modulating antirheumatic drugs (DMARDs) would be considered if there is extensive skin involvement and/or more than three joints involved. Methotrexate and leflunomide can be used (Noviani et al., 2020). They both may have mild improvement in skin and peripheral involvement, including synovitis and dactylitis. They have not been shown to halt axial disease or nail disease. Anti-tumor necrosis factor (TNF) agents (adalimumab, etanercept, certolizumab pegol, golimumab, and infliximab) with or without methotrexate are effective medications for arthritis, dactylitis, enthesitis, spondylitis, and skin disease (Frampton, 2107; Raychaudhuri, et al., 2017). Similar efficacy has been shown with both the IL-17 agents (secukinumab and ixekisumab) and IL-23 agents (guselkumab). A phosphodiesterase type-4 inhibitor (apremilast) can be used but has less efficacy than the other biologics. Janus kinase (JAK) inhibitors can be used. Currently tofacitinib is approved for psoriatic arthritis but not arthritis. Additional more selective JAK-inhibitors are being studied. Abatacept, an agent that blocks CD80 and CD86 pathways of T-cell costimulation, can also be used to treat psoriatic arthritis, but it is not approved in psoriasis. Careful monitoring and periodic adjustments may need to be made to medications for older adults (Caso et al., 2019). All of these medications increase the risk of infection and patients must be current with vaccinations (Caso et al., 2019; Raychaudhuri et al., 2107).

Follow-Up: Monitor the patient to determine management of symptoms, disease progression, impact on quality of life and function. Consider the development of comorbidities and monitor and refer as indicated.

Sequelae: As the disease progresses, severe joint deformity can manifest such as arthritis mutilans (Napolitano et al., 2016). Comorbidities associated with psoriasis include cardiovascular disease (CVD) (Queiro et al., 2019b), depression, diabetes, metabolic syndrome, and malignancy (Caso et al., 2019;

© F.A. Davis Publishing

Takeshita et al., 2017). Hepatic and pulmonary disorders can also occur (Ogdie et al., 2018). Studies have shown that hypertension is common in older adults who developed psoriasis (Alonso et al., 2016; Queiro et al., 2019a). The risk of fractures is increased for patients with psoriasis and psoriatic arthritis (Ogdie et al., 2107).

Prevention//Prophylaxis: There are no preventive measures for developing psoriasis. Maintaining a normal BMI, limiting alcohol, and smoking cessation maybe beneficial form having the disease progress (Ogdie & Gelfand, 2015).

Referral: Patients with psoriatic arthritis benefit from an interprofessional approach to care depending on the extent of the condition and how it has impacted their functional ability and quality of life. Referral to a rheumatologist is recommended for management of the complex cases not responding to treatment. Depending on comorbidities, referral to dermatology and cardiology referrals may be needed as the disease progresses (Tiwari & Brent, 2021). Patients may benefit from occupational therapy (OT) referral for adaptive equipment and to physical therapy (PT) to assist with treatment modalities aimed at maintaining and/or restoring joint function.

Education: Patients should be encouraged to limit or refrain from alcohol and smoking. A healthy diet and physical activity should be recommended to all patients. Depending on treatment prescribed, patients on immunosuppressive medications need to understand the side effects of these medications, the need to avoid infections, and the importance of keeping immunizations up to date (Tiwari & Brent, 2021).

AXIAL SPONDYLOARTHRITIS (NON-RADIOGRAPHIC AND ANKYLOSING SPONDYLITIS)

Description: Axial spondyloarthritis (axSpA)—both non-radiographic axSpA and ankylosing spondylitis—is a chronic, systemic inflammatory disease affecting the sacroiliac joints, spine, and occasionally the peripheral joints. In more advanced disease, sacroiliitis is present on plain film x-ray of the sacroiliac joints, and this is characteristic of ankylosing spondylitis. This is a later finding and can take several years before it presents, if at all. Patients with inflammatory back symptoms (discussed later) who do not have x-ray evidence of sacroiliitis may have sacroiliitis seen on magnetic resonance imaging (MRI); these patients are described as having non-radiographic axSpA. Some of these patients will never go on to develop sacroiliitis on x-ray, although their disease burden is similar to axSpA (Wenker & Quint, 2021).

Etiology: Genetics and environmental factors play a role. A close association has been shown to exist between the human leukocyte antigen (HLA) B27 and axSpA (Toussirot & Wendling, 2005).

Occurrence: Overall prevalence of ankylosing spondylitis in general U.S. population is 0.30% to 0.50%. In younger patients, axSpA is more common in men. In late-onset axSpA, the ratio of men to women is about equal (Toussirot & Wendling, 2005).

Age: Symptoms usually begin in late adolescence/early adulthood through the third decade of life. Although very rare, late-onset ankylosis spondylitis occurring after age 50 is overlooked for other rheumatic conditions such as rheumatoid arthritis (RA) and polymyalgia rheumatica (PMR) (Toussirot & Wendling, 2005). One study showed an estimate to be about 2 out of 100,000 people versus 7 out of 100,00 people for cases in those younger than 55 years of age (Carbone et al., 1992).

Contributing Factors: Strongest predictions for developing ankylosing spondylitis is the genetic predisposition for individuals who are HLA-B27 positive, and the rate of occurrence for ankylosing spondylitis increases in HLA-B27 positive individuals who have a family history. Ankylosing spondylitis also been linked to environmental factors. There is a strong association between the axial spondyloarthritis, including ankylosing spondylitis, and gut inflammation, namely involving *Klebsiella pneumonia* bacteria (Rashid et al., 2015). This linkage extends to high starch consumption because gut microbes such as *Klebsiella* are saccharolytic (involved in the process of fermentation of carbohydrates and starch), suggesting that high starch consumption is a risk factor to develop ankylosing spondylitis (Oh et al., 2012).

Signs and Symptoms: Patients present with insidious back pain longer than 3-month duration. Often the pain continues through the night, with patients waking with morning stiffness. Patients may also report limited spinal mobility and postural anomalies. Pain may extend to the buttock and hips. Patients may experience limited chest expansion ability (Moll & Wright, 1974). Axial as well as peripheral arthritis is common in late-onset axSpA (Wenker & Quint, 2021). Pain improves with exercise/movement, which is a way to help differentiate it from mechanical back pain. In late-onset spondyloarthropathy, older adults tend to present with increased levels of cervical spine manifestations and peripheral arthritis (Montilla et al., 2012; Toussirot & Wendling, 2005).

Differential Diagnosis: Rule out any mechanical low back pain in all patients with axSpA (Wenker & Quint, 2021). In older adults presenting with late-onset spondyloarthropathy, the differential diagnosis includes RA, PMR, and seronegative symmetric synovitis with pitting edema (Montilla et al., 2012; Toussirot & Wendling, 2005). Negative rheumatoid factor (RF) and response to NSAIDs often occurs in patients with axSpA and not in PMR. Seronegative symmetric synovitis generally only affects the wrists and hands. Ankylosing spondylitis often effects the lower limbs with asymmetric pitting edema, and the patient is positive for HLA-B27 (Toussirot & Wendling, 2005).

Diagnostic Tests: HLA-B27 may be ordered to support the diagnosis of axSpA, as evidence of antigen is found in 85% to 95% of people with ankylosing spondylitis, although some estimates are lower (Sieper & Poddubnyy, 2016). Acute-phase reactants such as the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) can be elevated. Platelet count can also be elevated in patients with inflammatory arthritis such as ankylosing spondylitis. X-rays of the sacroiliac joints can be diagnostic, showing bilateral sacroiliitis. In patients with non-radiographic axSpA, x-rays will be negative, but an MRI of the pelvis with T1 sequences will show sacroiliitis. Syndesmophytes can be seen in more advanced disease as well as spinal fusion present on x-ray (van Tubergen et al., 2012).

© F.A. Davis Publishing

Treatment: The course for ankylosing spondylitis can be variable; however, the first 10 years of disease may predict the subsequent course of the disease. Exercise is especially important in these patients and should always be recommended in addition to medications. Patients with high markers of inflammation, lack of response to NSAIDs, and early hip involvement predict a poor prognosis (Ward et al., 2019). As with other inflammatory diseases, early detection and initiating treatment is key. NSAIDs are first-line therapy and can improve symptoms. The 2019 Update of the American College of Rheumatology/Spondylitis Association of America/Spondylarthritis Research and Treatment Network Recommendations for the Treatment of Ankylosing Spondylitis and Non-radiographic Axial Spondyloarthritis have updated recommendations for treatment. If patients are not responding to treatment with NSAIDs, then the next line of treatments are to begin a tumor necrosis factor (TNF) inhibitor (TNFi), which are recommended over secukinumab or ixekizumab as the first biologic used in patients with axSpA. If a patient is not responding to a TNFi, it is recommended then to add one of the human monoclonal antibodies to interleukin-17A (secukinumab or ixekizumab) for patients who did not have a response to a TNFi rather than adding a second TNFi. It is not advised to prescribe low-dose methotrexate with TNFi, and sulfasalazine or methotrexate is only recommended in patients experiencing persistent peripheral arthritis or when TNFis are contraindicated (Ward et al., 2019).

Follow-Up: Monitoring the patients to determine management of symptoms, disease progression, impact on quality of life and function. Consider the development of comorbidities and monitor and refer as indicated.

Sequelae: In patients with late-onset axSpA, there is an increased risk of cardiovascular disease due to the inflammatory nature of this condition (Wenker & Quint, 2021). In addition, patients with axSpA tend to have poor sleep due to sleep apnea and complain of fatigue (Wang et al., 2020). Ankylosing spondylitis is part of a spectrum of spondyloarthropathy diseases, so patients are at risk for developing other inflammatory conditions, such as inflammatory bowel disease, uveitis, and psoriasis. Additionally, older patients with axSpA are at increased risk for developing fragility fractures (Wenker & Quint, 2021).

Prevention/Prophylaxis: There is no primary prevention known for axSpA. Smoking cessation is advised given that limited chest expansion often occurs in these patients (Dülger et al., 2019; Zhu et al., 2019). Exercise may be beneficial to patients with axSpA (Regal et al., 2016; Zhu et al., 2019).

Referral: Patients with complicated axSpA should be referred to a rheumatologist. Additionally, if patients have comorbid inflammatory conditions, such as inflammatory bowel disease or anterior uveitis, referral to specialist is warranted. As cardiac manifestations are the most common comorbidity in older patients with axSpA, monitoring for signs of cardiac conditions such as heart block or valvular disease and referral to cardiology early on in cases of late-onset axSpA are recommended. Patients would also benefit from physical therapy (PT) referral to enhance physical activity and range of motion (ROM) (Wenker & Quint, 2021).

Education: Patients can benefit from knowing that this is a progressive condition that benefits from both pharmacological as well as nonpharmacological interventions such as exercise and participating in PT and water therapy. Given that patients have limited chest expansion ability, they are at increased risk for pulmonary infection; thus, keeping immunizations current is highly recommended and smoking cessation is recommended (Wenker & Quint, 2021).

Clinical Recommendation	Evidence Rating	References
In a study comparing younger patients diagnosed with psoriatic arthritis compared with patients diagnosed with late-onset psoriatic arthritis, the majority of the patients were female and had higher body mass index, more joint damage, and less HLA-C*06.	B	Polachek et al., 2019
In a study comparing patients with psoriatic arthritis compared to patients without inflammatory arthritis, patients with psoriatic arthritis had higher frequencies of multiple comorbidities such as hypertension, diabetes, cardiovascular disease, and obesity.	A	Queiro et al., 2019b
In adults with active non-radiographic persistent axial spondyloarthritis (axSpA) despite treatment with NSAIDs, treatment with tumor necrosing factor medications is recommended.	A	Ward et al., 2019
Physical therapy is recommended for patients with axSpA.	B	Ward et al., 2019
Treatment with NSAIDs is recommended for first-line treatment of axSpA.	C	Ward et al., 2019

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. For information about the SORT evidence rating system, go to https://www.aafp.org/afp/2004/0201/p548.html.

OSTEOARTHRITIS

Signal Symptoms: Joint pain and stiffness that improves with rest; worsens with activity and weight-bearing. Often affects the hands, hips, knees, and low back causing functional limitations.

Description: Osteoarthritis (OA), or degenerative joint disease, is the most common form of arthritis and a significant cause of pain and disability in older adults. It is a progressive, heterogeneous joint disease driven by a combination of inflammatory

© F.A. Davis Publishing

and biomechanical processes with the progressive loss and destruction of articular cartilage leading to joint space narrowing, degeneration of ligaments, subchondral bone thickening, synovitis, hypertrophy of the joint capsule, and formation of osteophytes (Chen et al., 2017; Van Spil et al., 2019).

Etiology: No longer considered simply "wear and tear" arthritis, OA is a heterogeneous disease without a singular pathogenic mechanism of OA; considerable patient-specific variability exists. Predisposing risk factors include age, sex, past injury/trauma, and genetics (He et al., 2020). Emerging research seeks to understand this heterogeneity by focusing on gene expression and biomarkers in order to subtype OA into phenotypes/endotypes such as senescent, inflammatory, metabolic, genetic, and estrogen deficiency (Van Spil et al., 2019; Werdyani et al., 2021). Studies have shown that 39% to 78% of OA can be attributed to genetic factors (He et al., 2020).

Occurrence: The exact incidence and prevalence of OA vary based on the definition of OA, which can include radiographic, symptomatic, and doctor-diagnosed (Vina & Kwoh, 2018). According to the Centers for Disease Control and Prevention (CDC), 32.5 million adults in the United States are affected by OA, with half of these of working age (18 to 64 years of age) (CDC, 2020). The total number is expected to increase to 78 million by 2040 (He et al., 2020). In 2017, the worldwide prevalence of OA was estimated to be 303 million people, with the most common joints causing disability being the knees (60.9%), hands (23.5%), and hips (5.5%) (Global Health Metrics, 2019; Kloppenburg & Berenbaum, 2020). Musculoskeletal diseases, including OA, are the second leading cause of years lived with disability and the numbers are increasing due to aging and obesity (Loeser, 2017; Sebbag et al., 2019). Women reported a higher prevalence of provider-diagnosed arthritis compared to men (23.5% vs. 18.1%) (Barbour et al., 2017). Women are more likely to develop hand (specifically after menopause), foot, and knee OA, whereas men have a higher rate of shoulder and cervical spine OA (Vina & Kwoh, 2018).

Age: OA is not age dependent; however, the average person begins experiencing symptoms around 55 years of age and will live with the disease for approximately 26 years (Van Spil et al., 2019). In adults aged 65 or older, 22.2 million (49.6%) have OA compared to 8 million (7%) young adults (18 to 44 years) and approximately 24.2 million (29.3%) middle-aged adults (45 to 64 years) (Barbour et al., 2017).

Ethnicity: Non-Hispanic Whites (25.3 million) have the highest proportion of OA whereas Hispanics have the lowest, (78% vs. 7%) (Hochberg & Cisternas, 2019); however, Mexican Americans seem to have similar prevalence of knee OA compared to White Americans (Callahan et al., 2021). Compared to other ethnicities, African Americans are more likely to develop symptomatic knee and hip OA (Vina & Kwoh, 2018). Studies have shown an 80% to 90% decreased prevalence of hip OA within the Chinese population compared to Whites; however, the Third National Health and Nutrition Examination Survey indicated a 45% increased prevalence of knee OA in Chinese women compared to White women, with no difference in their male counterparts (Callahan et al., 2021).

Contributing Factors: In addition to risk factors of age, sex, and hormone profile, past injury/trauma/surgery, and genetics, OA is affected by obesity, chronic overload/overuse, inflammation, and metabolic syndrome (He et al., 2020). Modifiable risk factors include excess body weight, injuries/trauma, and occupations/hobbies that require repetitive overuse/overload (CDC, 2020). Higher rates of OA have been reported in individuals who have a high school education or less compared to those who have completed college or higher (Barbour et al., 2017). Increased bone mineral density has been linked to increased rates of hip, knee, and hand OA (Vina & Kwoh, 2019). Adults with obesity, diabetes, and heart disease were 1.5, 1.7, and 1.9 times more likely to have arthritis, respectively, compared to their counterparts without these comorbidities (Barbour et al., 2017).

Signs and Symptoms: Individuals seek medical attention for the concern of morning stiffness (<30 minutes) and/or pain with movement or mechanical loading of the affected joint often in the context of activities of daily living. Additional symptoms include muscle weakness, functional limitations, gait alternations/adaptations, fear of movement, joint instability, and/or sleep problems. Pain associated with OA may be described as sensitive to touch and pressure, dull and aching, throbbing, or sharp and stabbing (Rice et al., 2019). Early OA tends to be intermittent and with predicted activities; however, it can occur suddenly with subsequent joint instability—giving way or locking up such as with the knee. As OA advances, the pain can become more constant and can occur at night (Fu et al., 2018). OA may include mild warmth, minimal erythema, and varying degrees of swelling and tenderness to palpation; however, in general a big, red, hot, painful joint is more consistent with infection or an inflammatory arthritis, particularly a crystalline arthropathy.

Women are more prone to hand OA, particularly just after menopause; 67% of women compared to 55% of men show evidence of radiograph OA; however, most are asymptomatic. When symptomatic, common concerns are decreased dexterity and/or grip strength. Hand OA has the hallmark features of nontender bony Bouchard's nodes (nodules of the proximal interphalangeal [PIP] joints) and/or Heberden nodes (nodules of distal interphalangeal [DIP] joints). The carpometacarpal (CMC) joint is a very common area of OA known as "the squaring of the thumb" and can have crepitus upon examination. Erosive hand OA affects these same joints but tends to be more painful and cause joint destruction with erosions and ankylosis thereby decreasing function (Perrotta et al., 2019).

Hip and knee OA are a major cause of disability with decreased physical function and activity, both in working adults and older adults. In addition to reported pain and gait disturbances with hip OA, decreased external and internal rotation of the hip can easily be elicited on examination. Knee OA is worse with increased load bearing (e.g., walking down stairs). Crepitus from knee OA is easily palpated during examination. Medial knee tenderness is more common than lateral pain because medial knee joint space narrowing is more common. A knee effusion can occur with OA as well as trauma, inflammatory arthropathies, and infections (He et al., 2020).

Additional common areas of OA include the foot, specifically the first metatarsal; the cervical and lumbar spine; and the shoulders. All of these areas may be affected by pain with use and decreased function and range of motion (Vina & Kwoh, 2018). Cervical OA can cause a range of symptoms

© F.A. Davis Publishing

including headaches, referred pain to shoulders and scapula, and radiculopathy down the arm(s). Lumbosacral OA involves pain across the lower back with radiation to the buttock and thigh. Nerve root compression is likely with radiculopathy below the knee and possible motor, sensory, and reflex deficits (Lindsey & Dydyk, 2021).

Diagnostic Tests: X-rays and clinical examination are the mainstays for OA diagnosis. Radiographically, OA presents with joint space narrowing, osteophytes (bone spurs), subchondral sclerosis, cyst formation, and abnormalities of bone contour (He et al., 2020). X-rays are best ordered weight-bearing when applicable and in two- or three-view. Other types of imaging, such as ultrasound and magnetic resonance imaging (MRI), may be used to detect soft tissue damage/irritation of cartilage, ligaments, synovium, and/or tendons or to better assess radicular symptoms (Kloppenburg & Berenbaum, 2020). Arthrocentesis should be considered for joint effusions. The specimen should be sent for synovial fluid analysis that includes cell count, crystal analysis, and culture. The synovial fluid in OA is usually clear, colorless-yellow, and viscous, and has less than 2,000 white blood cells per μL (He et al., 2020). Laboratory studies, including complete blood count (CBC), comprehensive metabolic panel (CMP), and vitamin D level, should be obtained before initiating long-term drug therapy; if prolonged morning stiffness (>60 minutes) or inflammation is suspected, uric acid, C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), and rheumatoid factor (RF) may be ordered (Perrotta et al., 2019). Although still novel, in the future biomarkers could further delineate phenotypes to help direct treatment (Van Spil et al., 2019).

Differential Diagnosis: (Kontzias, 2020)

- Trauma: fracture, dislocation, soft tissue injury (bursitis; torn ligament, tendon, muscle)
- Inflammatory arthritis (rheumatoid arthritis [RA], polymyalgia rheumatica [PMR], systemic lupus erythematosus [SLE], spondyloarthropathy)
- Crystalline disease (gout, chondrocalcinosis/calcium pyrophosphate dihydrate [CPPD]/pseudogout)
- Infection/septic arthritis
- Cancer (metastatic disease, multiple myeloma, bone tumor)
- Other spinal conditions (spinal stenosis, disc herniation)
- Referred pain
- Avascular necrosis, particularly in patients with history of oral corticosteroid use
- Paget's disease

The presence of systematic symptoms in the setting of joint pain or divergent onset of symptoms warrants further work-up. Red flags as part of a spinal OA work-up include loss of bowel or bladder continence, saddle anesthesia, numbness, and/or fever/chills (Lindsey & Dydyk, 2021).

Treatment: The lack of any therapy that slows disease progression is a major limitation in the treatment of OA. Current pharmacological and nonpharmacological modalities seek to alleviate pain and focus on improving symptoms and function (Loeser, 2017). Management of OA is multifactorial utilizing oral, topical, and intra-articular medications as well as physical, surgical, behavioral, educational, and psychosocial interventions (Kolasinski et al., 2020).

Oral NSAIDs and acetaminophen are mainstay pharmacological treatment choices for OA. NSAIDs can be particularly efficacious at reducing inflammation and pain associated with OA; however, caution is advised due to risk of renal and cardiovascular side effects and gastrointestinal (GI) toxicity/bleeding. NSAIDs are best prescribed at the lowest effective dose on an as-needed basis instead of scheduled and with routine monitoring. As a selective NSAID, cyclooxygenase type 2 (COX-2) inhibitors offer the anti-inflammatory benefits with a better GI risk profile; however, these medications carry a higher cardiovascular risk and still require routine laboratory studies. Topical NSAIDs are not quite as effective, but they offer a better safety profile. Over-the-counter (OTC) topical preparations include lidocaine 4% and capsaicin, both of which offer variable patient responses. Acetaminophen can be effective against OA pain at higher therapeutic doses, but it is important to avoid alcohol and other medications that contain acetaminophen due to possible liver toxicity. Duloxetine, tramadol, and opioids are only conditionally recommended by the American College of Rheumatology, although duloxetine can help patients in multiple ways with pain and mood. Neither oral corticosteroids nor disease-modulating antirheumatic drugs (DMARDs), such as methotrexate and hydroxychloroquine, is recommended. Nutritional supplements such as glucosamine and chondroitin are not currently recommended due to a lack of unbiased evidence-proven efficacy (Kolasinski et al., 2020; Sen & Hurley, 2021).

Intra-articular joint injections can offer localized relief without extensive systemic effects. Corticosteroid injections work well in the setting of acute OA pain, and they are relatively low cost and low risk. As OA progresses, patients tend to experience a variable response, a risk of infection is possible with any injection, and (as with any corticosteroid) blood glucose can briefly elevate. There is ongoing controversy of repeated corticosteroid injections possibly accelerating OA progression and bone destruction (Kloppenburg & Berenbaum, 2020). Hyaluronic acid injections are a gel-like viscosupplementation primarily for knee OA. They are considerably more expensive and not always covered by insurance because of mixed evidence of efficacy compared to placebo. Any joint with suspected infection should never be injected, only arthrocentesis should be performed; and a joint with surgical hardware should not be punctured with a needle (Sen & Hurley, 2021). Emerging therapies for knee OA include the recently fast-tracked by the U.S. Food and Drug Administration (FDA), highly purified, injectable trans-capsaicin CNTX-4975. Studies are ongoing with CNTX-4975 to improve procedure protocol due to associated pain (Kloppenburg & Berenbaum, 2020). Regenerative medicine, including mesenchymal stem cell therapy and platelet rich plasma injections, so far have shown little to no benefit (Kloppenburg & Berenbaum, 2020).

Exercise and physical therapy (PT)/rehabilitation are first-line treatments for OA. Evidence-based OA treatment guidelines recommend both aerobic and resistance exercises for knee, hip, and hand OA as well as self-management programs. PT/occupational therapy (OT) can assist patients with splints, braces, and assistive devices. Weight loss is strongly recommended when appropriate. Tai chi is more strongly recommended than yoga; both help to maintain joint function and flexibility and reduce risk of falls in older adults (Kolasinski et al., 2020; Rice et al., 2019). Arthroscopic surgery including meniscus or anterior cruciate ligament repair,

© F.A. Davis Publishing

and joint débridement and/or irrigation may be appropriate for some patients to help reduce pain and improve function (Loeser, 2017; Rice et al., 2019). For end-stage hip or knee OA, a joint replacement may be an effective treatment option. However, joint replacements have a life span of approximately 15 to 25 years, they sometimes fail, and there is the risk of complications (Kloppenburg & Berenbaum, 2020).

No matter what treatment options are chosen, it is important to individualize the plan of care to the patient needs/preferences and work to address indirect aspects of OA that affect quality of life, including poor sleep, depression, central sensitization, and impaired coping skills. Current research aims to classify OA phenotypes to identify patients at higher risk of disease progression. This would then allow targeted treatment including prevention strategies for individuals with particular disease mechanisms and risk factors (Deveza et al., 2019).

Follow-Up: Patients should follow up with their health-care provider no longer than 4 weeks after initiation of treatment for OA. This will allow the patient adequate time to schedule and start an exercise program or PT and have an idea of how it is helping. If either of these are too difficult due to joint function and/or pain, water therapy should be considered. This timeline will also allow the patient to try any new pharmacological treatment options and to have laboratory values rechecked including a CMP and CBC. It is important to periodically repeat these laboratory tests to monitor renal and liver function and assess negative gastrointestinal (GI) effects in addition to the patient's reported symptoms.

Sequelae: As a progressive disease, OA will continue to worsen leading to pain, joint deformity and/or functional impairment. To date, only a total joint replacement will effectively fully treat OA; however, complications as high as fourfold in the year following surgery have been reported (Charlesworth et al., 2019).

Prevention/Prophylaxis: Maintaining optimal weight and consistent low-to-moderate levels of activity throughout one's lifetime are the best methods for prevention of OA and for helping mitigate the effects of OA. For individuals genetically predisposed to OA, it is advisable to avoid trauma/joint injuries and repetitive/overuse activities including occupations and hobbies.

Referral: Patients need referrals to PT/OT and in some instances water therapy. They may need a referral to orthopedics if they are not responding to standard nonsurgical treatments. Referral to rheumatology may be necessary for unusual presentation of the disease.

Education: In addition to weight management and exercise/rehabilitation, it is important to educate patients on effective physical and mental coping strategies to better help manage OA pain and impaired function, such as assistive devices and home modifications and self-management and cognitive behavioral therapy strategies. A healthy lifestyle that includes proper rest and nutrition can be beneficial; lower rates of clinical and radiographic knee OA have been observed when a Mediterranean diet is adhered to as well as high dietary fiber and sufficient vitamin D (Vina & Kwoh, 2019).

Clinical Recommendation	Evidence Rating	References
Encourage exercise that includes a combination of low-impact aerobic and resistance training tailored to the impairments, functional requirements, and preferences; use water therapy when land physical therapy is not tolerated.	A	Rice et al., 2019 Kolasinski et al., 2020
Tai chi is strongly recommended for knee and/or hip osteoarthritis (OA).	A	Kolasinski et al., 2020
Yoga and balance exercises are conditionally recommended for knee and/or hip OA.	B	Kolasinski et al., 2020
Weight loss: combination of strategies, including regular weight monitoring, increased physical activity, social support, meal plans, limiting portion size, reducing fat and sugar intake, time-restricted feeding, and addressing behavioral triggers to eating.	A	Rice et al., 2019 Kolasinski et al., 2020
Encourage active self-management and positive behavioral changes such as regular exercise, weight loss, good sleep hygiene and activity pacing.	A	Rice et al., 2019 Kolasinski et al., 2020
Cognitive behavioral therapy has small positive effects on OA pain and fatigue and moderate to large positive effects on self-efficacy and pain coping.	B/A	Rice et al., 2019 Kolasinski et al., 2020
Oral NSAIDs are strongly recommended for knee, hip, and/or hand OA.	A	Kolasinski et al., 2020
Topical NSAIDs are strongly recommended for knee OA and conditionally recommended for hand OA.	A/B	Kolasinski et al., 2020
Topical capsaicin is conditionally recommended for knee OA (and conditionally recommended *against* for hand OA due to possibly of then touching one's eyes/face).	B	Kolasinski et al., 2020
Acetaminophen, duloxetine, and tramadol are conditionally recommended for knee, hip, and/or hand OA.	B	Kolasinski et al., 2020
Glucosamine and chondroitin sulfate are recommended.	B	Charlesworth et al., 2019 Kolasinski et al., 2020

POLYMYALGIA RHEUMATICA AND GIANT CELL ARTERITIS

Signal Symptoms: New onset of stiffness and aching in neck, shoulders, pelvic girdle; unable to get out of bed in the morning without extreme difficulty; difficulty in lifting arms over one's head for polymyalgia rheumatica. Onset of a new headache, visual loss, jaw claudication, scalp tenderness in patients with giant cell arteritis (GCA).

Description: Polymyalgia rheumatica (PMR) is a clinical inflammatory syndrome characterized by fatigue, aching, pain, and stiffness, primarily in the neck, shoulders, hips, and pelvic girdle, occurring primarily in older adults. Older adults may relate the presentation of aches and pains to old age and delay seeking treatment. Initially, patients may report unilateral stiffness and aching, although muscle aching with guarded range of motion (ROM) will affect eventually both sides of the body (Milchert & Brzosko, 2017; Muller et al., 2016). Musculoskeletal symptoms have been linked to nonerosive articular and extra-articular synovitis (Camellino et al., 2019). Systemic manifestations include low-grade fever, anorexia, depression, weight loss, and malaise (Camellino et al., 2019; Mahmood et al., 2020).

Synovial proliferations are found in patients with PMR. Patients are often found to have an elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) level (Lally & Spiera, 2018). If both of these inflammatory markers are not elevated, the diagnosis of PMR cannot be discarded (Camellino et al., 2019; Lally & Spiera, 2018). There is a close association with patients presenting with PMR developing GCA, a common vascular condition in older adults; approximately 40% to 60% of patients who are diagnosed with GCA have clinical presentation of PMR (Lally & Spiera, 2018; Sharma et al., 2020). GCA is a chronic inflammatory condition (primary vasculitis) that involves large and medium-sized arteries (Nordborg et al., 2000; Sharma et al., 2020).

The percentage of patients with PMR who eventually develop GCA is around 10% to 20%, but varied percentages have been reported (Masson et al., 2017). Assessing for signs and symptoms of vasculitis early is important to avoid the complications of GCA, namely, irreversible blindness (Vodopivec & Rizzo, 2018). Patients need to be alerted to the symptoms of GSA because they are additive to PMR.

Etiology: The etiology of PMR and GCA is unknown. A relationship between the presence of the human leukocyte antigen (HLA) DR4 haplotype and presentation of PMR and GCA has been suggested (Camellino et al., 2019; Dinkin & Johnson, 2021; Nordborg et al., 2000).

Occurrence: For the United States, the highest incidence of PMR and GCA is found in northern states that have

© F.A. Davis Publishing

populations with similar ethnic backgrounds to northern European countries with rates of incidence found to be 20/1,000,000 adults (Acharya & Musa, 2021; Sharma et al., 2020). Throughout the world, the highest incidence of PMR and GCA is found in populations with northern European ancestry (Sharma et al., 2020). PMR and GCA are more common in women than men (Sharma et al., 2020).

Age: PMR and GCA occur predominantly in adults older than 50 years old, with an average age of peak incidence in the eighth decade of life (Lally & Spiera, 2018).

Ethnicity: PMR and GCA is six times more common in Whites than in Blacks, Alaskan Natives, Asians, and Hispanics (González-Gay & Pina, 2015). Patients who are descendants from northern European countries have the highest rate of PMR and GCA, whereas the lowest prevalence has been noted in the Japanese (Berti & Dejaco, 2018).

Contributing Factors: Advanced age and a possible genetic predisposition are thought to contribute to the development of PMR and GCA. Infectious conditions such as mycoplasma pneumonia, Epstein-Barr, and parvovirus suggested a connection with developing PMR and GCA (Acharya & Musa, 2021; Dinkin & Johnson, 2021). Patients with a history of myocardial infarction, peripheral vascular disease, and stroke have been shown to tend to develop PMR and GCA (Camellino et al., 2019). Risk factors for GCA also include history of smoking (Dinkin & Johnson, 2021).

Signs and Symptoms: Often, the onset of PMR occurs in patients who report good health prior to symptom presentation. Reports of impairment in function due to pain such as the ability to get up out of bed in the morning, raise arms to groom hair, getting up from chairs or the toilet. Patients complain of fatigue and generalized malaise and may attribute the symptoms to influenza or the exacerbation of existing arthritic conditions, such as osteoarthritis (OA) (Buttgereit et al., 2016). Additionally, patients usually have bilateral, proximal aching and stiffness in the neck, shoulders, upper arms (Acharya & Musa, 2021; Camellino et al., 2019), hips, thighs, and lower back, with patients reporting aching and pain in the shoulder girdle (Lally & Spiera, 2018). Stiffness occurs in the morning and may last more than 30 minutes to 1 hour; however, on exertion, fatigue and aching may return (Matteson & Dejaco, 2017). Pain at nighttime may impair sleep, limiting mobility and/or positional changes (e.g., inability to turn over in bed at night) (Acharya & Musa, 2021).

When the patient is questioned, there may be no report of actual peripheral joint pain. Musculoskeletal pain and related symptoms may be present about 1 month before the diagnosis is made; however, sudden onset of PMR can occur in older adults (Acharya & Musa, 2021). Fever, anorexia, weight loss, apathy, night sweating, fear, anxiety, and depression are also constitutional symptoms of PMR (Buttgereit et al., 2016; Milchert & Brzosko, 2017). Muscle weakness usually is not elicited on physical examination. It is important to note that pain often inhibits accurate assessment of muscle strength because patients can neither raise the thigh to resistance nor laterally abduct upper arms to resistance due to pain. Tenderness may be detected on palpation to the muscle groups mentioned earlier (Acharya & Musa, 2021). Examine for contracture of the shoulder or adhesive capsulitis resulting from extended limitation of movement due to persistent pain over time. Patients may report a decreased ability to grasp small objects. Check for signs of carpal tunnel syndrome, such as paresthesia of the thumb and index and middle fingers due to flexor tenosynovitis (Acharya & Musa, 2021). An unusual presentation of PMR is RS3PE, which involves distal extremity swelling with pitting edema present over the dorsum of hands, wrists, ankles, and tops of feet (Higashida-Konishi et al., 2021; Salvarani et al 2002). Examine for evidence of claudication in the lower extremities and/or pitting edema, which can be signs of GCA (Tracey & Su, 2020). Diagnostic studies may reveal anemia. Checking for signs of pallor is important.

Because GCA is associated with PMR, the work-up should include questions to evaluate for this vasculitis, such as complaints of occipital or temporal headaches, visual disturbances (amaurosis fugax [transient vision loss] or transient diplopia), high fever, jaw and tongue pain, sore throat, hoarseness, ear pain, painful scalp, and limb claudication as a result of vascular occlusion (Hayreh, 2021; Tracey & Su, 2020). Assess for tender temporal arteries and visual acuity (Dinkin & Johnson, 2021). Funduscopic examination may reveal retinal hemorrhages, cotton-wool patches, and edema of the optic disc (Salvarani et al., 2002). Neurological findings are also common in patients with GCA due to occlusion of internal carotid or vertebral arteries; neuropathies, transient ischemic attacks, and stroke have been known to occur in patients with extensive GCA (Dinkin & Johnson; 2021; Soriano et al., 2017). Consider, too, that patients with GCA may develop thoracic aortic aneurysm or even dissection; thus, attention to potential for these presenting conditions is warranted, especially for those who have history of hypertension (Tracey & Su, 2020).

Diagnostic Tests: An elevated ESR of more than 30 to 40 mm/hr and CRP level greater than 6 mg/dL are common findings in PMR (Mahmood et al., 2020). Obtain complete blood count (CBC) with indices to determine presence of normochromic, normocytic anemia, and thrombocytosis, which are common in patients with PMR (Milchert & Brzosko, 2017). The use of ultrasound in establishing diagnosis of PMR may find evidence of subdeltoid bursitis, tenosynovitis, hip synovitis, glenohumeral joint bursitis, and trochanteric bursitis (Buttgereit et al., 2016; Camellino et al., 2020). For patients with GCA, the ESR generally is found to be greater than 50 mg/hr, often elevated to 100 mm/hr or greater (Dinkin & Johnson, 2021). Patients with symptoms of GCA need to be referred for temporal artery biopsy (van der Geest et al., 2020). There have been cases of patients who had a positive temporal artery biopsy for GCA with normal CRP (Parikh et al., 2006). Ultrasound of the temporal artery is also being used to diagnose GCA (Rubenstein et al., 2020).

For patients with symptoms of claudication, imaging studies can be beneficial in determining presence of lower extremity vasculitis (Rubenstein et al., 2020). Liver enzyme tests often show elevated alkaline phosphate in patients with PMR and GCA (Milchert & Brzosko, 2017).

Considering the need for long-term corticosteroids, diagnostic studies should also include urea and electrolytes, thyroid-stimulating hormone (TSH) and dipstick urinalysis, and bone density testing if no recent results are available for the patient when the diagnosis is established and treatment with corticosteroids begins (Tracey & Su, 2020).

© F.A. Davis Publishing

Differential Diagnosis:

PMR:

- Late-onset rheumatoid arthritis (RA) (specifically, the absence of rheumatoid factor (RF) and normal anti-citrullinated protein antibody (anti-CCP) can rule out initial diagnosis of late-onset RA.
- Polymyositis (patients who have demonstrated proximal weakness characteristic of polymyositis would have a positive muscle biopsy)
- Fibromyalgia (generally fibromyalgia begins in younger adulthood and the ESR is normal)
- Hypothyroidism (thyroid hormone is not elevated as a result of PMR)
- Hyperparathyroidism (parathyroid hormone level is not elevated as a result of PMR)
- OA (radiographic changes would demonstrate evidence of OA and not PMR)
- Bursitis and tendinitis (constitutional symptoms generally are not evident in patients with bursitis and tendinitis)
- Rotator cuff injuries
- Carcinomatosis
- Chondrocalcinosis
- Depression
- Systemic lupus erythematosus (antinuclear antibody [ANA] would not be significantly elevated in patients with PMR; slight ANA elevation can be expected in older adults absent of disease)
- Multiple myeloma (patients with multiple myeloma do not respond to corticosteroids and noted absence of Bence Jones' protein in urine or serum or urine electrophoresis)
- Infective endocarditis
- Vasculitis
- Parkinson's disease (ESR is not elevated in patients with Parkinson's disease, and corticosteroid therapy would not produce a clinical response to the stiffness experienced)
- Calcium pyrophosphate dihydrate crystal deposition disease (arthrocentesis of affected joints would be negative for this condition and arthrocentesis would show crystals that typically present positive birefringence)
- Late-onset ankylosing spondylitis (radiographic findings of syndesmophytes)
- Diffuse idiopathic skeletal hyperostosis (DISH)
- Inflammatory amyloidosis
- Paraneoplastic syndrome from lung cancer (corticosteroid would not produce a clinical response and radiographic imaging would be negative)

GCA:

- Acute angle-closure glaucoma in emergency medicine
- Granulomatosis with polyangiitis
- Herpes zoster
- Iritis and uveitis
- Migraine headache
- Non-arteritic ischemic optic neuropathy
- Persistent idiopathic facial pain
- Retinal artery occlusion (RAO)
- Retinal vein occlusion (RVO)
- Transient ischemic attack

(Acharya & Musa, 2021; Camellino et al., 2019; Mahmood et al., 2020; Milchert, & Brzosko, 2017; Seetharaman, 2020)

In patients with symptoms typical of PMR and a normal ESR, also consider drug-induced myalgias from lipid-lowering agents, beta blockers, and dipyridamole (Camellino et al., 2019; Snyder, 1991).

Treatment: If the patient presents with signs and symptoms only of PMR, start low-dose prednisone 12.5 to 25 mg daily, to be tapered to a dose of 10 mg daily within 4 to 8 weeks and, thereafter, the daily dose should be decreased by 1.0 to 1.25 mg daily every 4 weeks (Camellino et al., 2020). Lower starting doses (7.5–10 mg) may be considered in patients of "smaller body habitus, milder symptoms, uncontrolled diabetes or risk for significant drug adverse reactions" (Mahmood, 2020, p. 552). Symptoms should begin to resolve after 24 hours. However, immediate relief from corticosteroids may not be indicative of PMR because multiple conditions that mimic PMR would also show sign and symptom improvement after prednisone is initiated (Matteson & Dejaco, 2017). Prednisone is tapered off slowly, continuing over months, when the symptoms have resolved and the ESR and CRP levels returns to normal level or near normal level from the patient's baseline (because ESR can be elevated normally because of increased age) (Alende-Castro et al., 2019). Patients presenting with visual disturbances, jaw claudication, or other symptoms of GCA need a higher dose of oral corticosteroids with a gradual tapering depending on symptoms and laboratory values. For GCA, the suggested initial dose of prednisone is 40 to 60 mg daily, a gradual tapering depending on symptoms and laboratory values. Tapered dose within 2 to 3 months should be reduced to 15 to 20 mg daily, and, after 1 year, to ≤5 mg daily (Camellino et al., 2020). Treatment may last 1 to 2 years (Mahmood et al., 2020).

Follow-Up: Assess the patient for proximal pain, morning stiffness, resolution of constitutional symptoms, and adverse reaction to corticosteroids. For patients with PMR, the ESR and/or CRP need monitoring until the levels decrease and previously reported symptoms are alleviated. The CBC can be repeated to determine whether the anemia has resolved. Generally, a return to normalization of ESR and CRP resolves within 2 to 4 weeks of treatment of corticosteroids in patients with PMR and GCA (González-Gay & Pina, 2015). Initially, the patients may need to return every couple of weeks to determine the clinical response to therapy. This is followed by approximately an every-3-month surveillance to determine response to treatment and any adverse reactions to the long-term corticosteroids. Additional monitoring of urea and electrolytes and glucose should continue every 3 months while on corticosteroids (Mundell et al., 2017).

Follow up on the results of the dual-energy x-ray absorptiometry scan. Prophylactic therapy to prevent osteoporosis with bisphosphonates and calcium and vitamin D supplementation of 800 to 1,000 IU daily is needed in patients taking glucocorticoids >7.5 mg for more than 3 months (Acharya & Musa, 2021; Camellino et al., 2019). Patients also presenting with GCA need to be monitored in the same way, with repeated eye examinations as warranted, including examination for cataracts resulting from corticosteroid therapy (Petri et al., 2015). Because patients with GCA are at risk for developing aortic aneurysm, follow-up abdominal examination for aortic aneurysm is needed. This complication is of great concern, especially with patients who are at high risk for developing aortic aneurysms, such as patients who

© F.A. Davis Publishing

smoke, are hypertensive, and have arteriosclerotic heart disease (Tracey & Su, 2020).

Sequelae: Patients diagnosed with PMR only should be alerted to the signs of GCA because patients with untreated GCA are at risk for blindness (Vodopivec & Rizzo, 2018). Additional complications from GCA include pericardial effusion, tongue necrosis and interstitial lung disease (ILD) (Dinkin & Johnson, 2021). Patients should be informed that they must complete all of the prescribed medication to avoid a relapse. Despite the initial symptom relief, extended treatment with corticosteroids is the mainstay of treatment. Patients often relapse following an initial case of PMR; up to 50% of patients have a recurrence of PMR (Lally & Spiera, 2018). Studies have shown that women, those with elevated ESR rates, and those with peripheral arthritis were at high risk for relapse (Camellino et al., 2020; Matteson & Dejaco, 2017). There has also been indication that a percentage of patients with PMR eventually develop late-onset RA (Kermani & Warrington, 2013).

Patients with PMR may be at risk for developing vascular disorders, especially cardiovascular disorders (Camellino et al., 2019); thus, these patients should be screened carefully. The incidence of cataracts has been found to increase in patients with PMR (Camellino et al., 2019). Practitioners will need to continue to monitor patients for any new symptoms following treatment for PMR. When examining a national database of patients with PMR, Muller and colleagues (2016) found a trend of new cancer diagnoses in patients with PMR, without pre-existing cancer, 6 months after initial diagnosis. In one systematic review, it was found that the rate of hematogenous cancer was significantly higher in patients with a diagnosis of PMR (Partington et al., 2018).

Prevention/Prophylaxis: No preventive measures exist for PMR, but because the disease can recur, patients should be advised to contact their health-care providers when any of the prevailing signs and symptoms reappear. Patients on long-term corticosteroids should be up to date on immunizations for influenza and pneumonia (Tanrıöver et al., 2016). Prophylaxis for *Pneumocystis carinii* pneumonia is recommended for patients on >20 mg prednisone for extended periods of time.

Referral: For patients with signs of visual disturbance, funduscopic changes, or both, referral to an ophthalmologist is warranted if the patient can be evaluated immediately. If not, these patients should be referred to an emergency department for immediate evaluation for probable temporal artery biopsy (Vodopivec & Rizzo, 2018). Consultation with a rheumatologist is warranted for patients who have GCA and for patients with PMR alone that have spinal involvement, who do not respond initially to corticosteroid treatment, are unable to take corticosteroids, and are candidates for a disease-modifying agent, or have prolonged duration of PMR of 6 to 12 months (Caylor & Perkins 2013).

Education: Patients should be taught the possible side effects of taking long-term glucocorticoids, such as insomnia, elevation of blood pressure and blood glucose level, hot flashes, edema, and exacerbation of heart failure. Patients and their caregivers need to be informed not to abruptly cease taking the glucocorticoids. In addition to being at risk for osteoporosis, the likelihood for developing infections, fractures, diabetes, peptic ulcers, cataracts, depression, and weight gain increases with steroid use. Patients should be instructed to include an adequate amount of dietary calcium and vitamin D in their diets (Acharya & Musa, 2021; Mahmood et al., 2020). Given the risk of vascular disorders, patients who smoke should be highly encouraged to begin smoking cessation. Patients who do not have GCA should be alerted to potential symptoms, such as visual disturbance, headache, temporal and scalp tenderness, jaw pain (especially while chewing), and limb pain given the development of late GCA after a PMR diagnosis (Liozon et al., 2018).

RHEUMATOID ARTHRITIS

Signal Symptoms: Symmetrical inflammatory arthritis; Joint pain and swelling, particularly of the metacarpophalangeals (MCPs) and proximal interphalangeals (PIPs), wrists, and metatarsophalangeals (MTPs); morning stiffness lasting longer than 60 minutes.

Description: Rheumatoid arthritis (RA) is the most common inflammatory arthritis. This chronic systemic autoimmune disease is characterized by joint pain, swelling, and morning stiffness, particularly of the hands and feet. If untreated or suboptimally treated, RA leads to joint deformity and loss of

© F.A. Davis Publishing

mobility (Terrie, 2021). RA is characterized by cytokine-mediated (tumor necrosis factor [TNF] and interleukins) persistent synovitis and formation of pannus, which is invasive synovial tissue that leads to destruction of the cartilage, subchondral bone, and soft tissues of the affected joint, including tendons and ligaments. Inflammatory infiltrates in the subchondral bone are an integral part of the pathogenesis of RA and can cause inflammatory cysts and later bone erosions (Ostrowska et al., 2018).

RA usually has an insidious onset but progresses rapidly over the first year. This rapid progression can continue for the next 5 to 6 years. Within 10 years of onset of symptoms, approximately 80% of individuals will develop permanent joint deformities (Kontzias, 2020). Early progression is associated with worse outcomes; therefore, it is important to diagnose and treat early with the goal of achieving remission or low disease activity and minimizing exacerbations (Bullock et al., 2018). In addition to decreased physical function, RA contributes to anxiety, depression, economic hardship, and overall decreased quality of life (Fiest et al., 2017). At least 10% of RA patients will experience severe disability despite proper treatment (Kontzias, 2020).

Extra-articular involvement can be significant with RA—affecting the lungs, heart, skin, and/or eyes. RA-related interstitial lung disease (ILD) is associated with high rates of morbidity and mortality, the median survival is 5 to 8 years after ILD becomes symptomatic. Cardiovascular disease increases the mortality rate to 1.5 to 3 times higher for patients with RA compared to the general population. Neurological manifestations are typically complications of articular inflammation that invades or compresses nerves including of the spinal cord (Kim & Suh, 2020). RA can also cause vasculitis, rheumatoid nodules, eye conditions (episcleritis, scleritis, and/or keratoconjunctivitis sicca), and indirectly glucocorticoid-induced osteoporosis and increased rates of infection. Patients with RA have a decreased life expectancy of 3 to 10 years (Kim & Suh, 2020; Kontzias, 2020).

Etiology: The exact cause of RA is unknown. Several contributing factors have been identified, including environmental, hormonal, immunological, and infectious components and genetics. It is estimated that genetic factors account for half of all RA cases. The strongest correlations have been noted with family history of RA, smoking/exposure to tobacco smoke, obesity, and/or female sex (Terrie, 2021).

Occurrence: An estimated 1.3 to 1.5 million individuals in the United States have RA (Fiest et al., 2017; Terrie, 2021). RA is prevalent in 0.5% to 1% of the population (Terrie, 2021). It is estimated that onset of RA in older adulthood accounts for 10% to approximately 30% of all cases of RA (Targońska-Stępniak et al., 2021). Compared to men, women are two to three times more likely to develop RA, with the greatest incidence of RA occurring in women 65 years and older. Women comprise 75% of RA diagnoses (Terrie, 2021).

Age: The onset of RA is typically between the ages of 35 years and 60 years. RA can affect the pediatric population, referred to as juvenile RA (Bullock et al., 2018; Terrie, 2021). Elderly onset rheumatoid arthritis (EORA) generally begins after age 65 (Kobak & Bes, 2018; Serhal et al., 2020).

Ethnicity: RA is highest among Whites with the highest age-standardized prevalence in high-income North America, Western Europe, and the Caribbean and the lowest in Southeast Asia, Oceania, and western sub-Saharan Africa (Safiri et al., 2019).

Contributing Factors: Socioeconomics, lifestyle, and psychological stressors very likely impact the development of RA and affect patient outcomes (Terrie, 2021). It is theorized that for some, RA develops when a genetically susceptible person has an autoimmune reaction triggered by external stimulus such as smoking, trauma, or infection (Paul et al., 2017). Obesity is considered a contributing factor because increased secretion of adipokines cause a chronic subclinical inflammatory state. Smoking and obesity account for RA incidence of 14% and 14.7%, respectively (Ye et al., 2021).

Signs and Symptoms: RA often begins with subtle symptoms, but it can present as a viral syndrome with low-grade fever, malaise, weakness, and poor appetite (Terrie, 2021). Onset of disease is symmetrical and targets MCPs, PIPs, wrists, MTPs and ankles. RA can also affect the knees, elbows, and cervical spine—rarely affecting the distal interphalangeals (DIPs) until late disease (Tanaka, 2020).

In addition to hand pain, common initial patient concerns include decreased grip strength and painful walking, both of which improve with activity. Morning stiffness classically lasts longer than 60 minutes and improves with activity. Patients often do not want to stop moving because rest causes "gel" phenomenon or gelling—the stiffness and pain return with prolonged inactivity (Kontzias, 2020).

Generalized fatigue is a common symptom both initially and during exacerbations (Terrie, 2021). Almost half of RA patients will experience dry eyes and/or dry mouth, approximately 35% will develop rheumatoid nodules on the extensor surface of the forearm (Cabling, 2020), 25% experience compressive neuropathy of the hands and feet, and close to 10% develop RA-associated ILD (Tanaka, 2020).

For patients with EORA, the signs and symptoms often present more acutely. There is an increase in the type of constitutional symptoms, such as weight loss, myalgias, and polymyalgia rheumatics (PMR)-like symptoms (Serhal et al., 2020). The larger joints, such as the shoulders and wrists, are more frequently involved than in younger patients with a new onset (Kobak & Bes, 2018; Serhal et al., 2020).

Examination of the patient should include all joints of upper and lower extremities for swelling, tenderness, and limitation of movement; and of the cervical spine to assess decreased range of motion (ROM) and pain, which could indicate atlantoaxial subluxation. Atlantoaxial subluxation (instability between C1 and C2 vertebrae) occurs in 65% of patients with RA; when severe, it increases the risk of spinal cord compression. Joints should be assessed for flexion contractures, which can develop rapidly particularly of the elbows. Patients often hold joints in a flexion position to minimize pain. Advanced and suboptimally treated disease can lead to ulnar deviation along with boutonnière and swan-neck deformities of the fingers and fusion (ankylosing) of the wrists and ankles (Kontzias, 2020).

Diagnostic Tests: Laboratory tests including rheumatoid factor (RF) (positive) and acute phase reactants: C-reactive protein (CRP) (elevated) and erythrocyte sedimentation rate (ESR) (elevated) are associated with RA and inflammation; however, the most sensitive and specific test for RA, at 90% or

© F.A. Davis Publishing

higher, is the anti-cyclic citrullinated peptide (anti-CCP). High levels of RF and anti-CCP indicate a more aggressive phenotype. It is possible to have a false-positive RF, such as with hepatitis C or systemic lupus erythematosus (SLE), or even a seronegative RA with both tests being negative, although this is less likely. The frequency of RF positivity has been found to be lower in patients with EORA (Kobak & Bes, 2018). Additional laboratory findings that act as acute phase reactants due to inflammation include elevated white blood cell (WBC) count, low hemoglobin, elevated ferritin, and/or low albumin.

Imaging is important both for diagnosing and monitoring RA progression. Ultrasound can be especially beneficial with early disease activity because radiographic findings will not appear until damage has already occurred (with the exception of soft tissue swelling). With established disease, common x-ray findings include joint space narrowing that indicates cartilage absorption, subluxation that indicates soft tissue involvement, and bone erosions that indicate bone destruction (Tanaka, 2020). Inflammatory infiltrates in the subchondral bone, which can lead to inflammatory cysts and later erosions, can be seen on magnetic resonance imaging (MRI) as bone marrow edema in early RA and are an indicator of rapid disease progression (Ostrowska et al., 2018).

Differential Diagnosis: Differential diagnoses for RA include the following (Kontzias, 2020):

- Crystal arthropathy: gout or chondrocalcinosis—joint aspiration would reveal monosodium urate crystals or calcium pyrophosphate crystals
- Osteoarthritis (OA)—radiographs, history, and negative serology
- SLE or mixed connective tissue disease—serology and distinguishing accompanying symptoms
- Spondyloarthropathy: psoriatic arthritis, reactive arthritis, ankylosing spondylitis—not typically symmetrical, peripheral joints (MCPs, MTPs); imaging and serology
- PMR—joints affected, laboratory test results, and rapid onset/rapid response to glucocorticoids
- Polymyositis—muscle enzymes and muscle biopsy
- Sarcoidosis—presentation (monoarticular or oligoarticular) and other physical findings
- Fibromyalgia—pain without stiffness, nonarticular, negative laboratory results
- Other arthritides: trauma—history and imaging; septic—typically one affected joint and Gram stain and culture from arthrocentesis; infectious (hepatitis B and C, HIV, and Lyme disease)—serology; malignancy-related—imaging

Treatment: Early diagnosis is key because the first 12 weeks after initial symptoms are the optimal treatment window to achieve less joint destruction, no functional impairment, and induce remission (Guo et al., 2018). Methotrexate (MTX), a conventional synthetic disease-modifying antirheumatic drug (cs-DMARD), is the recommended initial treatment unless contraindicated. If there is a contraindication for MTX, leflunomide or sulfasalazine should be initiated. If there is no improvement in 3 months or remission in 6 months even with appropriate dose adjustment, then either a JAK inhibitor or a biologic DMARD (bDMARD) should be added. Hydroxychloroquine (HCQ) is conditionally recommended for low disease activity or as part of triple therapy (Fraenkel et al., 2021). Azathioprine and cyclosporine are infrequently used unless for treatment of extra-articular complications. Low-dose glucocorticoids are recommended for short-term adjunctive therapy to alleviate pain and swelling at diagnosis and during exacerbations (Tanaka, 2020). Caution should be exercised, particularly with MTX and NSAIDs because of gastrointestinal (GI) cardiovascular risk. Aspirin is not recommended (Kontzias, 2020).

Biologic treatments include tumor necrosis factor (TNF)-alpha inhibitors: adalimumab, etanercept, infliximab (and biosimilars), golimumab, certolizumab pegol; Janus kinase (JAK) inhibitors: tofacitinib, baricitinib, upadacitinib; IL-6 inhibitors: sarilumab, tocilizumab; T-cell costimulatory molecule modulator: abatacept, which carries less risk of opportunistic infections; and B-cell depleter: rituximab, which is used for refractory patients. The interleukin (IL)-1 receptor inhibitor anakinra is not frequently used (Kontzias, 2020). With any immunosuppressive medication, patients need to be tested for hepatitis and tuberculosis. Additionally, a good history is important to determine any past infections that could cause complications such as histoplasmosis and past family medical history for multiple sclerosis or other demyelinating disease as TNF inhibitors place patients with this history at increased risk of developing multiple sclerosis (MS) (Bullock et al., 2018).

Biologics can predispose patients to increased risk of infection and the rare risk of lymphoma. TNF inhibitors should be used with caution in older adults with heart failure because they can worsen heart failure. Treatment should also include supportive measures such as exercise/weight management, rest, intermittent heat or cold, physical therapy/occupational therapy (PT/OT), splinting, surgery for severe joint damage, smoking cessation, and proper nutrition (the Mediterranean diet is recommended) (Kontzias, 2020; Ye et al., 2017).

Follow-Up: Patients should have regular appointments for joint assessment, for medication management, and for disease progression monitoring, in addition to urgent visits for exacerbations. Additionally, patients taking cs-DMARDs, particularly MTX, require routine monitoring of liver function, renal function, and blood counts. JAK inhibitors and IL-6 inhibitors require follow-up lipid panel testing after initiation as levels can increase. Of note, IL-6 inhibitors also suppress acute phase reactants inconsequential of disease control as IL-6 regulates acute phase protein synthesis. HCQ requires yearly eye examinations to monitor for retinal toxicity (Guo et al., 2018). All health-care providers of rheumatology patients should assess and address the psychosocial impact of disease, functional status, and ability to carry out activities of daily living (ADLs).

Sequelae: Many older adults with long-standing disease often have permanent joint deformities, such as ulnar deviation and joint fusion, even in the context of no active disease. Newer therapies and prompt diagnosis and treatment have helped decrease these complications. Cardiovascular disease risk reduction is important given the increased risk due to systemic inflammation. Patients need to be monitored for lung involvement due to increased mortality once symptomatic. Cervical radiographs may be needed before general anesthesia/intubation to assess risk of cervical myelopathy (Kontzias, 2020).

© F.A. Davis Publishing

Prevention/Prophylaxis: RA cannot be prevented, but the complications of it can be mitigated with prompt treatment. Individuals with a family medical history of RA can possibly reduce their risk by maintaining optimal body weight and not smoking (Ye et al., 2017).

Referral: Patients experiencing arthralgia that is not easily explained, not monoarticular, or not obviously OA, need further work-up that includes laboratory testing, imaging, and a referral to rheumatology. PT and OT are of great benefit for strengthening and exercise programs, addressing splinting and orthotic needs, and other providing adaptive equipment/modifications that provide independence in ADLs and improve physical function.

Education: Patient education should focus on the need for appropriate treatment and the evidence-based safety profile of available medications including biologics, which many patients fear. Patients should be educated on the importance of vaccinations and the proper timing of administration. Live vaccinations should be avoided while on treatment. Immunosuppressive medications should be held when there is active infection. Because many patients feel good on corticosteroids, they are sometimes reluctant to wean off them and consider other treatment options. Therefore, education should also include the known adverse effects of long-term moderate-high dose corticosteroids including increased risk of diabetes, osteoporosis, infection, osteonecrosis, Cushing, and cardiovascular, ophthalmological, and GI effects (Yasir et al., 2021). Inform patients and ensure they understand that pain management, particularly with narcotics, does not treat inflammation and systemic effects of RA and should be used judiciously. Education should help patients manage extra-articular manifestations such as dry eye, dry mouth, fatigue, and neuropathy.

SJÖGREN'S SYNDROME

Signal Symptoms: Dry eye, fatigue (most frequent symptom), systematic vasculitis, lung or neurological involvement that may be severe and life threatening. A rare complication is the development of B-cell lymphoma (Cornec et al., 2015).

Description: Sjögren's syndrome is an autoimmune disorder characterized by mononuclear cell infiltration in the exocrine glands, which can lead to dry eye (xerophthalmia), dry mouth (xerostomia) and (dysphagia). Dr. Henrik Sjögren coined the term *sicca condition* to describe the disease he studied in his lifetime as an ophthalmologist (Baer & Walitt, 2018). Sicca refers to a dry eye disease from tears not providing adequate moisture. However, it is now known that Sjögren's syndrome is a systemic rheumatic disease with autoimmune-induced inflammation of the lacrimal and salivary glands and mononuclear cell infiltration and destruction of the lacrimal and salivary glands, which result in impaired tear and saliva production. It can manifest in focal lesions, including focal or motor deficits, stroke, or cerebellar syndromes (Altun et al., 2021).

The autoimmune distinction is important because therapies directed at the immune system might be beneficial to those with Sjögren's syndrome (Baer & Walitt, 2018). Due to the syndrome's autoimmune nature, systemic manifestations can include cryoglobulinemic purpura, nonerosive symmetrical arthritis, interstitial lung disease (ILD), Raynaud's phenomenon, pericarditis, autoimmune hemolytic anemia, and renal disease, including glomerulonephritis to tubulointerstitial nephritis. Renal involvement is a systemic complication of primary Sjögren's syndrome. In some cases, a renal biopsy is necessary for definitive diagnosis of kidney involvement (Ramponi et al., 2020).

Etiology: Although the etiology is unknown, Sjögren's syndrome is known to be an autoimmune disorder. There is a decrease in tears and saliva occurring when the glands that produce these fluids are damaged by inflammation. Researchers believe that genes affect the risk of developing Sjögren's syndrome, but that development of the condition may be triggered by environmental or viral/bacterial stressors (Sam & George, 2020). There are two prevailing theories on the origin of the dry eye symptom. In one theory, the origin of dry eye may be due to neuropathic dry eye. The nerve dysfunction, either from nerves on the ocular surface (cornea

© F.A. Davis Publishing

or conjunctiva) or more centrally from higher order neurons. The cause of Sjögren's syndrome may be evaporative dry eye in which the tears dry too quickly, a dysfunction of the Meibomian glands.

Occurrence: The prevalence of primary Sjögren's syndrome ranges from 0.1% to 1% in the general population. When Sjögren's syndrome affects patients suffering from another connective tissue disease, such as systemic lupus erythematosus (SLE) or rheumatoid arthritis (RA), it is considered secondary. Secondary Sjögren's syndrome is present in up to 17% of patients with RA (Cornec et al., 2015). Sjögren's syndrome is the second most common systemic rheumatic disease (Baer & Walitt, 2018).

Age: Generally, the onset of Sjögren's syndrome occurs after 40 years of age. The condition predominantly affects women (9:1 ratio) in their middle age—both in premenopausal and postmenopausal women, but it can also affect different populations (Cornec et al., 2015; Ramponi et al., 2020). Within the research per Ramírez (2017), associated comorbidities vary by sex. Women are more prevalent with concomitant hypothyroidism. Men with primary Sjögren's syndrome were more frequently diagnosed with more severe, long-term form of the syndrome involving ILD, lymphadenopathy, and lymphoma.

Ethnicity: The syndrome affects between 1 and 23 persons per 10,000 inhabitants in European countries (Ramos-Casals et al., 2020). The average ethnicity affected is White and of European descent.

Contributing Factors: Multiple environmental factors may play a role in the pathogenesis of Sjögren's syndrome, including infectious, hormonal, and stress-related factors. Genetics may also have a role (Bautista-Vargus et al., 2020).

Signs and Symptoms: Clinical features include dry mouth, dry eyes, or dryness in the throat, nose, lips, or skin. The glands in the neck and face may swell up. Women may also experience vaginal dryness. Joint swelling and stiffness also occur. Symptoms of heartburn may occur from the stomach to the chest. Rare inflammation to liver, lungs, and kidneys may also occur. Those afflicted may have tiredness, numbness, and tingling in parts of their body (Sam & George, 2020).

Diagnostic Tests: In 2014, the American European Consensus group and American College of Rheumatology designated classification criteria for Sjögren's syndrome (Cornec et al., 2015). Blood studies include immunoglobin testing for Sjögren's syndrome and testing for elevated antinuclear antibodies (ANA), anti-RO/SSA and anti-La/SSB antibodies, or rheumatoid factor (RF), but these elevations are not always present. One study showed only 2% had positive immune serology when undergoing comprehensive ANA testing (Hadas, 2020). Patients with Sjögren's syndrome had lower lymphocyte, hemoglobin, and C3 levels but higher prevalence of RF, ANA, anti-rO/SSA and anti-La/SSB and higher immunoglobulin G (IgG) and median fluorescence intensity (MFI) levels compared to those with dry eye syndrome and controls. The novel multiplex serology method correctly identified anti SSA/B autoantibodies by ELISA among Sjögren's syndrome, patients with dry eye syndrome, and controls. Other laboratories include cryoglobulin testing, protein electrophoresis, hepatitis C and HIV (if at risk), and thyroid tests.

Sjögren's syndrome can involve salivary gland swelling in one-half of patients, and lymphoma may develop in 5% to 10% of patients (Sam & George, 2020). A salivary gland biopsy around the face or under the surface of the inner lip also may be used to make diagnosis. The minor salivary gland biopsy is invasive and has a moderate diagnostic performance. Ultrasound-guided core needle biopsy has good safety and results comparable to open biopsy of minor salivary gland of the lip. It can, however, cause permanent sensory loss of the lips (Borner et al., 2021). Less invasive methods, such as imaging, biomarkers, and skin biopsy are on the horizon (Bautista-Vargus et al., 2020). New testing includes ocular surface staining scores or salivary gland ultrasonography (Jousse-Joulin & Coiffier, 2020). Noninvasive tools include elastography, ultrasonography technique, magnetic resonance imaging (MRI), MR sialography, and fluorodeoxyglucose-positron emission tomography. Salivary gland ultrasonography should be the first choice in primary Sjögren's syndrome because of accessibility. It is noted that major salivary gland ultrasonography should be included in future classification criteria for primary Sjögren's syndrome. It is simple, noninvasive and less expensive.

Per the 2002 American-European Consensus group (AECG), assessing for Sjögren's syndrome should include a history/review of systems, examination, laboratories, ophthalmological examination, sialometry (measure of saliva flow), and imaging (Cornec et al., 2015). The 2002 AECG and the 2012 American College of Rheumatology (ACR) criteria can assist with diagnosis (Cornec et al., 2015). Schirmer test, tear breakup time, and ocular surface staining are used to evaluate for keratoconjunctivitis sicca. Schirmer test utilizes filter paper strips and measures moisture in both eyes simultaneously. Ocular surface staining with vital dyes allows slit-lamp visualization of devitalized conjunctival cells and corneal epithelial defects. Lissamine green is most used to stain the conjunctiva, and fluorescein is used in the cornea. It is more sensitive than the Schirmer test for detecting dry eye. Of note, the Schirmer test result is less accurate in older adults because the degree of wetting declines with age (Baer & Walitt, 2018; Cornec et al., 2015). Tear breakup time is used to assess the stability of the tear film. An abnormal result occurs with meibomian gland dysfunction (Baer & Walitt, 2018).

In 2016, the ACR and the European Alliance of Associations for Rheumatology (EULAR) Sjögren's syndrome classification criteria updated elements while maintaining a patient has either anti-RO/SSA antibodies or a positive minor salivary gland biopsy. Although there is not one specific diagnostic test for Sjögren's syndrome, criteria for diagnosis include if an individual having one symptom of ocular or oral dryness (positive response to at least one of five standardized questions), salivary gland enlargement, or a characteristic extraglandular manifestation of Sjögren's syndrome as defined by a positive domain in EULAR Sjögren's syndrome disease index. Drawbacks include antibody testing because antibodies to anti-Ro/SSA and ant-La/SSB are not specific to just Sjögren's syndrome; they can be positive in other rheumatic conditions (Shiboski et al., 2017).

Differential Diagnosis:

- Sicca syndrome
- Sarcoidosis
- Granulomatosis with polyangiitis or vasculitis

© F.A. Davis Publishing

- IgG4-related disease
- Chronic hepatitis C virus
- HIV
- Graft-versus-host disease
- Head and neck radiation therapy (Cornec et al., 2015)

Treatment: There is no curative treatment for Sjögren's syndrome currently. There are topical medications used in symptom management. Systemic immunomodulatory and immunosuppressive agents may be needed to manage various extraglandular manifestations. A multidisciplinary approach is needed (Ramos-Casals et al., 2020).

For dry eye symptoms, artificial tears/lubricant ointment are for immediate and long-term use. Topical ocular NSAIDs/corticosteroids may be prescribed by an ophthalmologist for a period of 2 to 4 weeks (Ramos-Casals et al., 2020). Many topical treatments studied are inconclusive. Hydroxychloroquine, immunosuppressive agents, or rituximab show inconclusive or negative results in studies. Regular eye examinations are recommended.

Dry mouth management includes drinking water, chewing gum, or saliva substitutes. Muscarinic agonists can substantially increase saliva production and to a lesser extent, tear flow. Care must be taken when these medications are prescribed to older adults. These drugs are contraindicated in patients with uncontrolled asthma and angle-closure glaucoma. Regular dental care is recommended as is fluoride (Baer & Walitt, 2018; Ramos-Casals et al., 2020; Vivino et al., 2016).

Joint pain management includes analgesics, topical NSAIDs, and hydroxychloroquine. The 2019 EULAR recommendations and a 2019 Cochrane review concluded that effects of topical ciclosporin on both symptoms and signs are inconsistent (Vehof et al., 2020). Those with systemic symptoms may require treatment with corticosteroids or immunosuppressive agents such as methotrexate, azathioprine, mycophenolate, or cyclophosphamide. Conventional disease-modulating antirheumatic drugs (DMARDs) and the newer biologic therapies, including tumor necrosis factor (TNF)-inhibiting drugs (etanercept, adalimumab, and infliximab) may be considered. Rituximab and other biologics are being evaluated for Sjögren's syndrome that affects the entire body (Ramos-Casals et al., 2020; Vivino et al., 2016).

Nasal dryness symptom management includes humidifiers and nasal saline irrigation. Heartburn remedies include proton pump inhibitors and H_2-receptor blockers to lessen acid reflux symptoms. Vaginal moisturizers and lubricants are initial treatment options for vaginal dryness (Baer & Walitt, 2018; Sam & George, 2020).

Follow-Up: Follow-up with specialists is required if comorbidities are present or organ damage exists. Regular eye examinations, dental cleanings, and further testing by specialists may be needed.

Sequelae: Most patients with Sjögren's syndrome have limited symptoms such as dry eye and mouth. Their general health and life expectancy are largely unaffected. Increased mortality may be related to conditions associated with SLE, lymphoma, RA, or primary biliary cirrhosis (Cornec et al., 2015).

Prevention/Prophylaxis: There are currently no prevention/prophylaxis measures known or practiced. Routine eye examinations are needed to detect further damage.

Referral: Refer to an ophthalmologist and a rheumatologist for specific testing and treatments. Coordinate with the primary care provider for symptoms such as fatigue. Referrals to support groups for new and ongoing diagnoses include the International Sjögren's Network, Sjogren's Syndrome Foundation in the United States (sjogrens.org) and the Arthritis Foundation.

Education: Inform patients on how to manage their symptoms. Advise patients that certain medications (both prescription and over-the-counter) may aggravate symptoms. Drugs that induce ocular or oral dryness include anticholinergics, histamine receptor antagonists, antidepressants, diuretics, antispasmodics, antihypertensives, and sedatives (Baer & Walitt, 2018).

Clinical Recommendation	Evidence Rating	References
Fluoride should be used in patients with a dry mouth to prevent caries.	A	Vivino et al., 2016

SYSTEMIC LUPUS ERYTHEMATOSUS

Signal Symptoms: Livedo reticularis (mottled purplish discoloration), malar rash (butterfly rash), mucocutaneous lesions, arthralgias, myalgias, pleurisy, myocardial dysfunction, hypertension, cognitive dysfunction, idiopathic thrombocytopenic purpura, lupus nephritis.

Description: Systemic lupus erythematosus (SLE) is one of the most complex autoimmune diseases and has multiple clinical presentations. The disease is characterized by multisystem involvement and has a chronic relapsing nature. The course of the disease is variable, alternating between periods of stable

© F.A. Davis Publishing

disease (remission) and/or flares with high disease activity. There are currently three different classification criteria to aid in the diagnosis of SLE (Pan et al., 2020): *1997 Update of the 1982 American College of Rheumatology Revised Criteria for Classification of Systemic Lupus Erythematosus* (American College of Rheumatology, 1997); Systemic Lupus International Collaborating Clinics—SLICC Criteria (Markowitz & D'agati, 2007); and the 2019 European League Against Rheumatism/American College of Rheumatology Classification Criteria for Systemic Lupus Erythematosus (Aringer et al., 2019).

Etiology: The pathogenesis of SLE is not quite well understood. It is characterized by the production of autoantibodies and the deposition of immune complexes, affecting a wide range of organs. Genetic factors, environmental factors, and hormonal factors are believed to contribute to the occurrence of SLE. Breakdown of self-tolerance plays a critical role in the occurrence and development of SLE. Innate and adaptive immune responses against self-antigen induce the production of autoantibodies and the deposition of immune complexes in tissues leads to the activation of complement, accumulation of neutrophils and monocytes, and self-reactive lymphocytes (Pan et al., 2020).

Occurrence: The incidence of SLE in the United States ranges from 2.0 to 7.6 cases per 100,000 persons per year. Prevalence ranges from 14.6 to 68 cases per 100,000 persons. SLE affects more women than men, with a ratio of 9:1 and a higher incidence among women of childbearing age. Men tend to have severe manifestations at the time of diagnosis.

Age: Lupus will mostly affect young men and women between the ages of 15 to 45. For older adults presenting with SLE for the first time, late onset is considered after age 50, which accounts for 10% to 20% of all lupus cases. There is usually less organ damage, but with insidious onset of disease (Aljohani et al., 2017).

Ethnicity: SLE Disproportionately affects Black women with a three to four times higher prevalence than Whites. There is a higher incidence of SLE among the Afro-Caribbean, Asian, American Indian, and Hispanic descent populations as compared to the White population. Black, Asian, and Hispanic individuals with SLE tend to develop more severe disease, exhibit a greater number of manifestations, and rapidly accumulate damage from lupus. Even after considering socioeconomic factors, race/ethnicity remains a key determinant of poor outcomes (Lewis & Jawad, 2017; Stefanidou et al., 2013; Stojan & Petri, 2018).

Contributing Factors: Recent studies have shown that genetic, epigenetic, immunoregulatory, ethnic, hormonal, family history of autoimmune disease, and environmental factors are associated with the development of the disease (Trentin et al., 2021). Given the high rate of polypharmacy in older adults, review all medications to determine whether there is drug-induced SLE suspected (Séguin et al., 2021). Rule out the following medications: Anti-tumor necrosis factor (TNF) drugs (adalimumab, certolizumab pegol, etanercept, and golimumab), hydralazine, anticonvulsants, isoniazid, thorazine, procainamide, penicillamine, and minocycline.

Signs and Symptoms: Common signs and symptoms of SLE include fatigue, weight loss, and fever without infection. Most patients also report arthralgias and myalgia (Lam et al., 2016). In addition to constitutional symptoms, prevalent signs and symptoms in specific organ systems include musculoskeletal, skin, renal, neuropsychiatric, hematological, cardiac, pulmonary, gastrointestinal (GI), or reticuloendothelial (Lam et al., 2016). Overall, late-onset SLE has lower systemic manifestations (Chanprapaph et al., 2021). In late-onset SLE, cutaneous manifestations are less common except for sicca symptoms, which are caused by lymphocytic infiltration of exocrine glands—most notably the salivary and lacrimal glands—causing xerophthalmia (dry eyes) and xerostomia (dry mouth), pericarditis, and lung involvement. (Lewis & Jawad, 2017; Medlin et al., 2016; Medlin et al., 2018; Stojan & Petri, 2018).

The pulmonary manifestations found in late-onset SLE include interstitial lung disease (ILD) and serositis (inflammation of the serous tissues that protect organs) as compared to findings in a younger population (Medlin et al., 2018). Late-onset SLE has lower lupus-associated autoantibody involvement (Chanprapaph et al., 2021).

Diagnostic Tests: The diagnosis of lupus is based on detailed history, clinical presentation, and laboratory analysis. The new European League Against Rheumatism/American College of Rheumatology Classification Criteria for Systemic Lupus Erythematosus classification system, although *not* diagnostic, delineates additive weighted criteria that guide clinicians toward the diagnosis of SLE (Aringer, 2019). The criteria (Fig. 16-1) indicates that an elevated antinuclear antibody (ANA) titer of ≥1:80 on Hep-2 cells is the established entry point in the decision making (Aringer et al., 2019). Positive laboratory work-up only, without presenting symptoms, does not support the diagnosis of SLE and does not require treatment. Although the diagnosis of SLE relies on both physical signs and laboratory data to confirm, the patient's prognosis and monitoring of treatments relies on regular diagnostic testing.

Complex laboratory work-up to SLE may include ANA. Note, however, that while present in 96% of patients with SLE, it has extremely poor specificity, with many false positives. It can be present in 10% of healthy individuals and may be positive in other autoimmune conditions, such as hypothyroidism. ANA alone is not a definitive test for SLE. If patient's symptoms are highly suspicious for SLE, referral to rheumatology is appropriate. Rheumatology may order the following tests:

- Anti-double-stranded DNA antibodies (anti-dsDNA)—present in 50% of patients with SLE Complement level 3 and 4 (C3 and C4)—abnormally low when active disease; it represents complement consumption, but it is not specific to SLE and can be seen in other complement deficiencies. Normal levels can indicate low disease activity. Chronic low C3 Can be associated with lupus nephritis.
- Antibodies to cytoplasmic components
  - Anti-Ro/SSA—mostly associated with primary Sjögren's syndrome but can be found in 20% to 30% of SLE patients; associated with subacute cutaneous lupus and photosensitivity.
  - Anti-La/SSB
- Anti-Smith antibodies—are present in 20% of SLE patients; interfere with ability to transcribe RNA to DNA.
- Antibodies to ribonucleoprotein (RNP)—interfere with RNA to bind to cytoplasm cells; present in mix connective

© F.A. Davis Publishing

Entry criterion

Antinuclear antibodies (ANA) at a titer of ≥ 1:80 on HEp-e cells or an equivalent positive test (ever)

If absent, do not classify as SLE
If present, apply additive criteria

Additive criteria

Do not count a criterion if there is a more likely explanation than SLE.
Occurrence of a criterion on at least one occasion is sufficient.
SLE classification requires at least one clinical criterion and ≥ 10 points.
Criteria need not occur simultaneously.
Within each domain, only the highest weighted criterion is counted toward the total score.

Clinical domain and criteria	Weight
Constitutional	
Fever	2
Hematologic	
Leukopenia	3
Thrombocytopenia	4
Autoimmune hemolysis	4
Neuropsychiatric	
Delirium	2
Psychosis	3
Seizure	5
Mucocutaneous	
Non-scarring alopecia	2
Oral ulcers	2
Subacute cutaneous OR discoid lupus	4
Acute cutaneous lupus	6
Serosal	
Pleural or pericardial effusion	5
Acute pericarditis	6
Musculoskeletal	
Joint involvement	6
Renal	
Proteinuria > 0.5g/24h	4
Renal biopsy Class II or V lupus nephritis	8
Renal biopsy Class III or IV lupus nephritis	10

Immunology domains and criteria	Weight
Antiphospholipid antibodies	
Anti-cardiolipin antibodies OR Anti-β2GP1 antibodies OR Lupus anticoagulant	2
Complement proteins	
Low C3 or low C4	3
Low C3 AND low C4	4
SLE-specific antibodies	
Anti-dsDNA antibody* OR Anti-Smith antibody	6

Total score:

Classify as Systemic Lupus Erythematosus with a score of 10 or more if entry criterion fulfilled.

FIGURE 16-1 Classification Criteria for Systemic Lupus Erythematosus. (Reprinted from Aringer, M., et al. (2019). 2019 European League Against Rheumatism/American College of Rheumatology classification criteria for systemic lupus erythematosus. *Arthritis & Rheumatology, 71*(9), 400–1412 with permission.)

tissue disease; patients usually present with Raynaud's phenomenon, pulmonary hypertension, and puffy hands.
- Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)—indicates level of inflammation; does not always relate to disease activity.
- Anti-histone—present in drug-induced SLE and rheumatoid arthritis (RA)

Patients with suspected SLE should also have a complete blood count (CBC) to identify lymphopenia, thrombocytopenia, and anemia; comprehensive metabolic panel (CMP) to evaluate hepatic and renal function; and urine analysis with microscopy to check for protein and the protein and creatinine ratio, which can identify hematuria, pyuria, and proteinuria (Ali, 2018). When following a patient with SLE, consider ordering CBC/CMP/ESR/CRP, C3 levels, C4 levels, anti-double-stranded DNA (anti-dsDNA) levels, and urine with microscopy to monitor the effectiveness of treatment and the progression of the illness (Wallace, 2014; West, 2019).

Differential Diagnosis: Because of its varied presentations and multisystem involvement, the differential diagnosis for SLE is broad, and can include the following (Ali, 2018; Lam et al., 2016; Wallace, 2014):

© F.A. Davis Publishing

- Malignancies
- Infectious processes (cytomegalovirus, Epstein-Barr virus, HIV, and hepatitis)
- RA
- Scleroderma
- Fibromyalgia
- Thrombotic thrombocytopenic purpura
- Multiple sclerosis (MS)
- Myositis/dermatomyositis
- Vasculitis
- Hashimoto's thyroiditis
- Psoriatic arthritis
- Sarcoidosis
- Chronic fatigue syndrome
- Adult-onset Still's disease

Treatment: The treatment for SLE is as complex as the disease, with multiple medications being required for different manifestations. Management of SLE in older adults should be under the care of rheumatology. Table 16-1 delineates select medication treatment for SLE depending on the organ system(s) involved and progression of the disease.

Follow-Up: In older patients with SLE, follow-up needs to focus on potential sequelae. Patients with SLE/lupus nephritis are at increased risk for infections. They should be encouraged via shared decision making to receive inactivated vaccines, such as the pneumococcal polysaccharide vaccine (PPV-23), the pneumococcal conjugate vaccine (Prevnar 13), and annual influenza vaccine following Centers for Disease Control and Prevention (CDC) recommendations for patients who are immunosuppressed. If not already diagnosed with underlying heart disease, patients with SLE have a 7.5-fold increase in coronary artery disease. The combined coronary artery disease-promoting effects of SLE and chronic kidney disease lead to an even higher cardiovascular risk. Routine care for patients with SLE should include screening for cardiovascular risk factors, counseling for lifestyle modification such as smoking cessation, encouraging physical activity and weight loss, and screening for symptoms suggestive of heart disease. Another concern is the development of osteoporosis because of the long-term use of glucocorticoids. According to the 2017 American College of Rheumatology guidelines; more than 10% of patients who receive long-term glucocorticoid treatment are diagnosed with a fracture, and 30% to 40% have radiographic evidence of vertebral fractures. The highest rate of bone loss occurs within the first 3 to 6 months of glucocorticoid treatment, and a slower decline continues with persistent use (Buckley et al., 2017). Consider periodic screening for depression and anxiety, which can impact quality of life for patients with SLE (Figueiredo-Braga et al., 2018). Screening, diagnosis, and referral to mental health providers should be part of normal health assessment by the primary care provider (Lam et al., 2016).

Sequelae: A study done by Petri and Magder (2018) demonstrated that even patients who achieve low disease activity have organ damage, including musculoskeletal, central nervous system (CNS), and renal damage; osteoporotic fractures; and myocardial infarction.

Prevention/Prophylaxis: There is no prevention or prophylaxis for the development of SLE. Disease flare prevention and rapid treatment of flares are key to decreased progression of SLE. Patients should be educated on recognizing well-known triggers for flares, including sun exposure and infections, and advised to contact their providers as soon as a flare begins.

TABLE 16-1 Medications for SLE Management

MEDICATION	USES	SIDE EFFECTS
Topical steroids (e.g., hydrocortisone, triamcinolone, fluocinolone)	• Can be used short term to treat lupus rashes and skin lesions	• Burning or stinging sensation when applied • Thinning of skin with extensive use
NSAIDs	• Can be used to help treat arthralgias, polyarthritis, and myalgias. • Must add a proton pump inhibitor. • The clinician should watch blood count and creatinine. • Avoid use if kidney involvement is present. • Never for long-term use.	• Development of peptic ulcer disease, acute renal failure, and stroke/myocardial infarction with long-term use
Antimalarial drugs (mainstem of SLE treatment) Hydroxychloroquine (HCQ; most prescribed): 6.5 mg/kg up to a maximum of 400 mg daily. Has less ocular and GI reactions than chloroquine.	• Modulates the immune system, reducing flares by as much as 50%. • May prevent activation of plasmacytoid dendritic cells. • Benefits of hydroxychloroquine include maintaining remission, protecting against vascular and thrombotic events. • Is safe to use during pregnancy and while breastfeeding. • Protects against ultraviolet light and may improve skin lesions. • Can improve muscle and joint pain, pericarditis, pleuritis, fatigue, and fever. • Patients should get an eye examination by an ophthalmologist prior to initiation and annually after 5 years of regular HCQ use.	• Prevalence of retinal toxicity was <2% during the first 10 years of use; however, it increased to ~20% after 20 years of routine HCQ use. • Nausea and diarrhea—most common side effects • Skin rashes—bluish color • Cardiomyopathy (rare)

Continued

© F.A. Davis Publishing

TABLE 16-1 Medications for SLE Management—Continued

MEDICATION	USES	SIDE EFFECTS
Glucocorticoids (oral, IV, and topical forms) Acthar gel (repository corticotropin injection)—activates adrenal gland to produce glucocorticoids; has the same effect and side effects as glucocorticoids	• Dose dependent on severity and complication. • Should be avoided as long-term treatment. • High-dose therapy should be reserved for organ threatening presentation, such as SLE, nephritis, hemolytic anemia.	• Decreased bone density • Infections • Sodium retention • Edema • Hypertension • Glucose intolerance • Hypokalemia • Insomnia • Euphoria, depression, and mania • Osteonecrosis • Moon face and buffalo hump • Glaucoma, cataracts
Methotrexate	• Antimetabolite and cytotoxic agent • Reduces antigen-dependent T-cell proliferation and suppresses inflammation. • Dose varies in patients with SLE from 10 to 25 mg weekly with folic acid or folinic acid supplementation. • Mostly used to treat joint pain; can be used to treat some skin manifestations of SLE.	• Anemia, neutropenia • Stomatitis and oral ulcers (can be prevented or alleviated by folate) • Nodulosis, hepatic fibrosis, pulmonary fibrosis, lethargy, fatigue, and renal insufficiency • Contraindicated in pregnancy. It is considered a teratogenic agent. Should be given under cover of two forms of contraception. • Hair loss
Mycophenolate mofetil	• Inhibits B and T cell proliferation. • Used for organ-threatening disease such as lupus nephritis. Patients are typically started at 500 mg/day, with maintenance target of 2–3 g/day. • No consistent data on the tapering schedule during maintenance phase.	• Serious infections and gastrointestinal manifestations. Contraindicated in pregnancy due to increased risk of birth defects and miscarriages. Should be given under cover of two forms of contraception. Stop at least 12 weeks before planned pregnancy.
Cyclophosphamide	• Potent immunosuppressive and alkylating agent that depletes B + T cells. • Used to treat severe manifestations of autoimmune/inflammatory diseases. • Has a well-established efficacy in lupus nephritis and is given in lower doses than typically prescribed for cancer chemotherapy. • Due to a high rate of clinical relapse, it sometimes requires a repeated course of treatment.	• Nausea, vomiting, hair loss (reversible) • Increase risk of common and opportunistic infections. • Teratogenicity, sterility, and secondary hematological malignancy • Toxicity to the urinary bladder, including hemorrhagic cystitis and bladder cancer
Belimumab	• Blocks the activity of B lymphocytes. • Available in both subcutaneous and IV formulations. • Currently approved to be used in the treatment of lupus nephritis in addition to standard treatment. • Moderate efficacy in serologically active patients with skin and joint involvement.	• Infections • Headaches • Depression
Voclosporin	• A next-generation calcineurin inhibitor approved in 2019 to be used in combination therapy for the treatment of lupus nephritis. Structurally like cyclosporine A but has increase potency and faster elimination. • Does not require drug levels to be checked.	• Opportunistic infections • Gastrointestinal disorders • Kidney dysfunction • Hyperkalemia • Diabetes • Increased blood pressure

Sources: *Fanouriakis & Bertsias, 2019; Fanouriakis et al., 2019; Fava & Petri, 2019; Golder & Tsang-A-Sjoe, 2020; Guerreiro Castro & Isenberg, 2017; Samotij & Reich, 2019; Rovin et al., 2021.*

Referral: Patients with SLE should be referred to a rheumatologist as soon as the diagnosis is suspected. Other specialists such as nephrology and neurology should be considered depending on the presentation and progression of the disease.

Education: Recent studies have linked worse outcomes to low health literacy in patients with SLE. In order to increase understanding and compliance, patient education is paramount for patients and their families. All aspects of the disease, including manifestation, treatments and flare prevention should be initiated as soon as the diagnosis is made. Referral to patient education Web sites and foundation will help the patient cope with the recent diagnosis and the complications of such a complex disease. (Katz et al., 2021).

VASCULITIS

Signal Symptoms: Blood vessel inflammation often with palpable purpura, livedo reticularis, urticaria, ulcers and/or nodules with acute symptoms of fever, fatigue, weakness, weight loss, and/or arthralgia (Sangolli & Lakshmi, 2019).

Description: Vasculitis can be either primary or secondary. Vasculitis can cause inflammation of any size blood vessel—venules, arterioles, capillaries, veins, and/or arteries. This inflammation often leads to ischemia, necrosis, and possible organ inflammation. Clinical manifestations depend on which blood vessels are involved. Small vessel vasculitis (SVV) includes granulomatosis with polyangiitis (GPA, formerly known as Wegener's granulomatosis), which affects the upper and lower respiratory tract and kidneys; eosinophilic granulomatosis with polyangiitis (known as Churg-Strauss' syndrome), which affects the respiratory tract; microscopic polyangiitis (MPA); Henoch-Schönlein's purpura (HSP), which is an immunoglobulin A (IgA) vasculitis notably affecting the skin (most common in children); cryoglobulinemia; and leukocytoclastic vasculitis affecting the skin. Medium vessel vasculitis (MVV) includes thromboangiitis obliterans (also known as Buerger's disease), polyarteritis nodosa, and Kawasaki's disease, which primarily affects children. Large vessel vasculitis (LVV) is composed of Takayasu's arteritis, affecting the aorta and its major branches; and giant cell arteritis (GCA, also known as temporal arteritis), commonly affecting the temporal artery, although it can also affect the aorta and its major branches (Langford, 2003; Sangolli & Lakshmi, 2019; Villa-Forte, 2020). Vasculitides are also classified using the Chapel Hill nomenclature to indicate antineutrophil cytoplasmic antibody (ANCA)-associated such as GPA and MPA, immune complex such as Cryoglobulinemic vasculitis (CV) and HSP, variable vessel such as Behçet's disease, single organ such as cutaneous or central nervous system (CNS), and those associated with systemic disease (Okazaki et al., 2017).

Etiology: Primary vasculitis occurs in the absence of any associated disease or any precipitating cause with the initial event being the vessel wall inflammation. In primary vasculitis, an autoimmune mechanism is believed to be the key contributor. Secondary vasculitis may appear with a pre-existing inflammatory disorder or with cancer; it can also be triggered by a drug, toxin, or infection. (Sangolli & Lakshmi, 2019; Villa-Forte, 2020).

Occurrence: Vasculitis is relatively rare, affecting approximately 38 to 40 individuals per million. GCA is the most common form of vasculitis with a pooled prevalence of 51/100,000 among adults older than 50 years of age (Li et al., 2021). Within cutaneous vasculitis cases, infection accounts for 22%, drugs 20%, autoimmune/connective tissue disorders 12%, HSP 10%, and less than 5% each in primary vasculitis, systemic inflammatory disease, or malignancy (Sangolli & Lakshmi, 2019). Takayasu's arteritis and GCA are more common in women, whereas HSP, polyarteritis nodosa, Behçet's disease, and thromboangiitis obliterans affect more men (Langford, 2003). Death due to vasculitis, in general, is more common in women than men (Rodriguez-Pla & Rossello-Urgell, 2021).

Age: Vasculitis is more common in adults than in children. The mean age of onset is 47 years old in adults and 7 years old in children. GCA is rarely seen in individuals younger than 50 years of age (Li et al., 2021; Sangolli & Lakshmi, 2019).

Ethnicity: GCA affects individuals with a Scandinavian background the most and individuals with Asian ancestry the least (Li et al., 2021). Behçet's disease classically affects individuals with ancestry from Eastern Asia, the Middle East, or the Mediterranean (Okazaki et al., 2017).

Contributing Factors: There is no known etiology for primary vasculitis, but it is believed that immune regulatory mechanisms, genetics, and environmental factors increase susceptibility to developing vasculitis (Sangolli & Lakshmi, 2019). Contributing factors to secondary vasculitis include systemic

© F.A. Davis Publishing

autoimmune diseases such as systemic lupus erythematosus (SLE), rheumatoid vasculitis, sarcoid vasculitis, or relapsing polychondritis vasculitis (Okazaki et al., 2017). There is a very strong correlation with use of tobacco products and/or cannabis and thromboangiitis obliterans (Olin, 2018).

Signs and Symptoms: Clinical manifestations of vasculitis are directly related to the impaired blood vessel function and eventual vessel wall breakdown. Inflammation causes an insufficient blood supply leading to a localized tissue reaction, which can lead to organ dysfunction. Regardless of the type of vasculitis, patients may also present with systemic symptoms, including fever, malaise, fatigue, weakness, arthralgia, poor appetite, or weight loss. Because of these symptoms it is essential to rule out malignancy, specifically solid tumors, in older adults (Sangolli & Lakshmi, 2019).

Cutaneous manifestations are observed with all three vessel sizes vasculitides. With small vessel vasculitis, the most common findings are urticaria, palpable purpura (often of the legs), targetoid lesions, or vesiculobullous lesions. In medium vessel disease, livedo reticularis, ulcers, pitted scars, subcutaneous nodules, or gangrene can occur. Oral and/or genital ulcers, as well as skin lesions and joint pain can be seen with Behçet's disease. Nerve damage, which initially presents as hypoesthesia or hyperesthesia, can be seen with medium vessel disease in addition to myalgia, lymphadenopathy, new-onset hypertension or coronary artery aneurysms (Sangolli & Lakshmi, 2019; Villa-Forte, 2020).

GCA presents as unilateral temporal headache, jaw claudication, exquisite scalp tenderness, and is often accompanied by acute systemic symptoms including fatigue and unintended weight loss. Approximately 20% of patients with GCA will have a history of polymyalgia rheumatica (PMR) (Li et al., 2021). Large vessel cutaneous symptoms tend to occur secondary to the underlying disease but can include severe, emergent symptoms such as CNS symptoms of stroke or unequal pulse and/or blood pressures in extremities, limb claudication, or limb/digit ischemia (Sangolli & Lakshmi, 2019; Villa-Forte, 2020). Other organ-threatening or life-threatening manifestations of vasculitis include hematuria, proteinuria, and casts associated with rapidly progressive glomerulonephritis (SVV); bloody, foamy sputum associated with pulmonary alveolar hemorrhage; abdominal pain associated with mesenteric ischemia (MVV); and any cardiac involvement (Chung et al., 2021; Sangolli & Lakshmi, 2019).

Diagnostic Tests: Clinical assessment cannot be underestimated in the evaluation of vasculitis; this will direct the differential diagnosis and thus what testing is necessary. Initial laboratory studies should include a complete blood count (CBC), comprehensive metabolic panel (CMP), C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), hepatitis panel, and a urinalysis. Additional testing, such as antineutrophil cytoplasmic antibodies (ANCA) and cryoglobulins, would be considered based on clinical findings and normally completed by rheumatology. Tissue biopsy is standard in the diagnosis of vasculitis, the earlier in the disease process the better, although appropriate imaging with expertise in reading the imaging results can be less invasive and more cost-effective (Dejaco et al., 2018; Sangolli & Lakshmi, 2019).

Imaging in vasculitis depends in part on the size of the vessel disease suspected but is especially useful with LVV. Ultrasound and magnetic resonance imaging (MRI) (high resolution) are the preferred choice for GCA and Takayasu's arteritis because these tests highlight the characteristic vessel wall abnormalities. Computed tomography (CT), CT angiography, and positron emission tomography (PET) scans may be used as an alternative in the evaluation of the aorta and extracranial arteries; they are not recommended for evaluation of cranial arteries (Dejaco et al., 2018).

Differential Diagnosis: The differential diagnoses for vasculitis include conditions that mimic the disease and thus need to be excluded first as well as primary diseases that can cause secondary vasculitis (Sangolli & Lakshmi, 2019).

- Infection/infectious disease including infective endocarditis, hepatitis, HIV, tuberculosis, syphilis, rickettsial infection
- Drug toxicity/toxin exposure including hydralazine, montelukast, propylthiouracil, hormonal contraceptives, tobacco/cannabis, cocaine
- Malignancy/lymphoma
- Thrombotic/thromboembolic conditions, including antiphospholipid syndrome and sickle cell disease; history should include obstetric history of recurrent spontaneous abortions
- Systemic disease including amyloidosis, rheumatoid arthritis (RA), SLE, sarcoidosis

Treatment: Treatment for vasculitis typically includes corticosteroids during the acute phase and lower doses for maintenance therapy when necessary. Best practice for an accurate diagnosis is to obtain testing and/or imaging before initiation of corticosteroids given the significant response within the first week of treatment. Depending on the nature of the vasculitis, some are acute and self-limiting, lasting less than 6 months, whereas others will remain a lifelong condition. Treatment of secondary vasculitis should focus on addressing the primary cause.

Most treatments for vasculitis include immunosuppressants and disease-modulating antirheumatic drugs (DMARDs) such as hydroxychloroquine, methotrexate, cyclophosphamide, mycophenolate mofetil, or azathioprine. Colchicine is the mainstay for treatment of Behçet's disease. Dapsone is the usual treatment for cutaneous vasculitis, but patients must first be tested for G6PD before starting this medication. Antivirals are the standard for hepatitis C cryoglobulinemia. Biologic therapies include tumor necrosis factor (TNF) inhibitors (adalimumab, etanercept, infliximab), abatacept, tocilizumab, or rituximab (Sangolli & Lakshmi, 2019).

Follow-Up: Patients will need to follow up regularly with rheumatology (at least every 3 months) and for laboratory studies every 2 to 3 months—most often a CMP and CBC. Patients with stable vasculitis may be able to stretch visits and labs out to every 6 months. Patients taking hydroxychloroquine will require yearly retinal eye examinations.

Sequelae: In addition to possible complications of glomerulonephritis, pulmonary alveolar hemorrhage, limb/digit, or mesenteric ischemia, with GCA there is concern for severe, permanent blindness if left untreated or suboptimally controlled. This blindness is monocular, on the side with temporal arteritis, rarely affecting both eyes at the same time. In MVV, mononeuritis multiplex progression can lead to wrist or foot drop or paralysis. Patients can also have complications of immunosuppressive therapy, which should be monitored both through labs as well as a thorough review of systems to identify any new problems (Sangolli & Lakshmi, 2019).

© F.A. Davis Publishing

Prevention/Prophylaxis: There is no prevention for primary vasculitis, but it is important to adhere to treatment to minimize disease activity. Precautionary measures to reduce the risk of secondary vasculitis requires good control of underlying conditions and avoidance of triggers, including toxins, drug allergies, and tobacco.

Referral: After initial work-up or in cases of suspected vasculitis, the patient should be referred to rheumatology for evaluation and management.

Education: General measures include medication compliance, routine lab testing, regular follow-ups, and avoidance of smoking/tobacco use. Patients need to be aware that any new symptoms and any medication changes require notifying their health-care provider immediately; severe, acute symptoms should be directed to the emergency department. Corticosteroids, immunosuppressants, and biologics predispose patients to increased risk of infection and corticosteroids increase risk of osteoporosis, so it is important to educate patients on these effects and treat appropriately. Patients need to update any new provider, and specifically before any procedures such as dental work, that they are taking immunosuppressants and/or biologics. Patients taking these medications should not receive live vaccines; timing of other vaccinations may depend on timing of immunosuppressive medications, so this should be discussed with the prescribing provider. Patients of childbearing age should be counseled on use of appropriate birth control and preconception planning (Sangolli & Lakshmi, 2019).

Clinical Recommendation	Evidence Rating	References
Early imaging in patients with suspected large vessel vasculitis (LVV), particularly giant cell arteritis (GCA), is strongly recommended with the expectation that it will not delay initiation of treatment.	A	Dejaco et al., 2018
Ultrasound should be the primary imaging test in patients with suspected GCA presenting predominantly with cranial symptoms because of easy access, evidence of good test performance, low cost, and the absence of radiation or other procedural risks. The "halo" sign of temporal arteries is the most relevant ultrasound finding in GCA.	A	Dejaco et al., 2018
Ultrasound and/or magnetic resonance imaging (MRI) are first choices for evaluating cranial arteries, GCA, and Takayasu's arteritis.	A	Dejaco et al., 2018
Positron emission tomography, MRI, and/or computed tomography may be used for detection of mural inflammation and/or luminal changes in extracranial arteries to support the diagnosis of LVV, GCA, or Takayasu's arteritis.	A	Dejaco et al., 2018
Temporal artery biopsy is the gold standard test for the diagnosis of GCA.	C	Dejaco et al., 2018
GCA can be diagnosed with high clinical suspicion and a positive imaging test; diagnosis does not require additional tests (further imaging or biopsy).	A	Dejaco et al., 2018

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. For information about the SORT evidence rating system, go to https://www.aafp.org/afp/2004/0201/p548.html.

CASE STUDY

Ruby, an 86-year-old, thin, osteoporotic woman, gets up onto a stepstool to reach something on the top shelf of her cabinet. She loses her balance and falls onto her left side. She finds that she cannot sit up without pain. Her daughter later finds her and calls an ambulance to take her to the emergency department. Per radiograph, left femoral fracture is present. Surgery is scheduled for open reduction with internal fixation (ORIF). Blood clot prevention injections and pain medications are prescribed. Next, the patient is monitored for postoperative anemia and infection. After discharge, Ruby has rehabilitation for inpatient and then nursing home temporary care for 30 days. She is discharged to her daughter's home with home health and assistive equipment.

Today's visit:

Chief complaint: "I am still recovering from my fall last month and now am staying at my daughter's but want to go home."

Objective: Blood pressure (BP) 100/60 mm Hg, pulse 87, respiratory rate 20 breaths/min

1. What additional subjective data are you seeking?
2. What additional subjective data will you be assessing for?
3. Are there any national guidelines you want to consult for the postoperative and rehabilitation care of this patient with an ORIF related to osteopenia of the left femur?
4. What tests will you want to order as part of this follow-up visit?
5. Are there any new differential diagnoses you need to consider?
6. What is your plan of care?
7. What additional patient teaching may be needed?
8. Are there additional community resources to consider?
9. Will you be looking to add any referrals for this patient?

CHAPTER 17

Central and Peripheral Nervous System Disorders

Laurie Kennedy-Malone

ASSESSMENT

The neurological assessment of the older adult begins with the initial encounter with the patient, taking into consideration the overall appearance, hygiene, facial expression, gait, and posture (Seraji-Bzorgzad et al., 2019). Whether it is the masked facial expression of Parkinson's disease (PD), the facial dystonia of progressive supranuclear palsy (PSP), or the ptosis of myasthenia gravis (MG), certain neurodegenerative conditions are often visually initially recognizable and should be considered in the differential diagnosis when patients present with acute and progressive neurological signs and symptoms.

Early in the neurological examination is an assessment of cognition to ensure accuracy of the patient's comprehensive history or chief complaint. Consider, however, the need to obtain historical information from collateral sources (Seraji-Bzorgzad et al., 2019). The interview should begin with an assessment of level of consciousness, speech pattern, mood and affect, concentration ability, short-term memory, and orientation. This information can usually be obtained during the course of a standard interview. "The key to appreciating a memory impairment or subtle dementing illness is to perceive incongruities among the patient's appearance, dress, language or behavior" (Williams, 2009, p 236). There are several short screening tools that can be administered to the patient to assess cognition:

- The Mini-Cog is a short dementia assessment that combines three-word recall with clock-drawing capability. Patients are given a total score reflecting accuracy in clock drawing and recollection of the given three words. A score of 0 to 2 is a positive screen for dementia (Borson, 2000).
- The St. Louis University Mental Status Examination (SLUMS), a 12-item assessment, has been shown to detect mild neurocognitive disorders. A patient's level of high school is considered when interpreting the score. A score of 19 or below in any patient is indicative of dementia (Tariq et al., 2006). If any questions regarding the mental status arise, family members may be asked for additional information to investigate the patient's cognitive abilities further.
- The Montreal Cognitive Assessment (MoCA Version 7.1) is a tool designed to measure the status of a patient's attention, concentration, executive function, memory, and orientation. It has been tested on patients with a variety of neurodegenerative conditions, as well as those with a history of substance abuse (Berstein et al., 2011.). The score can be adjusted for patients with a lower level of education. (Milani et al., 2018). A score of 26 or higher out of a possible score of 30 is considered normal cognition (Nasreddine et al., 2005).

With neurological conditions, in addition to asking questions about the initial/current presentation (onset, duration, sequential progression of signs and symptoms), question that patient about the time of day, acute versus progressive, have any of the signs and symptoms temporarily subsided (as in remission) (Armitage, 2015). The focused interview for a neurological complaint should include asking about the following signs and symptoms in older adults:

- Loss of consciousness or presyncope, including a full description of any episodes and their precipitating factors
- Any speech or language disturbances as in the ability to recall words, correct selection of words, or constant repeating of phrases
- Change in vision, including diplopia, ptosis, loss of vision
- Change in hearing, including tinnitus or acute hearing loss
- Change in the sense of smell or taste and possible precipitating factors (such as COVID-19)
- Any mood swings, new onset of headaches, and change in level of awareness or reversal or alteration in judgment or memory
- Pertinent family history of any acute neurological or neurodegenerative disease or unknown conditions with specific symptomatology
- Information about previous occupations and hobbies that may have involved trauma or chemical exposure for each patient

© F.A. Davis Publishing

- All medications (including over-the-counter [OTC] medications)
- Diet and sleep patterns
- A careful assessment of social history, including alcohol use and any current or previous substance abuse
- Any episodes of seizures, "spells," shaking palsy, dizziness, falls, weakness or paralysis, tremors, involuntary movements, pain, numbness, paresthesia, gait problems, or restlessness of the legs

The positive findings determined in the history of present illness and review of systems will guide the episodic neurological examination. A complete neurological examination, however, begins with testing of the cranial nerve function.

Cranial Nerve Function

CRANIAL NERVE I (OLFACTORY)

As anosmia (loss of the sense of smell) and hyposmia (diminished sense of smell) are symptoms present in older adults who have a number of both acute and chronic conditions as well as part of normal aging (atrophy of the olfactory bulb), cranial nerve I should be routinely tested. Loss of the sense of smell in one nostril would be an abnormal finding (Besdine, 2019). Make sure to test one nostril at a time using familiar scents such as coffee. Olfactory Sniffin' Sticks Test could be used for comprehensive evaluation (Bagnasco et al., 2021; Rebholz et al., 2020). This sense may be lessened or absent because of COVID-19, allergic rhinitis, influenza, common cold, head trauma, smoking, use of cocaine, or normal aging. It may also be congenitally absent (Gladstone & Black, 2002a). A distorted sense of smell in both nostrils of familiar odors has been found in patients early in the progression of neurodegenerative conditions such as Alzheimer's disease (AD). Other neurogenerative conditions that patients experience anosmia or hyposmia include PD, amyotrophic lateral sclerosis (ALS), and Huntington's disease. Patients with hyposmia or anosmia are at risk for safety issues (such as eating rancid foods or the inability to detect smoke, gas, or other noxious chemicals) and malnutrition (Rebholz et al., 2020).

CRANIAL NERVE II (OPTIC)

When examining the eyes of an older person, you may note that upward gaze and, to a lesser extent, downward gaze can be slightly limited. Eye movements, when tracking an examiner's finger during evaluation of visual fields, may appear jerky and slightly irregular or have subtle changes (Seraji-Bzorgzad et al., 2019). Assess pupillary reactions to light and visual fields. Presbyopia, the loss of accommodation, is a normal aging change. Older adults experience difficulty with depth perception, decreased color discrimination affected by yellowing of the lens (ability to discern between blue and green colors) (Salvi et al., 2006), slowed adjustment to low light, and reduced contrast sensitivity (Besdine, 2019). Older patients should be encouraged to continue ophthalmical examinations; the goal should remain for vision to be corrected as needed to 20/20. Funduscopic examination will reveal disc or small vessel abnormalities (Salvi et al., 2006).

CRANIAL NERVES III, IV, AND VI (OCULOMOTOR, TROCHLEAR, AND ABDUCENS)

These nerves may be examined together by testing extraocular movements and convergence. Inspect for ptosis. While weakening of the levator muscle's ability to attach to the lid can be contributed to aging, there are several conditions that cause acquired ptosis, such as MG, diabetes, stroke, brain tumor, and Bell's palsy. Generally, pupils are smaller in an older adult, a condition known as senile miosis. A hallmark of PSP is supranuclear vertical gaze palsy; however, limitation of vertical gaze and convergence are common age-related changes noted on testing of cranial nerves (Seraji-Bzorgzad et al., 2019).

CRANIAL NERVE V (TRIGEMINAL)

The motor function of this nerve can be assessed by palpating the temporal and masseter muscles. If the patient has no teeth, this test may be difficult to interpret. The sensory function of this nerve should be tested with sharp and dull stimuli in all three branches: ophthalmic, maxillary, and mandibular (Edvinsson et al., 2020). If any abnormalities are noted, light touch and temperature sensation should also be assessed. The corneal reflex should be assessed using a wisp of cotton. Patients who wear contact lenses may have diminished corneal reflexes. Older adults may naturally have decreased lacrimal secretions; certain medications, such as anticholinergics, may exacerbate this condition (Gladstone & Black, 2002a).

CRANIAL NERVE VII (FACIAL)

Observe the patient's face at rest and continue to observe throughout the examination for any asymmetry. Motor function may be tested by asking the patient to smile, frown, raise both eyebrows, close eyes tightly and resist the examiner's attempts to open them, and puff out both cheeks. A peripheral injury to this nerve, such as Bell's palsy, may affect both the upper and the lower face, whereas a central lesion mainly affects the lower face (Suneja et al., 2020).

CRANIAL NERVE VIII (ACOUSTIC)

Assess auditory acuity using the whisper test. If hearing loss is present, test for lateralization using the Weber test and for air versus bone conduction using the Rinne's test. The ear canals should be checked for cerumen impaction or ruptured tympanic membrane, which are leading causes of conductive hearing loss and could contribute to overall hearing loss. Presbycusis, a normal aging change, results in older adults losing the ability to hear at higher tones (Michels et al., 2019).

CRANIAL NERVES IX AND X (GLOSSOPHARYNGEAL AND VAGUS)

Observe the quality of the patient's voice. Hoarseness may indicate vocal cord paralysis; a nasal quality may indicate paralysis of the palate. Difficulty in swallowing could indicate palatal or pharyngeal weakness. Inspect movement of the palate and pharynx when the patient swallows. (Armitage, 2015). Test the gag reflex by stimulating the back of the throat on each side (Suneja et al., 2020). Older adults experience a decrease in taste perception of saltiness, sweetness, sourness, and bitterness (Malaty & Malaty, 2013).

CRANIAL NERVE XI (SPINAL ACCESSORY)

Observe for atrophy or fasciculations in the trapezius muscles. Test motor strength bilaterally with a shoulder shrug (Armitage, 2015).

CRANIAL NERVE XII (HYPOGLOSSAL)

Inspect for fasciculations of the tongue at rest. Look for asymmetry of movement, atrophy, or deviation from midline. Atrophy or fasciculations suggest peripheral lesion. If there

© F.A. Davis Publishing

is an upper motor neuron lesion, the protruded tongue will diverge toward the side of the lesion, and fasciculations of the tongue will be present; however, no fasciculations or atrophy appears in upper motor neuron disease. The tongue will deviate away from the side of the lesion (Armitage, 2015; Suneja et al., 2020).

Motor Function

Assessment of motor function should focus on inspection of body position and involuntary movements (tremors, tics, or fasciculations). Note that the incidence of benign essential tremor increases with aging. Inspect the patient's muscle bulk, comparing sizes and contours of muscles. Pay particular attention to the hands, shoulders, and thighs. Atrophy of the hand muscles may occur with normal aging. Muscular atrophy may also result from diseases of the peripheral nervous system, motor neuron disease, rheumatoid arthritis, muscle disuse, and malnutrition.

Motor assessment also includes inspection of muscle tone, best assessed by the patient's resistance to passive stretch. Inspect tone in all extremities during flexion and extension. Increased tone that is worst at extremes of the range is known as spasticity; resistance that persists throughout and in both directions is known as lead-pipe rigidity. Decreased resistance suggests peripheral nervous system disease, cerebellar disease, or the acute stage of spinal cord injury. If a passive resistant movement in any direction is noted, consider dementia reflecting bilateral frontal lobe dysfunction; this irregular movement is referred to as partonia or greenalite (Gladstone & Black, 2002b). In patients with cogwheel rigidity, ratchet-like jerking movements can be detected by the examiner on passive flexion and extension of the muscle. Initially a unilateral, asymmetric tremor presents in patients with PD who develop tremor; if it is a drug-induced PD, the tremor is often symmetric (Seraji-Bzorgzad et al., 2019).

Assess muscle strength against resistance in all major muscle groups and grade on a scale from 0 to 5, with 5 being active movement against full resistance. Test the biceps and triceps; grip strength; finger abductions; opposition of the thumb; trunk strength; flexion, extension, abduction, and adduction at the hip; flexion and extension at the knee; and dorsiflexion and plantarflexion of the foot during passive range-of-motion (ROM) exercises (Larson & Wilbur, 2020). If you note weakness, assess strength against gravity alone or with gravity eliminated. Many clinicians make further distinctions by using plus or minus signs toward the stronger end of the scale (Williams, 2009). Determine whether there are patterns of objective weakness that are asymmetrical, distal, and/or proximal only (Larson & Wilbur, 2020).

It is first important to rule out whether any weakness is subjective, which is actually found to be fatigue rather than the loss or alteration of normal strength. Patients, however, may experience both fatigue and true weakness. Differentiate between constant versus intermittent weakness, and establish the patterns of weakness:

- Weak arm and leg (same side): hemiparesis or hemiplegia
- Weak legs, normal arms: paraparesis
- All four limbs weak: tetraparesis
- One limb weak: monoparesis
- Proximal muscle weakness (often from a myopathy)
- Distal muscle weakness (often from a neuropathy) (Larson & Wilbur, 2020)

Determining subjectively the patient's limitations in activities of daily living (ADLs) can further help the practitioner establish the severity of the weakness. Ask questions pertaining to function of the upper extremities, such as the ability to lift one's arms over the head for grooming or dressing (proximal upper extremity weakness) versus the ability to use utensils or turn a door handle (distal upper extremity weakness). For lower extremity, proximal weakness questions can be asked about the ability to climb stairs or cross one's legs.

It is critical to accurately assess the presentation of weakness in older adults because it is a common complaint. When evaluating a patient presenting with generalized weakness, the practitioner must consider the presence of sarcopenia coexisting with frailty (Larson & Wilbur, 2020).

An overall test of weakness and mobility is the Get Up and Go Test. It includes a number of tasks, such as standing from a sitting position, walking, turning, stopping, and sitting down, all of which are important tasks needed for a person to be independently mobile. These tasks also help determine whether the patient is having proximal weakness of the lower extremities (von Haehling et al., 2010).

Test coordination using rapid alternating movements of the hands, fingers, and feet and point-to-point movements. In some neurodegenerative conditions such as PD, movements may be slow and irregular with imprecise timing. The inability to perform repetitive movements in a rapid rhythmic method is called dysdiadochokinesia (Gladstone & Black, 2002c).

Patients with appendicular ataxia may have difficulty with finger-to-nose testing. The examiner may note undershooting (hypometria) and overshooting (hypermetria) of a target (dysmetria), as well as the decomposition of a movement or the inability to complete a movement (Suneja et al., 2020).

Gait function should be tested. Assess tandem gait, walking on toes and heels, hopping in place, and shallow knee bends on each side. All components of gait should be assessed; they include initiation of walking; step length, height, symmetry, continuity, and cadence (rhythm); velocity (speed of walking); stride width; progression; turn ability; walking posture; and need for any assistive devices. It is important to consider sensation, musculoskeletal and motor control, and attention, which are components needed for independent, coordinated walking (Jerome et al., 2015; Nnodim et al., 2020). Romberg's test is to evaluate position sense and is performed with the patient's feet together and eyes closed for 20 to 30 seconds without support. Only minimal swaying should occur in patients with a normal finding (Besdine, 2019). This test may be combined with the pronator drift test, in which the patient stands with eyes closed and both arms straight forward, palms up. Normally, this position may be held for 20 to 30 seconds. After instructing the patient to maintain this position, tap the patient's arms briskly downward. The arms should return smoothly to the horizontal position; a downward drift indicates muscle weakness. Allow extra time for the older patient to perform gait and coordination maneuvers (Seraji-Bzorgzad et al., 2019).

Sensory Function

Assessment of sensory function helps to establish a lesion of the sensory cortex, the level of a spinal cord lesion, or the location of a peripheral lesion. Sensory function is tested using pain and temperature (spinothalamic tract), position and vibration (posterior column), and touch (posterior horn).

© F.A. Davis Publishing

When you locate an area of hypersensitivity or sensory loss, map out its boundaries in detail. Unilateral sensory loss suggests a lesion in the spinal cord or higher pathways; a symmetrical sensory loss suggests a neuropathy such as that experienced by persons with diabetes. Touch and vibratory sensations may diminish because of normal aging (Seraji-Bzorgzad et al., 2019). Discriminative sensations test the ability of the sensory cortex to analyze and interpret stimuli. These techniques include stereognosis, number identification, two-point discrimination, point localization, and extinction (Suneja et al., 2020).

Reflexes

During assessment of the reflexes, the patient should be relaxed, with limbs positioned symmetrically. Palpate the tendon to locate position and make sure the tendon is slightly stretched. Strike the tendon briskly and note the speed, force, and amplitude of response. Grade on a scale from 0 to 4 pluses, with the normal response at 2 pluses. The older adult may have diminished or absent reflexes, usually affecting lower extremities (Achilles' tendon most notably) (Besdine, 2019).

If the response is asymmetrical, check the force and location of the strike. Nurse practitioners who elicit reflexes on patients with multi-infarct dementia may, however, note brisk asymmetrical reflexes as a sign of focal corticospinal tract dysfunction (Gladstone & Black, 2002d). If the response is symmetrically diminished, the examiner may use reinforcement, in which isometric contraction of other muscles may increase reflex activity. Ask the patient to clench the teeth when testing upper extremities and to lock hands together and pull hands against each other when testing lower extremities (Gladstone & Black, 2002a).

Assess all reflexes: biceps (C5, C6), triceps (C6, C7), brachioradialis (C5, C6), patellar (L2, L3, L4), and ankle (S1). Assess the abdominal reflex by stroking each side of the abdomen both above (T8, T9, T10) and below (T10, T11, T12) the umbilicus (Gladstone & Black, 2002d; Suneja et al., 2020). Evaluate the plantar response by stimulating the lateral aspect of the sole of the foot from the heel to the ball of the foot, curving medially across the ball. Look for flexion of the toes as a normal response. If dorsiflexion of the big toe and fanning of the other toes is noted, this constitutes a positive Babinski response, indicating a central nervous system (CNS) lesion. This response may also be noted in certain unconscious states (e.g., drug or alcohol intoxication, postictal state) (Suneja et al., 2020).

The clinical significance of positive findings when testing primitive reflexes such as palmomental, glabellar, and grasp remains controversial. Numerous studies have shown that primitive reflexes are common findings in the general aging population without any CNS disorder (Snow, 2020). If a patient when tested has several primitive reflexes versus just one, the likelihood of underlying neurological condition increases (Gladstone & Black, 2002d; Seraji-Bzorgzad et al., 2019).

Abnormal or Involuntary Movements

With the incidence of neurodegenerative conditions increasing with older adulthood, the practitioner needs to assess for any involuntary movements such as fasciculations, spasms, chorea, tremors, tics, and athetosis (Seraji-Bzorgzad et al., 2019). Abnormal movements could also be a side effect of psychotropic medications that can cause extrapyramidal symptoms (Gladstone & Black, 2002a). Make sure to document completely all findings of the neurological examination, especially if additional diagnostic testing is indicated. The identification of subtle nervous system abnormalities has been shown to be associated with the risk of stroke and even death in healthy older adults (Inzitari et al., 2008).

BELL'S PALSY

Signal Symptoms: Unilateral isolated acute facial weakness.

Description: Bell's palsy is characterized by an acute onset (72 hours or fewer), unilateral facial weakness. It is an isolated peripheral neuropathy affecting the seventh cranial nerve (facial nerve) on one side of the face. Taste may be diminished on the ipsilateral tongue, and hyperacusis may occur in the ipsilateral ear. The facial palsy is self-limited and typically improves over several weeks to months, with complete recovery by 1 year in up to 85% of patients. Risk factors for incomplete recovery include age older than 55 years, hypertension, pain (except for ear pain), complete facial paralysis, and reduced lacrimation.

Etiology: The cause of Bell's palsy is unknown, though it is hypothesized to be a herpes viral infection (Gilden, 2004).

Occurrence: Bell's palsy develops in 11 to 40 per 100,000 people annually worldwide (De Diego et al., 1999) and affects men and women equally.

Age: Average age at onset is 40 years, with a higher incidence in people over 70 years of age.

Ethnicity: Bell's palsy affects all ethnicities.

Contributing Factors: Diabetes, pregnancy, severe preeclampsia, obesity, upper respiratory ailments, and hypertension have been reported as risk factors for Bell's palsy (Baugh et al., 2013).

Signs and Symptoms: Patients with Bell's palsy develop unilateral weakness of the face over 1 to 2 days. The facial weakness is in a lower motor neuron pattern (Table 17-1), causing difficulty showing teeth, puffing cheeks, pursing lips, whistling, flaring the nostril, raising the forehead, and closing the eye. Patients may experience loss of taste on one side because the facial nerve innervates the taste for the anterior two-thirds of the tongue, and sometimes this is the initial symptom. The lacrimal and minor salivary glands may be affected, though most patients don't report dry eye or mouth. Facial pain (particularly postauricular) is common. There may be an abnormal sensitivity to sound (hyperacusis) due to dysfunction of the stapedius muscle.

Physical examination is notable for unilateral weakness affecting the upper and lower face muscles, including the frontalis and orbicularis oculi. Although many patients with Bell's palsy report facial "numbness," formal testing should demonstrate intact sensation. Taste may be diminished and

© F.A. Davis Publishing

TABLE 17-1 Features of Lower Motor Neuron Versus Upper Motor Neuron Facial Weakness

	LOWER MOTOR NEURON	UPPER MOTOR NEURON
Location of lesion	• Facial nerve • Facial nerve nucleus or fascicle in the pons (usually accompanied by other neurological signs)	Central nervous system lesion in the corticobulbar tract (motor cortex, corona radiata, internal capsule, brainstem)
Pattern of weakness	Upper and lower facial muscles affected	Upper face spared (i.e., eye closure and forehead elevation)
Ipsilateral taste and lacrimation	May be affected	Unaffected
Ipsilateral hyperacusis	May be present	Absent
Features of smile on examination	Genuine and forced smiles are affected equally.	Genuine smile is stronger than forced smile.
Ipsilateral arm weakness	Absent	Usually present

can be tested using a cotton swab dipped in lemon or sugar water applied to the anterior tongue on the affected side. The rest of the neurological and head and neck examination is normal, including a thorough cranial nerve and strength examination and inspection of the palate and auditory canal for vesicular herpes zoster lesions (Reich, 2017).

Diagnostic Tests: The diagnosis of Bell's palsy is clinical, based on patient history and examination. If the presentation is typical (i.e., a spontaneous, acute, unilateral, isolated peripheral facial palsy), and there are no red flag features in the history or examination (including a detailed neurological and head and neck examination) to indicate an alternate diagnosis, then no diagnostic tests are needed. Electrodiagnostic studies such as electromyography (EMG) and electroneuronography are not recommended for routine use in patients with Bell's palsy, though these studies can be offered to patients with complete facial paralysis for prognostic purposes (Baugh et al., 2013; Guntinas-Lichius et al., 2020).

Any atypical features in the history or examination require further work-up to exclude other etiologies causing facial weakness. Magnetic resonance imaging (MRI) of the brain with contrast in a patient with Bell's palsy may show enhancement of the facial nerve. MRI can also evaluate for alternate diagnoses such as tumor, stroke, multiple sclerosis (MS), and stroke. If concerning features such as severe headache or multiple cranial neuropathies are present, lumbar puncture should be considered to evaluate for meningitis. Serum laboratory studies can be sent to evaluate for infections and inflammatory disorders that can cause facial nerval palsies, particularly if the facial nerve palsy is recurrent or bilateral (Reich, 2017).

Differential Diagnosis: The differential diagnosis of facial weakness is broad, including:

- Tumors compressing the facial nerve or along the corticobulbar tract in the brain
- Infections, particularly acute HIV, mononucleosis, varicella zoster, Lyme disease, syphilis, and otitis media
- Guillain-Barré syndrome (GBS) (usually accompanied by limb weakness and areflexia)
- Meningitis (including infectious, inflammatory, neoplastic); may cause multiple cranial nerve palsies and symptoms of meningeal irritation (headache, light sensitivity, neck stiffness, pain with eye movements)
- Trauma
- Stroke; can cause unilateral facial weakness, though it is typically in an upper motor neuron pattern and accompanied by additional features
- Inflammatory conditions (such as sarcoidosis and Sjögren's syndrome); can cause facial nerve palsies, often bilaterally (Reich, 2017)

Reactivated varicella zoster virus causing a facial nerve palsy is referred to as Ramsay Hunt's syndrome. This condition commonly causes a rash in the external auditory canal or on the palate and can also affect cranial nerve VIII, leading to concurrent hearing loss and vertigo.

Treatment: The majority of patients with Bell's palsy will recover without treatment. Steroids, when started within the first 72 hours of symptom onset, increase the probability of recovery of facial weakness and should be offered (Baugh et al., 2013; Gronseth et al., 2012). The addition of an antiviral medication to steroids may have a modest effect on the likelihood of recovery and can be considered, although results of studies are mixed (Baugh et al., 2013; Sullivan et al., 2016). Antiviral medications should not be used as monotherapy for the treatment of Bell's palsy (Cao et al., 2021; Gagyor et al., 2019).

Because Bell's palsy causes weakness of eye closure, it is important to protect the eye from injury, particularly during sleep. Loss of the ability to blink and close the eyelid can lead to corneal drying, abrasion, and ulceration. The patient should keep the eye moist and protected by using artificial tears frequently during the day and an artificial tear ointment and/or taping the eyelid closed at night (MacIntosh & Fay, 2019).

Follow-Up: The patient should be reexamined after treatment to assess for symptom improvement.

Prevention/Prophylaxis: There is no prevention for Bell's palsy.

Referral: If the patient's symptoms do not recover by 3 months or worsen beyond the acute setting, or if other neurological signs are evident, the patient should be referred to a neurologist or other facial nerve specialist. The patient should be referred to an ophthalmologist if they experience any signs of corneal irritation or injury.

Education: Patients should be counseled that Bell's palsy is usually a self-limited and benign condition. Education about the importance of meticulous eye care is important to prevent corneal injury.

BRAIN TUMOR

Signal Symptoms: Headaches, with or without nausea and vomiting; seizures; changes in mental function or personality; motor or language deficits; visual problems.

Description: A brain tumor is a malignant or benign neoplasm of the brain or its supportive structures, which may arise from glial cells, blood vessels, connective tissue, meninges, or pituitary or pineal glands. Brain tumors may be considered low grade or slow growing or high grade, which tend to grow quickly and invade the surrounding tissues. Primary brain tumors include gliomas, meningiomas, medulloblastomas, gangliogliomas, and schwannomas. Non-Hodgkin's lymphomas may also originate in the central nervous system (CNS) and are called primary CNS lymphomas (American Cancer Society [ACS], 2021a).

Etiology: The etiology of brain tumors is largely unknown. CNS tumors have been associated with rare genetic conditions, including Li-Fraumeni's syndrome, neurofibromatosis 1 and 2, and Von Hippel-Lindau's disease (ACS, 2021b).

Occurrence: Each year, more than 24,000 cases of brain and CNS cancer are diagnosed. More than 18,000 deaths are attributable to brain and CNS cancers. The 5-year survival rate is 32.6% (National Cancer Institute [NCI], 2021; National Comprehensive Cancer Network [NCCN], 2021). Brain tumors are more common in males than females (NCI, 2021).

Age: Median age of diagnosis is 66 years (NCI, 2021).

Ethnicity: Whites have a higher incidence compared to Blacks, Asian/Pacific Islanders, and American Indian/Alaskan Natives (NCI, 2021).

Contributing Factors: High-dose ionizing radiation given for other cancers is a risk factor. Patients with neurofibromatosis types 1 and 2, Von Hippel-Lindau's syndrome, Li-Fraumeni's syndrome, and Turcot's syndrome are also at increased risk (ACS, 2021b). CNS lymphoma is associated with an immunocompromised immune system (ACS, 2021b).

Signs and Symptoms: Signs and symptoms are produced by tumor infiltration of nervous tissue, displacement of brain structures by tumor mass, or increased intracranial pressure (ICP). Symptoms may be physical—including headaches, fatigue, or focal signs—or behavioral—including hallucinations, anxiety, depression, memory problems, and decreased attention and concentration (Comelli et al., 2017). Headaches occur more than half of the time and are often associated with seizures, visual disturbances, and persistent nausea with vomiting (Wong & Wu, 2021). Generalized headache can be associated with increased ICP.

Memory loss and other cognitive changes may be subtle. Patients may report having decreased energy, fatigue, increased desire to sleep, and lack of interest in normal activities (Wong & Wu, 2021).

Seizures may affect 50% to 80% of patients with brain tumors. New-onset focal seizures in individuals older than 40 years are suspicious for brain tumor until proven otherwise. Syncope due to an increase in ICP can mimic a seizure with a few tonic-clonic jerks. Papilledema may be present in increased ICP, though less commonly in older adults (Wong & Wu, 2021).

Focal neurological changes are related to the area of the brain invaded by tumor. Frontal and parietal lobe tumors may cause changes in memory, behavior, and cognitive function. Memory, hearing, vision, and emotions are affected most often by temporal lobe tumors. Symptoms of temporal lobe tumors may mimic symptoms of affective or psychotic thought disorders. Visual changes can occur with occipital lobe tumors, in addition to speech, motor, and sensory changes for left-sided occipital masses and an inability to grasp abstract concepts for right-sided occipital masses. Lesions in the cerebellum affect balance and coordination. Pituitary tumors may present with the symptoms of hypothyroidism, hypercortisolism, diabetes insipidus, or visual changes (Wong & Wu, 2021).

Diagnostic Tests: The following tests are recommended for a person with suspected brain tumor:

- Complete blood count (CBC) to assess for anemia or infection
- Thyroid-stimulating hormone (TSH) because hypothyroidism or hyperthyroidism can be associated with mental status changes or hypothyroidism with pituitary tumors
- Venereal disease research laboratory (VDRL) if neurosyphilis is a possibility

© F.A. Davis Publishing

- Chemistries to assess for electrolyte and chemical imbalances
- Gadolinium-enhanced magnetic resonance imaging (MRI) of the brain is the preferred radiological examination for either brain tumor or suspected bleeding in the brain. Computed tomography (CT) scan with contrast enhancement is acceptable in special circumstances, such as when a patient is uncooperative or when MRI is unavailable. Magnetic resonance spectroscopy (MRS) is used in specialized circumstances.
- Positron emission tomography (PET) scan is not used to diagnose tumors of the CNS but may have an ancillary role to examine for metastasis or after treatment.
- Electroencephalogram (EEG) is useful for evaluating possible seizure activity.
- Lumbar puncture should not be performed before MRI or CT scan because of the potential for fatal brain herniation to result. Lumbar puncture can yield pressure readings and cerebrospinal fluid (CSF) for cytology, protein, glucose, and tumor markers.
- Testing blood for tumor markers, α-fetoprotein, or β–human chorionic gonadotropin is useful for the diagnosis of some brain tumors.
- Histological examination of a biopsy specimen of brain tissue may be preferred when feasible (Wong & Wu, 2021).

A careful history of symptoms is invaluable. Complete physical examination should include skin survey for stigmata of neurocutaneous syndromes or melanoma, lymph node examination, abdominal examination for hepatomegaly or splenomegaly, and rectal examination with guaiac stool testing. Breast and pelvic examinations in women and cardiopulmonary examination are recommended. The neurological evaluation should include a mental status evaluation, testing for cognitive deficits or memory loss, and assessment for personality changes. Family members may be able to provide clues about subtle personality changes. Ophthalmical examination is essential to assess for papilledema, although this may not be present in patients 55 years old and older. Test also for asymmetry of strength, sensation, visual fields, reflex activity, cranial nerve function, and radicular signs.

Differential Diagnosis:

- Stroke: There is acute onset of headache with persistent focal neurological deficits. CT scan or MRI is diagnostic.
- Aneurysm: In acute rupture, there is a sudden intense headache, often with signs of meningeal irritation. MRI is preferred for diagnosis.
- Arteriovenous malformation: There is a chronic unilateral throbbing headache with no prodromal or associated symptoms. CT scan or MRI may be diagnostic.
- Meningitis: Headache usually is associated with fever and nuchal rigidity. Cerebrospinal fluid is obtained through a lumbar puncture for diagnosis.
- Abscess: Abscess is often associated with fever or other signs of infection.
- Syphilis: Neurosyphilis may occur at any time during infection and up to 35 years later. Symptoms vary according to the area infected. Diagnosis is based on CSF abnormalities and a reactive serological test for syphilis.
- HIV: Various neurological manifestations can be caused by the virus or opportunistic infections; the incidence of CNS lymphoma is increasing in these patients.
- Subdural hematoma: Persistent headache occurs after trauma, with poorly defined intellectual impairment. This may be ruled out by noncontrast CT scan or MRI.
- Postconcussion syndrome: A dull, constant headache occurs within 24 hours of trauma. The patient may complain of loss of concentration, giddiness, irritability, and anxiety.
- Trauma: History of injury to the head or neck is present.
- Temporal arteritis: This is usually characterized by a slow-onset headache that is worse at night, temporal in more than one-half of patients, often with jaw claudication and temporal artery tenderness as well as an elevated erythrocyte sedimentation rate (ESR).
- Normal pressure hydrocephalus (NPH): This condition often presents with dementia, gait disturbances, and incontinence of bladder or bowel.
- Multi-infarct dementia: This may present with impaired cognition and symptoms of upper motor neuron disease in patients with a history of hypertension, atrial fibrillation, diabetes, carotid artery disease, or smoking.
- Alzheimer's disease: This presents with progressive dementia, memory disturbances, and behavioral changes, which are usually gradual over years.
- Chemical poisoning: History of exposure to chemicals, such as carbon monoxide, pesticides, or industrial materials, is present.
- Migraine: Migraine is characterized by an often-unilateral headache with a pulsating quality, associated with nausea and vomiting, photophobia, or phonophobia; prodromal or aura symptoms may be present (Wong & Wu, 2021).

Treatment: Treatment of brain tumor includes surgery, radiation, chemotherapy, glucocorticoids, anticonvulsants, immunotherapy, and gene therapy (NCCN, 2021).

Follow-Up: Prognosis depends on the tumor type, patient age, functional neurological status, extent of resection, tumor location, and extent of metastasis at diagnosis. Tumor grade, patient age, functional status, and complete surgical resection are the important prognostic factors for survival in people with malignant gliomas (NCCN, 2021). During the first year after treatment, the patient should have a focused history and physical examination, including a neurological and funduscopic examination every 3 months. MRI of the brain is recommended 2 to 6 weeks after radiation, then every 2 to 4 months for 2 to 3 years, and then less frequently (NCCN, 2021). Patients receiving palliative care should be seen as necessary for pain and symptom control; hospice care is recommended for these patients.

Sequelae: Various neurological deficits, personality changes, seizure disorders, and chronic head pain can result from brain tumor. Paraplegia, hemiplegia, and quadriplegia are also consequences of brain tumor. Bradycardia, hypertension, and respiratory arrest can occur with increased ICP. Brain herniation is a life-threatening emergent complication.

Prevention/Prophylaxis: Instruct patients to avoid radiation exposure.

Referral: Refer patients to a neurosurgeon, oncologist, radiation oncologist, and hospice, as appropriate.

Education: Genetic counseling is warranted in hereditary syndromes of brain tumor.

MYASTHENIA GRAVIS

Signal Symptoms: Diplopia, ptosis, dysphagia, dysphonia, nasal tone, jaw fatigue, neck fatigue, respiratory difficulty. Less frequently: weakness in the hands, difficulty raising hands above head, weakness of legs.

Description: The diagnosis of myasthenia gravis (MG) relies on a history of fatigable muscle weakness (Lazaridis & Tzartos, 2020; Rousseff, 2021). Patients suffer from intermittent, fatigable muscle weakness that worsens with prolonged muscle exertion and improves with rest (Behin & Le Panse, 2018). Gilhus et al. (2019) report involvement of muscle groups is either generalized or localized. Generalized MG comprises 85% of patients while 15% experience only ocular symptoms. More often innervated cranial nerves are affected leading to asymmetric weakness of extraocular muscles which results in diplopia and ptosis. Speech, swallowing, and facial muscles are also frequently affected. During a myasthenic crisis, bulbar (cranial nerves IX, X, XI, and XII) and respiratory muscle involvement is grossly impaired and can be life threatening.

Etiology: Myasthenia gravis is an uncommon neuromuscular disease caused by an immune-mediated decrease in viable nicotinic acetylcholine receptors (AChRs) (Rousseff, 2021). In this autoimmune process, portions of the neuromuscular junction (NMJ) on the postsynaptic membrane of striated skeletal muscles are attacked (Behin & Le Panse, 2018). The reduction of electrical impulses over the NMJ results in a failure of the muscle fiber to generate an action potential, and ultimately, in muscle weakness (Gilhus et al., 2019). Most patients can be diagnosed by specific autoantibodies: AChR, muscle-specific kinase (MuSK), low-density lipoprotein-related protein 4 (LRP4), and double-seropositive MG (Behin & Le Panse, 2018, Rousseff, 2021). Autoantibodies or anti-muscle-specific kinase (anti-MuSK) proteins are found at the neuromuscular junction (Lazaridis & Tzartos, 2020). Anti-MuSK proteins are generated by the immune system and assail muscle-specific kinases (Lazaridis & Tzartos, 2020). Research indicates anti-MuSK antibodies impede the transmission of signals linking muscles and nerves (Lazaridis & Tzartos, 2020). The LRP-4 facilitates signaling to MuSK and is present in roughly 20% of MuSK-MG. The LRP-4 was determined to be a causative agent in the past 10 years, and it is not clearly diagnostic like acetylcholine-receptor binding antibody (AChR-Ab) or muscle-specific kinase antibody (MuSK-Ab) (Rousseff, 2021). Patients who are treatment resistant require further investigation for double-seropositive MG. Double-seropositive patients may exhibit fewer typical features than those of AChR patients and require a comprehensive approach to diagnosis and management (Rousseff, 2021).

Thymoma is found in approximately 15% of patients, frequently in those with AChR antibodies (Gilhus et al., 2019). Abnormalities in the thymus and the link to MG are well known; however, the direct correlation remains unclear (Lisak & Richman, 2020). The thymus is part of the lymphoid system where B and T cells form antibodies. As the central immunity regulation organ, it is logical to suspect aberrations effect tolerance that initiates an immune facilitated attack on AChR (Lisak & Richman, 2020). The presence of a thymoma significantly increases the patient's chance of having severe disease, refractory MG, more severe electromyography (EMG) findings, and overall poorer outcomes (Mantegazza & Antozzi, 2018). Whether the pathogenesis of MG is primary or secondary to abnormal thymus function remains unknown. Imaging of the thymus is recommended in patients where MG is suspected (Mantegazza & Antozzi, 2018).

Occurrence: In the United States, the Myasthenia Gravis Foundation of America (2021) reports there is an annual incidence of roughly 14 to 20 per 100,000. Prevalence of the disorder is difficult to assess because many patients likely remain undiagnosed (Narayanaswami et al., 2021). The Myasthenia Gravis Foundation of America reports somewhere around 36,000 to 60,000 people are living with MG nationally.

Age: Myasthenia gravis is present among all cultures and demonstrates no geographic predilection (Narayanaswami et al., 2021). Females have higher rates in the second and third decades of life, whereas male occurrence are highest in

© F.A. Davis Publishing

the seventh or eighth decade (Larson & Wilbur, 2020). Myasthenia gravis can occur at any age; however, onset typically occurs after age 50 (Larson & Wilbur, 2020).

Ethnicity: Studies have shown that myasthenia gravis can occur in people of all race and ethnic backgrounds and has been found to be slightly more prevalent in patients of African ancestry. Additionally it is more prevalent in people living in countries located near the equator (Dresser et al., 2021).

Contributing Factors: Jowkar (2018) reports contributing factors to aggravating MG include worsening of existing chronic illness, pregnancy, menstrual cycle, mental health issues, surgical procedures, infection, warm climates, and decreasing immunosuppression.

Signs and Symptoms: Examiners should obtain a thorough history including the onset, duration, and progression of symptoms. Onset is typically insidious with a slow and progressive development (Larson & Wilbur, 2020). Patients will present with or report a history of one or more of the following: diplopia, ptosis, dysarthria, dysphagia, masticatory weakness, nasal toned speech, neck fatigue, and, in severe cases, respiratory difficulty (Rousseff, 2021). Ptosis is a symptom of an underlying failure of the oculomotor nerve of the levator palpebrae superioris and is found exclusively in 15% to 20 % of MG patients (Gilhus et al., 2019). Ptosis occurs in patients of any age and has numerous etiologies (Jabbehdari & Golnik, 2018). To examine for ptosis, the patient looks up for one minute. Initiation or worsening of ptosis occurs during this test (Larson & Wilbur, 2020). Tight closure of the eyelids may force fatigue of the orbicularis oculi muscles in which the sclera is seen (Larson & Wilbur, 2020). To examine for diplopia, the patient stares at an object laterally for 30 to 60 seconds (Larson & Wilbur, 2020).

Larson and Wilbur (2020) report extremity weakness typically is more severe proximally than distally. To examine muscle fatigue, formal strength assessment using a muscle grading tool is essential to aid in the diagnosis. Note whether repetition of movement of the extremity induces fatiguability. Careful attention is paid to the distribution of weakness, whether proximal or distal and asymmetrical versus symmetrical. Visually assess any signs of muscle atrophy, fasciculations, or involuntary movements. A comprehensive examination also includes cranial nerve testing. To examine upper extremity weakness, the patient abducts the arms for two minutes while the examiner watches for slow fatiguing of the deltoid muscles. To evaluate leg strength, the supine patient raises one leg at a time, off the examining table, and holds for 90 seconds. Failure to hold the leg for the full 90 seconds indicates weakness. When assessing respiratory function, ask the patient to count to 20 on a single breath. The number the patient is able to reach multiplied by 100 provides a rough estimate of vital capacity (Larson & Wilbur, 2020).

Diagnostic Tests:

Serum Antibody Tests: All patients presenting with common clinical features of MG should first receive serum testing for AChR-Ab (Lazaridis & Tzartos, 2020). Eighty-five percent of patients are noted to have AChR-Ab (Lazaridis & Tzartos, 2020). Patients with singularly ocular involvement represent 50% with AChR-Ab (Lazaridis & Tzartos, 2020). Identifying autoantibodies to acetylcholine-receptor binding, which are specific to MG, is key to confirming a diagnosis. An anti-MuSK antibody test identifies circulating autoantibodies and helps to confirm the type of MG or exclude a diagnosis of MG (Lazaridis & Tzartos, 2020).

Blood Work: Patients with suspected ocular MG may have hyperthyroidism and should receive additional testing via thyroid function tests to eliminate any association with hyperthyroidism or other metabolic states (Larson & Wilbur, 2020).

Electrodiagnostic Testing: A neuromuscular specialist applies a stimulating electrode probe to select muscles. Electrical impulses are sent to the muscles and nerve activity is recorded. This test is only part of the diagnostic picture, as patients with severe MG may have normal results (Gilus et al., 2019). For those with MuSK MG, repetitive nerve stimulation testing is only about 50% sensitive but higher in those with AChR MG at roughly 80%. Nerve stimulation is more specific for MG than single-fiber EMG (Gilus et al., 2019).

Computed Tomography (CT) of the Chest: CT is ordered after the confirmation of MG. This procedure examines the presence of thymoma. Thymomas occur in 10% to 15% of patients (Gilus et al., 2019).

Differential Diagnosis:

- Amyotrophic lateral sclerosis (ALS): Commonly causes muscle fasciculations and spares ocular movements. An EMG and laboratory tests aid in confirming of the diagnosis (Larson & Wilbur, 2020).
- Aponeurotic ptosis: Most common form of eyelid drooping and is found commonly in older adults. An ophthalmologist or neurologist confirms diagnosis (Latting et al., 2017).
- Brainstem glioma: A form of brain cancer where a patient may complain of diplopia, weakness, gait instability, dysphagia, and headache. Imaging confirms the diagnosis. (Ney, 2018).
- Graves' disease: An autoimmune disorder in which patients present with several symptoms, including muscle weakness and fatigue. Laboratory work results include an abnormally low thyroid-stimulating hormone (TSH) level (Subekti & Pramono, 2018).
- Guillain-Barré syndrome (GBS): The most frequently seen cause of neuromuscular weakness. Patients display ascending, progressive, symmetrical weakness of the feet and legs with a reduction or loss in tendon reflexes. Patients may or may not have peripheral sensory changes. Cerebrospinal fluid tests and nerve conduction studies with EMG are advantageous to diagnosis (Liu et al., 2018).
- Lambert-Eaton's myasthenic syndrome: Characterized by proximal weakness; autonomic dysfunction and areflexia are findings in this paraneoplastic neuromuscular junction disorder. Symptoms result from antibodies that work to diminish release of acetylcholine. More than half of patients with Lambert-Eaton's have small cell lung carcinoma. Antibody testing and electrophysiological studies assist in confirming the diagnosis (Kesner et al., 2018).
- Multiple sclerosis (MS): Inflammatory disease of the central nervous system (CNS); patients may experience diplopia or unilateral vision loss as a result of optic neuritis.

© F.A. Davis Publishing

Ataxia, fatigue, weakness of limbs (due to transverse myelitis), and paresthesias of the hands and feet are also frequent findings. Bowel or bladder dysfunction may be present. Imaging to examine for brain or spinal lesions as well as cerebrospinal fluid (CSF) studies validate or refute the diagnosis (Reich et al., 2018).

- Neurosarcoidosis: A form of sarcoidosis in which facial nerves are affected. Cranial neuropathy comprises 50% to 70% of cases. A clinical examination and imaging are helpful in determining the diagnosis (Voortman et al., 2019).
- Polymyositis: Patients typically complain of acute difficulty with climbing stairs, walking, raising arms above the head. Pain is also frequently reported. Work-up includes blood work with complete blood count (CBC) demonstrating leukocytosis, positive rheumatoid factor, and elevated erythrocyte sedimentation rate or C-reactive protein (CRP) levels (Schmidt, 2018).
- Tolosa-Hunt's syndrome: Patients possess ipsilateral oculomotor paralysis with unilateral orbital pain. Patients respond quickly to steroids (Bugeme et al., 2020).

Treatment: The care plan should be aggressive with the goal for significant improvement or resolution of symptoms (Gilhus et al., 2019). The subgroup of MG dictates treatment with consideration given to appropriateness of thymectomy, acetylcholinesterase inhibitors, immunotherapy, intravenous immunoglobulin, and plasma exchange.

Medications: Anticholinesterase inhibitors—Farmakidis et al. (2018) report the most commonly used acetylcholinesterase inhibitor is pyridostigmine. Acetylcholinesterase inhibitors act on the neuromuscular junction by improving interactions between the acetylcholine and the acetylcholine receptor. Pyridostigmine works most effectively when taken approximately every 4 hours. Starting dose is 60 mg and may be titrated up 60 to 120 mg every 4 hours and increased to a daily maximum dose of 1,500 mg for regular release or 1,080 mg for extended release. Side effects most commonly seen are loose stools, flatulence, and abdominal cramping. Patients with AChR autoantibody MG respond at higher rates to anticholinesterase inhibitors than do MuSK+ patients. Response in ocular MG patients is limited. During a myasthenia crisis, anticholinesterase inhibitors can complicate respiratory management due to increasing secretions.

Immunotherapy—Corticosteroid treatment is selected for patients who demonstrate inadequate response to pyridostigmine alone (Gilus et al., 2019). Because immunotherapy drugs prednisone and prednisolone act quickly to affect the symptoms of MG, they are the preferred first-line medications (Gilus et al., 2019). Patients with severe MG need higher doses and response typically occurs in 2 to 4 weeks (Gilus et al., 2019). A common dosing regimen will begin with prednisone 20 mg daily with incremental 5 mg increases every 3 to 5 days until symptoms subside (Gilus et al., 2019). Patients may be tapered in 4 weeks or kept on a maintenance dosage (Gilus et al., 2019). Favorable outcomes are seen with maintenance of low-dose steroids in all MG patient groups (Gilus et al., 2019). Bulbar patients receiving high-dose corticosteroids should be watched closely during the first week of treatment (Gilus et al., 2019). Patients with ocular MG experience good outcomes with lower doses of corticosteroids, which are considered first-line treatment (Alhaidar et al., 2022). Patients in respiratory crisis benefit from high-dose, daily treatments of corticosteroids in conjunction with IV immunoglobulin (IVIg) or plasma exchange treatment (PLEX) (Gilus et al., 2019). High-dose steroids have adverse side effects, including weight gain, increased appetite, impaired glucose tolerance, mood lability, osteoporosis, increased risk of infections, and skin atrophy. Because of known side effects, steroids are often added at a lower dose to a treatment regimen that includes immunosuppression drugs (Behin & Le Panse, 2018). Other frequently used immune-suppressing drugs include azathioprine, mycophenolate, methotrexate, tacrolimus, and cyclosporine (Gilus et al., 2019). Suppression takes on many mechanisms of action. Immunotherapy drugs work by curbing antigen production and diminishing circulating T cells (corticosteroids), hindering T and B cell production via cell cycle reduction (azathioprine, methotrexate, and mycophenolate), and obstructing T cell activation (cyclosporine, tacrolimus) (Menon et al., 2020). Patients on immunosuppressive therapies typically require less pyridostigmine and experience stabilization of disease with remission of symptoms (Gilus et al., 2019). Immunotherapy has seen decades of use with demonstrated efficacy for MG (Menon et al., 2020). These medications also have enumerable side effects, including increased incidence of susceptibility to cancer and vulnerability to life-threatening infections (Menon et al., 2020).

Rituximab—This monoclonal antibody targets the transmembrane protein CD20 found on the surface of B lymphocytes (Farmakidis et al., 2018; Gilhus et al., 2019). Rituximab works by impeding antibody creation and suppressing humoral immunity by decreasing circulating CD20+B cells (Gilhus et al., 2019). It is indicated for patients with MuSK Ab+ who fail to see results with initial immunotherapy or those with refractory MG (Gilhus et al., 2019). A typical regimen for infusion is 375 mg/m^2 given weekly for 4 weeks or two administrations of 1 g infusions, separated by 2 weeks. Patients may need additional infusion therapy every 4 to 6 months. Side effects include headache, fever, nausea, weakness, diarrhea, and infections from lowered immunity (Farmakidis et al., 2018; Gilhus et al., 2019).

Eculizumab—This drug was approved by the U.S. Food and Drug Administration (FDA) in 2017 and is a human monoclonal antibody that works on the complement cascade (Farmakidis et al., 2018). Patients with generalized MG who are AChR-Ab positive and have moderate to severe disease are candidates; however, current recommendations cite its use only when other immunotherapies have failed to see a response (Farmakidis et al., 2018; Narayanaswami et al., 2021). Eculizumab is administered through an intravenous infusion. Dosing starts at 900 mg per week for the first 4 weeks and is increased to 1,200 mg the fifth week and for subsequent dosages (Farmakidis et al., 2018). Patients must receive a meningococcal vaccine before starting therapy (Farmakidis et al., 2018).

IVIgs—Administered intravenously, IVIg works by preventing antigen cell interaction with T cells and neutralizing cytokines and antibodies (Gilhus et al., 2019). Typically, IVIg is utilized in conjunction with high-dose steroids in respiratory crisis (Gilhus et al., 2019; Menon et al., 2020). It may also be given prior to initiating immunotherapies in an attempt to bring symptoms under control. Both IVIg and PLEX are fast-acting treatments that result in immediate response (Gilhus et al. 2019).

© F.A. Davis Publishing

Plasmapheresis (Plasma Exchange, PLEX)—Plasmapheresis is conducted through a central or peripheral line and works by removing plasma-soluble autoantibodies and cytokines (Farmakidis et al., 2018). To date, there is no definitive study that demonstrates that PLEX improves MG patient outcomes; however, evidence suggests it can be beneficial (Farmakidis et al., 2018). Short-term plasmapheresis is useful during a respiratory crisis or an impending crisis (Farmakidis et al., 2018). It may also be tried in patients who fail to respond to immunosuppressant therapies with moderate disease (Farmakidis et al., 2018). Improvement is seen for most patients by the third treatment with the effects lasting weeks (Farmakidis et al., 2018).

Thymectomy: This procedure involves removing the thymus and tumor. Histological studies guide appropriate chemotherapy, radiation, and observation (Farmakidis et al., 2018). Older adults with small, slow-growing thymomas should have regular surveillance scans with magnetic resonance imaging (MRI) or CT and typically do not require surgery (Gilus et al., 2019).

Follow-Up: Patients are typically maintained on pyridostigmine. Those who fail to show response should be questioned about their dosing intervals. Lack of clinical improvement may be due to adherence issues (difficulty taking it every 4 hours), underdosing, or overdosing. The patient should be asked about noted instances of shortness of breath because this can indicate impending respiratory compromise. Questions regarding lifestyle are also important to ask because MG can by triggered by lifestyle events such as emotional stress (Jowkar, 2018).

Sequelae: Most patients who respond to treatment can obtain a semblance of normal function and quality of life. Full strength and use of muscles is usually good with adequate treatment; lifelong damage of muscles is rare (Gilhus et al., 2021). Dysphagia can result in nutritional deficits, and patients should be evaluated for worsening difficulties with intake. In severe cases, the nerves that innervate the diaphragm are compromised and respiratory distress is life threatening (Gilhus et al., 2019).

Prevention/Prophylaxis: No recommendations exist for prevention of MG; however, some medications that may worsen MG should be avoided. (This is not an exhaustive list.)

- Antibiotics—Patients should refrain from using antibiotics unless there is a clear indication. Penicillins or cephalosporins are preferred when possible.
- Anti-seizure—Patients can experience worsening symptoms with phenytoin, phenobarbital and gabapentin and should be monitored closely.
- Arrhythmia drugs—Quinidine, procainamide, and disopyramide may exacerbate MG.
- Arthritis medications—Penicillamine and antimalarials (chloroquine, hydroxychloroquine, quinine) can further exacerbate weakness.
- Hypertension—Calcium channel blockers and beta blockers may worsen weakness.
- Magnesium—All forms should be avoided except for multivitamins, which generally have acceptable levels of magnesium.
- Narcotics/sedatives/hypnotics—These medications decrease respiratory drive, which may already be compromised in patients with MG patients. Use with caution. Patients undergoing surgery with the use of anesthesia should consult with their neurology provider prior to the procedure (Narayanaswami et al., 2021; Sheikh et al., 2021).

Referral: Referral to a neurologist is appropriate for patients who do not respond to medication therapy and/or who need EMG testing. Patients with bulbar symptoms may need to be seen by a speech therapist for evaluation of dysphagia or dysphonia. Patients with ocular MG or those with vision involvement may also benefit from consulting a neuro-ophthalmologist (Jabbehdari & Golnik, 2018). Generalized weakness is common in MG, and an evaluation with a customized care plan from physical therapy to optimize activities of daily living may be of benefit (Farrugia & Goodfellow, 2020). Patients who develop dysfunctional breathing may need a referral to respiratory therapy for further evaluation (Farrugia & Goodfellow, 2020).

Education: Older patients will likely have comorbidities that may exacerbate MG, and counseling is directed toward minimizing these factors. Patients should be educated on signs and symptoms of worsening respiratory distress because this condition is a medical emergency. A comprehensive treatment plan includes physical activity with exercise. Refer patients to seek additional information through the Myasthenia Gravis Foundation of America at https://myasthenia.org/.

PARKINSON'S DISEASE

Signal Symptoms: Bradykinesia, rest tremor, rigidity, akinesia, impaired postural reflexes.

Description: Parkinson's disease (PD) is the second most common chronic progressive neurodegenerative disorder. PD occurs as the result of the loss of dopamine-producing cells in the substantia nigra, located in the basal ganglia. The formation of Lewy bodies from alpha-synuclein cytoplasmic inclusions in the remaining dopaminergic neurons are the pathological features of PD. This causes degeneration of the dopamine pathway in the brain and is responsible for the development of motor symptoms in PD (Cerri et al., 2019). Motor symptoms include resting tremor, rigidity, akinesia, bradykinesia, and impaired postural reflexes (resulting in postural instability). Subtle motor impairments may precede the development of overt clinical signs and symptoms by many years.

Etiology: The cause of primary or idiopathic PD is unknown. It is thought to be a confluence of genetic factors, environmental risks, mitochondrial dysfunction, oxidative stress, and possibly chronic inflammation (Tysnes & Storstein, 2017). Secondary PD (Parkinson's syndrome) may be caused by head injury, toxins, heavy metals, herbicides, pesticides, dopamine-depleting drugs, encephalitis, hypoparathyroidism, and Wilson's disease. Parkinsonism includes known variants of PD, including multisystem atrophy (MSA), progressive supranuclear palsy (PSP), corticobasal degeneration (CBD), Lewy body dementia (LBD), vascular parkinsonism, and neuroleptic-induced parkinsonism.

Occurrence: It is estimated that PD affects 4 million people worldwide and 1 million in the United States. In the United States, 60,000 people are being diagnosed each year. (Halli-Tierney et al., 2020). The incidence of PD in men is higher than in women at a ratio of 2:1. The disease tends to progress faster in women and is associated with higher mortality when compared with men (Cerri et al., 2019).

Age: The incidence of PD increases with age. It affects 3% of those older than the age of 65 and up to 5% of those older than 85 (Cerri et al., 2019). It is rarely seen before the age of 40.

Ethnicity: PD can be found in all cultures and ethnic backgrounds. According to a nationwide Medicare database, there is a lower prevalence among the Asian and African American populations and a higher prevalence in European American and Latino populations in the United States (Marras et al., 2018).

Contributing Factors: Stress is not a direct causative factor in PD, but it may contribute to worsening symptoms. A major life stressor is often reported with the diagnosis of PD (another medical or surgical concern, a move, retirement, loss of a job, a fire, or loss of a child). Carbon monoxide exposure, MPTP (an illicit drug), and a combination of genetic and environmental factors contribute to the diagnosis of PD. In certain families, genetic factors do result in an increased risk of developing PD.

Signs and Symptoms: Though not everyone with PD will develop tremors, PD does commonly present initially as a unilateral rest tremor in the upper extremities that disappears with movement. This is often referred to as a pill-rolling tremor, which describes the appearance of rolling a pill between the thumb and forefinger. Tremor can also affect the legs, lips, chin, and tongue. Patients may also describe an internal tremor that may not be visible but rather felt inside. Rigidity is another primary feature of PD and is defined as increased resistance to passive range of motion of a joint, such as the elbow or wrist. Bradykinesia is defined as slowness of movements, small movements, and a decrease in automatic movements. It is one of the cardinal symptoms of PD and manifests in many ways, including decreased speed or amplitude in finger taps, hand grasps, and hesitation or arrest of movements (freezing). Patients develop decreased facial expression in which there is a decrease in eye blinking (masked facies) and mouth movements. Patients take small, shuffling steps and have decreased arm swing during ambulation. Other gait changes include stooped posture in which the trunk leans forward and the back is kyphotic. This stooped posture causes the trunk to be in front of the patients' normal center of gravity. This leads to a festinating

© F.A. Davis Publishing

gait, in which the patient takes small and fast steps in an attempt to catch up to the top half of their body to recover their balance. This commonly leads to postural instability and falls. Patients also experience an associated softening of the voice (hypophonia) and drooling (sialorrhea) due to decreased spontaneous swallowing. Handwriting size is smaller (micrographia).

In addition to the above motor symptoms in PD, there are non-motor symptoms that can be equally debilitating and often undertreated. Therefore, it is essential to assess for and treat these symptoms. Mood changes are widespread in PD and range from depression, anxiety, and apathy to pseudobulbar affect, irritability, and labile moods. Depression and anxiety affect some 35% of patients with PD. Dementia affects 30% to 40% of patients with PD and may be associated with hallucinations, illusions, or delusions (Parkinson's psychosis) (Hayes, 2019). Slowed cognitive processing and impairment of executive functions and impairment of visuospatial memory are common in PD (i.e., the ability to plan, organize, pay attention, remember details, strategize, and manage time and space). Orthostatic hypotension is also common in PD and causes safety concerns because it increases the risk of falls. Rapid eye movement (REM) sleep behavior disorder causes patients to act out their dreams at night (i.e., kicking, yelling, punching, hitting). In severe cases, patients can injure their bed partner or themselves. Constipation, impotence, and urinary urgency/incontinence are also common issues.

The neurological examination will reveal most PD motor symptoms, and noting the patient's movement, coordination, and gait is crucial. The examiner will observe the patient while in the seated position with hands at rest for signs of tremor, noting the frequency and amplitude of the tremor. To assess rigidity, the examiner will passively move the head/neck, arms, and legs and feel for any resistance or difficulty achieving full range of motion (ROM) or cogwheeling. Bradykinesia is assessed by observing the patient tapping their fingers, opening and closing their hands, alternating pronation and supination of the hands, and toe tapping, noting any differences in speed, amplitude, or arrest of the movements. Observe facial expression and voice changes (Tarakad & Jankovic, 2017). Postural stability is assessed using the pull test. The examiner stands behind the patient and informs the patient that they will be pulled with two hands on the shoulders backward; then the patient is pulled, and the recovery is documented. Note whether the postural reflexes are impaired or absent. During gait assessment, observe for small shuffle steps, kyphotic or stooped posture, and reduced or absent arm swing. Also assess for en bloc turning, where a patient takes multiple small steps to turn around instead of turning on a pivot (Hayes, 2019). Tandem walking (heel-to-toe in a straight line) can also help assess balance.

Strength generally does not deteriorate despite the rigidity. Tendon reflexes are almost always normal. Orthostatic vitals should be obtained to assess for orthostatic hypotension. Early in the diagnostic phase, the patient's cognitive status needs to be assessed to provide a baseline, given the prevalence of dementia developing in patients with PD. This can be done using the Montreal Cognitive Assessment (MoCA). Smell is commonly impaired (hyposmia) early in PD; therefore, evaluating cranial nerve I (olfactory nerve) could be helpful. Check the patient's ocular movements; impairment of upward or downward gaze is common in progressive supranuclear palsy but not in idiopathic PD.

Diagnostic Tests: Diagnosis of PD is made clinically based on history and physical examination findings and requires the presence of two cardinal signs—bradykinesia with either rigidity or rest tremor, or both. Improvement of motor symptoms with levodopa supports the diagnosis. The most definitive diagnostic test for PD is the pathological features noted in the brain during autopsy (Tarakad & Jankovic, 2017). Magnetic resonance imaging (MRI) may be ordered to rule out suspected brain lesions or abnormalities, such as NPH or atypical conditions such as vascular parkinsonism or corticobasal syndrome. In cases when the diagnosis is unclear, a DaTSCAN (ioflupane [123I]) injection, also known as phenyltropane, can be ordered to indicate the presence of PD. The radiotracer is injected into the blood and circulates to the brain, attaching itself to dopamine transporter molecules on dopamine neurons, which then can be detected using special imaging equipment. In PD, there will be less signal seen on the scan indicating a loss of dopamine neurons (Armstrong & Okun, 2020). Also, olfactory dysfunction, REM sleep behavior disorder, autonomic dysfunction (constipation), and depression are strongly linked to PD and commonly occur years before a diagnosis of PD. The loss of smell and REM sleep behavior disorder especially help to support the diagnosis.

Differential Diagnosis:

- Drug-induced parkinsonism: Confirmed by improvement with the withdrawal of dopamine blocking medication such as neuroleptics and metoclopramide
- Essential (benign familial) tremor: Tremor is an action tremor 6 to 8 Hz compared with PD tremor, which is at rest and has a 3 to 6 Hz frequency.
- Corticobasal degeneration: Unilateral rigidity and coarse tremor, apraxia, and myoclonus of affected limb; poor response to levodopa
- PSP: Supranuclear gaze abnormality, gait instability, and falls, with axial-predominant rigidity. Tremor is usually absent.
- LBD: Dementia, hallucinations, delusions, and fluctuations in lucidity that worsen rapidly with progression (Hayes, 2019)
- Multisystem atrophy (MSA): Early and prominent autonomic dysfunction and poor response to dopamine
- MSA-parkinsonian subtype (MSA-P) (formerly called striatal nigral degeneration): Autonomic dysfunction and dystonia are present.
- MSA-cerebellar subtype (MSA-C) (formerly called olivopontocerebellar atrophy): Distinguished by inherited parkinsonism, progressive ataxia, dementia, difficulty with balance, and dysarthria (Jellinger, 2018)
- Huntington's disease: This disorder is genetic in origin and characterized by chorea, clumsiness, and cognitive decline.
- Creutzfeldt-Jakob's disease: A rapidly progressive syndrome of mental deterioration, lead-pipe rigidity, myoclonus, aphasia, apraxia, and hallucinations
- Normal pressure hydrocephalus (NPH): Gait apraxia, urinary incontinence, and dementia are present.

Treatment: There are various medications for both motor and non-motor symptoms and surgical options available to treat PD. Patients with mild disease and no interference with ADLs may not require treatment (Tarakad & Jankovic, 2017).

© F.A. Davis Publishing

Medications for Motor Symptoms:

- Carbidopa/levodopa (Sinemet): Used for bothersome symptoms or in older adults. Replenishes depleted dopamine in the brain by increasing the dopamine precursor levodopa to stimulate dopamine receptors. Start carbidopa/levodopa 25/100 (carbidopa 25 mg, levodopa 100 mg) one tablet tid. Titrate slowly to symptomatic relief.
- Dopamine agonists: Less potent than carbidopa/levodopa. Used for mild symptoms. Watch for compulsive behaviors, fatigue, and daytime somnolence.
  - Ropinirole (Requip): Start 0.25 mg tid, increase gradually. Max: 24 mg/day
  - Pramipexole (Mirapex): Start 0.125 mg tid, increase weekly. Max: 4.5 mg/day
  - Rotigotine (Neupro patch): Start 2 mg/day, increase weekly. Max: 8 mg/day
- Amantadine: Is thought to augment dopamine release from presynaptic nerve terminals or to inhibit dopamine reuptake and antagonized *N*-methyl-D-aspartate (NMDA) receptors. Reduces dyskinesia and improves tremor and other motor symptoms. Start 100 mg daily, increase weekly. Max: 100 mg tid
- Entacapone (Comtan): Given with each dose of levodopa to extend the effectiveness of levodopa. Stalevo is the combination of carbidopa, levodopa, and entacapone. Stalevo dosages reflect the amount of levodopa (50, 75, 100, 125, 150, and 200) in each pill combined with carbidopa and Comtan 200 mg.
- Selegiline (Deprenyl, Eldepryl): Monoamine oxidase-B inhibitor that inhibits the enzyme responsible for inactivating dopamine. Adding selegiline 5 mg/day (increasing to 10 mg/day within 1 week) can improve the wearing-off effect of levodopa (doses to be given before lunch).
- Rasagiline (Azilect): Monoamine oxidase-B inhibitor that can be used alone or with Sinemet. Start 0.5 mg/day, increase to 1 mg/day.
- Rytary: Extended-release carbidopa/levodopa; used for people who experience wearing-off symptoms
- Duodopa: Levodopa/carbidopa gel continuously administered using a pump and percutaneous endoscopic jejunostomy tube. Indicated in late PD because it offers the possibility of more on time when the patient can function.
- Rescue medications: Indicated for abrupt wearing off of medications or "freezing" episodes where the patient is unable to move (Tarakad & Jankovic, 2017).
  - Apomorphine (Apokyn): Subcutaneous injectable (2 to 4 mg)
  - Apomorphine (Kynmobi): Sublingual film for "off" episodes
  - Levodopa inhalation powder (Inbrija): Orally inhaled levodopa (42 mg)

Medications for Non-motor Symptoms:

- Dementia: Rivastigmine patch, donepezil, memantine
- Parkinson psychosis: Pimvaserin, quetiapine
- Orthostatic hypotension: Droxidopa (Northera), midodrine, fludrocortisone
- Constipation: MiraLAX and Senokot
- Orthostasis and constipation may also be treated with adequate water intake.

Surgical Management

- Deep brain stimulation (DBS): A surgical procedure that implants microelectrodes in the brain and a battery device implanted in the chest that generates impulses that stimulates the brain through the microelectrodes. The two most common targets utilized for PD are the subthalamic nucleus and globus pallidus interna. Settings are programmed in the clinic and can be adjusted over time as the disease progresses.
- High-frequency ultrasound: Consists of directing beams of ultrasonic energy precisely and accurately on targets deep in the brain without damaging surrounding normal tissue.

Nonpharmacologics

- Physical therapy: Most effective treatment for balance issues in PD
- Speech therapy: Used for hypophonia, dysarthria, dysphagia
- Exercise: Research indicates improvement in motor and non-motor symptoms and quality of life in patients with PD who consistently exercise an average of 40 to 60 minutes, 3 times/week, for 4 to 12 weeks (Wu et al., 2017).

Follow-Up: Typically, every 3 to 6 months to assess for disease progression and effectiveness of treatment for both motor and non-motor symptoms.

Sequelae: PD results in chronic and progressive immobility. As the disease advances, the patient is at risk of injury from falls due to postural instability. The hazards of immobility (Olson et al., 1990) can prove deadly, including megacolon from constipation, aspiration pneumonia, pulmonary embolism, decreased appetite from inactivity (anorexia), urinary tract infections, and sepsis resulting from disruption in skin integrity. With medical therapies, surgery, and regular exercise, a patient with PD can have a relatively normal life expectancy.

Prevention/Prophylaxis: No pharmacological treatments are available to slow or prevent disease progression in PD. Some research indicates high intensity exercise significantly slows the worsening of motor symptoms in PD (Armstrong & Okun, 2020).

Referral: Refer patients with unusual presentation or bothersome complications and those who do not respond to the initial medication regimen to a neurologist or movement disorder neurologist. Early referral to physical therapy (PT), occupational therapy (OT), and speech therapy is recommended.

Education: Provide patients and family members with written information about PD, including information about local support groups. The following are helpful resources:

- National Institute of Neurological Disorders and Stroke (https://www.ninds.nih.gov/)
- Parkinson's Foundation (https://www.parkinson.org/Living-with-Parkinsons/Resources-and-Support or contact the helpline at 1-800-4PD-INFO [473-4636])

PERIODIC LIMB MOVEMENT DISORDER

Signal Symptoms: Tightening, bending, or flexing of one or both legs at the hip, knee, ankle, or toes.

Description: Periodic limb movement disorder (PLMD) is disrupted sleep caused by periodic limb movements of sleep (PLMS), which are rhythmic movements (tightening, bending, or flexing) of one or both legs at the hip, knee, ankle, or toes every 5 to 90 seconds. To be considered PLMD, this movement must occur at least 15 times a night, disrupt sleep, and not be caused by any other sleep disorder (Stefani & Hogl, 2019). Each movement lasts approximately 2 seconds, although they can last longer, and they occur in light non-rapid eye movement (REM) stages of sleep during the first half of the night.

Etiology: Although the exact cause is unknown, PLMD has been associated with low iron levels, vitamin deficiencies, restless legs syndrome (RLS), diabetes, and kidney disease.

Occurrence: The exact prevalence is unknown because it is difficult to isolate PLMD from other sleep disorders, but one study did show 28.6% of subjects had more than 15 PLMS an hour (Haba-Rubio et al., 2016), and another study showed a prevalence in their subjects was 21.1% (Doan et al., 2018). Older studies estimate a prevalence between 3% and 11%.

Age: It can occur in both children and adults but is more common as people age.

Ethnicity: Data regarding ethnicity is limited. However, in a study of individuals with both RLS and PLMS, it was found that the combination of these was present more in White and Hispanic individuals as compared to Black and Chinese American individuals (Doan et al., 2018).

Contributing Factors: PLMS/PLMD is often associated with other sleep disorders such as RLS, REM sleep behavior disorder, sleep apnea, and narcolepsy. It has been associated with diabetes, kidney disease, attention deficit disorder, iron deficiency, and withdrawal from benzodiazepines and may be aggravated by caffeine, alcohol, antidepressants, neuroleptics, and antiemetics (Sleep Foundation, 2021).

Signs and Symptoms: A rhythmic movement (tightening, bending, or flexing) of one or both legs at the hip, knee, ankle, or toe every 5 to 90 seconds. The disruption of sleep this causes can result in excessive daytime sleepiness or fatigue for both the individual experiencing the movements and the bed partner whose sleep is also disturbed. The focused interview for PLMD should include the following:

- Ask about the urge to move or unpleasant sensations and if they are partially or totally relieved by movement such as walking or stretching (to differentiate from RLS) or if they have been told they yell out, kick, or hit in their sleep (to differentiate from REM sleep behavior disorder).
- Ask if they have noticed any activities or other contributing factors that make their symptoms worse.
- Ask about sleep patterns. Does the patient keep their partner awake?
- Ask if they are tired during the day from an interrupted night of sleeping?

Diagnostic Tests: PLMS are identified on a sleep study known as a polysomnogram (PSG), which is considered the gold standard for diagnosis (Kurtis et al., 2018). Laboratory work such as ferritin, iron studies, folate, vitamin B_{12}, magnesium, thyroid function tests, and a basic metabolic panel can also be ordered to identify deficiencies and metabolic concerns.

Differential Diagnosis: Differential diagnoses for PLMD include but are not limited to:

- Restless legs syndrome (also in this chapter)
- REM sleep behavior disorder (physically and verbally acting out dreams during REM stages of sleep)
- Sleep-related breathing disorder
- Hypnagogic foot tremor
- Myoclonus

Treatment: There are limited studies on the treatment of PLMS/PLMD, and isolated PLMD may not require treatment. When PLMS occurs in association with another sleep disorder, the treatment typically focuses on other disorders such as RLS. A meta-analysis done by Meng-Ni and associates (2018) did show that the patch, rotigotine (Neupro), is efficacious in treating PLMS as are the dopamine agonists, ropinirole (Requip) and pramipexole (Mirapex). Alpha-2-delta ligands can be used if needed. Deficiencies such as

© F.A. Davis Publishing

iron deficiency should be treated. Good sleep hygiene should be reviewed, and stress-reduction measures should be instituted.

Follow-Up: Ask about sleep, exercise, and relationships. Sleep disturbances can cause hypertension (check blood pressure at each visit) and stress in relationships.

Sequelae: True PLMD results in disruptive sleep. Sleep deprivation can cause relationship problems, hypertension, and daytime sleepiness that can compromise safety. PLMS/PLMD has also been associated with cardiovascular events (Winkelman et al., 2017).

Prevention/Prophylaxis: There is no specific prevention of PLMD, although treating other sleep disorders and preventing deficiencies and other medical comorbidities may help.

Referral: If PLMD is suspected, refer to a sleep center for a PSG sleep study. If difficult to treat, a referral should be made to a sleep specialist, who will address other sleep issues such as sleep apnea, if present, or a movement disorders neurologist.

PERIPHERAL NEUROPATHY

Signal Symptoms: Paresthesia, allodynia, sensory impairment, altered gait.

Description: Peripheral neuropathy (also known as polyneuropathy [Jin, 2021]) is a common neurological syndrome involving the peripheral nerves of the dorsal, ventral spinal nerve roots, dorsal root ganglia, brachial, lumbosacral plexus, cranial nerves, sensory, motor, autonomic, or mixed nerves (Castelli et al., 2020), producing variable signs and symptoms. The pathology and severity of the disease differ due to an array of medical disorders. Although the specific mechanisms affecting peripheral nerves are unknown, peripheral nerves respond in three ways: Wallerian degeneration, axonal degeneration, and segmental demyelination (Jin, 2021). In axonal degeneration (dying-back phenomenon), the axon degenerates at the distal end of the axon causing a symmetrical degeneration in a distal to proximal gradient as it progresses. Early sensory alteration includes numbness, pain, or burning sensation in a stocking and glove pattern of the lower extremities. Later stages involve proximal numbness, distal weakness, or atrophy. Other symptoms may be an electric shock sensation, allodynia, hyperalgesia, and hyperesthesia (Castelli et al., 2020; Choi & Di Maria, 2021; Jin, 2021). Segmental demyelination refers to focal degeneration of the myelin sheath with preservation of the axon. This is least common compared to axonal degeneration. It has a rapid course as in Guillain-Barré syndrome (GBS), focal mononeuropathies, generalized sensorimotor or motor neuropathies, hereditary neuropathies, immune-mediated diseases (Choi & Di Maria, 2021; Jin, 2021).

Etiology: The etiology of peripheral neuropathy is poorly understood (Kaeley et al., 2019). Peripheral neuropathy can be caused by multiple factors affecting the sensory, motor, or autonomic fibers, leading to a host of signs and symptoms that may be acute (as seen with trauma or nerve infarction), subacute (existing over a period of months, as seen when the causative agent may be related to drugs, toxins, or metabolic diseases), or insidious/chronic (as occurring with chronic inflammatory demyelinating neuropathies) (Motiwala, 2021). Common causes of peripheral neuropathy are attributed to nerve entrapment, vasculitis, amyloidosis (Kaeyle et al., 2019), nutritional deficiencies (vitamin B_{12} deficiencies), metabolic diseases (diabetes mellitus), inflammatory processes, hereditary processes, autoimmune diseases (rheumatoid arthritis), toxins and drugs (chemotherapy agents), systemic diseases (hypothyroidism, uremia), infections (HIV), and malignancies (Castelli et al., 2020; Choi & Di Maria 2021). Vitamin D deficiency is associated with paresthesia and parasympathetic dysfunction and is highly prevalent in diabetic populations (Iqbal et al., 2018).

Occurrence: The prevalence of peripheral neuropathy in the general population is approximately 1% to 7% with higher rate among those older than age 50 (Castelli et al., 2020; Lipsitz et al., 2018). Peripheral neuropathy affects 25% to 50% of individuals with diabetes, and is dependent upon age, number of years with diabetes, and the degree of diabetic control (Castelli et al., 2020; Hicks et al., 2021).

Peripheral neuropathy exists in approximately 70% of persons with chronic diseases (Lipsitz al., 2018). Diffuse symmetrical distal sensorimotor neuropathy is the most common manifestation in diabetic peripheral neuropathy and is thought to affect about 34% of persons with diabetes (Hicks et al., 2021). About 39% of the population with rheumatoid

© F.A. Davis Publishing

arthritis have sensorimotor axonal neuropathy and pure sensory type peripheral neuropathy (Kaeley et al., 2019).

Approximately 25% to 46% of peripheral neuropathy is idiopathic (Castelli et al., 2020).

Age: The incidence of peripheral neuropathy increases with age at an estimate of 8% per 100,000 in persons older than 55 (Castelli et al.; 2020; Choi & Di Maria, 2021; Motiwala, 2021; Zhou, 2021).

Ethnicity: There is no specific ethnic group. The high prevalence of peripheral neuropathy increases due to the increasing diagnosis of diabetes mellitus (England & Asbury, 2004).

Contributing Factors: Although there are many causes, diabetes is the most frequent cause, accounting for 30% to 45% of patients with polyneuropathy (Lipsitz et al., 2018; Rutkove, 2021).

Signs and Symptoms: The presentation of peripheral neuropathy can be nonspecific and vary depending upon the pattern of neuropathy. Many symptoms reported may exist in other neurological diseases. Peripheral neuropathies vary in severity. The earliest symptoms are sensory related: numbness, burning, paraesthesia, or dysesthesia in the feet or toes. These are chronic and slowly progressive, and medical attention is not sought until months to years after the onset of symptoms when they have worsened (Motiwala, 2021).

The signs on examination include decrease in pin or vibration sense and reduced deep tendon reflexes. Weakness is an uncommon complaint and rarely found on examination except in advanced cases (Jin, 2021).

Autonomic symptoms may include postural dizziness and syncope; erectile dysfunction; bladder involvement; alteration in bowel pattern (diarrhea or constipation); dryness of mouth, eyes, and skin; skin discoloration; callus; and trophic changes related to the joints and enlarged joints such as Charcot's joints (Motiwala, 2021; Rutkove, 2021). Positive symptoms caused from uninhibited or abnormal spontaneous nerve activity may result in pain, muscle cramps or twitching. Negative symptoms indicate nerve reduction activity and lead to a loss of sensation, weakness, ataxia, and atrophy. For example, distal sensory loss may be a contributing factor to delayed wound healing and loss of balance in darkened surroundings or after closing the eyes. Neuropathic pain is often more common and observed at rest and bedtime (Motiwala, 2021).

A diagnosis can be made or suspected by history taking (Zhou, 2021). A detailed history of symptoms is important in helping to narrow the differential diagnosis. It includes symptom onset and timing; whether acute, subacute, or chronic; location; and distribution pattern (focal, multifocal, and symmetrical patterns). Aggravating and remitting factors give clues to exogenous causes, and a systems review should evaluate for autonomics and vasomotor symptoms. A nutritional assessment identifies nutritional deficiencies (such as vitamins B and D deficiencies or anemia). The occupational and military history gives clues for potential exposure to neurotoxic agents, environmental toxins, chemical exposures, or pesticides. History of chronic alcohol use, family history, and immunizations also provide clues (Castelli et al., 2020).

The review of systems includes a history of the overall functional ability to perform activities of daily living (ADLs) (Castelli et al., 2020) and factors such as clumsiness, any falls or injuries, gait disturbances (slapping, stomping, antalgic gait, ataxia), difficulty getting out of low chairs and climbing stairs, recurrent tripping while stepping off curbs (partial foot drop), difficulty with eating, nausea, vomiting, anorexia, problems with bowel and bladder functions (e.g., constipation, diarrhea, incontinence), any sensory changes such as numbness, dysesthesias, or pain, and any incidence of burn injuries due to decreased ability to detect temperature changes/hot or cold.

To confirm a suspected diagnosis of neuropathy that is based on a patient's history, a comprehensive physical examination should be performed to rule out other causes of weaknesses or sensory loss such as radiculopathy or central disorders. Normal changes of aging in older adults older than 65 include a decline in vibration sense and ankle reflexes. These findings in otherwise healthy older adults may obscure the distinction from polyneuropathy. Components of the physical examination include a motor and sensory examination, reflexes, gait, and relevant cerebellar and cranial nerve examinations (Motiwala, 2021).

Motor Examination: Observe for muscle atrophy of distal muscles; atrophy of small muscles of the feet and prominence of intermetatarsal spaces in the feet, loss of prominence of extensor digitorum brevis muscle bulk over lateral aspect of dorsum of foot, loss of plantar muscle fullness; and in the upper extremities, muscle mass loss in the first web space over the dorsal aspect of hand and flattening of thenar and hypothenar muscle prominence. Passive movement of the joints will reveal a reduced resistance and floppiness when the tone is reduced in significant neuropathy. Check for muscle weakness, which may be symmetrical or asymmetrical; observe whether the weakness follows a dermatome or a nerve distribution. In length-dependent neuropathies, weakness first involves distal muscles in early stages—as seen in inflammatory neuropathies (chronic inflammatory demyelinating polyneuropathy). Functional testing identifies functional disabilities along with subtle weakness often overlooked during strength testing. Arising from a seated position without support of the chair or performing knee bends will reveal the proximal lower extremity strength. Walking on heels may identify mild ankle dorsiflexor muscle weakness, and walking on the toes may detect subtle ankle plantar flexor muscle weakness (Jin, 2021; Motiwala, 2021).

Sensory Examination: Begin the sensory examination distally and compare distal segments with proximal segments, one side with the other side, and lower extremities with upper extremities.

Check for stocking and glove pattern sensory loss, sensory ataxia, positive Romberg's sign, reduced or absent reflexes, and pseudoathetosis. Sensory impairment precedes motor weakness in common neuropathies. With no sensory complaint, a cotton wisp, pin, or tuning fork to the feet will suffice. Large fibers carry the sensation of fine, light touch, vibration, and proprioception, whereas small fibers carry impulses from receptors and are responsible for crude touch, pain, and temperature. In most peripheral neuropathies, the sensory findings are prominent distally in lower extremities and then spread proximally as the condition progresses. Fingers become involved after the symptoms spread toward the knees and lower extremities. Sensation can be present but may show a slight reduction in intensity. Loss of vibratory

© F.A. Davis Publishing

sense or reduction of it suggest neuropathy. If vibration sense is absent distally, more proximal boney prominences should be assessed until normal sensation is detected. Significant proprioceptive loss may be indicated in the presence of abnormal movements in the fingers of the outstretched hand when the eyes are closed (called pseudoathetosis). If the distribution differs from the typical distal or length-dependent pattern, other diagnoses should be explored. Sensory loss in a dermatomal pattern should alert you to radiculopathy. If sensory loss conforms to a large peripheral nerve, a diagnosis of mononeuropathy should be explored (such as C6 radiculopathy, peroneal neuropathy, or L5 radiculopathy [Jin, 2021; Motiwala, 2021]).

Reflexes are affected distally in a length-dependent fashion, and ankle reflexes will be diminished or absent. A significant asymmetry of reflexes is unusual and indicates an associated condition. Coexisting conditions such as radiculopathy would cause asymmetrical loss of reflexes or conditions such as cervical spondylotic myelopathy that can preserve deep tendon reflexes even in the midst of neuropathy (Rutkove, 2021).

Examination of gait and balance is observed by tandem gait, proximal lower extremity strength and ambulation. A positive Romberg's sign is often associated with abnormal gait. Abnormal gait (ataxia, steppage gait, stomping, antalgic) is a cause of multiple falls in older adults (Motiwala, 2021).

Bilateral facial weakness is commonly seen in Guillain-Barré. Pupillary abnormalities may be associated with diabetic neuropathy. Dysarthria and nystagmus may be associated with cerebellar disorders and not neuropathy. The cerebellar examination guides in distinguishing sensory ataxia from cerebellar ataxia. In addition, look for skin rashes as in vasculitis, connective tissue disorders, skeletal muscle involvement as in pes cavus, and scoliosis as in hereditary neuropathy (Castelli et al., 2020; Gjerum & Midttun, 2017; Motiwala, 2021).

Diagnostic Tests: The etiology of neuropathy is not always clear based on history and examination alone. Approximately 20% to 30% of patients with peripheral neuropathy do not have a determinable cause. Selective use of laboratory tests in patients with polyneuropathy should be based on history and clinical features as well as electrodiagnostic tests (Castelli et al., 2020; Rutkove, 2021; Zhou, 2021). Rather than testing for every possible cause of neuropathy, the American Academy of Neurology recommends tests with the highest yield. Routine laboratory studies include basic metabolic function panel with fasting glucose, complete blood cell count, liver function panel, vitamin B_{12}, vitamin B_1, serum protein immunofixation electrophoresis, thyroid function testing, antinuclear antigen, and Sjögren's syndrome antibodies A and B (anti-R, anti-La) (Jin, 2021).

Consider in some patients depending on risk and clinical findings: 2h glucose tolerance test, methylmalonic acid, homocysteine level, vitamin E, vitamin B_6, copper, zinc, HIV, Lyme disease, hepatitis B and hepatitis C, cryoglobulin, rheumatoid factor, erythrocyte sedimentation rate, C-reactive protein, antigliadin antibodies, anti-transglutaminase antibodies, serum light chains, urine immunofixations, electrophoresis, and light chains (Castelli et al., 2020; Jin, 2021; Zhou, 2021).

Electromyogram and nerve conduction studies are the most useful diagnostic tests for initial work-up in evaluating patients with suspected peripheral neuropathy and should be done first (Castelli et al., 2020; Jin, 2021; Rutkove, 2021). These tests validate the presence of a neuropathy, specify what type of nerve fibers are involved (sensory, motor, or a combination), and help in establishing the differential diagnosis (Choi & Di Maria, 2021; Jin, 2021). A nerve conduction study may be normal in patients with small fiber neuropathy because the test evaluates large fiber function. When a large fiber neuropathy is found by a nerve conduction study or electromyography (EMG), a diagnosis of peripheral neuropathy is established, and a skin biopsy is unnecessary (Zhou, 2021). EMG distinguishes myopathies from neuropathies (Choi & Di Maria, 2021).

Skin biopsy is the gold standard for diagnosing peripheral neuropathy/small fiber neuropathy with a high diagnostic efficiency. It is useful in confirming distal sensory polyneuropathy in patients older than 75, when there are absent sural sensory responses that are attributed to aging changes (Rutkove, 2021; Zhou, 2021).

Quantitative sensory testing has been validated for evaluating symptoms of sensory neuropathy but has significant limitation in that it cannot differentiate whether impaired response to sensory stimuli is due to peripheral nerve disease or a central nervous system (CNS) disease. It is not recommended as a stand-alone test (Zhou, 2021).

Although not widely available, autonomic testing evaluates postganglionic sympathetic unmyelinated sudomotor axon nerve function and is helpful in evaluating autonomic symptoms. It may be ordered if there are sweating abnormalities (Zhou, 2021). Genetic testing should be considered if a positive family history exists (Castelli et al., 2020; Zhou, 2021).

Differential Diagnosis: Neurological disorders involve some form of disturbance of sensation, motor function, and balance. The presence of these symptoms is nonspecific to peripheral neuropathy because they can cause dysfunction in other parts of the nervous system. Determining the part of the nervous system is helpful for diagnostic accuracy. Atypical neuropathies are acute, non–length-dependent patterns of symptoms and have a more prominent motor component. Many atypical neuropathies are accompanied by other systemic symptoms (Jin, 2021).

- Cerebrovascular accident, neoplasm, multiple sclerosis (MS) (Jin, 2021)
- Myelopathy (degenerative and joint disease of the cervical spine) (Jin, 2021)
- Radiculopathy (degenerative disc disease of the cervical and lumbar spine) (Jin, 2021)
- Amyotrophic lateral sclerosis (ALS) (Jin, 2021)
- Sjögren's syndrome, cisplatin chemotherapy, paraneoplastic syndrome, vitamin B_6 toxicity
- Neuromuscular disorders (myasthenia gravis [MG]) (Jin, 2021)
- Muscle myopathy (dermatomyositis, steroid myopathy) (Rutkove, 2021)
- Chronic inflammatory demyelinating polyneuropathy (Rutkove, 2021)
- Nerve entrapment (Faktorovich et al., 2021)
- Syringomyelia/dorsal column disorders (Faktorovich et al., 2021)
- Upper motor neuron disorders (spasticity/hyperreflexia) (Motiwala, 2021)

© F.A. Davis Publishing

Treatment: Peripheral neuropathy is an irreversible disease. Treatment is mostly supportive and directed at preventing disease progression and controlling complications (Hicks & Selvin, 2019). Management of peripheral neuropathy involves treating the identifiable underlying cause, optimizing daily function, preventing injury (Hicks & Selvin, 2019; Zhou, 2021), and managing neuropathic pain. Pain management may be difficult and challenging in older adults because of safety and tolerability of medications. Tailor treatment based on comorbidities, drug tolerability, and potential drug-to-drug interactions. Rarely is there complete relief of neuropathic pain. Pharmacological interventions (Table 17-2) provide approximately 30% to 50%

TABLE 17-2 Pharmacological Agents for Neuropathic Pain

DRUG	DESCRIPTION
Tricyclic antidepressants (TCAs) • Amitriptyline • Desipramine • Nortriptyline	• May be used as the first- or second-line • Have a higher risk profile, especially in the older adult population • Are thought indirectly modulate the opioid system in the brain via serotonergic and norepinephrine neuromodulation, among other properties (Iqbal et al., 2018) • Are effective for constant and lancinating, paroxysmal pain. • Require up titration to effective doses over a period of 6–8 weeks before efficacy is observed • Baseline electrocardiogram recommended before administration • Caution should be taken in older adults and in patients who have ischemic heart disease, narrow-angle glaucoma, or prostatism **Amitriptyline** • Has the greatest efficacy among TCAs. • Is initiated at a low dose (10–25 mg) daily • Maintenance dose: 25–100 mg once daily (Iqbal et al., 2018). • At higher doses, sedation, confusion, anticholinergic effects, and orthostatic hypotension are common, especially in older adults.
Antidepressants • Venlafaxine • Duloxetine	**Venlafaxine** • Initial dose 37.5 mg daily. • Maintenance dose 75–225 mg daily. • Side effects: nausea, dizziness, anticholinergic effects • Is not FDA approved for treatment of painful diabetic peripheral neuropathy (DPN) and must be slowly weaned to reduce the potential for adverse side effects **Duloxetine** • At 40 mg and 60 mg shows efficacy in treating painful DPN • Initial dose: 20–30 mg daily • Maintenance dose: 60–120 mg/day; has a moderate effect in reducing pain by about 30% • Side effects: nausea, constipation, sweating, asthenia, and dry mouth • Monitor: hyponatremia sodium levels and blood pressure
Anticonvulsants • Gabapentin • Pregabalin	• Often given to suppress shooting or stabbing pain **Gabapentin** • Initial dose 100–300 mg tid • Titrate dose up by 300 mg increments every 3–5 days until adequate pain relief is achieved. • The median effective dose ranges from 900 to 1600 mg, although some patients may require doses of 3600 mg/day. **Pregabalin** • Effective ranges: 150–600 mg/day • Initial dose: 25–75 mg tid • Maintenance dose: 300–600 mg daily
Opioids (nonnarcotic centrally acting analgesia) • Tramadol • Tapentadol	• Dose: 200–400 mg/day • Well-tolerated but transient nausea and constipation occur in about 20% of patients • Use with caution in patients with impaired hepatic or renal function and in patients taking other psychoactive medications. • May be used for breakthrough pain in combination with other neuropathic agents (Iqbal et al., 2018).
Topical agents • Capsaicin • 5% lidocaine patch	• Dose: 0.025%–0.075% applied to affected area tid–qid • May be useful in patients with painful, burning feet • Presumably produces pain relief through the depletion of substance P in unmyelinated nociceptive fibers • Intense burning sensation of the skin occurs after initial application before improvement is seen. • Allow at least 4 weeks to determine efficacy. • Even after 4 weeks the beneficial effect may be marginal. • Some patients may have relief from burning feet and allodynia by topical application of 5% lidocaine patch.

Sources: *Finnerup et al. (2010); Iqbal et al. (2018); Mahmoud & Tampi (2011).*

© F.A. Davis Publishing

reduction in pain intensity; greater than 50% pain relief is considered a good outcome (Harati & Bosh, 2008; Iqbal et al., 2018; Motiwala, 2021; Zhou, 2021).

Several oral medications help to alleviate neuropathic pain. Gabapentin, pregabalin, and antidepressants (amitriptyline, nortriptyline, venlafaxine, duloxetine, bupropion) appear to be moderately effective and are recommended as first-line options in managing neuropathic pain (Castelli et al., 2020). Duloxetine and pregabalin remain first-line therapy for neuropathic pain in diabetic peripheral neuropathy in five major guidelines published by the American Association of Clinical Endocrinologists, American Academy of Neurology, European Federation of Neurological Societies, National Institute of Clinical Excellence (United Kingdom), and the American Diabetes Association, and their use has been approved by the U.S. Food and Drug Administration (FDA) (Iqbal et al., 2018).

Topical medications include lidocaine and capsaicin as adjuncts to oral medications (Castelli et al., 2021). Tramadol drugs or NSAIDs may be necessary for breakthrough pain (Rutkove, 2021). Opioids are reserved as a last-line option and should not be used routinely because of limited effectiveness, long-term safety concerns and abuse potential (Castelli et al., 2021; Hicks & Selvin, 2019).

Tricyclic antidepressants have been shown to reduce neuropathic pain but have not been given approval by the FDA because of serious side effects and risks (Hicks & Selvin, 2019). Duloxetine has been associated with a reduction in opioid use compared with other modalities and lower health care cost (Hicks & Selvin, 2019).

A pilot study on the effectiveness of topical cannabidiol (CBD) oil in supportive relief of peripheral neuropathy of the lower extremities conducted by Xu et al. (2020) demonstrated that transdermal application of CBD oil 250 mg applied four times a day improved pain and sensation in patients with peripheral neuropathy (Xu et al., 2020).

Follow-Up: Because peripheral neuropathy is a persistent disease process, follow-up is based on the underlying disease processes involved (Motiwala, 2021).

Sequelae: Peripheral neuropathy causes a range of complications and has a debilitating impact on quality of life. Common difficulties in daily activities include sleep disturbances, difficulty walking (a tendency to trip easily), climbing stairs, and performing daily chores involving gripping objects (Win et al., 2019). It is a major contributing factor for balance problems and falls leading to a significant loss of functional decline and mobility. In the United States, approximately 30% of adults aged 65 and older fall each year. Both large and small fiber dysfunction contribute to the inability to recognize position sense or to ascertain where the feet are on the floor thereby increasing the risk of falls (Lipsitz et al., 2018; Zhou, 2021). Orthostatic hypotension is another contributing factor of falls (Gjerum & Midttun, 2017).

Atrophic change in an enervated immobile extremity combined with recurrent painless trauma predisposes the skin to ulceration and poor wound healing. Severe infections such as osteomyelitis or osteolysis may eventually result in limb amputation. Approximately 25% of persons having diabetes may develop foot ulcers during their lifetime, which progress to infection and may require amputation. This unfortunate sequence of events can be avoidable with proper care (Abdissa et al., 2020; Hicks & Selvin, 2019; Zhou, 2021).

Because of the physical and mental component of quality of life, anxiety and depression have been reported in 43% of the population with peripheral neuropathy and 45% to 53% of patients employed average about 5.5 missed workdays per month (Hicks & Selvin, 2019).

Prevention/Prophylaxis: There are several health-promoting activities patients can do prophylactically:

- Avoid repetitive motions, cramped positions, constant exposure to offending toxins, and excessive alcohol consumption.
- Meticulous foot care, ankle braces, foot orthosis, and proper shoes help to reduce the risk of falls and injury, the development of ulcers, or the worsening of slow-healing wounds due to sensory impairment.
- Assistive walking devices used due to substantial leg weakness will help to ensure safety and reduction of falls and injury.
- Avoid inactivity. Exercise can increase microvascular circulation, for release of neurotrophic factors, attenuation of oxidative stress and for physiological well-being of the body (Abdissa et al., 2020).
- Hand or wrist splints will be helpful if the hands or wrists are involved.

Wearing padded socks and supportive shoes provides foot protection and facilitates wound healing. Foot care and emollient creams moisturize dry skin. Regularly inspect skin for prevention and early detection of ulcer (Rutkove, 2021; Zhou, 2021).

Referral: Referral to a neurologist should be considered when initial laboratory testing, history, and physical examination findings are unrevealing; for acute, subacute, severe, or progressive symptoms to prevent a delay in treatment; for polyradiculoneuropathy or multifocal neuropathy deviating from the usual presentations that match anatomic distribution; and pure motor or autonomic signs in the absence of sensory changes (Castelli et al., 2020; Choi & Di Maria, 2021; Jin, 2021; Motiwala, 2021). Referral to podiatry is beneficial for appropriate shoes for extra depth and special orthotics with positive finding of proprioception sensory impairment or gait disturbances and for ankle-foot orthoses for foot drop (Choi & Di Maria, 2021). Occupational therapy may assist with appropriate assistive ambulation devices, splints, and braces (Rutkove, 2021). Psychological support is beneficial for those experiencing anxiety and depression (Zhou, 2021). Physical therapy referral is beneficial. Older adults with peripheral neuropathy of the lower extremities typically have balance and gait disturbances because of sensory ataxia. Physical therapy can help with gait and transfers (sit to stand) (Iqbal et al., 2018; Lipsitz, 2018).

Education: Discuss the typical course of the disease and its impact on daily life, foot care and surveillance, the importance of healthy eating and weight loss, and fall precautions. Lifestyle modifications include testing bath water with a body part without numbness before submerging the feet and avoiding sitting too close to fireplaces, if present. Instruct patients to avoid crossing the legs at the knee to avoid prolonged pressure or constriction and further nerve damage. Advise patients of the need for regular follow-up visits, even if no symptoms are present (Zhou, 2021).

RESTLESS LEGS SYNDROME

Signal Symptoms: Urge to move legs when at rest.

Description: Restless legs syndrome (RLS) is a common neurological and sleep disorder characterized by an intense urge to move the legs (or sometimes the arms). It may be associated with discomfort and the inability to resist the urge to move their legs. The sensations causing the urge may be described as aching, burning, creeping, crawling, cramping, gnawing, pulling, painful, throbbing, tingling, restless, or itchy, though sometimes individuals state they are unable to describe the feeling. Movement of affected limbs provides relief, but discomfort recurs unless the movement continues. RLS symptoms have circadian rhythmicity, starting or worsening at night. Symptoms are elicited by sitting or lying down.

Etiology: RLS may be idiopathic or primary or may be secondary due to a medical condition. There is a known genetics component because it can be found in families with approximately 25% of family members of those with RLS also experiencing symptoms (Sundaresan et al., 2019).

Occurrence: According to the Restless Legs Syndrome Foundation (2021), 7% to 8% of the population has RLS, with 2% to 3% having symptoms severe enough to require treatment. RLS occurs twice as much in women as in men.

Age: RLS can occur in people of all ages, including children. Primary RLS typically has an onset before age 45 (often familial) but is more common in older adults (Didato et al., 2020).

Ethnicity: RLS has a prevalence of 5% to 10% in the White population and is less common in Asian and Black populations.

Contributing Factors: Inheritability is estimated at 54% to 64.9% (Seeman, 2020). Many medications, such as antidepressants, antipsychotics, antiemetics, antihypertensives, and neuroleptics, as well as herbal and over-the-counter (OTC) cold and allergy medications, can aggravate RLS symptoms. Alcohol, caffeine, and nicotine are other substances that may aggravate RLS. Iron-deficiency anemia, vitamin B_{12} deficiency, folate deficiency, and renal disease can all contribute to symptoms. Depression and anxiety and attention-deficit disorder have been associated with RLS, although the former two may be more related to their treatment (Seeman, 2020).

Signs and Symptoms: Symptoms are worse at night while at rest but can occur during the day. An urge to move the legs (or other body parts) is usually accompanied or caused by uncomfortable and unpleasant sensations in the legs. The focused interview for RLS should include the following:

- Ask about the urge to move or unpleasant sensations and if they are partially or completely relieved by movement such as walking or stretching.
- Ask if the urge to move or unpleasant sensations are worse or only occur in the evening or night or during the day.
- Ask about any activities or contributing factors that make their symptoms worse.
- Ask about sleep patterns. Does the patient keep their partner awake?
- Is the patient tired during the day from an interrupted night of sleeping?

Diagnostic Tests: Typically, the diagnosis of RLS is based on subjective complaints meeting the criteria of the International Restless Legs Syndrome Study Group (IRLSSG) Rating Scale. Box 17-1 lists the essential diagnostic criteria. Blood work to identify contributing causes should be ordered (ferritin and iron studies for anemia, B_{12} level, and a metabolic panel for diabetes or kidney disease). If iron deficiency is found, the underlying cause should be sought.

Differential Diagnosis: Common disorders to rule out are listed, but many disorders may masquerade as RLS, such as:

- Akathisia (including hypotensive and neuroleptic-induced)
- Vascular or neurogenic claudication
- Neuropathy/radiculopathy
- Chronic pain syndrome associated with (lumbar, cervical) positional discomfort
- Nocturnal leg cramps
- Hypnic jerks

© F.A. Davis Publishing

BOX 17-1

Essential Diagnostic Criteria for Restless Legs Syndrome

An urge to move the legs, usually accompanied or caused by uncomfortable and unpleasant sensations in the legs (sometimes the urge to move is present without the uncomfortable sensations, and sometimes the arms or other body parts are involved in addition to the legs).
The urge to move or unpleasant sensations begin or worsen during periods of rest or inactivity, such as lying or sitting.
The urge to move or unpleasant sensations are partially or totally relieved by movement, such as walking or stretching, at least as long as the activity continues.
The urge to move or unpleasant sensations are worse in the evening or night than during the day, or only occur in the evening or night (when symptoms are very severe, the worsening at night may not be noticeable, but must have been previously present).

SUPPORTIVE CRITERIA

Positive family history
Positive response to dopaminergic drugs
Periodic leg movement during wakefulness or sleep as assessed with polysomnography or leg activity

ASSOCIATED FEATURES

Natural clinical course of the disorder: RLS can begin at any age, but most patients seen in clinical practice are middle-aged or older. Most patients have a progressive clinical course, but a static clinical course is sometimes seen. Remissions of a month or more are sometimes reported.
Sleep disorders are a frequent but unspecific symptom of RLS.
Medical evaluation/physical examination: The neurological examination is usually normal. Probable causes for secondary RLS should be excluded. A low serum ferritin (<45–50 mcg/L) may be found in RLS patients (Connor et al., 2017).

- Depression with somatic syndrome
- Volitional movements
- Lower limb arthritis
- Fibromyalgia
- Chronic venous insufficiency (Sundaresan et al., 2019)

Diabetic neuropathy is damage to the peripheral nerves due to diabetes and is most common in the legs and feet. Symptoms include numbness, tingling, hypersensitivity, muscle weakness, and sharp pain.

Leg cramps are sudden, painful, and involuntary contractions of the muscles of the legs; these may have no real cause but can be bothersome. If leg cramping is disturbing sleep, assess and consider these causes as possibilities: diuretics, Addison's disease, Parkinson's disease (PD), muscle overextension and overexercise, diabetes, hypoglycemia, hemodialysis, calcium channel blockers, peripheral artery disease, nerve compression, diabetes, and dehydration.

Periodic limb movements are repetitive, rhythmic flexing or jerking of the legs only occurring during sleep. It is a sleep disorder and can disturb sleep and result in daytime sleepiness. It may be associated with RLS but is different.

Radiculopathy, a type of neuropathy, occurs from compression on nerves in the spine, resulting in pain, tingling, numbness, and weakness. "Sciatica" pain radiating to the legs is an example. Pain can occur from a herniated disk, bone spur, osteoarthritis, tumor, infection, scoliosis, and stenosis.

Akathisia is an inner restlessness causing the patient to make frequent position changes and movements. This is often caused by neuroleptics (Kwatra et al., 2018).

Treatment: Although RLS is a chronic condition, the symptoms may be intermittent. When severe or disruptive to sleep, treatment is recommended. The patient should make lifestyle changes to remove aggravating factors and to reduce or abstain from alcohol or nicotine. Conservative measures such as good sleep hygiene, hot or cold packs, relaxation techniques, and exercise (though excessive exercise can worsen symptoms) should be recommended. Repetitive transcranial magnetic stimulation, compression devices, counterstrain manipulation, infrared therapy, and standard acupuncture may reduce restless legs syndrome severity (Harrison et al., 2019). Low levels of B_{12}, ferritin (less than 75 µg/L), transferrin saturation (less than 20%), and folate should be treated. Medications the patient is taking should be evaluated to see whether they may be contributing to RLS symptoms and if they are still needed or can be changed to a similar medication that does not worsen RLS.

For medical treatment of chronic, persistent RLS causing distress and when nonmedical therapies do not relieve the symptoms, the following medications may be considered:

- Iron (if indicated), 325 mg ferrous sulfate once daily (should be separated from levodopa by 2 hours if the patient also has PD and is prescribed medication containing levodopa). Ferritin and iron saturation should be monitored every 3 to 6 months to avoid iron overload, and treatment can be discontinued when adequate levels are reached (ferritin >75 µg/L and transferrin saturation >20%).
- Alpha-2-delta calcium channel ligands are the initial drugs of choice (Kwatra et al., 2018).
  - Gabapentin (Neurontin): Starting dose is 100 to 300 mg 2 hours before bedtime.
  - Gabapentin enacarbil (Horizant): 600 mg once daily at 5:00 p.m.
  - Pregabalin (Lyrica): Starting dose is 50 to 75 mg 2 hours before bedtime.
- Dopamine agonists
  - Pramipexole (Mirapex): Starting dose is 0.125 mg 2 hours before bedtime.
  - Ropinirole (Requip): Starting dose is 0.25 mg 2 hours before bedtime.
  - Rotigotine (Neupro) patch: Starting dose is 1 mg/24 hours.

Oxycodone/naloxone is also considered efficacious (Winkelmann et al., 2018), but opioids should be avoided and only used as a last resort for refractory RLS. Tramadol and methadone may also be considered (Gossard et al., 2021) but with caution.

Follow-Up: Evaluate the success of treatment and for augmentation every 6 to 12 months or more frequently if needed.

© F.A. Davis Publishing

Augmentation often occurs with RLS treatment, meaning symptoms can be more intense and can occur earlier and earlier in the day, requiring more medication. The alpha-2-delta calcium channel ligands are less likely to cause augmentation than dopaminergic medications.

Ask about sleep, exercise, and relationships because sleep disturbances can cause hypertension and tension in relationships. Check blood pressure at each visit.

Sequelae: RLS can cause difficulty falling asleep or staying asleep. Sleep deprivation can cause relationship problems, hypertension, and daytime sleepiness and can affect safety.

Prevention/Prophylaxis: There is no prevention for RLS, but recommend daily exercise and a healthy diet, review the tenets of sleep hygiene, and monitor and treat relevant deficiencies and disorders.

Referral: Refer to a sleep or movement disorders specialist if it is an unusual case or if the patient is nonresponsive to initial treatment.

Education: Provide patients and families with written information about RLS, including support groups in the community if available. They can also learn more about RLS, including updates in treatments and clinical trials, at www.rls.org.

SEIZURE DISORDERS

Signal Symptoms: Brief periods of confusion, loss of consciousness, staring with little or no motor activity, bizarre behavior, memory changes, falls, cognitive changes, sleep disorders, twitching, and involuntary movements.

Description: *Seizure* is a transient occurrence of signs and symptoms attributable to abnormal, excessive, or synchronous neuronal activity in the brain and can result from many causes (American Association of Neuroscience Nurses [AANN], 2016; Fisher et al., 2014). *Epilepsy* is a disease of the brain defined by at least two unprovoked (or reflex) seizures separated by at least 24 hours; one unprovoked (or reflex) seizure and the probability of further seizures similar to the general recurrence risk of at least 60% after two unprovoked seizures occurring over the next 10 years; or the diagnosis of an epilepsy syndrome (Thijs et al., 2019). In 2017, the International League Against Epilepsy simplified the seizure classification so that a basic version could be used by general practitioners and a more descriptive version could be used by specialists (Pack, 2019). Specifically, now the seizure classification starts with whether the initial manifestation of the seizure is focal or generalized. Focal seizures (formally called partial seizures) originate within a neuronal network limited to one hemisphere and may be discretely localized or more widely distributed. Generalized seizures originate at some point within the brain and rapidly engage bilateral distributed networks. Seizures of unknown onset are classified as such if the onset is missed or unclear (Pack, 2019). Acute symptomatic seizures are those occurring in close temporal relationship to the acute central nervous system (CNS) insult, which could consist of a metabolic, a toxic, a structural, or an infectious origin or an inflammation process. (Beghi et al., 2015). Epilepsy is considered resolved for people who had an age-dependent syndrome but have passed the applicable age and are seizure-free or, in other cases of epilepsy, for those who have been seizure-free for the past 10 years and have not taken antiepileptic drugs for the past 5 years (Thijs et al., 2019).

In the older adult, precipitating factors could be a nervous system infection, acute traumatic brain injury, and fluctuations in blood sugar or electrolyte levels. It is also important to distinguish nonepileptic episodic events, which may resemble epileptic seizures but are distinguished by differences in symptomatology as well as the lack of abnormal epileptiform activity indicated on an electroencephalogram (EEG) (Hopp, 2019). The focus of this section is on new-onset seizures and epilepsy in older adults. Underdiagnosis of seizures is common in the older adult.

Etiology: Epilepsy is mainly due to mechanical stimulation of a stroke lesion, nerve cell degeneration around the lesion, and glial scar formation (Liu et al., 2016). Understanding the epidemiology of epilepsy in older adults is important because of the association with poorer quality of life. There are unique challenges in terms of diagnosis and treatment within this group because of differences in clinical presentations and etiology compared with younger patients, presence of comorbidities and cognitive difficulties, and physiological

© F.A. Davis Publishing

changes that affect pharmacological management (Acharya & Acharya, 2014). Recognizing that persons older than age 65 years are a heterogeneous group, recommendations have been made to divide patients into three groups based on age: 65 to 74 years (young-old); 75 to 84 years (middle-old); and older than 85 years (old-old). These groups are further subdivided based on health status: patients with only epilepsy, patients with epilepsy and multiple medical comorbidities, and the frail older adults. In addition, consideration should be given to persons living independently and those living in nursing homes.

Cerebrovascular disease accounts for 20% to 50% of seizures in older adults. Likewise, 10% of patients with stroke are at risk of developing seizures within 5 years. Hemorrhagic strokes are more likely to be associated with seizures than infarcts. In contrast, patients with transient ischemic attacks (TIAs) have a relatively low incidence of seizures. Additional causes of epilepsy in older adults include cryptogenic or stroke-related seizure, followed by dementia and tumors. (Lee, 2019). Neurodegenerative disease accounts for 10% to 20% of epilepsy that is due to dementia and neurodegenerative disease associated with cognitive impairment. Patients with Alzheimer's disease (AD) have a 10 times higher risk of epilepsy, which increases as the disease progresses. Recognition of seizures in this population may be difficult; however, older adults do respond well to antiepileptic drugs (AEDs) (Acharya & Acharya, 2014). Trauma, particularly head trauma, accounts for up to 20% of epilepsy in the older adult. Being age 65 years or older has been identified as a risk factor for developing epilepsy after a head injury. Brain tumors are responsible for approximately 10% to 30% of seizures in the older adult and are more likely with low-grade, slow-growing tumors (Acharya & Acharya, 2014). However, underlying etiologies can be found in only 50% (Liu et al., 2016; National Institute of Neurological Disorders and Stroke [NINDS], 2019).

Occurrence: The incidence and prevalence of seizure disorders is highest in the older adult; therefore, older adult patients are the fastest growing demographic within patients with epilepsy. Estimated incidence and prevalence rates of epilepsy among older adults in the United States are 2.41/1,000 and 10.8/1,000, respectively (Lee, 2019). The prevalence rate has been found to be higher among nursing home residents than community-dwelling older adults. Incidence rates are slightly higher for women than men and increase with age. Prevalence and incidence rates may be underestimated due to the difficulty in identifying seizures and diagnosing epilepsy. Status epilepticus is two to five times more common in older adults than in young adults with an annual incidence of 86 per 100,000 in individuals older than 60 years (Lee, 2019). These rates indicate an under-recognized public health issue.

Age: There is a bimodal presentation of seizures over the life span, with the second initial presentation beginning around age 50 (Thijs et al., 2019).

Ethnicity: Overall, epilepsy is more common in people of Hispanic background than in non-Hispanics. African Americans, however, are more likely to develop epilepsy over the lifetime with the higher rate for stroke and hypertension among African Americans as a possible contributing factor to seizure disorders as one ages (Epilepsy Foundation, 2019).

Contributing Factors: As noted, stroke and other cerebrovascular diseases are the most important risk factor for new-onset seizures. Neurodegenerative disease, brain tumor, and brain trauma are known risk factors for developing new-onset seizures in older adults. Additional precipitating factors could be nervous system infection, fluctuations in blood sugar or electrolyte levels, metabolic or toxic factors (e.g., drugs or excessive amounts of alcohol), depression, and coexisting conditions such as diabetes and hypertension (Chi Vu et al., 2018).

Multiple drugs have been shown to either cause seizures or potentially lower seizure thresholds. These include psychotropic drugs, theophylline, narcotics, tramadol (Ultram), antimicrobials, chemotherapeutic agents (methotrexate, chlorambucil), general anesthetics (ketamine, enflurane), local anesthetics, stimulants, antiarrhythmics (verapamil, mexiletine, procainamide, propranolol), diphenhydramine, baclofen, and chlorpromazine (Krupa et al., 2019).

Signs and Symptoms: Under the International League Against Epilepsy's 2017 system, seizures are first classified by onset as either focal (originate within networks in a hemisphere), generalized (originate in a point and quickly spread to involve bilateral networks), or unknown. Level of awareness subdivides focal seizures in those with retained awareness and impaired awareness. Focal seizures are further categorized by the earliest and most prominent motor or non-motor manifestation. All classifiers are optional and depend on the available level of detail. Generalized seizures are divided into motor and non-motor (absence) seizures. Seizures of unknown onset might have features that can still be classified (Thijs et al., 2019). Rather than using labels (e.g., simple partial, myoclonic), the labels have been removed and more descriptive terminology is used. The term *semiology* is used to describe the sensory/motor/behavioral presentations. An important point is that new-onset (or first-ever) seizure age is not an independent predictor of seizure recurrence, and older patients are more likely than younger ones to sustain a seizure-related injury. Treatment for older patients should be based on risk factors for recurrence rather than age (Lawn et al., 2013).

Diagnosing new-onset seizures in older adults is challenging due to the presentation and comorbidities. As noted, the most common seizures in the older adult are focal in onset. Confusion and memory problems are common presenting symptoms, and the postictal phase may be prolonged. A reliable history and an eye-witnessed event are the most important diagnostic factors, especially in new-onset seizures (Thijs et al., 2019). Obtain information concerning family history of seizures, any head injuries or other history of trauma (observe bruises, cuts, burns), and any past history of seizures. Information concerning whether the individual has lived outside of the United States (particularly in unincorporated areas with poor sanitation) can raise suspicion of neurocysticercosis. This parasitic infection results from ingestion of eggs from the adult tapeworm and is the most common parasitic infection of the brain with epilepsy as the most common presentation. With the immigration of people from Latin America to the United States, this disease is a growing problem (Sharma et al., 2015).

Obtain a complete description of the seizure, including any aura (a warning of the seizure), along with a complete description of the patient's behavior during the seizure and

© F.A. Davis Publishing

in the postictal period. If the seizure was observed, note whether there was evidence of pallor, cyanosis, abnormal movements, tongue biting, urinary incontinence, impaired continence, or postictal symptoms such as confusion, headache, and drowsiness. As noted previously, new-onset seizures are associated with dementia and cerebrovascular disease in older adults; therefore, it is imperative to include cognitive function screening. An estimate of the time for each phase of the seizure is helpful. How the patient felt before and after the seizure can offer insight into the potential nature of the cause of the event. A thorough neurological examination is performed, with particular attention paid to any focal or localizing symptoms. If the individual is currently taking AEDs, screen for any symptoms of toxicity, including nystagmus, ataxia, and slurred or slowed speech.

Diagnostic Tests: A detailed history is imperative from the patient and, if possible, an eyewitness. The diagnostic approach is similar to that of a younger person. To begin, ascertain if the symptoms were epileptic seizures or nonepileptic in nature (see Differential Diagnosis). Older adult patients may not have prominent automatisms, as in focal seizures. Postictal confusion can last from hours to days. In the initial work-up of a new-onset seizure in an older adult, multiple diagnostic tests are needed. Blood tests include blood glucose because extreme hypoglycemia or hyperglycemia can cause provoked generalized tonic-clonic seizures (GTCS); complete blood count (CBC) (an elevated white blood count can indicate a systemic or CNS infection, which can lead to a provoked GTCS); and electrolyte panel (hyponatremia, hypernatremia, or uremia can lead to a provoked GTCS). Erythrocyte sedimentation rate (ESR), renal function tests, liver function tests, and calcium tests should be done. Baseline tests allow decisions to be made about potential medications. A thyroid screen (i.e., thyroid-stimulating hormone [TSH]) is done because hypothyroid neuropathy may be confused with focal seizure activity.

A toxicology screen may be indicated because illicit substances may cause an unprovoked GTCS. A rapid plasma reagin (RPR) may be done to rule out the possibility of syphilis, which, in tertiary form, may present as a seizure disorder. A lumbar puncture may be performed if there is concern for a primary CNS infection. A basic electrocardiogram (ECG) can confirm syncope in association with a cardiac arrhythmia. In the event that there is an abnormal ECG, an echocardiogram may be required. Tilt-table testing can be useful to detect baroreceptor and vasopressor dysfunction or sympathetic failure due to autonomic neuropathy in older people. EEG and brain magnetic resonance imaging (MRI) are the most important tests for unprovoked seizures (Thijs et al., 2019), although a routine EEG may be of limited use in older adults due to low sensitivity and specificity. An ambulatory prolonged EEG may be indicated. The MRI is the preferred test because it is more accurate than a computed tomography (CT) scan. A brain MRI with and without contrast should be done to rule out old scar tissue, mesial temporal sclerosis, or other structural reasons for the seizures. Neuroimaging with contrast increases the ability to identify tumors, inflammatory disease, and abscesses. An EEG is indicated after any unprovoked seizure event to support the diagnosis of idiopathic generalized or focal-onset epilepsy. A normal result does not prove the patient does not have a potential for seizures; multiple EEG studies may be indicated.

Differential Diagnosis: The most common differential diagnoses for seizures include:

- Neurological: TIA, transient global amnesia, confusional migraine, RLS
- Cardiovascular: syncope, orthostatic hypotension, cardiac arrhythmias, carotid sinus syndrome
- Drug intoxication
- Infections
- Endocrine/metabolic disturbances (e.g., hypoglycemia, hyperglycemia, hyponatremia, hypokalemia)
- Sleep disturbances: obstructive sleep apnea, hypnic jerks
- Dementia
- Psychological: nonepileptic, psychogenic seizures
- Drug induced: alcohol withdrawal (peak incidence of first seizures occurs late in life); use of one or more drugs in high doses with coexisting illness (antihistamines, antidepressants, antipsychotics, hypoglycemic drugs) (Acharya & Acharya, 2014; Chi Vu et al., 2018)

Treatment: Patients with provoked seizures need to be treated for the underlying cause and usually do not need AEDs. With unprovoked seizures, the decision to treat depends on whether the patient has a single seizure or recurrent seizures (epilepsy). Unlike management in younger adults, AEDs may be appropriate after a single seizure in the older adult because of the high rate of recurrence. It is generally easier to achieve seizure-free status in older patients compared with younger age-groups (Chi Vu et al., 2018). The goal of management should be the maintenance of a normal lifestyle, with complete control of seizures with minimal side effects. Seizures in the older adult tend to respond better to AEDs than those in young individuals and can often be appropriately controlled with monotherapy. Pharmacotherapy continues to be the mainstay of treatment for seizures; however, AED management can be complicated because of the coexistence of other diseases (e.g., dementia, polypharmacy), and the likelihood of dose-related and adverse side effects. These medications should be introduced slowly, titrating up depending on symptoms (Thijs et al., 2019).

Concern when prescribing AEDs for older adults include changes in pharmacokinetic parameters, polytherapy, and susceptibility to adverse effects (Lee, 2019). AEDs are commonly prescribed to the older adult and to about 10% of nursing home residents for a variety of reasons, including migraine prophylaxis, psychiatric disorders, pain management, and seizures. AEDs are the fifth most common cause of drug side effects in the older adult and, therefore, need to be carefully prescribed and monitored. The pharmacokinetics and pharmacodynamics of AEDs are distinct in older adult patients. Physiological changes relevant to pharmacotherapy in the older adult include decreased gastrointestinal motility, decreased serum albumin, increased body fat to lean mass ratio, decreased total body water, decreased liver mass and blood flow, decreased cytochrome P450 enzyme activity, decreased renal flow and weight, and decreased glomerular filtration rate, among others. The dose of medications may need to be reduced in patients with decreasing glomerular filtration rates 30 to 59 mL/min (Lee, 2019). For example,

© F.A. Davis Publishing

reduction in serum albumin levels leads to reduction in protein binding and increase in free fraction of the drug. This is an issue for high protein bound drugs such as phenytoin, carbamazepine, and valproic acid because of the increased risk of toxicity.

Older adults have a narrower therapeutic window than younger adults. Many AEDs are metabolized by the liver, especially the P450 enzyme, which is decreased. The potential for drug interactions is a major consideration in selecting an AED. Older AEDs (e.g., phenytoin, phenobarbital, carbamazepine) are enzyme-inducers, which increases the likelihood of interactions with other medications. Newer medications such as lamotrigine and levetiracetam are better choices for older adults on multiple medications. Calcium and vitamin D supplements should be considered because of the risk of osteoporosis with AED use. Pharmacodynamic changes include alterations in receptor distribution and density, receptor affinity and function, neurotransmitter release, and autonomic and homeostatic function. Toxicity from medications is poorly recognized in the older adult and can be attributed to multiple causes. Older adults with multiple chronic illnesses are more likely to be taking medications that interfere with AEDs.

Benzodiazepines (diazepam, lorazepam) are most commonly used for rescue or only in the acute setting. Although these are generally considered CNS depressants, the older adult may experience idiosyncratic effects such as restlessness, hyperactivity, and psychosis. Phenobarbital has been used in the treatment of seizures since the 1950s. Some older adult patients may have been on the medication for many years and will continue to require consistent monitoring. Phenobarbital is not recommended for a patient with new-onset seizures.

The newer AEDs offer some advantages for older adult, including a better side-effect profile. However, they are more expensive, and the name brands may not be covered by various insurance programs. Lacosamide is indicated as monotherapy and as adjunctive therapy for focal seizures. It blocks sodium channels and converts to inactive metabolites in the liver (Abou-Khalil, 2019). Oxcarbazepine is a second generation carbamazepine but with fewer side effects. This drug is only 38% protein bound and can be introduced more quickly in the older adult than carbamazepine. A concern for prescribing oxcarbazepine is possible hyponatremia, especially in older adults taking diuretics (Abou-Khalil, 2019). Lamotrigine is well absorbed orally by the older adult. Although the medication is eliminated by hepatic metabolism and then excreted renally, the drug is safely used in the older adult with renal failure. Side effects are minimal, and several studies have shown that it is well tolerated by the older adult. Lamotrigine has some mood-stabilizing effects, which may also help in treatment of the older adult. Levetiracetam is not metabolized by the P450 system and is entirely renally excreted. Dosage in renal failure may need adjustment. Gabapentin is also completely excreted unchanged in the urine. This drug is generally well tolerated in the older adult and is less likely to be involved in drug interactions; however, high dosages are often required for effective seizure control.

Topiramate has demonstrated good efficacy in older adult patients but may interact with digoxin and warfarin. Selection of topiramate, however, should not be considered for first-line treatment in older adults with cognitive impairment because of adverse effects (Abou-Khalil, 2019; Sommer & Fenn, 2010). Pregabalin has oral bioavailability exceeding 90%, is not bound to plasma proteins, and readily crosses the blood-brain barrier. The dosage must be titrated slowly to avoid adverse cognitive effects. Felbamate is primarily metabolized by the liver and has a number of drug interactions. Used carefully, this can be a good choice in pharmacoresistant seizures. Tiagabine is also metabolized by the liver and has a drug interaction profile similar to carbamazepine. Zonisamide is 40% bound to protein and its major elimination pathway is hepatic, but it can be safely used in the older adult. Long-term use of Depakote is not recommended in older adults because adverse side effects include reversible parkinsonism, tardive dyskinesia, gait disorder, dementia, and brain atrophy (Abou-Khalil, 2019).

Caution should be exercised in the use of generic medications because these have been shown not to have the same efficacy as brand-name medications. A patient who is stable on generic medications can become toxic or have breakthrough seizures if switched to brand-name medications. Similarly, the patient who is stable on brand-name medications and is switched to generic may experience a significant decrease in serum levels, leading to breakthrough seizures.

Seizure surgery can be considered in the older adult if the seizures are medically intractable, and the seizures are related to a focal structural lesion. A study by Punia and colleagues (2018) found that resective epilepsy surgery (RES) is often underutilized for people 65 and older. A cohort of older adults who underwent RES had comparable outcomes to a younger group of patients despite having more comorbidities and diagnosed for a longer duration of time (Punia et al., 2018).

Vagus nerve stimulation (VNS) has also been used in patients with refractory epilepsy. VNS is provided by a surgically implanted device programmed to deliver a brief electric stimulation on a schedule. The efficacy of this treatment has been established in general populations, but the data on the older adult are sparse.

Follow-Up: Seizure management is a significant challenge, and the patient and any caretakers should be seen frequently. A seizure calendar/journal is maintained by the patient and should be reviewed on each visit. Precipitating factors for an increase in seizures, such as stress, sleep deprivation, or viral illness, should be noted. Questions concerning potential medication side effects are asked on each visit. For some medications, periodic levels are monitored and adjusted to ensure therapeutic levels. The incidence of depression in adults with epilepsy has been reported as high as 50%. Causes of the depression include lifestyle changes, loss of confidence and independence, as well as biochemical alterations in the brain due to the seizures. The potential loss of freedom following a seizure is heightened by driving restrictions, which are based on the laws of the individual state and range from 6 months to at least 1 year seizure free.

Sequelae: Sudden unexpected death in epilepsy (SUDEP) is defined specifically as the sudden, unexpected, witnessed, or unwitnessed, nontraumatic, and nondrowning death in patients with epilepsy with or without evidence for a seizure, and excluding documented status epilepticus, in which postmortem examination does not reveal a structural or toxicological cause for death. Individuals with epilepsy have a mortality rate two to three times greater than that of the population at large (Thijs et al., 2019). SUDEP accounts for 8% to 17% of these deaths and is more likely to occur in

© F.A. Davis Publishing

those with frequent seizures. Patients and their families need to be warned of the potential for SUDEP and the importance of controlling the variables that can lead to SUDEP, such as abrupt cessation of AEDs.

Convulsive status epilepticus incidence is almost twice that of the general population. Associated mortality rate is also higher in older patients, 38% in those older than 60 years and more than 50% in those older than 80 years. Nonconvulsive status epilepticus (NCSE) is equally common in the older adult, but much more difficult to diagnose because it can present with general symptoms such as confusion, psychosis, lethargy, or coma, or a more focal cognitive disturbance with aphasia. These symptoms are very general and may not be associated with any observable seizure activity. Due to the nonspecific nature of the symptoms, the presence of seizures on the EEG is the most important diagnostic step. Incidence rate of all types of status epilepticus in the older adult is 54.2 per 100,000 people.

Prevention/Prophylaxis: Prevention of potential causative factors such as stroke, meningitis, and active management of disease processes such as AD and dementia is an important part of prevention of seizures. Care in preventing falls may also decrease the incidence of head injuries leading to seizures. Prophylactic use of AEDs following head injury and stroke remains controversial but may be indicated.

Referral: For new-onset seizures, referral to a neurologist/epileptologist or to a comprehensive epilepsy center would be in the best interest of the patient. If traditional medications become difficult to manage, the patient should be referred to a neurologist.

Education: Comprehensive education should be provided to patients and their families/caregivers. This education includes seizure recognition and first aid, treatment plans and side effects, safety practices to prevent injury during seizures, and lifestyle considerations appropriate for age (e.g., driving, work, sleep, coping skills, stress management). Community resources, as well as evidence-based Web-based resources, should be discussed (e.g., Epilepsy Foundation, NINDS). Educating patients and their families about SUDEP, ascertaining seizure precipitants, and promoting compliance with treatment are important strategies. Very specific information should be provided to patients who are nonadherent with medications or appear to be in denial of the diagnosis. Patients should maintain a seizure calendar that chronicles seizures and all precipitants. Strategies to ensure compliance with daily medication include the use of medication boxes and telephone alarms. Patients should inform the provider of any changes in other medications to avoid potential interactions. Inform patients and family members that abrupt cessation of medications is very dangerous and that all AEDs should be carefully weaned.

STROKE

Signal Symptoms: Sudden weakness or numbness on one side of the body, language impairment, trouble seeing in one or both eyes, alteration in balance and/or coordination, severe headache without known cause.

Description: Stroke is a rapidly evolving cerebrovascular syndrome of sudden onset, with symptoms suggestive of a nonepileptic focal neurological deficit. There are two major types of strokes: ischemic, indicating blockage of an artery, and hemorrhagic, usually resulting from a leak or rupture in an artery wall. Acute stroke is a medical emergency.

Etiology: Approximately 87% of all strokes are ischemic (Virani et al., 2020) and develop when an artery in the brain is obstructed by a clot that eithers forms in the brain or travels from somewhere else. Ischemic strokes are classified into casual subtypes: cardioembolic, small vessel occlusion (lacunar stroke), large vessel atherothrombotic, other unusual, determined etiology, and undetermined etiology. Cardioembolic strokes occur when a blood clot forms elsewhere in the body, travels to the brain through the circulatory system, and becomes lodged in a cerebral artery. Cardioembolic strokes are generally associated with atrial fibrillation, valvular disorders, heart failure, and other states associated with thrombus formation. Large vessel strokes occur when a major artery in the brain is blocked, presumably by a blood clot that forms as a result of an inflammatory response to an unstable

© F.A. Davis Publishing

atherosclerotic plaque. Lacunar infarcts occur in the small arteries that branch from main cerebral arteries. Unusual etiologies of stroke include nonatherosclerotic vasculopathies, hypercoagulable states, or hematological disorders. An exhaustive work-up, an incomplete work-up, and more than one possible source can lead to a label of undetermined etiology (Kleindorfer et al., 2021).

Hemorrhagic stroke usually results from either a nonstructural or structural cause, where a weakened area of an artery in or around the brain ruptures. The most common nonstructural hemorrhage is caused by pathophysiological changes that occur in small arteries from long-standing hypertension, often triggered by an accelerated hypertensive episode. Structural etiologies include ruptured aneurysms and arteriovenous malformations. Incidence is varied by race and mechanism. Approximately 10% of all events are intracerebral hemorrhage (ICH) and 3% are subarachnoid hemorrhage (Virani et al., 2020). *Hemorrhagic transformation* is a term that refers to bleeding into infarcted tissue and is thought to be associated with reperfusion. It occurs within days or weeks from stroke onset.

A transient ischemic attack (TIA) is an episode of focal neurological impairment of presumed ischemic origin, typically lasting only a few minutes with no permanent deficits. The episode of neurological dysfunction is caused by focal brain, spinal cord, or retinal ischemia without acute infarction (Kleindorfer et al., 2021). Absence of tissue findings makes TIA a tissue-based definition rather than a time-defined definition. Transient hypotension, in conjunction with significant carotid stenosis, may also cause a TIA. The significance of TIA lies in the heightened short-term risk of stroke, with a 3% to 10% risk at 2 days and a 9% to 17% risk of stroke within 90 days of a TIA. Over the following 10 years, there is a 4% per year risk of stroke, myocardial infarction (MI), or vascular death (Virani et al., 2020).

Occurrence: Stroke is the leading neurological cause of death and disability in the United States, with an estimated 795,000 people each year suffering a new or recurrent stroke (Virani et al., 2020). The stroke incidence rate is higher for men compared with women at younger ages, but not at older ages. Lifetime risk for women is higher than men, with rates one in five for women and approximately one in six for men ages 55 to 75 years. Prevalence of TIA increases with age. True prevalence is difficult to ascertain, as many fail to report neurological symptoms to their health-care provider (Virani et al., 2020).

Age: Approximately 7.0 million Americans 20 years old and older have had a stroke. The prevalence of silent cerebral infarction rises from 6% to 28% with increasing age. With an aging population, by 2030 prevalence is expected to increase 20.5% in those 18 years old and older, adding 3.4 million more people with stroke (Virani et al., 2020).

Ethnicity: Native Americans, Alaskan Natives, Hispanics, and Blacks have more TIAs and are at higher risk for stroke and stroke mortality than Whites. Blacks carry the highest risk and Hispanics carry a moderate risk, whereas Whites carry the lowest risk (Virani et al., 2020).

Contributing Factors: Risk factors for stroke include advanced age, family history of stroke, hypertension, diabetes, smoking, prior history of TIA or stroke, hyperlipidemia, cardiovascular disease, carotid stenosis, atrial fibrillation, obesity, sedentary lifestyle, alcohol abuse, and some infections (endocarditis, bacterial meningitis). Less common risk factors include sleep apnea, drug abuse, migraine, hypercoagulable disorders, hormone replacement therapy or oral contraceptive use, sickle cell anemia, and other inflammatory processes (Kleindorfer et al., 2021).

Signs and Symptoms: Determination of time last known well is critical. TIA is a precursor to stroke in 15% of all cases. Patients having a TIA or ischemic stroke may report sudden onset of the following symptoms: weakness, numbness, or paralysis in the face, hand, arm, or leg (usually unilateral); difficulty speaking or understanding verbal communication; blurred, doubled, or decreased monocular or binocular vision; loss of balance or coordination; and severe headache. Cortical symptoms, including aphasia, gaze deviation, hemianopia, and neglect are correlated with large vessel occlusions (LVO) (Powers et al., 2019).

Patients with a hemorrhagic stroke may report any of these symptoms, along with nausea and vomiting, altered mental status, sensitivity to light, and neck stiffness. Physical signs may include one or more of the following: decreased visual acuity or field cut, diplopia, slurred speech, aphasia, and hemiparesis or sensory changes of the face, arm, or leg. A decrease in coordination or unsteady gait can occur. Elevated blood pressure is common along with acute confusion (Hemphill et al., 2015).

Any other focal signs on neurological examination should be assessed carefully. Physical examination should include repeated measures of vital signs and examination of the head and neck for signs of trauma and infection, checks of the peripheral and carotid pulses, auscultation of the neck for bruits, and a complete neurological examination for focal abnormalities. The consequent impairment depends on the location and extent of the stroke (Hemphill et al., 2015). Recommended is the National Institutes of Health Stroke Scale (NIHSS), a validated tool that standardizes approach to the neurological examination (Powers et al., 2019).

Diagnostic Tests: All patients with symptoms consistent with stroke should be transported via emergency medical services (EMS) to the nearest certified stroke facility for rapid assessment and early treatment. For patients with a suspected LVO, noninvasive imaging with computed tomography (CT) angiography and/or magnetic resonance angiography should be done emergently up to 24 hours. Perfusion CT and magnetic resonance imaging (MRI) are recommended for patients eligible for reperfusion between 6 and 24 hours. Even for patients whose symptoms have resolved, immediate diagnostic tests should include a noncontrast CT scan or MRI of the head to evaluate for presence of hemorrhage, electrocardiogram (ECG), and laboratory assessment (oxygen saturation, complete blood count [CBC], prothrombin time/activated partial thromboplastin time [PT/aPTT], troponin, lipids, and complete blood chemistry) (Powers et al., 2019).

A head CT scan is almost 100% sensitive for ICH. Ischemic events may not be visible on CT scan for 24 to 48 hours and may be noted anywhere in the cerebral cortex, cerebellum, or brainstem. MRI is helpful in early diagnosis of ischemic or hemorrhagic strokes but may not be available in all centers. If a hemorrhagic stroke is confirmed, consider referral to a neurosurgeon. Further diagnostic testing includes carotid

© F.A. Davis Publishing

duplex studies, CT angiography and/or magnetic resonance angiography, if not done emergently, to look for intracranial and extracranial vascular occlusion in the head or neck, as well as cardiac monitoring and an echocardiogram (Powers et al., 2019). Treatment choices will depend on results of initial assessments and time elapsed between onset of symptoms and confirmed diagnosis (Hemphill et al., 2015; Powers et al., 2019). The purpose of acute hospitalization is to establish stroke etiology in order to prevent subsequent events.

Differential Diagnosis:

- Seizure with Todd's paralysis: loss of consciousness, seizure activity, incontinence, postictal state
- Migraine aura: more common in women, history of similar event, preceding aura, with or without headache, photophobia
- Syncope/dizziness/vertigo: common types include neurocardiogenic (vasovagal), situational, orthostatic, and syncope related to cardiac ischemia or arrhythmia. Associated with sweating, pallor, and nausea. May have dim vision, decreased alertness, and transient loss of consciousness.
- Transient global amnesia: poor recall of recent events with impaired ability to retain new memories without other cognitive or focal neurological impairment
- Toxic-metabolic disorders: hypoglycemia, hyperglycemia, hyponatremia, drug or alcohol intoxication, ruled out based on history and laboratory findings
- Multiple sclerosis (MS): paroxysmal transient attacks of ataxia and dysarthria
- Brain tumor: gradual progression of symptoms, other primary malignancy, seizure at onset, ruled out based on brain imaging studies
- Systemic infections: acute illness with recrudescence of previous stroke symptoms
- Conversion disorder: inconsistent clinical examination, nonfocal symptoms, neurological findings in a nonvascular distribution, increased risk in those with recent stress or trauma or with history of mental health condition

Treatment: Emergency transport to the nearest designated stroke center should be initiated for patients with suspected stroke, regardless of the severity of neurological deficits, and be evaluated as high priority triage. Patients should be given nothing by mouth (NPO) with IV fluids (isotonic sodium chloride) started to maintain euvolemic status in most patients. Patients with fever (greater than 38°C [100.4°F]) should be treated with antipyretics and an aggressive search for the source of fever initiated. Hypoglycemia and hyperglycemia should be identified and treated promptly. Both can produce symptoms that mimic ischemic stroke, and both may worsen neuronal injury. The goal for hypoglycemia treatment is to achieve normoglycemia. Hyperglycemia during the first 24 hours is associated with poor outcomes, thus glucose level goals of 140 to 180 mg/dL with avoidance of hypoglycemia is advised. Supplemental oxygen is recommended to attain oxygen saturation greater than 94% (Powers et al., 2019).

For eligible patients who present within 4.5 hours of the onset of symptoms and a hemorrhagic event is ruled out, recombinant tissue-type plasminogen activator (alteplase, also known as t-PA), an IV thrombolytic agent, has been established to decrease long-term disability. The most important factor in successful treatment is early administration. Additionally, for patients who have an LVO, intra-arterial treatment with mechanical thrombectomy within 24 hours of symptom onset has been found to be safe and effective, demonstrating improved outcomes and reduced mortality. Other investigational methods of reperfusion, including intra-arterial thrombolysis remain unproven. Endovascular and research availability depends on location; treatment should only be performed at an experienced stroke center. The American Stroke Association guidelines support that cities, counties, regions, and states develop a stroke system of care that will enable patient access to optimal care (Powers et al., 2019).

Early administration of aspirin within 24 to 48 hours following stroke has shown benefit and is recommended in ischemic events but is generally delayed until 24 hours after alteplase administration. Urgent anticoagulation to prevent recurrent stroke, avoid neurological worsening, or improve outcomes is not recommended (Powers et al., 2019).

Hypertension is common in acute stroke and may spontaneously decline within 90 minutes of stroke onset. Aggressive use of antihypertensives may reduce perfusion pressure and prolong or worsen ischemia. Rapid reduction of blood pressure regardless of the degree of hypertension may be harmful. The consensus recommendation is to lower the blood pressure by 15% during the first 24 hours if the systolic pressure is greater than 220 mm Hg or diastolic blood pressure is greater than 120 mm Hg. Note: a systolic pressure greater than 185 mm Hg or a diastolic pressure greater than 110 mm Hg is a contraindication for thrombolytic therapy. Therefore, the management of blood pressure in acute ischemic stroke will depend on whether the patient is a candidate for thrombolytic therapy. There is no evidence to determine which antihypertensive should be used; an individualized approach is best (Powers et al., 2019).

Hemorrhagic events should be initially managed in an intensive care or stroke unit. For patients taking anticoagulation medications, reversal may be indicated. If patients present with systolic pressures 150 to 220 mm Hg, aggressive reduction is considered safe down to 140 mm Hg. Prophylactic antiepileptics are not recommended. Ideally, neurosurgical care should be available, though the usefulness of surgery for most patients is not well established. Patients should be monitored at frequent intervals for signs of cerebral edema, and control of other comorbid diseases are also indicated (Hemphill et al., 2015).

Follow-Up: Indications for follow-up depend on the type and extent of the stroke. Rehabilitation should begin during the acute phase as soon as the patient can tolerate, with all patients undergoing a formal rehabilitation needs assessment prior to discharge. Post-acute goals support the pursuit of the highest level of functioning possible. A stroke-specific rehabilitation environment is preferred, if available. Rehabilitation targets should be designed around (1) functional outcomes, (2) lifestyle interventions, (3) enhancement of cardiorespiratory fitness, (4) prevention of complications and deconditioning, and (5) social reintegration. Education regarding stroke, rehabilitation, recovery, and what to expect is critical for the survivor, family, and caregivers. Whenever possible, the stroke survivor, family, and caregivers should be involved in decision making regarding treatment and care planning. Use of standardized assessment instruments will be helpful in

© F.A. Davis Publishing

establishing baseline, setting goals, and tracking progress. Standardized stroke assessment instruments are found in Box 17-2 (Powers et al., 2019; Winstein et al., 2016).

Whenever possible after a stroke, patients should have regular contact with a care team with expertise in stroke rehabilitation to assess for changes in level of function, control medical comorbidities, manage pain, assess for depression/anxiety, address complex rehabilitation issues, and implement prevention strategies for secondary stroke prevention (Winstein et al., 2016). Community- or home-based rehabilitation services are recommended following discharge from either acute hospitalization or inpatient rehabilitation, when feasible, and should include a team approach with nursing, medical interventions, and specialized equipment as needed. Given today's electronic climate, it is reasonable to consider other methods for follow-up at home, especially for those in rural environments, including the use of discharge phone calls, telehealth, and Web-based or smart-phone enabled support (Winstein et al., 2016).

Sequelae: Stroke survivors are at high risk for complications related to immobility, such as skin breakdown and contractures, loss of muscle strength, and pulmonary compromise. Risk assessments should routinely be performed for other common complications including malnutrition, bowel and bladder incontinence, deep vein thrombosis, pain, falls, seizures, and osteoporosis. Assessment of cognition and memory, communication abilities, sensorimotor impairment, and psychosocial status should be undertaken regularly in the subacute and chronic phases of stroke recovery. Speech and swallowing difficulties also may persist after a stroke. Depression and anxiety are also common. Stroke survivors should be screened for depression both during the acute phase and regularly thereafter, with treatment as indicated (Winstein et al., 2016). Monitoring of the caregiver burden and access to available community resources is also imperative. Finally, all stroke survivors are at risk for recurrent stroke and other cardiovascular events (Kleindorfer et al., 2021). Appropriate strategies should be implemented for prevention/prophylaxis.

BOX 17-2

Standardized, Validated Instruments for Assessment of Stroke Survivors

- Global disability (Rankin scale)
- Measures of disability/ADLs (Barthel Index; Functional Independence Measure [FIM™])
- Instrumental activities of daily living (PGC Instrumental Activities of Daily Living; Frenchay Activities Index)
- Mental status (Folstein Mini-Mental State Examination; Neurobehavioral Cognition Status Exam [NCSE])
- Speech and language (Boston Diagnostic Aphasia Examination; Porch Index of Communicative Ability [PICA]; Western Aphasia Battery)
- Paresis/strength (Motricity Index, muscle strength, grip pinch dynamometry)
- Tone (Modified Ashworth scale)
- Sensorimotor impairment (Fugl-Meyer, Chedoke McMaster Stroke Assessment, impairment inventory)
- Upper extremity function (Action Research Arm Test, Box and Block Test, Chedoke Arm and Hand Activity index, Wolf Motor Function Test)
- Balance (Berg Balance Scale, Functional Reach Test)
- Mobility (walking speed, Timed Up and Go, 6-minute walk test, functional ambulation category, observational gait analysis)
- Self-reported impairments, limitations, and restrictions (Stroke Impact scale, motor activity log, Activities-Specific Balance Confidence Scale)
- Technology for monitoring activity and participation (accelerometers, step activity monitors, pedometers)
- Depression (Beck Depression Inventory [BDI]; Center for Epidemiologic Studies Depression [CES-D]; Geriatric Depression Scale [GDS])

Sources: Winstein et al. (2016).

Prevention/Prophylaxis: Strategies to prevent stroke are similar to strategies used to prevent other cardiovascular diseases: control of hypertension, diabetes, dyslipidemia, sleep apnea, and cardiac disease through lifestyle and pharmacotherapeutic agents. Encourage patients to eat healthy, increase physical activity levels, lose weight (if indicated), avoid heavy alcohol intake, and stop smoking. Secondary stroke prevention with antithrombotics, including antiplatelet or anticoagulant agents, is recommended for virtually all patients without contraindications. For those with noncardioembolic ischemic TIA or minor stroke or identified carotid disease, short-term treatment with dual antiplatelets is recommended (Kleindorfer et al., 2021; Powers et al., 2019). Anticoagulation therapy is recommended in survivors of stroke with known arrhythmias or hypercoagulable states. Atrial fibrillation is the most common stroke causing arrythmia for which four direct-acting oral anticoagulants are available that are preferable to warfarin because they are as effective and may be safer (have lower risk profiles), they do not require routine blood tests, and they do not require dietary adjustment in patients with embolic stroke. In patients with a cryptogenic stroke of unknown embolic etiology with ongoing screening, almost 30% will be diagnosed with atrial fibrillation, which will alter treatment course. Carotid endarterectomy (CEA) or carotid angioplasty and stenting (CAS) may be considered for stenosis greater than 50% (Kleindorfer et al., 2019).

Referral: Referrals depend on the type and severity of impairment from the stroke and the influence of any comorbid illnesses. Referrals to physiatry (rehabilitation medicine), neurology, interventional neuroradiology, vascular surgery, psychiatry, and cardiology for consultation are common.

Education: Stroke education should address stroke prevention, treatment, and recovery. For stroke survivors, emphasize the cause of the stroke, control of individual risk factors to prevent future events, and importance of early identification with EMS activation and treatment of recurrent stroke. A Mediterranean-type diet is recommended. A home exercise program to maintain or improve functional levels should be introduced and strongly encouraged. Programs with balance training components have been shown to reduce falls (Winstein et al., 2016). The individually tailored exercise program will also enhance cardiorespiratory fitness and

© F.A. Davis Publishing

reduce risk of recurrent stroke, as well as improve cognition and memory. Information to access stroke support groups for patients and caregivers should be provided. Emphasis should be placed on the importance of periodic follow-up with the primary care provider for recovery monitoring, surveillance for complications, ongoing management of risk factors, and secondary prevention. The American Stroke Association offers help and support to stroke survivors and caregivers. Contact them via the Stroke Family Warmline at Stroke.org/speakwithus and at 1-888-4STROKE (1-888-478-7653). Up-to-date, stroke-specific guidelines and scientific statements for professionals are available online at the American Heart Association, https://professional.heart.org/en/guidelines-and-statements.

TRIGEMINAL NEURALGIA

Signal Symptoms: Paroxysms of shooting pain affecting one dermatome of the face.

Description: Also known as *tic douloureux,* trigeminal neuralgia is a painful disorder of the trigeminal nerve (cranial nerve V) that causes unilateral, brief, and recurrent paroxysms of shock-like electric pain that are sudden in onset and termination and are limited to the dermatome of one (or two contiguous) branches of the trigeminal nerve. In addition, there may be a less severe persistent pain in the same nerve distribution. Characteristically, the pain is triggered by normally innocuous tactile stimuli to the face or mouth, such as wind blowing across the face, chewing, and shaving (Headache Classification Committee of the International Headache Society [IHS], 2018). Trigeminal neuralgia is a chronic condition, though patients may experience periods of remission.

Etiology: Classical trigeminal neuralgia is caused by intracranial vascular compression of the trigeminal nerve root, most often by the superior cerebellar artery. Secondary trigeminal neuralgia is due to an underlying neurological or medical condition such as a cerebellopontine angle tumor or multiple sclerosis with demyelination of the axons of the fifth cranial nerve. Idiopathic trigeminal neuralgia has no identifiable cause (Cruccu et al., 2020).

Occurrence: Trigeminal neuralgia affects 12.6 to 28.9 per 100,000 people annually (van Hecke et al., 2014) and is more common in women than men.

Age: The incidence of trigeminal neuralgia increases with age.

Ethnicity: All ethnicities are affected, but trigeminal neuralgia may be less common among Jewish populations (Rothman & Monson, 1973).

Contributing Factors: Hypertension, migraine, and multiple sclerosis (MS) are risk factors for developing trigeminal neuralgia.

Signs and Symptoms: Trigeminal neuralgia is a clinical diagnosis (Bendtsen et al., 2020). Patients with trigeminal neuralgia have unilateral orofacial pain restricted to the territory of one or more divisions of the trigeminal nerve (Fig. 17-1). The maxillary and mandibular divisions are more commonly affected. The pain is paroxysmal in nature and brief in duration (from <1 second to 2 minutes, but usually a few seconds). The pain is described as a "shock" or an "electric sensation" and occurs from 1 to >50 times daily. Pain can be triggered by innocuous stimuli on the face or mouth in the vast majority of patients (Headache Classification Committee of the IHS, 2018). This triggered paroxysmal pain is specific for trigeminal neuralgia and may be pathognomonic for the disease (Cruccu et al., 2020). The pain is typically severe and can be disabling. Patients may refrain from activities that trigger the pain such as eating, shaving, and going outside when in the cold or wind. Patients may develop situational depression and even suicidal ideation due to the pain of trigeminal neuralgia.

Neurological examination is normal in patients with classical or idiopathic trigeminal neuralgia, except for mild hypoesthesia in the affected facial dermatome reported in some patients. The typical paroxysmal pain can be elicited on examination using provocative maneuvers, such as touching or moving the face; this solidifies the diagnosis of clinically established trigeminal neuralgia. These paroxysms of pain may be accompanied by brisk muscle contractions due to involuntary facial movement in response to pain (Cruccu et al., 2016).

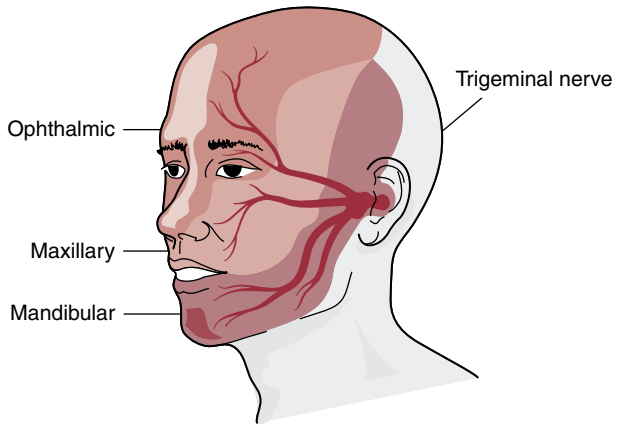

FIGURE 17-1 Dermatomes of the three trigeminal nerve branches: ophthalmic (V1), maxillary (V2), and mandibular (V3).

Diagnostic Tests: Brain magnetic resonance imaging (MRI) is recommended to evaluate for the underlying etiology of the trigeminal neuralgia (Bendtsen et al., 2019). Neurovascular compression is seen in classical trigeminal neuralgia and a structural lesion affecting the trigeminal nerve is seen in secondary trigeminal neuralgia. Patients with idiopathic trigeminal neuralgia have normal brain imaging.

Differential Diagnosis: There are many potential causes of orofacial pain, and the differential diagnosis is broad (Headache Classification Committee of the IHS, 2018). Other primary headache and facial pain disorders include:

- Glossopharyngeal neuralgia: paroxysmal stabbing pain affecting the ear, throat, base of the tongue, or beneath the angle of the jaw
- Optic neuritis: pain behind the affected eye with associated vision changes due to demyelination of the optic nerve
- Ischemic ocular motor nerve palsy: headache and binocular diplopia due to ischemic injury of cranial nerve III, IV, or VI
- Persistent idiopathic facial pain (previously known as atypical facial pain): persistent facial and/or oral pain with a normal examination and no identifiable cause
- Short-lasting unilateral neuralgiform headache attacks: These trigeminal autonomic cephalalgias are a group of primary headache disorders that cause stabbing pain in the trigeminal nerve distribution on one side at a time (though can change sides) with associated autonomic features (conjunctival injection, lacrimation, nasal congestion, rhinorrhea, eyelid edema, ptosis, miosis, or facial sweating).
- Primary stabbing headache: stabbing pain on the scalp

© F.A. Davis Publishing

Secondary causes of orofacial pain include:

- Painful trigeminal neuropathy: facial pain in an area of sensory loss, caused by damage to the trigeminal nerve (such as acute herpes zoster, post-herpetic neuralgia, tumor, or trauma)
- Dental pain
- Temporomandibular disorder
- Giant cell arteritis (also known as temporal arteritis): chronic vasculitis that often causes pain in the temporal area, with associated tenderness to palpation and jaw claudication. Left untreated, patients can suffer permanent blindness or other neurological complications.
- Facial pain due to carotid or vertebral artery dissection

Treatment: Carbamazepine or oxcarbazepine are recommended as first-line agents for trigeminal neuralgia. Oxcarbazepine is generally better tolerated than carbamazepine. If ineffective, second-line or add-on treatments include gabapentin, pregabalin, lamotrigine, phenytoin, baclofen, or botulinum toxin injections (Bendtsen et al., 2020).

In refractory cases, surgical management can be considered. For classical trigeminal neuralgia, microvascular decompression is the procedure of choice. Ablation procedures can be considered when there is no neurovascular compression (Bendtsen et al., 2020).

Follow-Up: Patients should be monitored for symptom control and medication side effects. Carbamazepine and oxcarbazepine have many potential side effects, including sedation, nausea, dizziness, diplopia, hyponatremia, rash, and hematological complications. Patients should also be monitored for psychiatric comorbidities; depression, including suicidal ideation, has been described as a sequela of unrelenting trigeminal neuralgia pain. Patients should have routine follow-up with their dentist because oral hygiene may be poor in patients whose pain is triggered by brushing teeth (Bendtsen et al., 2020).

Prevention/Prophylaxis: There is no prevention for trigeminal neuralgia.

Referral: If the patient's symptoms do not improve with medications, if atypical features are present, or if other neurological signs are evident, the patient should be referred to a neurologist. If the symptoms are refractory to medical management, referral for neurosurgical consultation should be considered. Psychology referral should be considered for patients experiencing anxiety and depression and to learn pain coping skills (Bendtsen et al., 2020).

Education: Patients should be counseled about avoiding triggers, possible medication side effects, and available neurosurgical procedures.

Clinical Recommendation	Evidence Rating	References
Trigeminal neuralgia is a clinical diagnosis.	C	Cruccu et al., 2016 Headache Classification Committee of the IHS, 2018 Scholz et al., 2019
Brain magnetic resonance imaging should be performed to evaluate for an underlying structural etiology upon diagnosis of trigeminal neuralgia.	B	Bendtsen et al., 2019
First-line medications for the treatment of trigeminal neuralgia are carbamazepine or oxcarbazepine.	A	Bendtsen et al., 2019
Surgical treatments can be curative; the best results are seen with microvascular decompression surgery for classical trigeminal neuralgia (62%–89% achieve pain freedom).	B	Bendtsen et al., 2019
Medical management is recommended prior to offering surgery for trigeminal neuralgia.	C	Bendtsen et al., 2020

CASE STUDY

Sue is a 68-year-old healthy woman with no significant medical history. She is in the office today with complaint of intractable nausea and vomiting for the past 5 weeks with an 11-pound weight loss. On review of systems, she also has noted a dull, persistent headache, difficulty with concentration, and some blurred vision. She states these other problems are likely due to this gastrointestinal "bug" that will not go away. She denies similar symptoms in the past. Her mother died of complications of diabetes at 42 years old, her father died of a heart attack in his late 50s, one brother died in a car accident in his late teens, and the other died of complications of diabetes in his late teens. She is a nurse, married, with two adult children who are in good health. She drinks a beer or glass of wine on most days, sometimes two. She has never used tobacco products or illegal drugs.

CHAPTER 18

Endocrine and Metabolic Disorders

Laurie Kennedy-Malone

ASSESSMENT

With the multiple hormonal and metabolic changes that occur with aging, the incidence of endocrine and metabolic age-related conditions, such as type 2 diabetes, osteoporosis, and hyperlipidemia, increases as adults age (Lewiecki, 2021; Spinelli et al., 2020). Recognizing that normal aging changes of the endocrine system are primarily related to a decrease in pancreatic function (inability to sufficiently secrete insulin) and alterations in thyroid function, the nurse practitioner needs to screen older adults periodically when signs and symptoms of underlying endocrine conditions become apparent (Cai et al., 2012). Endocrine disorders in older adults are commonly detected when screening for other medical conditions. For example, a new onset of atrial fibrillation can result from undiagnosed hyperthyroidism (Jones & Boelaert, 2015; Modawal et al., 2004), and Paget's disease may be evident when a person sustains a fracture (Cundy, 2018).

Overall, the nurse practitioner managing the care of older adults needs to differentiate among four clinical states:

1. Endocrine function that is altered relative to that of younger patients but is an expected consequence of normal aging
2. Altered endocrine function secondary to coincident nonendocrine disease, but is not of known pathological significance
3. Iatrogenic changes in endocrine function that largely reflect the polypharmacy seen in the older adult population
4. Authentic endocrinopathy (Davis et al., 2007)

Recognition of Endocrine and Metabolic Disorders

Accurate history taking of complaints associated with endocrine and metabolic disorders is essential for completing the examination of the older adult. Because changes in the endocrine system may appear subtle to the older person or atypical as compared to younger patients, it may be difficult to pinpoint the onset of the presentation (Silverman, 1990; van den Beld et al., 2018). Reevaluate the patient's family history for endocrine and metabolic disease (Resnick, 2022). Explore with the patient any difficulty with temperature regulation, changes in skin texture, or distribution of body hair. Review with the patient any episodes of unexplained weight loss or gain, new or increased fatigue, weakness, malaise, and recent infections (Ahmed & Haboubi, 2010; Leslie & Hankey, 2015).

Focusing the Endocrine and Metabolic Disorder Review of Systems

Given the vagueness or atypical presentation of endocrine and metabolic disorders in older adults, specific questions directed at these conditions are imperative during the review of systems:

- Is there any alteration in the ability to carry out activities of daily living (ADLs) or instrumental ADLs due to fatigue, lethargy, or weakness?
- Has there been any acute changes in memory or mood?
- Has there been any decrease in appetite or reported change in weight?
- Has the patient noticed any excessive thirst, appetite, or urination?
- Is the patient experiencing incontinence for the first time?
- Has the patient experienced any repeated yeast infections?
- Has the patient had a skin ulcer that has failed to heal?
- Are there any mouth ulcerations?
- Is the patient reporting lethargy or fatigue?
- Are there any new episodes of chest pain, palpitations, tachycardia, dyspnea?
- Is the patient reporting dizziness?
- Is the patient reporting any abdominal area pain?
- Has the patient noticed a new onset of constipation or diarrhea?
- Has the patient noticed any complaints of paresthesias or carpal tunnel syndrome?
- Has the patient reported any hoarseness of the voice?
- Is the patient reporting depression, irritability, or anxiety?
- Has the patient experienced vertigo or gait disturbances?
- Are there any changes in the color or texture of the skin?
- Is there any noticeable dryness to hair, loss of hair?
- Has the patient noticed any intolerance to heat, sweating, or flushing?
- Are there any changes to tolerance of cold or heat?
- Is there any new presentation of abdominal pain and associated symptoms such as nausea or vomiting?
- Any decrease in libido and is the male patient reporting impotence?
- Has the patient reported perceived loss of height?

© F.A. Davis Publishing

- Any reports of back pain?
- Any noted bone pain, especially upon rising and/or deformities in the lower extremities?
- Any recent fractures?
- Has there been any change in hearing?
- Has the patient noticed a need to change hat sizes, or do they experience marks from wearing a hat?

It is important to determine from the patient what therapeutic measures have been initiated or prescribed in the past to alleviate any of the symptoms and what response occurred following treatment (Suneja et al., 2020).

Approach to the Physical Examination

The physical examination should focus on the clinical signs of endocrine and metabolic disorders prevalent in older adults, recognizing, however, that they may present atypically. Evaluation of previously recorded vital signs, weight, and height should be completed when recording current measures; note differences that could indicate unintentional weight loss (malnutrition or frailty), vertebral fractures (reduction in inches), and alteration in temperature, pulse, respiration, and blood pressure (underlying thyroid disease). Any noted change in general appearance since previous visits should be noted. Examine the skin for changes in texture, temperature, evidence of infection and/or rashes, lesions and/or open, nonhealing wounds. Examine for any areas of hyperpigmentation such as acanthosis nigricans found in patients with endocrine disorders (Brady & Rawla, 2021). Look for evidence of eruptive xanthoma—red, yellow papules often found on the elbows or knees in patients with elevated triglycerides.

Inspect the hair distribution and note any dryness, coarseness, or brittleness of hair. Determine whether the hair distribution of the eyebrows has changed (known as madarosis or Queen Anne's sign), which is a presentation found in hypothyroidism (Kumar & Karthikeyan, 2012). Perform a thyroid examination, looking for enlargement, tenderness, and evidence of goiter or nodularity (Williams, 2009). Look for any enlargement of the skull. Examine for any noted bone deformities, such as lateral curvature of femur and anterior curvature of tibia. If positive findings, question the patient about changes in hearing and consider gross hearing screening (Cundy, 2018; Maia et al., 2014).

Note any changes to the nailbeds. Are they brittle, cracked, peeling, or discolored? When examining the hands, look for small muscle wasting of the dorsum of the hand and between the thumb and index finger. Examine for evidence of Dupuytren's contracture, which can be found in patients who have diabetes mellitus (Grazina et al., 2019).

A thorough cardiac and respiratory examination is essential given the new manifestations of conditions such as angina, atrial fibrillation, hypertension, or heart failure in patients with undiagnosed hyperthyroid disease. Has the patient reported a rapid heartbeat or palpitations? Is there any evidence of a new murmur, cardiac arrythmia, or adventitious breath sounds (Knight, 2021)?

A focused examination for suspected pancreatitis may reveal jaundice, palpable mass and, during percussion, an enlarged pancreas with tenderness being elicited when palpating the epigastrium and behind the umbilicus. There may be notable guarding and possible signs of peritoneal irritation with abdominal distension, or rigidity. In severe disease, older adults may present with impaired cognition (Quinlan, 2014).

In patients with suspected osteoporosis, physical examination may reveal skeletal deformities due to a history of fractures. Patients may exhibit a loss of height, kyphosis, or have a diminished rib-pelvis space. Consider testing the patient's balance because of the risk of falls and associated fractures (Lewiecki, 2021).

Examine the lower extremities for edema; nonpitting edema is a clinical sign of pretibial myxedema. Inspect for diabetic dermopathy, which are atrophic, brownish patches usually found on the anterior lower legs of patients with diabetes with peripheral neuropathy. Necrobiosis lipoidica diabeticorum is a rash of raised plaques that may ulcerate and are generally larger than diabetic dermopathy (Lima et al., 2017).

Neurological examination in older patients with undiagnosed diabetes mellitus may reveal alterations in temperature, vibratory sense, and sensation. A fine tremor in the fingers and hands may be noted (Jones & Boelaert, 2015). Reflexes in an older adult may be altered by abnormal thyroid function. Testing the patient's proximal and distal strength is also important because weakness can manifest in thyroid disease. As patients and/or their caregivers may report changes in behavior, or cognition, an objective assessment of mental status is warranted in patients with untreated thyroid disease (Resnick, 2022).

Medication Review

A thorough review of all medications, including over the counter medications and home remedies, is important to discern if drug-drug interactions are responsible for alterations in the absorption of medications. Certain medications may be responsible for a new onset of anorexia, diarrhea, or constipation (Elsawy & Higgins, 2011). Also do a thorough review of how the patient and/or medical facility are administering the medications (timing the doses to not conflict with food). Finally, review patient adherence to and understanding of the medication regimen.

CALCIUM DISORDERS

Signal Symptoms: Many older adults with hypocalcemia or hypercalcemia may be asymptomatic. Calcium (Ca^{2+}) disorders can erroneously be attributed to other disease processes or dangerously dismissed as an expected deviation in the aging process due to the vague presentation.

Hypocalcemia: More severe and emergent presentation of hypocalcemia could include seizures, tetany, paresthesia, laryngospasm, and prolonged QT interval.

Hypercalcemia: Shortened QT interval, headache, and in rare cases coma and stupor may also be seen. Individuals with primary hyperparathyroidism my develop life-threatening severe hypercalcemia. Symptoms can include changes in mental status (cognitive impairment, confusion), bone disease (pain), dehydration, and kidney stones. Some individuals with hypercalcemia or mild hyperparathyroidism later develop parathyroid crisis. In other individuals, a parathyroid crisis can be the

© F.A. Davis Publishing

first sign of the disorder (Fuleihan & Silverberg, 2020). Hypercalcemic crisis is defined by a rapid-onset, albumin-corrected serum calcium level greater than 14 mg/dL and signs or symptoms of multiorgan dysfunction (Wilhelm et al., 2016).

Description: The human body tightly regulates calcium to maintain physiological homeostasis to control bidirectional fluctuations in the 1% of extracellular Ca^{2+} at the level of the intestine, bone, and kidney via the parathyroid (PTH) hormone, vitamin D, and serum Ca^{2+} axis (Tinawi, 2021; Veldurthy et al., 2016). Extracellular Ca^{2+} is tightly regulated by the parathyroid gland to maintain minimal variations in extracellular Ca^{2+} (Goldfarb, 2021). PTH hormone, vitamin D, and serum Ca^{2+} are integral components of a feedback loop to maintain physiological homeostasis with minimal variance (Tinawi, 2021; Veldurthy et al., 2016). Normal serum calcium levels are 8.8 to 10.3 mg/dL (2.2–2.6 mmol/L or 4.4–5.2 mEq/L [Yu et al., 2021]). Serum calcium concentration is determined by the state of hydration and the total of calcium bound to proteins (15%, mostly albumin), calcium bound to organic and inorganic anions (40%, sulfate, citrate, phosphate, and lactate), and calcium circulating as physiologically active ionized (free) calcium (45% [Tinawi, 2021; Yu et al., 2021]). Bone is a calcium reservoir that maintains normal plasma ionized calcium concentration (Goldfarb, 2021).

Etiology: PTH is the main regulator of renal Ca^{2+}; therefore, elevation in PTH with elevated serum calcium is indicative of disease. PTH deficiency affects the gastrointestinal (GI) tract, kidneys, and bones with resulting hypocalcemia. Disruption in Ca^{2+} absorption from small intestines, bone turnover or resorption, and renal excretion adversely affects extracellular Ca^{2+}. In response to low Ca^{2+}, PTH increases, which triggers the bone to release Ca^{2+} and phosphate. The PTH triggers the kidney to increase phosphate excretion, increase calcium reabsorption, calcitriol production, and intestinal dicalcium phosphate. The net effect is an increase in serum calcium with no change in phosphate levels (Veldurthy et al., 2016).

Hypocalcemia: In the absence of PTH, homeostasis is maintained by reclaiming calcium from the kidney and GI tract and depleting skeletal calcium, leading to evidential bone mass remodeling and hyperphosphatemia (Bilezikian et al., 2016). The most common cause of hypocalcemia in an older adult is low serum albumin; therefore, measurement of the serum albumin is essential to distinguish true hypocalcemia and factitious hypocalcemia. Hypocalcemia may be acquired or hereditary. Acquired causes include hypoparathyroidism, liver or kidney disease, COVID-19, dietary deficiency, medication, and surgery (Goltzman et al., 2018).

Primary hypoparathyroidism may be due to an autoimmune response against the parathyroid gland or activating antibodies against calcium sensor receptors (CaSR) that regulate PTH secretion from the parathyroid gland (Tinawi, 2021).

Hypercalcemia: Primary hyperparathyroidism is most commonly due to a benign adenoma in 99% of the cases (Wilhelm et al., 2016). Secondary hyperparathyroidism is an adaptive parathyroid gland hyperplasia with increased production of PTH in response to another disease process.

Occurrence: Hypercalcemia due to primary hyperparathyroidism is common in the general population and affects 2 million Americans each year (Dombroskwy et al., 2018). Prevalence of primary hyperparathyroidism is higher in women (233/100,000) than men (85/100,000). Data are lacking on incidence and prevalence in transgender populations (Sluis et al., 2019). A single parathyroid adenoma is responsible for 80% to 85% of hyperparathyroidism-related hypercalcemia; double adenomas account for 4% to 5%; and parathyroid hyperplasias are seen 10% to 12% of cases (Wolfe & Sharma, 2021). Parathyroid carcinomas are very rare causes of hyperparathyroidism and account for less 1% of disease (Wolfe & Sharma, 2021).

Older adults are more likely to have undiagnosed primary hyperparathyroidism. Rationales found in the literature include lack of acknowledgement of elevated calcium, frequent provider turnover, abnormal calcium noted but not evaluated, PTH was high and symptoms were present but undiagnosed, evaluation of hypercalcemia was planned but not completed, attribution of high calcium to other reasons (chronic kidney disease [CKD], calcium supplementation) without appropriate diagnostic evaluation, patient deference, physician decision, and surgeon deference (Dombrowsky et al., 2018).

Age: Variable based on chronic disease states. Increases for both sexes with advancing age (Dombrowsky et al., 2018; Sluis et al., 2019). Primary hyperparathyroidism prevalence peaks in women 60 to 79 years of age (492/100,000) and in men older than 80 years of age (264/100,000) (Sluis et al., 2019).

Ethnicity: The incidence is highest among Blacks, followed by Whites, then Asians, Latinx, and other ethnicities.

Contributing Factors:

Hypocalcemia: Certain gadolinium-based contrast agents (gadodiamide, gadoversetamide) may cause spurious hypocalcemia by interfering with laboratory measurement of total calcium (Goltzman et al., 2018).

Hypercalcemia: Hyperparathyroidism and malignancies account for 90% of hypercalcemia (Shane, 2020). Vitamin D deficiency triggers a transient increase in PTH to maintain normal extracellular calcium levels that resolves with treatment (Sterns, 2021).

Signs and Symptoms:

Hypocalcemia: Most patients with chronic hypocalcemia are asymptomatic; however, symptoms can range from asymptomatic to life-threatening. Mild hypocalcemia may present with muscle weakness, fatigue, confusion, depression, and memory loss. Hypocalcemia may be present with other electrolyte disorders, specifically phosphorus, magnesium.

Hypercalcemia: Symptoms of chronic hypercalcemia are also nonspecific and may present with other electrolyte disorders (e.g., phosphorus, magnesium). Fatigue, increased sleepiness, vague GI symptoms (nausea, abdominal pain, constipation), and renal manifestations (polyuria, nephrolithiasis), and musculoskeletal symptoms (variable bone pain).

Diagnostic Tests: The hormone regulators for Ca^{2+} homeostasis are PTH and calcitriol (1,25 dihydroxyvitamin D [the most active form of vitamin D]) and serum ionized (free) Ca^{2+} (or albumin-bound serum Ca^{2+} corrected calculation). Abnormal total serum calcium concentration in the presence of normal ionized calcium (free) can occur in hypoalbuminemia or hyperalbuminemia and multiple myeloma.

© F.A. Davis Publishing

Laboratory Studies: Complete metabolic panel. Total serum calcium levels is variable and will change based on the amount of Ca^{2+} bound to albumin; therefore, it is important to evaluate both total and ionized (free) Ca^{2+} (Yu et al., 2021). Commonly used correction formulas have poor accuracy in a variety of populations including those with chronic kidney disease; thus, measurement of ionized calcium is the gold standard for evaluating Ca^{2+} status and confirmation of an elevated result (Yu et al., 2021).

In some instances, the ionized Ca^{2+} will differ from total serum Ca^{2+}. Confirm elevated serum calcium level with ionized calcium (Goltzman et al., 2018). If the ionized calcium level is not available, use the corrected calcium (for albumin) regardless of albumin level to confirm the calcium elevation (Shane, 2020). If used, Yu et al. (2021) suggests this formula:

$$\text{Corrected } [Ca^{2+}] = \text{Measured total } [Ca^{2+}] + (0.08 \times (4.0 - [\text{Albumin}]))$$

Upon confirmation of the elevated Ca^{2+}, measure intact PTH (elevation with elevated ionized or corrected calcium is indicative of primary hyperparathyroidism), 1, 25-dihydroxyvitamin D (if elevated, suspect lymphoma or granulomatous disease); 25-hydroxyvitamin D (elevation indicative of vitamin D toxicity). If vitamin D results are normal, consider serum protein electrophoresis and urine protein electrophoresis to evaluate for multiple myeloma. Other diagnostic tests needed are 24-hour urine calcium to evaluate absorption abnormalities, thyroid panel to evaluate for hyperthyroidism, serum magnesium (low levels may suppress PTH secretion or cause PTH resistance; associated with normal, low, or high PTH levels), and serum phosphorus (Goldfarb, 2021; Shane, 2020). Inappropriate normal PTH results refers to the failure of the homeostatic negative feedback system (and disease state), whereby calcium levels fail to suppress PTH levels as expected (Mizamtsidi et al., 2018).

Physical Examination: Findings are variable depending on the underlying cause and may be nonspecific. Acute mental confusion, hypotension, tachycardia, tachypnea, Grey-Turner's sign, Cullen's sign, Fox's sign, Chvostek's sign, and Trousseau's sign are strongly suggestive of hypocalcemia (Goltzman et al., 2018). Assess for musculoskeletal pain (pattern and intensity), cognitive impairment (possibly transient in hyperparathyroidism and responsive to parathyroidectomy), and depression. Check for ankle reflexes by having the patient place both feet firmly on the floor and then use your reflex hammer to tap behind the Achilles' tendon and feel for muscle contraction in the base of the gastrocnemius and soleus muscles.

Differential Diagnosis:

Hypocalcemia: History of present illness, past medical history, clinical clues, and electrolyte imbalances guide differential diagnosis. Autoimmune diseases; HIV; isolated, infiltrative, or pseudohypoparathyroidism; iatrogenic hypoparathyroidism post-parathyroidectomy; hungry-bone syndrome post-parathyroidectomy; and systemic illness (sepsis, acute pancreatitis, renal failure, burns, rhabdomyolysis, tumor lysis syndrome) should be considered.

Iatrogenic differentials include treatment with inhibitors of bone resorption (especially in vitamin D deficiency), cinacalcet (parathyroid calcium receptor sensitivity enhancer in chronic disease), calcium chelators, foscarnet (due to intravascular complexing with calcium), and phenytoin (due to conversion of vitamin D to inactive metabolites). Laboratory investigation should include PTH, serum phosphorus, magnesium, 25-hydroxyvitamin D, 1,25 dihydroxyvitamin D, and serum creatinine to differentiate pathophysiological etiologies.

Hypercalcemia: Differential diagnoses can be categorized by metabolic, oncological, congenital, or iatrogenic.

- **Metabolic differentials with laboratory findings**
  - Parathyroid-mediated disease (hereditary or acquired): Classic presentation—serum Ca^{2+} ↑, 24-hour Ca^{2+} ↑, PTH ↑ or inappropriately normal in comparison to calcium; bone density T-score <–2.5
  - Hyperthyroidism: Serum Ca^{2+} ↑; PTH normal or ↓; TSH ↓
  - Secondary hyperparathyroidism due to CKD: Serum Ca^{2+} varies; serum creatinine ↑, vitamin D varies
  - Sarcoidosis: Serum Ca^{2+} ↑; PTH normal or ↓; Chest x-ray: hilar adenopathy, Calcitriol ↑
  - Paget's disease: Serum Ca^{2+} ↑; PTH undetectable; alkaline phosphatase ↑; lytic or sclerotic changes on x-ray
- **Oncological**
  - Multiple myeloma: Serum Ca^{2+} ↑; ionized Ca^{2+} normal or ↑; PTH ↓; serum protein electrophoresis: monoclonal gammopathy
  - Osteopenia, osteolytic lesions, or pathological fractures
  - Secondary malignancy: Serum Ca^{2+} ↑; parathyroid hormone related protein (PTHrP) normal or ↑
- **Iatrogenic differentials for hypercalcemia (consider risk versus benefit of continuance; change in treatment or discontinuance)**
  - Lithium (~15% of long-term use)
  - Amiloride
  - Thiazide diuretics
  - Vitamin D or A toxicity
  - Teriparatide
  - Abaloparatide
  - Theophylline toxicity

(Fuleihan & Silverberg, 2020; Shane, 2020; Sterns, 2021)

Other differential diagnoses to consider include prolonged immobilization, milk-alkali syndrome (particular in postmenopausal women), granulomatous disease (tuberculosis), acromegaly, pheochromocytoma, adrenal insufficiency, or lymphoma (Shane, 2020).

Treatment: Treatment depends on the patient's goals of care, longevity, functional capacity, and the disease-related etiology and sequelae (Galassi et al., 2019).

Hyperparathyroidism can create a significant disruption in quality of life. Discuss all options and expected outcomes with all patients.

Primary Hyperparathyroidism: The standard of care to manage primary hyperparathyroidism to achieve cure is surgical removal (Kuo et al., 2019; Perrier et al., 2020; Wilhelm et al., 2016). However, this standard is less clear in older patients over the age of 85 (O'Sullivan et al., 2021; Sluis et al., 2019).

© F.A. Davis Publishing

Benefits of parathyroidectomy include advantages in survival, increased bone density, reduced fatigue, and improve subjective measures (Sluis et al., 2019). Criteria for parathyroidectomy to resolve primary hyperparathyroidism are age <50 years, serum calcium >11.3 mg/dL, T-score ≤–2.5 at any site (normal ≥–1), 24-hour urine calcium >400 mg (reference ≤300 mg/24 hr), or nephrolithiasis (likely calcium based). Additional indications for parathyroidectomy include fracture or other neurocognitive, GI, or cardiovascular sequelae of primary hyperparathyroidism (Kuo et al., 2019; Perrier et al., 2020; Wilhelm et al., 2016). Bone hunger syndrome and transient hypoparathyroidism are expected sequelae post-parathyroidectomy (Milas, 2020). Calcium supplementation is based on the elemental calcium in supplements (Kuo et al., 2019).

Medical management may include isotonic saline hydration therapy to increase calcium excretion, a calcium-sensing receptor agonist to reduce PTH (indicated for parathyroid carcinoma, secondary hyperparathyroidism in CKD), loop diuretics (judiciously), and glucocorticoids (decreases intestinal absorption), bisphosphonates (inhibit bone resorption) depending upon renal function, tolerability, and comorbid conditions (Sluis et al., 2019; Tinawi, 2021).

Secondary Hyperparathyroidism Due to Chronic Kidney Disease: Chronic kidney disease mineral and bone disorder (CKD-MBD) encompasses abnormalities in biochemicals (i.e., calcium, PTH, phosphate, and vitamin D). The approach to management is driven by the estimated glomerular filtration rate. The risk of hypercalcemia is greater than mild and symptomatic hypocalcemia; therefore, correction of vitamin D deficiency and hyperphosphatemia may be of benefit (Quarles & Berkoben, 2020). Those with end-stage renal disease (ESRD) who are symptomatic with markedly elevated PTH levels with symptoms that are recalcitrant to medical management should be referred for surgical consult. Preoperative hypocalcemia is a contraindication to surgery (Milas, 2020). Postoperatively, ESRD patients are more likely to develop transient hypocalcemia after parathyroid surgery due to hungry bone syndrome (Milas, 2020).

The prognosis for a cure of hyperparathyroidism with traditional bilateral neck exploration is more than 95%, with complication rates less than 3% (Wolfe & Sharma, 2021).

Follow-Up: Nurse practitioners are critical to appropriate and prompt diagnosis, evaluation, and management of older adults with calcium disorders. Follow-up is dependent upon therapeutic intervention (surgery versus nonsurgical management), changes made in the treatment plan, response to treatment, specialist involvement (with the primary care provider as the team leader and gatekeeper), and clinical judgment based on medical necessity. Order DEXA scan, PTH with calcium (together), measurement of renal function, intestinal resorption (24-hour urine calcium), and vitamin D every 3 to 6 months or based on medical necessity long term to monitor homeostatic stability and response to treatment.

Sequelae: Sustained elevation in PTH can cause high-turnover bone disease, fracture, hypercalcemia, osteitis fibrosa, nephrolithiasis, and hyperphosphatemia. Postsurgical risk includes hungry bone syndrome, infection, vocal cord dysfunction (rare), constipation, and transient hypocalcemia requiring aggressive calcium supplementation. Stool softeners or fiber laxatives are critical to prevent constipation from calcium supplement (Kuo et al., 2019; Wilhelm et al., 2016).

Prevention/Prophylaxis: Review diet, prescription and nonprescription medications, herbal preparations, calcium intake, and vitamin supplements to assess for milk-alkali syndrome and drug-induced hypercalcemia.

Referral: Refer to an endocrinology surgical specialist trained in parathyroidectomy if surgery is indicated and desired. A team approach including endocrinology and nephrology is indicated for these patients and those who choose conservative management and have concomitant kidney disease.

Education: Patients should be advised of the risk and benefit of all treatment options and included in the decision making process. Instruction about the complications associated with each decision (surgical or nonsurgical) should be provided in lay language verbally and in written format with family members present so the information can be reinforced.

With the exception of patients with contraindications due to ESRD or other comorbid condition, routine postsurgery care will include patient education on pain and its management, incision care, potential complications, and postoperative medications.

Medications: Anticoagulant and antiplatelet therapy resumption is under the surgeon's discretion. Calcium supplements (2,000 mg of Tums Ultra three times a day) will be needed for 1 week post-surgery. Calcium will be continued at 1,000 mg dosage three times a day. Additional calcium may be needed if symptoms of hypocalcemia develop. Daily cholecalciferol 2,000 IU is recommended (Milas et al., 2021). Concomitant vitamin D deficiency should be corrected slowly post parathyroidectomy (Milas et al., 2021; Perrier et al., 2020).

DIABETES MELLITUS, TYPES 1 AND 2

Signal Symptoms: Anorexia, paresthesias, proteinuria, chronic skin infections, blurred vision, nausea, gastroparesis, yeast vaginitis, impotence, fatigue, weight loss or gain, polydipsia, polyuria, polyphagia.

Description: Diabetes mellitus is a chronic state of hyperglycemia that is divided primarily into two types: type 1 and type 2. Formerly, type 1 diabetes was called *juvenile diabetes or insulin-dependent diabetes.* There are two subtypes of type 1 diabetes that have a slower onset: latent autoimmune diabetes of the adult (LADA) and latent autoimmune diabetes of the young (LADY). LADY will not be discussed in this text but is considered as a similar disease entity as LADA but occurring in the younger patient.

Type 2 diabetes was formerly called *adult-onset diabetes or non–insulin-dependent diabetes,* primarily to signify the age of onset of disease and whether insulin therapy was the required treatment. Diabetes in the older adult is increasing in prevalence—mostly due to increased life expectancy (Sesti et al., 2017). With the general population living longer, risk for diabetes goes up for many, including multi-organ functional alterations, impaired function of insulin secreting beta cells, impaired insulin sensitivity, age-related variations in body composition including a reduction in fat-free mass such as muscle, bone, and water, as well as functional impairments (Sesti et al., 2017). This combination of normal changes with aging and lack of typical presentation results in the underdiagnosis of diabetes in the older adult.

Etiology: Type 1 diabetes most often occurs in childhood. It is characterized by low or absent levels of insulin, often resulting from an autoimmune response leading to pancreatic beta cell antibodies. Individuals with type 1 diabetes require insulin therapy for survival. Type 2 diabetes usually occurs in adulthood and is thought to be the result of insulin resistance and deficiency. This early understanding of diabetes has been expanded by the discovery of other hormones involved in the regulation of glucose, including insulin, glucagon, amylin, and incretin hormones. These discoveries have resulted in new classes of medications to treat diabetes. Genetic predisposition for developing diabetes is more evident in type 2 diabetes. Hyperglycemic states that have not reached levels that warrant a type 2 diabetes diagnosis are identified as impaired glucose tolerance. Evidence indicates that individuals with impaired glucose tolerance have an increased risk of developing type 2 diabetes within 5 to 10 years of onset.

LADA accounts for 2% to 12% of all patients with diabetes (Buzzetti et al., 2020). LADA has features of both type 1 and type 2 diabetes and has considerable variability; however, because of its autoimmune nature it is considered a part of the type 1 diabetes spectrum with slow but variable beta cell failure (Buzzetti et al., 2020).

© F.A. Davis Publishing

Occurrence: According to the Centers for Disease Control and Prevention (CDC, 2020), it is estimated that 34.2 million people in the United States, or approximately 10.5% of the population, have diabetes, and of those, 7.3 million people (21.4% are undiagnosed). Type 1 diabetes is only about 5% to 10% of that total. There are 88 million people older than the age of 18 in the United States with prediabetes, which is 34.5% of the total adult population. Of those, 24.2 million are 65 years of age or older. Type 1 diabetes and LADA affect men and women equally. Type 2 diabetes affects men more commonly than women.

Age: The onset of type 1 diabetes usually occurs in childhood, with the major incidence of disease occurring in individuals younger than 30 years old. Onset of LADA occurs after age 30 years (Buzzetti et al., 2020). The onset of type 2 diabetes usually occurs after age 40 years, with a mean age of 51 years. Age, however, cannot be the only factor used to determine the classification of diabetes because type 1, LADA, or type 2 diabetes can occur at any age.

Ethnicity: Type 1 diabetes primarily affects individuals who are White. LADA is reported more frequently in individuals of northern European and Chinese descent, compared with African American and Hispanic individuals (Buzzetti et al., 2020). Native Americans and Alaskan Natives have the highest prevalence of type 2 diabetes for both men and women, with non-Hispanic African Americans and Hispanics next, followed by Whites and Asian Americans.

Contributing Factors: Although the exact causes of type 1 diabetes and LADA are unknown, they have been linked to environmental, autoimmune, and viral toxins. A predisposition for acquiring type 1 diabetes has not been identified. Contributing factors for the development of type 2 diabetes have strongly been associated with obesity, sedentary lifestyle, and familial history. The following risk factors have been identified as significantly increasing an individual's risk of developing type 2 diabetes: age 45 years and older, a positive family history (parents or siblings with diabetes), hyperlipidemia, a history of gestational diabetes, obesity (body mass index [BMI] greater than or equal to 25 kg/m^2), smoking, physical inactivity (exercising less than 150 minutes per week, spread over 3 days [American Diabetes Association (ADA), 2021]), high blood pressure (greater than 140/90 mm Hg,), and a history of impaired fasting glucose or impaired glucose tolerance.

There is a known association between the use of statin drugs and increased insulin resistance and progression to diabetes (Mansi et al., 2021). High-potency statins are particularly diabetogenic, causing insulin insensitivity and decreased insulin secretion. Pravastatin is the least diabetogenic statin. The value of statins' ability to decrease the risk of cardiovascular disease outweighs the risk of developing diabetes, but it does provide another indication for vigilant monitoring for the development of diabetes. The greater number of risk factors present increases the risk of development of the disease.

Signs and Symptoms: Among adults 40 years and older, diabetes often is discovered as an incidental finding during the work-up for cardiovascular, renal, neurological, or infectious diseases. The primary presentation may be due to complications of underlying and undiagnosed hyperglycemia in conditions such as stroke, myocardial infarction (MI) and ischemia, intermittent claudication, impotence, peripheral neuropathy, proteinuria, retinopathy, slow wound healing, or fatigue. Often the classic symptoms of polyuria, polydipsia, and polyphagia with weight loss are attributed to other disease entities and overlooked among older adults. The classic triad may be absent entirely due to an impaired thirst mechanism and an increased renal threshold for glucose. Screening is recommended for adults of any age who are overweight and present with any of the additional risk factors (ADA, 2021). Screening should begin for the general population at 45 years old and be repeated at 3-year intervals. More frequent and earlier screening is recommended for individuals with several risk factors.

The determination of whether the diabetes is type 1, LADA, or type 2 is based on a variety of characteristics to include age of onset, serum markers of autoimmunity and beta cell function, and BMI. The most definitive diagnostic tools available to distinguish between them include the use of antibody testing and testing C-peptide levels. In terms of antibody testing, glutamic acid decarboxylase antibody (GADA) is considered the most sensitive marker of autoimmune type 1 diabetes and LADA, with approximately 90% of patients with type 1 diabetes and LADA being positive (Buzzetti et al., 2020). Antibodies to islet cells and beta cells are present in 70% to 80% of individuals with type 1 diabetes. In terms of beta cell function, C-peptide is a by-product of insulin production, and extremely low levels are consistent with type 1 diabetes. Type 2 diabetes primarily occurs in individuals who are 40 years and older, and have a BMI of more than 27, as well as preservation of beta cell function (albeit with some decline). Beta cell function should be quantified anytime a diagnosis of diabetes is made and needs to be repeated and monitored because it can vary with disease progression. C-peptide should be checked with any significant loss of glycemic control or any development of ketonemia.

Diagnostic Tests: The criterion for the diagnosis of diabetes is either two fasting blood glucose readings with results greater than or equal to 126 mg/dL or a random blood glucose reading greater than or equal to 200 mg/dL if symptoms of diabetes are present. In many people older than the age of 60, diabetes and prediabetes is not diagnosed unless an oral glucose tolerance test (OGTT) is performed (LeRoith & Halter, 2020). This is due in part to the physiological changes in glucose regulation that occur as a result of aging (Lodhi, 2021). Therefore, diabetes will be diagnosed sooner with the OGTT than with fasting glucose alone. Hemoglobin A1c (Hb A1c) measurement greater than or equal to 6.5 is indicative of type 2 diabetes (ADA, 2021). In the absence of unequivocal disease, the same test should be repeated at least once; so, for example, if the Hb A1c is greater than or equal to 6.5, a second Hb A1c result should be compared rather than comparing it to a fasting glucose level (ADA, 2021). An advantage of using the Hb A1c is that fasting is not required and it is less effected by day-to-day issues in the patient, such as illness or stress. An individual with a casual plasma glucose level greater than or equal to 200 mg/dL, but without symptoms, should have fasting plasma glucose, 2-hour OGTT, or Hb A1c measured. Fasting is defined as no caloric intake for at least 8 hours. Parameters for the estimated average glucose levels based on Hb A1c levels can be found in Table 18-1.

When hyperglycemia has been established, C-peptide levels and GAD antibodies will help to differentiate between

type 1 and type 2 diabetes. C-peptide levels can vary. At the onset of type 1 diabetes, there may be some lingering beta cell function, thus C-peptide alone is not enough to help make the diagnosis; GAD antibodies should also be measured. After about 1 year those with type 1 diabetes will usually have undetectable C-peptide levels as beta cell function declines. This process often takes much longer in LADA. With type 2 diabetes, varying levels of C-peptide are usually detectable throughout the disease.

Differential Diagnosis:

- Drug toxicity and endocrine disorders that may affect glucose tolerance, interfere with insulin secretion, and induce insulin resistance.
- Drugs associated with hyperglycemia include alcohol, beta-adrenergic agents, calcium channel blockers, corticosteroids, lithium salts, rifampin, asparaginase, diazoxide, diuretics, glycerol, niacin, phenytoin, and sympathomimetics.
- Drugs associated with hypoglycemia include anabolic steroids, beta-adrenergic blockers, chloroquine, disopyramide, pentamidine, salicylates, warfarin, ethanol, and sulfonamides.
- Endocrine disorders that may induce hyperglycemia include Cushing's syndrome, glucagonoma, acromegaly, and pheochromocytoma.

Treatment: The goal of treatment for patients with type 2 diabetes is good glycemic control, good nutritional status with weight management, and exercise. Evidence shows that patients with type 2 diabetes benefit from maintaining near-normal glucose levels. The 2021 ADA Diabetes Standards of Care outline recommendations for glucose control, blood pressure goals, cholesterol goals, and recommendations for screening for both microvascular and macrovascular complications. They recommend patient-centered care plans with individualized goals based on several factors, including duration of diabetes, age/life expectancy, comorbid conditions, known cardiovascular disease (CVD) or advanced microvascular complications, hypoglycemia unawareness, and individual patient considerations. The specific framework that the ADA utilizes is broken up into three categories based on the presence of chronic illnesses and functional status: healthy, complex/intermediate, and very complex/poor health. For example, fasting values vary from 80 to 130 and an Hb A1c target of 7% to 7.5% for the healthy older adult to a fasting value of 100 to 180 and avoiding reliance on the Hb A1c for clinical judgment and instead making decisions based on prevention of hypoglycemia and symptomatic hyperglycemia in those with very complex/poor health (Table 18-2). These new guidelines are based in part on the data from the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study, which concluded that the risk of hypoglycemia and the morbidity resulting from those episodes may outweigh the benefits of tighter control. Aggressive glycemic control that compromises functional independence and quality of life and increases the risk of hypoglycemic episodes would be counterproductive.

The 2021 ADA recommendations focus on patient-centered care plans that include head-to-head trials of antihyperglycemic agents. Treatment goals and the choice of agent to reach those goals should be made after a careful assessment of the patient's health beliefs, comorbidities, life expectancy, cognitive function, functional status, economic situation, and availability of support services.

Nonpharmacological Treatment: Nonpharmacological therapy is recommended as first-line therapy for newly diagnosed type 2 diabetes with mild-to-moderate hyperglycemia. Lifestyle modifications of weight loss and exercise are particularly important in lowering Hb A1c. Although weight loss in frail older adults is not recommended due to the risk of sarcopenia, exercise of even a modest nature can be beneficial in decreasing insulin resistance. If after 3 to 6 months nonpharmacological treatment fails or the hyperglycemia is severe (fasting plasma glucose 200 to 300 mg/dL or casual plasma glucose 250 to 350 mg/dL), oral agents may be added to the treatment regimen. Metformin is also recommended for prevention or delay of type 2 diabetes in patients with a BMI greater than or equal to 35 kg/m^2 or anyone with a history of gestational diabetes or patients with a rising Hb A1c despite lifestyle modifications (ADA, 2021).

Pharmacological Treatment: Pharmacological treatment options for diabetes include oral agents and injectable agents. There are now seven classes of oral glucose-lowering agents: biguanides, sulfonylureas, meglitinides, thiazolidinediones, dipeptidyl peptidase-4 (DPP-4) inhibitors, alpha-glucosidase inhibitors, sodium-glucose cotransporter 2 (SGLT2) inhibitors, and one oral preparation of a glucagon-like peptide–1 (GLP-1) receptor agonist. Other oral agents that may be used in the management of type 2 diabetes include the bile acid sequestrant and the dopamine-2 agonist. Injectable agents include insulin and the GLP-1 receptor agonists.

Oral Agents: Metformin (Glucophage, Glucophage XR) is a biguanide that acts by decreasing hepatic glucose production, decreasing glucose intestinal absorption, and increasing insulin sensitivity. It is considered first-line therapy in treating type 2 diabetes and may be initiated with lifestyle changes in many individuals (ADA, 2021). This agent generally does not increase endogenous insulin production and has few hypoglycemic effects. In addition to glucose control with improved Hb A1c of 1% to 2%, patients may lose weight and improve lipid profiles.

TABLE 18-2 **Framework for Considering Treatment Goals for Glycemia, Blood Pressure, and Dyslipidemia in Older Adults With Diabetes**

PATIENT CHARACTERISTICS/ HEALTH STATUS	RATIONALE	REASONABLE A1c GOAL‡	FASTING OR PREPRANDIAL GLUCOSE	BEDTIME GLUCOSE	BLOOD PRESSURE	LIPIDS
Healthy (few coexisting chronic illnesses, intact cognitive and functional status)	Longer remaining life expectancy	<7.0–7.5% (53–58 mmol/mol)	80–130 mg/dL (4.4–7.2 mmol/L)	80–180 mg/dL (4.4–10.0 mmol/L	<140/90 mm Hg	Statin unless contraindicated or not tolerated
Complex/intermediate (multiple coexisting chronic illnesses* or 2+ instrumental ADL impairments or mild-to-moderate cognitive impairment)	Intermediate remaining life expectancy, high treatment burden, hypoglycemia vulnerability, fall risk	<8.0% (64 mmol/mol)	90–150 mg/dL (5.0–8.3 mmol/L)	100–180 mg/dL (5.6–10.0 mmol/L)	<140/90 mm Hg	Statin unless contraindicated or not tolerated
Very complex/poor health (LTC or end-stage chronic illnesses** or moderate-to-severe cognitive impairment or 2+ ADL impairments)	Limited remaining life expectancy makes benefit uncertain	Avoid reliance on A1c; glucose control decisions should be based on avoiding hypoglycemia and symptomatic hyperglycemia	100–180 mg/dL (5.6–10.0 mmol/L)	110–200 mg/dL (6.1–11.1 mmol/L)	<150/90 mm Hg	Consider likelihood of benefit with statin

This table represents a consensus framework for considering glycemic treatment and treatment goals for glycemia, blood pressure, and dyslipidemia in older adults with diabetes. The patient characteristic categories are general concepts. Not every patient will clearly fall into a particular category. Consideration of patient and caregiver preferences is an important aspect of treatment individualization. Additionally, a patient's health status and preferences may change over time. ADL, activities of daily living; LTC, long-term care.

‡A lower A1c goal may be set for an individual if achievable without recurrent or severe hypoglycemia or undue treatment burden.

**Coexisting chronic illnesses are conditions serious enough to require medications or lifestyle management and may include arthritis, cancer, heart failure, depression, emphysema, falls, hypertension, incontinence, stage 3 or worse chronic kidney disease, myocardial infarction, and stroke.*

*** The presence of a single end-stage chronic illness, such as stages 3–4 heart failure or oxygen-dependent lung disease, chronic kidney disease requiring dialysis, or uncontrolled metastatic cancer, may cause significant symptoms or impairment of functional status and significantly reduce life expectancy.*

Side effects include nausea, vomiting, diarrhea, abdominal pain, anorexia, and taste disturbances.

A rare but potentially life-threatening reaction is the development of lactic acidosis. Metformin is contraindicated in patients with renal insufficiency because the risk of lactic acidosis is increased in these patients as metformin depends on adequate renal function for clearance from the body. Although uncommon, lactic acidosis has a very high mortality rate. The estimated glomerular filtration rate (eGFR) at which metformin was contraindicated had been less than 60, but recent recommendations are that it may be used safely in patients with estimated glomerular filtration rate ≥30 mL/min/1.73 m (ADA, 2021). In hospitalized patients at risk for acute or chronic renal insufficiency, consider holding metformin. Other contraindications include hepatic insufficiency, heart failure, and alcohol abuse.

Care should be taken when patients who are taking metformin undergo IV contrast studies. It is important to withhold the medication for 1 to 2 days after the contrast agent has been administered to ensure normal renal function. Usually, metformin is started at 500 mg once a day, given before the evening meal, and increased gradually to a maximum dose of 2,000 mg daily in the older adult. This slow uptitration can minimize gastrointestinal (GI) side effects that can result in patient intolerance. When given with food, the GI side effects tend to be decreased and absorption is increased. An extended-release formulation is available and may be very useful for increasing adherence to therapy and decreasing side effects. When switching from regular release to extended-release metformin, the total daily dose should remain the same. For some patients on 2,000 mg of extended release a day, dividing the dose into two 1,000 mg tablets may be more effective.

Sulfonylureas are insulin secretagogues and act by increasing pancreatic insulin secretion. They tend to lower Hb A1c by 1% to 2% (Cornell, 2014). The second generation sulfonylureas include glipizide (Glucotrol, Glucotrol XL), glimepiride (Amaryl), and glyburide (DiaBeta, Micronase, Glynase). All of these preparations with the exception of glipizide are on the *Beers List: Potentially Inappropriate Drugs for Elderly* and, along with the first generation agents (chlorpropamide, tolazamide, and tolbutamide), should be avoided. They may be continued only in patients who are already adequately controlled on those medications and not experiencing side effects. Because sulfonylureas are renally cleared and renal function declines with aging, an increase of the level of sulfonylurea in the blood may result in an increased risk of hypoglycemia. If sulfonylureas are used, the preferred choice would be glipizide because it has the shortest half-life. Side effects of this class of medications include weight gain, nausea, hypoglycemia, weakness, and photosensitivity. These agents should not be used in patients who have had diabetic ketoacidosis and caution should be exercised in patients who are allergic to sulfonamides. The starting dose depends on the particular drug but should be initiated at the lowest possible dose and increased as tolerated.

Meglitinides are another class of insulin secretagogues and include nateglinide (Starlix) and repaglinide (Prandin). They act quickly to increase the endogenous release of insulin from the pancreas and must be taken 1 to 30 minutes before a meal, typically three times a day. They have less effect on Hb A1c than sulfonylureas, with about a 1% reduction (Cornell, 2014). Though frequent dosing may be seen as a drawback, it can be an advantage in patients with irregular eating habits when the medications are not taken if a meal is skipped. Side effects include hypoglycemia, headache, upper respiratory infection, nausea, vomiting, constipation, diarrhea, muscle aches, and chest pain. Repaglinide is metabolized by the liver, with less than 10% renally excreted, and does not need dose adjustment in renal insufficiency. It is also somewhat better in lowering Hb A1c than nateglinide, so repaglinide can be initial therapy in patients who are not candidates for metformin or sulfonylureas. All insulin secretagogues should be used with caution in those with hepatic insufficiency.

Thiazolidinediones (TZDs), which include pioglitazone (Actos) and rosiglitazone (Avandia), are insulin sensitizers. They act by increasing sensitivity to insulin by acting on adipose, muscle, and liver to increase glucose utilization and decrease hepatic glucose production. TZDs have a favorable effect on lipids and can improve beta cell function. They reduce Hb A1c by 1% to 1.5% (Cornell, 2014). Side effects include headache, weight gain, edema, and anemia. TZDs should not be used in patients with heart failure, bladder cancer, osteoporosis, or liver disease. Serious reactions include liver toxicity and worsening heart failure. Liver function tests should be performed prior to initiation and periodically after that. TZDs have a very slow onset of action. Initial effects are noted in 2 weeks, but as monotherapy the maximum effect is not seen for 10 to 16 weeks.

Dipeptidyl peptidase-4 (DPP-4) inhibitors include sitagliptin (Januvia), linagliptin (Tradjenta), saxagliptin (Onglyza), and alogliptin (Nesina). All are once-daily oral medications that help the body reduce its own blood sugar levels. They have a unique action by inhibiting the enzyme DPP-4, which breaks down GLP-1, thereby increasing the bioavailability of GLP-1. GLP-1 is secreted by the small intestinal L cell, and it is a potent anti-hyperglycemic hormone that works by glucose-dependent insulin stimulation (so the risk of hypoglycemia is low). It also suppresses inappropriate glucagon secretion, slows gastric emptying, and reduces food intake. DPP-4 inhibitors also improve beta cell function. Hb A1c reduction is comparable to that of sulfonylureas and TZDs (Cornell, 2014). When used as monotherapy, DPP-4 inhibitors have a low risk of hypoglycemia but may increase the risk of hypoglycemia when used with sulfonylureas. Side effects of DPP-4 inhibitors include upper respiratory tract infection, nasopharyngitis, and headache. Dose reduction in patients with moderate to severe renal insufficiency is required for all DPP-4 inhibitors except linagliptin, and they should not be used in patients with a history of pancreatitis.

The alpha-glucosidase inhibitors acarbose (Precose) and miglitol (Glyset) act to decrease or delay glucose absorption and lower blood glucose levels. Serum triglycerides tend to be lowered also, and this may be their greatest benefit. Side effects include flatulence, diarrhea, abdominal pain, and rash. Both are dosed three times a day and should be taken with the first bite of each meal. This class of medications is contraindicated in patients who have had ketoacidosis, inflammatory bowel disease, intestinal obstruction, or renal impairment. The primary side effect of these medications is flatulence and patients' lack of tolerance to this side effect results in this class rarely being used. There is only a minor reduction in Hb A1c, 0.8%, which further contributes to their minor clinical usefulness.

© F.A. Davis Publishing

The newest addition to the oral options is the SGLT2 inhibitors, dapagliflozin (Forxiga), canagliflozin (Invokana), empagliflozin (Jardiance), and ertugliflozin (Steglatro). They block glucose reabsorption in the proximal renal tubule by inhibiting the action of SGLT2, which reduces glucose reabsorption and increases urinary glucose excretion. The action of SGLT2 inhibitors is not dependent on insulin and has a modest effect on glucose lowering (ADA, 2021). Specific to the brand Invokana (canagliflozin) is a black box warning regarding a twofold increase of leg and foot amputation in those patients with type 2 diabetes and established cardiovascular disease. Risk factors include prior amputation, history of peripheral vascular disease, neuropathy, and history of diabetic foot ulcers. The recommendation is to monitor patients at risk for infection, new pain or tenderness, and sores or ulcers on lower extremities.

The choice of an appropriate oral agent is a complex clinical decision. The SGLT2 inhibitors empagliflozin, canagliflozin, and dapagliflozin have also demonstrated benefit for cardiorenal outcomes, especially for heart failure hospitalization, risk of kidney disease progression, and mortality (ADA, 2021). When compared with placebo, the GLP-1 receptor agonists liraglutide, semaglutide, and dulaglutide demonstrated favorable atherosclerotic cardiovascular and renal outcomes (ADA, 2021). These benefits were found serendipitously when certain agents were being tested for cardiovascular effects as a standard set forth by the FDA for all diabetic drugs. In 2008, the U.S. Food and Drug Administration added long-term cardiovascular outcomes trials as another safety step in the approval process for diabetes agents because of the possible adverse cardiovascular effects of some diabetes drugs that came to light well after they had been approved (Seaborg, 2020).

Based on these findings, the American Diabetes Association Standards of Medical Care (2021) recommend that patients with type 2 diabetes who have established atherosclerotic cardiovascular disease or indicators of high risk, established kidney disease, or heart failure include a sodium-glucose cotransporter 2 inhibitor or glucagon-like peptide 1 receptor agonist with demonstrated cardiovascular disease benefit as part of the glucose-lowering regimen independent of A1c and in consideration of patient-specific factors (ADA, 2021). Other considerations for selection of agents include the severity of the hyperglycemia and the need for Hb A1c reduction. The newest guidelines specifically indicate that a biguanide (metformin) should be the first-line agent; however, if atherosclerotic heart disease, heart failure, or chronic kidney disease exists—independent of A1c, A1c target, or metformin use—an SGLT2 inhibitor or GLP-1 agonist should be initiated (ADA, 2021).

If there are contraindications to the use of metformin, GLP-1 RA, or SGLT2-inhibitors, a sulfonylurea could be an alternative, keeping in mind that it carries the risk of hypoglycemia and often results in weight gain. DPP-4 inhibitors are another possibility for initial treatment with a similar effect on Hb A1c to that of sulfonylureas without the risk of hypoglycemia, but they are expensive. The newest agents, SGLT2 inhibitors, are also approved for monotherapy, but are also expensive and have less effect on Hb A1c. If monotherapy with any of these agents is unsuccessful after 3 months, combination therapy with metformin, sulfonylurea, thiazolidinedione, DPP-4 inhibitors, SGLT2 inhibitors, GLP-1 receptor agonists, or basal insulin should be considered. If irregular meals are an issue, adding a meglitinide to either metformin or a DPP-4 inhibitor, or an SGLT2 inhibitor may be a reasonable option. The injectable glucagon-like peptide–1 (GLP-1) receptor agonists are non-insulin options for combination therapy and have a side benefit of weight loss as well as the cardiorenal benefits mentioned above. Insulin therapy is a reasonable choice at any point in the patient diagnosed with type 2 diabetes, but it is usually reserved as second-line therapy when combination therapy fails. Insulin therapy may be required either as a single agent or in addition to a sulfonylurea, metformin, DPP-4 inhibitor, SGLT2 inhibitor or GLP-1 agonist.

Injectables: Glucagon-like peptide–1 (GLP-1) receptor agonists are within the drug class called incretins. Those available in the United States include exenatide (Byetta), liraglutide (Victoza), lixisenatide (Lyxumia), albiglutide (Tanzeum), dulaglutide (Trulicity), and semaglutide (Ozempic). Unlike endogenous GLP-1, these medications are resistant to degradation by the DPP-4 enzyme and have a longer half-life than endogenous GLP-1. These medications are effective in reducing glucose levels, as well as inducing weight loss, and also have the added benefit of improving cardiovascular and renal outcomes as outlined above. They can lower Hb A1c by 0.5% to 1.5% and can induce weight loss of 2% to 5%. They may also be prescribed for patients with impaired fasting glucose to delay the onset of type 2 diabetes. Side effects include nausea and a feeling of fullness that may dissipate after a few weeks of treatment. Other common side effects include hypoglycemia when used with sulfonylureas or insulin, vomiting, diarrhea, headache, nervousness, and stomach discomfort. Patients may also experience decreased appetite, acid reflux, and increased sweating. GLP-1 agonists are contraindicated for use in type 1 diabetes and patients with a history of diabetic ketoacidosis. A black box warning exists for patients with medullary thyroid carcinoma or a family history of that disease or with multiple endocrine neoplasia syndrome type 2 (MEN2). GLP-1 agonists should be used with caution in patients with a history of pancreatitis or gastroparesis. All of these drugs are expensive, but the benefits may outweigh the cost.

Insulin Therapy

After many years of having type 2 diabetes, almost all patients will require insulin therapy due to the decline of beta cells in the pancreas and endogenous insulin supply. The body's normal production of insulin is biphasic, with about one-half slowly released around the clock to suppress glucagon release from the liver between meals and while we sleep, and one-half released in response to a rise in blood sugar after food intake. Insulins are the most natural agents and are always effective in lowering blood sugar. They all work alike; the difference is in the onset and duration of action. Insulin therapy may be added when optimal glycemic control is not achieved with an oral regimen or the addition of a GLP-1 agonist.

Every patient with type 2 diabetes needs to understand that the longer they live with diabetes the more likely it is that they will need to use insulin. The ADA Standards of Medical Care in Diabetes 2021 emphasize the importance of introducing the role of insulin from the beginning to avoid the implication that insulin is punishment for poor diabetic

© F.A. Davis Publishing

control. Insulin should always be used as first-line therapy in type 1 diabetes or with patients who have had diabetic ketoacidosis. A variety of regimens are used in the administration of insulin based on the time of onset of action, time of peak effects, and the duration of action. Currently, the most frequently used regimen is the basal/bolus insulin concept. This reflects the body's physiological insulin response. Basal insulins have an intermediate to long duration of action, whereas bolus insulins, which are immediate or rapid in their action, provide postprandial coverage.

Basal Insulins: Basal insulins suppress glucose production between meals and overnight and provide nearly constant levels of insulin. Basal insulin includes the intermediate-acting insulin, neutral protein Hagedorn (NPH); long-acting insulins, glargine (Lantus, Toujeo, Basaglar) and insulin detemir (Levemir); and ultra-long-acting insulin, degludec (Tresiba). Head-to-head studies comparing insulin glargine to NPH found a higher incidence of hypoglycemia and increased weight gain with the NPH (Owens et al., 2017). Administration of insulin glargine and detemir in the morning had even less incidence of nighttime hypoglycemia. Whereas NPH insulin has a distinct peak of action at 4 to 12 hours, insulin glargine and detemir are considered to have no peak. NPH and insulin detemir both may be dosed twice a day.

Bolus Insulins: Mealtime bolus insulins include regular human insulin and the analogues aspart (NovoLog), glulisine (Apidra), or lispro (Humalog). Regular insulin is considered fast acting, with an onset and duration of action that exceeds that of the analogues. It is given 30 minutes before eating and has a peak in 2 to 4 hours. The analogues are considered immediate acting, with an onset within 15 minutes and a peak in 1 to 2 hours. The analogues should not be given until the person is eating and may be given immediately after a meal if the injection was forgotten. Bolus insulins have the advantage of being adaptable to the day. Less can be given if the person is exercising after a meal, and they may not be given at all if a meal will be missed. It is important to understand how to adjust the dose of bolus insulin. It is not sliding scale adjusted in response to the pre-prandial glucose of the meal that is about to be consumed, but rather it should be adjusted based on the preprandial glucose of the next meal (so the dose given at breakfast would be changed based on the lunchtime pre-prandial glucose).

Premixed insulin combinations of long- and short-acting insulins are available and offer less control but more convenience than the basal/bolus concept. A classic mixture has been the combination of NPH and regular insulin 70/30, with the NPH being 70% and Regular being 30% of that mixture. By adding protamine to insulin aspart or insulin lispro, the release of those insulins is delayed. Humalog mix is the delayed-acting insulin lispro protamine and the immediate-acting lispro and is available as 50/50 or 75/25. The protamine lispro is 75% of that mixture and the immediate-acting lispro is 25%. Novolog mix 70/30 is the delayed-acting insulin aspart protamine with the immediate-acting aspart. The insulin protamine aspart is the 70% and the immediate-acting aspart is 30% of that solution. These mixtures are often dosed twice a day before breakfast and again before dinner.

Although the ability to control mealtime spikes in blood glucose is decreased with these split mixed insulins, the fact that fewer injections are required may be more agreeable to the patient. The participation of the patient in decision making is an essential part of individualized care. To further improve convenience of administration, insulin pens are available for all of these mixtures. Insulin pens are not self-explanatory, however, and taking the time to demonstrate their use with the patient returning the demonstration is essential for accurate insulin administration. Insulin pumps are available and most often used for type 1 diabetes. Documentation of very low C-peptide levels is often required for coverage of insulin pumps by insurance companies. The types of insulin, their onset, peak, and the duration of action and how the insulin is normally used are delineated in Table 18-3.

The frequency and timing of self-monitoring of blood glucose levels (SMBGs) need to be individualized based on several factors, including age, ability to adhere, and oral versus insulin therapies. SMBG aids in promoting glycemic control and reinforcing adherence to therapy. Even patients maintaining glucose levels by nonpharmacological means may benefit from intermittent SMBG either postprandial or fasting. Patients requiring oral medications who are capable of SMBG should test glucose levels two to three times per week, preferably alternating before breakfast, the evening meal, and at bedtime, as well as an occasional 2-hour postprandial measurements. Patients receiving insulin therapy should perform SMBG at least two to three times daily. For all patients with diabetes, SMBG monitoring should increase during illness, changes in diet and exercise, or a change in medications.

Follow-Up: Patients with diabetes should be scheduled for appropriate follow-up to evaluate response, tolerability to therapy, goal reassessment, and management of acute and chronic complications. Response to treatment is judged based on home glucose monitoring results and Hb A1c. The Hb A1c reflects the average control over the past 3 months and is not useful for judging the response to recent treatment adjustments. Older patients and patients on insulin therapy may need to be seen every 3 months. When there is a sudden change in health status or treatment regimen, follow-up of 1 month or less may be indicated. For stable patients who are able to maintain treatment goals, follow-up may be every 3 to 6 months.

The following evaluations are recommended at follow-up visits: blood pressure, review records of home glucose monitoring, review of medications, examination of the feet for complications, annual eye examination including dilation of pupils and inspection of retina and eye grounds, routine urinalysis including evaluation for albuminuria and albumin to creatinine ratio, serum creatinine levels and eGFR, annual electrocardiogram and fasting lipid profile, Hb A1c every 3 to 6 months, evaluation for neurovascular complications, self-management education, immunization update including influenza and pneumococcal vaccines, and a biannual oral examination. A special nutritional benefit is available from Medicare for patients with diabetes and should be taken advantage of yearly. Medicare also covers the yearly ophthalmological examination for patients with diabetes.

Sequelae: Acute complications requiring immediate attention include diabetic ketoacidosis, recurring fasting hyperglycemia of greater than 300 mg/dL, Hb A1c of greater than 13%, or severe hypoglycemia with changes in sensorium, altered behavior, seizures, or coma. Complications resulting from

TABLE 18-3 Insulin Types—Onset, Peak, Duration of Action, and Typical Use

TYPE OF INSULIN (INCLUDES BRAND NAMES)	ONSET OF ACTION	PEAK ACTION	DURATION OF ACTION	ROLE OF INSULIN IN MEAL PLANS
Rapid Acting				
Lispro (Humalog)	15–30 min	30–90 min	3–5 hr	Take at same time as meal along with longer-acting insulin.
Aspart (Novolog)	10–20 min	40–50 min	3–5 hr	
Glulisine (Apidra)	20–30 min	30–90 min	1–2.5 hr	
Short Acting				
Regular-Humulin or Novolin	30 min–1 hr	2–5 hr	5–8 hr	Take within 30–60 min of eating along with longer-acting insulin.
Vesosulin (pump)		2–3 hr	2–3 hr	
Intermediate Acting				
NPH (N)	1–2 hr	4–12 hr	18–24 hr	Covers insulin needs for one-half day or overnight. Often combined with rapid- or short-acting insulin.
Long Acting				
Glargine (Lantus, Toujeo)	1–1.5 hr	No peak	20–24 hr	Covers up to 1 full day. May be combined with short- or rapid-acting insulin.
Detemir (Levemir)	1–2 hr	6–8 hr	Up to 24 hr	
Ultra Long Acting				
Degludec (Tresiba)				Greater than 24-hr coverage but dosed daily and may be combined with short or rapid acting insulin.
Premixed				
Humulin 70/30	30 min	2–4 hr	16–24 hr	Usually taken twice a day before meals. Premixed are combination intermediate- and short-acting insulin. The numbers indicate how much of each type of insulin.
Novolin 70/30	30 min	2–12 hr	Up to 24 hr	
Novolog 70/30	10–20 min	1–4 hr	Up to 24 hr	
Humulin 50/50	30 min	2–5 hr	18–24 hr	
Humalog mix 75/25	15 min	0.5–2.5 hr	16–20 hr	

prolonged hyperglycemia include renal failure, blindness, coronary artery disease, stroke, peripheral vascular disease, slow-healing wounds, autonomic neuropathies, hypertension, sexual problems, and genitourinary system disorders. Macrovascular complications from diabetes substantially increase the risk of morbidity and death from coronary artery disease, stroke, and peripheral vascular disease. End-stage renal disease and lower extremity amputations may also occur. Complications may result from either type 1 or type 2 diabetes. Evidence indicates that the degree of severity with respect to microvascular, neuropathic, and possibly macrovascular complications seems in part to be related to the number of years a patient has had hyperglycemia and the magnitude of the glucose elevation.

Prevention/Prophylaxis: The focus of prevention for developing type 2 diabetes is diet modification and exercise with subsequent weight loss. In adults with obesity and diabetes even a modest weight loss of 7% can improve glycemic control (ADA, 2021). When a patient is diagnosed with type 2 diabetes, the maintenance of glucose levels at as near-normal levels as possible is extremely beneficial in preventing complications from the disease. Monitoring and controlling serum lipid levels and blood pressure can greatly reduce complications from coronary artery disease and stroke. The ADA (2021) recommends considering the use of aspirin (75 to 162 mg daily) as primary prevention in both men and women aged 50 years and older with diabetes and at least one additional major risk factor. Equally important is maintaining routine examinations recommended by the primary care provider.

Referral: Patients with type 2 diabetes should be referred when acute complications requiring hospitalization develop, such as ketoacidosis, severe hyperglycemia, or hypoglycemia. Patients with fasting glucose levels that are consistently greater than 300 mg/dL or Hb A1c of greater than 13% also should be referred to an endocrinologist for further assessment. Annual eye and oral examinations should be referred to appropriate providers. Patients with uncontrolled hypertension, hyperlipidemia, unmanageable skin disorders, or renal insufficiency should be referred to appropriate providers. Consider referring all patients interested in greater control of self-management of the disease to diabetes educators.

Education: The cornerstone of education for patients with diabetes is disease self-management. Assess the patient's knowledge and understanding of the disease, treatment goals, management, and response to complications. Include in the

© F.A. Davis Publishing

assessment barriers to treatment, which include cultural influences, health beliefs and behaviors, socioeconomic status, psychological factors, and education and skills deficits that may preclude the ability to self-manage diabetes adequately. Explicit instructions should be given to patients who participate in daily SMBG. For optimal results, families of patients with diabetes should always be included in the education and management of the disease. Information and helpful tools that may be printed pertaining to diabetes can be obtained from the American Diabetes Association, 2451 Crystal Drive, Suite 900, Arlington, VA 22202, 1-800-DIABETES (1-800-342-2383), www.diabetes.org.

Clinical Recommendation	Evidence Rating	References
Diagnosis of type 2 diabetes mellitus: two fasting blood glucoses ≥126 mg/dL or two random blood glucoses ≥200 mg/dL.	C	American Diabetes Association (ADA), 2021
In a systematic review of the evidence, support is given to the use of Hb A1c as a measure for screening. The ADA endorsed Hb A1c as a diagnostic test for diabetes at a cut-off of ≥6.5% with the provision that this be measured in a laboratory using a NGSP-certified assay aligned to the Diabetes Control and Complications Trial, and that in the absence of unequivocal hyperglycemia the test should be repeated. It is important to understand that values <6.5 does not exclude the diagnosis. Using this criteria, one-third of patients will be missed that would have been diagnosed with the use of a fasting glucose of ≥126 mg/dL.	A	ADA, 2021
The 2-hour plasma glucose during an oral glucose tolerance test rises much more steeply than fasting glucose levels with aging.	A	Lodhi, 2021
For some patients, Hb A1c may not accurately reflect control. Other options include fructosamine and glycated albumin.	C	ADA, 2021
Counsel patients regarding lifestyle modification (weight loss, exercise) (expected decrease in Hb A1c 1%–2%).	C	ADA, 2021

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. For information about the SORT evidence rating system, go to https://www.aafp.org/afp/2004/0201/p548.html.

HYPERLIPIDEMIA

Signal Symptoms: Body mass index (BMI) greater than 25, central obesity, metabolic syndrome, diabetes, familial hypercholesterolemia, thyroid dysfunction, corneal arcus, xanthelasma, xanthoma.

Description: Hyperlipidemia is a major cardiovascular risk factor that increases the rate of atherosclerotic cardiovascular disease (ASCVD) in the general population as well as in older adults. Other terms used to denote this condition are *hypercholesterolemia, hypertriglyceridemia, dyslipidemia,* and *mixed dyslipidemia*. Hyperlipidemia is generally classified as primary or secondary.

Cholesterol is significant for body functions, including nerve conduction, intracellular transport of vitamins (A, D, E, and K), being a precursor of molecules such as steroid and sex hormones, and being part of all cell membranes (Orkaby, 2020). As with frailty and other declining states that are common in older adults, elevated levels of cholesterol have been hypothesized as protective in the very old age. Guidelines from the American College of Cardiology and American Heart Association (ACC/AHA) (Carson, et al., 2020) and the National Lipid Association (NLA) Part 2 (Orringer, et al., 2020), however, both support the pharmacological treatment of hyperlipidemia in the older adult with risk factors.

Etiology: Cholesterol is essential to the structure and function of cell membranes and the synthesis of vitamins and hormones. It is formed in the human body in three different ways: food absorption, bile acids produced by the liver and reabsorbed through the intestinal tract, and cellular synthesis. The latter two have a strong genetic component. Cholesterol is transported in our circulation by lipoproteins. Cholesterol and triglycerides are insoluble in water and are transported in association with proteins (Feingold, 2020). Lipoproteins in the blood are divided into seven classes based on their size, densities, and apolipoproteins. These are chylomicrons, chylomicron remnants, very low-density lipoproteins (VLDLs), intermediate-density lipoproteins (IDLs), low-density lipoproteins (LDLs), high-density lipoproteins (HDL), and Lp(a), which is an LDL particle that has a lipoprotein (a) and is proatherogenic (Feingold, 2021). The degree of lipid in a lipoprotein affects its density—the lower the density of a lipoprotein, the more lipid it contains relative to protein. The total plasma cholesterol measured in a lipid panel is determined by the supply of cholesterol from VLDL, IDL, LDL, and HDL (Healthwise Staff, 2021).

Occurrence: According to data from 2013–2016 Heart Disease and Stroke Statistics (Virani et al., 2020), an estimated 28.5 million adults 20 years of age and older have

© F.A. Davis Publishing

serum total cholesterol levels greater than or equal to 240 mg/dL, with a prevalence of 11.7%. These data indicate a steady decline in the prevalence of high LDL cholesterol over the past four decades. According to the Centers for Disease Control and Prevention (CDC), the number of people in the United States with high cholesterol has decreased by >30%. These data reveal that the national guidelines are making a difference in the management and treatment of patients. Most groups of people met the goal of Healthy People 2020, which aimed to reduce the percentage of adults with elevated cholesterol to 13.5% (Upham, 2020).

Age: Hyperlipidemia can occur at any age due to genetic syndromes that are associated with accelerated atherosclerosis and early cardiovascular disease (CVD). The effects of cholesterol levels on coronary artery disease mortality rates are much higher in the older adult. In men, the level of total cholesterol increases with age from puberty until age 45 to 55 years, followed by a plateau until age 70 years, at which time a mild decrease is observed. In women, the level continues to rise another 10 years before it begins to decrease. However, the levels in women usually remain higher than men of similar age-group. This mild drop in total cholesterol with aging is thought to be a result of a decrease in LDL synthesis related to a decline in liver function because of decreased hepatic blood flow. An age-related decrease in glomerular filtration rate (GFR), changes in cytochrome P450 (CYP450) enzymes, and diminished drug esterase associated with frailty (Streja & Streja, 2020) also occur.

Until recently, women have been underrepresented in randomized controlled trials of lipid-lowering therapies. The most recent data available indicate that more women than men die annually from CVD and women account for 60% of deaths due to stroke (Garcia et al., 2016).

Ethnicity: Patients who are Hispanic have a lower coronary calcium burden than non-Hispanic Whites and Asian Americans (Reiter-Brennan et al., 2020). However, mortality rates remain higher in Hispanics compared to Whites and Asian Americans. Black Americans also have higher rates of coronary artery disease, even though they also have lower coronary calcium store.

Contributing Factors: Both modifiable and nonmodifiable influences contribute to the risk of hyperlipidemia. Age, sex assigned at birth, and family history are risk factors that cannot be changed; however, diets high in saturated and trans fats, inactivity, and excess weight are strong controllable factors that have a significant impact on cholesterol parameters. Obesity is associated with increased total cholesterol, LDL, VLDL, and triglycerides and decreased levels of HDL. Other contributing factors to hyperlipidemia include alcoholism, steroid use, and smoking. Cigarette smoking lowers HDL levels and is an independent risk factor for CVD. The pathological process of atherosclerosis is influenced by many other factors as well. Age (older than 45 years for men and 55 years for women); male gender; genetic abnormalities in lipoprotein metabolism; and comorbidities such as diabetes, chronic kidney disease (CKD), and hypertension all contribute significantly to this disease process. Guidelines from the 2019 ACC/AHA and the NLA both focus on primary prevention strategies to include a plant-based diet instead of animal-based protein. The guidelines also recommended limiting dietary cholesterol to <200 mg/dL to lower LDL cholesterol (Carson et al., 2019). Secondary causes of hypercholesterolemia include hypothyroidism, liver disease. Systemic disease processes can also stimulate the inflammatory process and can cause atherosclerotic problems and dyslipidemia such as psoriasis, Crohn's disease, depression, chronic pain, and irritable bowel syndrome (Hill & Bordoni, 2021).

Certain medications can influence hyperlipidemia. Older adults are often on polypharmacy; therefore, medications should be evaluated thoroughly. Herinkand Ito (2015) did a review looking at medications that induced changes in lipid and lipoproteins. Medications listed in their report include:

- Antihypertensive drugs (diuretics and β-adrenergic blockers)
- Other cardiovascular drugs (amiodarone)
- Steroid hormones (estrogens and progestins)
- Anabolic steroids (Danazol)
- Androgens (testosterone replacement)
- Retinoids (oral isotretinoin)
- Antipsychotics (clozapine)
- Immunosuppressives (corticosteroids, cyclosporine, and tacrolimus)
- HIV therapy (protease inhibitors)
- Interferons

Signs and Symptoms: Hyperlipidemia is typically asymptomatic and is usually detected during a routine lipid screening. Occasionally, in patients with genetic disorders such as familial hypercholesterolemia, xanthelasma and xanthomas may be present. These are fatty deposits under the skin surface, on the hands, elbows, knees, heels, or eyelids, and found in patients with very high cholesterol. Ocular signs of hyperlipidemia may include arcus senilis and xanthelasma palpebrarum. Arcus senilis is a yellowish white ring around the cornea that is caused by lipid deposition in the peripheral cornea. Xanthelasma palpebrarum is a plaque-like yellow lesion near the inner canthus of the eyelids that is caused by lipid deposition in the dermis (Dahl, 2021).

Diagnostic Tests: Screening for lipid disorders should include a total cholesterol (TC), LDL, HDL, and triglyceride level, as well as a measurement of non-HDL cholesterol (non–HDL-C). This number is simply the difference between the TC concentration and the HDL cholesterol concentration. The non-HDL number provides a single index of atherogenic cholesterol particles, and many researchers believe this provides a better assessment of heart disease risk (Jacobson et al., 2017).

Table 18-4 displays the NLA recommendations for lipid management according to risk category. The atherogenic cholesterol (non–HDL-C and LDL-C) levels are considered the appropriate targets of therapy. In patients 65 years of age and older, for whom treatment with medication is questionable, a coronary artery calcium (CAC) score may be considered to obtained additional objective information for treatment decisions. A CAC score of zero in asymptomatic patients may indicate nonpharmacological treatment as an option (Orringer et al., 2020).

Both the ACC/AHA and the NLA utilize risk calculation tools in their primary prevention risk assessment. These tools are used in select older adult individuals with one additional risk factor to further assess risk. However, the two organizations differ in their cut points of high risk and the use of specific treatment goals. Instead of the traditional NLA ATP III risk factor stratification, treat-to-goal approach, the ACC/AHA

TABLE 18-4 Treatment Goals and Levels to Consider Drug Therapy According to Risk Category

	TREATMENT GOAL	CONSIDER DRUG THERAPY
RISK CATEGORY	**Non-HDL-C mg/dL**	**LDL-C mg/dL**
Low	<130	≥190
	<100	≥160
Moderate	<30	≥160
	<100	≥130
High	<130	≥130
	<70	≥100
Very High	<100	≥100
	<70	≥70

2020 guidelines group patients according to their risk (high risk versus very high risk) and recommend non-statin therapies as add-ons when LDL remains greater than 70. Statins and non-statin therapy will be discussed in more detail in the section on Treatment. The four "at risk" patient groups that were identified by the ACC/AHA task force include:

1. Patients with clinical ASCVD
2. Patients with primary elevations in LDL cholesterol greater than or equal to 190 mg/dL
3. Patients with type 1 or 2 diabetes between the ages of 40 and 75 years
4. Patients with an estimated 10-year ASCVD risk greater than or equal to 7.5%

The 10-year risk estimator tool is called the ASCVD Risk Estimator Plus (previously called the Pooled Cohort Cardiovascular Risk Estimator) and was updated in October 2021 (ACC, 2021). This risk calculator combines the original ASCVD risk calculator with the 2016 Million Hearts Longitudinal ASCVD Risk Assessment tool and allows for 10-year risk calculation for those patients already on statin therapy (ACC, 2021). The ASCVD Risk Estimator Plus is recommended instead of the traditional Framingham Risk Score (FRS). Components assessed in the risk calculation include sex, age, race, TC, HDL, systolic blood pressure, treatment for hypertension, diabetes, and smoking status. The new tool adds diabetes, race, and CAC. The risk calculation includes stroke in the outcome; however, it can only be used to calculate the 10-year risk in patients between 40 and 79 years of age (Lloyd-Jones et al., 2019). The risk calculator can be found at http://tools.acc.org/ASCVD-Risk-Estimator.

The CAC test is an expedient and highly reproducible computed tomography (CT) scan of the heart. This does not require use of contrast or intravenous access to perform the test. It can be performed on any CT scanner that also has the capability to perform electrocardiogram (ECG) gating. This gating technique uses data obtained during a specific part of the cardiac cycle (Orringer et al., 2020). The CAC reports the score for each individual coronary artery and the total score for the patient. The absolute CAC score has been found to be the most efficient predictor of near-term absolute risk over a 5-year time and best for guiding lipid-lowering therapy. The lower the score the lower the risk. For example, someone who is 50 on any CAC score is classified as a high lifetime risk.

Conversely, a patient who is older than 70 years of age with a score of 10 can have a similar risk as a younger person but a lower risk when compared to age, sex, and race/ethnicity-matched peers; therefore, they will have a lower lifetime risk in light of other competing risks in older adults (Orringer et al., 2020). The addition of the CAC score is effective in stratifying risk and improves risk estimation (Reiter-Brennan et al., 2020).

Recommendations are for adults between the ages of 40 and 75 years, with LDL of 70 to 189 mg/dL and a 10-year ASCVD risk of 5% to 19.9%, CAC may be useful to help the practitioner decide whether to use intense preventive therapy with statins. In older patients whose estimated 10-year risk using the Pooled Cohort Equations is driven by age, a CAC = 0 or a low CAC score can influence the decision to hold statin therapy. CAC is not recommended for those with ASCVD (Orringer et al., 2020).

Recommendations for lipid management from the 2017 NLA Expert Panel on older patients differs somewhat from that of the ACC/AHA. A 10-year ASCVD risk greater than or equal to 15% is used instead of greater than or equal to 7.5% in the ASCVD Risk Estimator Plus, and the ATP III Framingham Risk Calculator is recommended. The use of risk calculators should be used with caution in the older adult because advanced age is often the major driver of increased ASCVD risk and could result in potential overtreatment of lower risk older adult individuals.

Differential Diagnosis: When evaluating older patients with hyperlipidemia it is important to think through other potential medical causes. Differential diagnosis is discussed here based on their lipoprotein abnormality. Hypercholesterolemia (elevated TC and LDL) can be attributed to hypothyroidism, nephrotic syndrome, and malnutrition. Hypertriglyceridemia (elevated triglycerides) can be secondary to diabetes mellitus, obesity, metabolic syndrome, alcohol use, oral estrogen, renal failure, hypothyroidism, retinoic acid, and lipodystrophies. Combined hyperlipidemia (high TC, LDL, and triglycerides) can be caused by diabetes mellitus, obesity, metabolic syndrome, nephrotic syndrome, hypothyroidism, and lipodystrophies. Lastly, low HDL cholesterol can be linked to diabetes mellitus, obesity, metabolic syndrome, hypertriglyceridemia, smoking, and the use of anabolic steroids. Specifically, in type 2 diabetes, patients will have increased serum triglycerides, VLDLs and IDLs, but LDL levels are no different than in those patients without diabetes (Feingold, 2020). Medication causes are discussed in the section Etiology. Investigating and treating these secondary causes can often improve abnormal lipid disorders without aggressive statin therapy.

Treatment: Managing modifiable risk factors such as hyperlipidemia remains the primary method to prevent ASCVD. Hypercholesterolemia is common in the older population and decision making regarding treatment can be challenging. Ideally, patients at risk for ASCVD should begin treatment well before they reach older age. Treatment strategies in this population require careful consideration and should be made on an individual patient basis.

Older adults should follow the general principals of a healthy lifestyle recommended by the 2015–2020 Dietary

© F.A. Davis Publishing

Guidelines for Americans (DGA). A balance between energy intake (calories in) and expenditure (calories out) is emphasized to maintain a healthy body weight. The following are key general recommendations that can help older individuals achieve healthy eating patterns within calorie limits:

- Consume less than 10% of calories per day from added sugars.
- Consume less than 10% of calories per day from saturated fats.
- Consume less than 2,300 mg per day of sodium.
- If alcohol is consumed, it should be consumed in moderation (seven drinks or less per week for women and 14 drinks or less per week for men) (U.S. Department of Agriculture and U. S. Department of Health and Human Services, 2020).

A recent recommendation from the NLA expert panel, based on results from randomized controlled trials, indicates that dietary cholesterol has modest effects on levels of TC, LDL, and HDL cholesterol, and that saturated fatty acids and trans fatty acids have a more predictable impact on levels of atherogenic cholesterol (Jacobson et al., 2017). The Mediterranean style diet and the Dietary Approaches to Stop Hypertension (DASH) diets are recommended for the reduction of cholesterol. These diets focus on fruits, vegetables, whole grains, fat-free or low-fat foods, lean protein, nuts, seeds, and liquid vegetable oils. Choosing plant-based protein sources are an effective way to limit cholesterol intake (Carson et al., 2019).

Regular physical activity is essential for healthy aging. Adults aged 65 years and older gain substantial health benefits from regular physical activity. According to the Office of Disease Prevention and Health Promotion (DPHP), older adults should follow these recommendations for exercise:

- All older adults should avoid inactivity. Some physical activity is better than none, and older adults who participate in any amount of physical activity gain some health benefits.
- For substantial health benefits, older adults should do at least 150 minutes (2 hours and 30 minutes) a week of moderate-intensity, or 75 minutes (1 hour and 15 minutes) a week of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity aerobic activity. Aerobic activity should be performed in episodes of at least 10 minutes, and preferably, it should be spread throughout the week.
- For additional and more extensive health benefits, older adults should increase their aerobic physical activity to 300 minutes (5 hours) a week of moderate-intensity, or 150 minutes a week of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity activity. Additional health benefits are gained by engaging in physical activity beyond this amount.
- Older adults should also do muscle-strengthening activities that are moderate or high intensity and involve all major muscle groups on 2 or more days a week, as these activities provide additional health benefits.
- When older adults cannot do 150 minutes of moderate-intensity aerobic activity a week because of chronic conditions, they should be as physically active as their abilities and conditions allow.
- Older adults should do exercises that maintain or improve balance if they are at risk of falling.
- Older adults should determine their level of effort for physical activity relative to their level of fitness.
- Older adults with chronic conditions should understand whether and how their conditions affect their ability to do regular physical activity safely.

It has been well established in multiple clinical trials and in more than 27 years of clinical use that 3-hydroxy-3-methyglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) are one effective treatment to reduce ASCVD risk, particularly for secondary prevention. In addition to their cholesterol-lowering properties, statins also have anti-inflammatory effects that are believed to contribute to plaque stabilization. There are currently seven statin medications available: rosuvastatin, atorvastatin, pitavastatin, simvastatin, lovastatin, pravastatin, and fluvastatin. Statins should be prescribed according to potency and intensity as recommended in both the NLA and ACC/AHA guidelines (see Table 18-5).

Safety of these agents, particularly in the older adult, remains a concern. Advancing age, multiple comorbidities, and polypharmacy can cause pharmacokinetic and pharmacodynamic variability, resulting in potential adverse effects (Grundy et al., 2019).

Unfortunately, the subject of deprescription of statin therapy in older adult patients has a paucity of recommendations or guidelines. In a systematic review of guidelines for the instructions and suggestions of discontinuing statin therapy in older adults by van der Ploeg and colleagues (2020), the researchers identified 18 international guidelines on statin therapy. Of these, three groups of instructions were identified for statin discontinuation *only* in the setting of statin intolerance. None were specific to older patients. Three guidelines did include a recommendation for discontinuation of statins in patients with poor health (van der Ploeg et al., 2020). Higher level evidence and new guidelines are suggested to meet the needs of providers. More detailed recommendations regarding the discontinuation of statins in the treatment of dyslipidemia in older adults is warranted.

The National Institute for Health and Care Excellence (NICE) guidelines do recommend that providers should treat older patients up to the age of 84 as they would adults of any age. They further recommend that moderate intensity statins

TABLE 18-5 Intensity of Statin Therapy

HIGH INTENSITY DAILY DOSE ↓ LDL-C ≥50%	MODERATE INTENSITY DAILY DOSE ↓ LDL-C 30 TO <50%
Atorvastatin 40–80 mg	Atorvastatin 10–20 mg
Rosuvastatin 20–40 mg	Fluvastatin 40 mg bid
	Fluvastatin XL 80 mg
	Lovastatin 40 mg
	Pitavastatin 2–4 mg
	Pravastatin 40–80 mg
	Rosuvastatin 5–10 mg
	Simvastatin 20–40 mg

© F.A. Davis Publishing

should be considered for the prevention of non-fatal myocardial infarctions (MIs) in individuals older than 85 years (Horodinischi et. al., 2019). Patients who are frail are susceptible to adverse effects of statin therapy. However, these patients can still benefit from just 1 year of therapy and have been found to have lower mortality rates and slower functional decline (Last et al., 2017). As with any clinical decision in patient care, the medication benefit must outweigh the associated risk.

Elevations in liver enzymes and hepatic damage have been a concern since the first statin was introduced in 1987. However, there is no evidence that routine monitoring of hepatic function is effective in identifying the rare case of liver injury. According to a prospective study by Guo and associates (2019) that evaluated liver enzyme elevation in older adults, the prevalence of elevated liver enzymes (transaminases) was found to be more pronounced in the very old. However, statins were found to be safe for patients older than 80 years. Consequently, liver enzyme tests are recommended prior to beginning statin therapy and as clinically indicated thereafter (U.S. Food and Drug Administration [USDA], 2016).

There are many non-statin therapy regimens available to treat hyperlipidemia. No clinical trial has studied the effect of combination therapy on ASCVD risk reduction in the older population and met the primary endpoint. The ACC/AHA guidelines only recommend non-statin therapies in high-risk patients who either fail therapy on a maximum tolerated statin or are completely intolerant to statins. However, the NLA recommends treating to specific LDL and non-HDL cholesterol goals, making the addition of non-statin medication an option to reach these goals in high-risk patients.

Non-statin therapy includes PCSK9 inhibitors, ezetimibe, niacin, fibrates, bile acid sequestrants, and omega-3 fatty acids (O3FAs). When making clinical decisions regarding the use of non-statin or combination therapy, careful consideration of polypharmacy, drug-drug interactions, and adverse effects must be a priority. Equally, it is important to recognize that older adults are less likely to tolerate high-dose statins and some lower-dose combination therapies may be an excellent choice to achieve treatment goals with minimal side effects.

Proprotein convertase subtilisin/kexin type 9 (PCSK-9) inhibitors are now being considered for a specific cohort of patients. These patients are of higher risk for ASCVD, have a high burden of ASCVD, have poorly controlled hyperlipidemia, or have adverse risk factors. In a consensus statement by the NLA in 2019, PCSK9 inhibitors can provide reasonable value when LDL is ≥70 in patients with very high risk ASCVD without peripheral arterial disease and lower levels of poorly controlled risk factors (Robinson et al., 2019). This treatment regimen can also be considered for patients with less prominent ASCVD but high risk, heterozygous familial hypercholesterolemia, or severe hypercholesterolemia with untreated LDL levels ≥220.

These drugs lower LDL by 50% to 60% by binding PCSK9 labeling of LDL receptors for degradation, and thereby prolonging LDL receptor activity in the cell membrane. This prevents LDL receptors from returning to the surface of the hepatocyte to bind to additional LDL particles resulting in reduced LDL levels (Rosenson et al., 2018). Alirocumab and evolocumab are available for those patients who are not well controlled on statin therapy and/or lifestyle modifications. Alirocumab (Praluent) is provided in 75 mg and 150 mg subcutaneous injections given every 2 weeks and 300 mg subcutaneous injection once a month. Evolocumab (Repatha) is provided in 140 mg subcutaneous injections every 2 weeks and 420 mg subcutaneous injections once monthly. Often patients can perform self-injections after instructions from the pharmacist or provider. Both of these PCSK9 inhibitors have been shown in clinical trials to raise HDL cholesterol by 5% to 10%, lower LDL from 48% to 60%, lower triglycerides by 10% to 15%, and lower lipoprotein (a) by 25% to 30% (Rosenson et al., 2018). Both the FOURIER trial in 2017 and ODYSSEY OUTCOMES trial in 2018 found benefits of PCSK-9 inhibitors in patients older than 65 years of age without cognitive deficits or myalgias (Rosenson et al., 2018).

Ezetimibe is a cholesterol absorption inhibitor and is the only agent in its class. It can be used alone for a modest LDL lowering effect (18%) or in combination with a statin for a more robust lowering effect (54%).

Niacin, or nicotinic acid, is a form of vitamin B_3 and has been available for the treatment of cholesterol disorders since the early 1950s. Niacin's primary use has been in the treatment of low HDL cholesterol disorders, but it has also been used to treat elevated LDL cholesterol. Its main mechanism of action is in the reverse transport of cellular cholesterol and macrophages from the body. Niacin is used with caution in older adults due to safety and tolerability concerns. In addition, recent secondary prevention studies have failed to show any additional benefit of using niacin with maximum dose statins (i.e., AIM-HIGH, HPS2-THRIVE) (Feingold, 2020).

Fibrates are a non-statin therapy that is primarily used to treat high triglycerides and VLDL cholesterol, but they also have a modest effect on raising the HDL cholesterol. These medications work by enhancing the catabolism of triglyceride-rich particles and reducing the secretion of VLDL. Gemfibrozil use is contraindicated with simvastatin due to increased risk of myopathies. Fenofibrate is therefore preferred in combination with statins. The researchers of the FIELD study (2011) found that fenofibrate reduced albuminuria and delayed GFR impairment in type 2 diabetes (Davis et al., 2011). However, gemfibrozil is preferred in patients with CKD because its effect on serum creatinine levels is more favorable when compared with fenofibrates.

Bile acid sequestrants (BASs), sometimes referred to as resins, include cholestyramine, colesevelam, and colestipol. They are recommended in patients with hypercholesterolemia without hypertriglyceridemia. These drugs bind with cholesterol-containing bile acids in the intestines and are then eliminated in the stool. The primary effect of BASs is a 5% to 30% reduction in LDL cholesterol; however, these medications also have a beneficial clinical effect in the treatment of diabetes. These drugs can cause significant GI side effects and are contraindicated in patients with biliary obstruction. Therefore, their use is usually limited to those patients unable to tolerate a statin (Feingold, 2020).

Omega-3 fatty acids (O3FAs) refer to the long-chain polyunsaturated fatty acids docosahexaenoic (DHA) and eicosapentaenoic (EPA). There are currently two prescription strength O3FAs on the market, omega-3-acid ethyl esters (Lovaza) and icosapent ethyl (Vascepa), which are indicated for the treatment of moderate to severe hypertriglyceridemia. These products are generally well tolerated but can inhibit platelet aggregation and should be used with caution in patients taking antiplatelet or anticoagulation therapies. With the antiplatelet effect on O3FA products, the FDA prescribing information recommends that in those patients taking an

© F.A. Davis Publishing

anticoagulant or antiplatelet medication should be monitored periodically, but no specific schedule is suggested. The REDUCE-IT trial (2019) did report a trend in increased bleeding, but no fatal bleeding events (Skulas-Ray et al., 2019).

Follow-Up: The NLA Recommendations for Patient-Centered Management of Dyslipidemia – Part 1 (Reiter-Brennan et al., 2020) advise a follow-up visit 4 to 6 weeks after the primary diagnosis of hyperlipidemia and repeated every 3 to 12 months as needed. Patients on drug therapy should be evaluated every 3 to 6 months to monitor compliance and potential side effects. Weight, dietary adherence, and exercise level should be evaluated. This visit should also include a lipid panel to measure atherogenic cholesterol response to TLC. If the patient is not at goal, these recommendations should be reinforced, and a referral to a dietitian for medical nutritional therapy should be considered. If the patient is not to goal, then TLC should be intensified, and drug therapy should be considered. For patients at high risk for ASCVD, drug therapy and TLC may be initiated concurrently.

Sequelae: Complications related to untreated or undertreated hypercholesterolemia include heart disease (acute coronary syndrome and ischemic heart disease), stroke, organ insufficiency (erectile dysfunction, CKD), peripheral vascular disease (PVD), aneurysms, type 2 diabetes, and pancreatitis. High cholesterol can also create bile imbalance, raising the risk of cholelithiasis (Luo & Grey, 2020). Early screening and management of high cholesterol is the cornerstone of preventing these life-threatening conditions.

Prevention/Prophylaxis: Primary prevention strategies in patients 65 to 79 years old should follow the NLA Recommendations of Patient-Centered Management of Dyslipidemia-Part 1. Prevention focuses on a healthy lifestyle of good nutrition and physical activity. The NLA Expert Panel supports a cardioprotective eating pattern for the management of dyslipidemia. This includes minimal intake of trans fatty acids, viscous fiber intake (5 to 10 g/day), fiber-rich whole grains that have 1.1 g or more of fiber per 10 g of carbohydrate, vegetables, nuts, and restriction of alcohol and refined carbohydrates. The recommended minimal frequency, intensity, and duration of exercise for improving the lipid profile (reduce triglyceride and modestly raise high-density lipoprotein cholesterol [HDL-C]) are 5 or more days/week at 40% to 75% aerobic capacity, and at least 30 to 60 minutes of accumulated daily physical activity (at least 150 minutes per week). This level of physical activity is consistent with the NLA expert panel and public health recommendations.

Other NLA recommendations include:

1. Consideration of moderate- or high-intensity statin medication for patients 65 to 75 years of age with ASCVD or diabetes mellitus.
2. Similar statin doses are recommended for patients 75 to 80 years of age after careful risk-benefit ratio assessment.
3. For patients older than 80 years of age, moderate-intensity statin may be considered after careful evaluation of polypharmacy and drug-to-drug interaction, comorbidities, cost, and patient preference.

Referral: The treatment of lipid disorders in older patients can generally be managed by the practitioner in primary care; however, a team-based collaborative approach, including a dietitian for medical nutritional therapy and a personal trainer who specializes in cardiovascular fitness for seniors, is an excellent approach. Patients with ASCVD should also be monitored by a cardiologist to track progression or stabilization of the disease. Lipid clinics are available if practitioners feel a lipid specialist is necessary.

Education: Education should focus on improving patient outcomes. When patients do not understand their disease or condition and the importance of the treatment regimen, they are less likely to be compliant. Take the time to educate patients on what to expect from their treatment, as well as the risks versus benefits. Considerations in the older adult include cost, dosing frequency of medication, physical difficulties in taking the drug, and risk of adverse drug reactions as perceived by the patient. Identify and discuss any barriers to adherence and formulate strategies for overcoming them.

Clinical Recommendation	Evidence Rating	References
In treating patients more than 65 years to less than 80 years of age with ASCVD or diabetes mellitus, moderate- or high-intensity statin therapy should be considered after a careful consideration of the individual risk-benefit ratio.	A	Jacobson et al., 2017
Older, primary prevention patients who are statin-eligible should undergo a patient-centered discussion with their provider about the risks and benefits of statin therapy so that they can make a more informed decision about taking statins over the long term.	C	Jacobson et al., 2017 Dixon et al., 2015
For patients reporting statin intolerance, consider the use of alternate statin regimens such as low-intensity statin therapy or non-daily moderate-intensity statin therapy; low-dose statin combination therapy with ezetimibe, bile acid sequestrants, or niacin; or non-statin as a second-line option.	B	Jacobson et al., 2017 Dixon et al., 2015
When treating for secondary prevention of hyperlipidemia in patients >80 years of age, consider using one of the moderate-intensity statins based on a provider-patient discussion of the risks and benefits of such therapy, consideration of drug-drug interactions, polypharmacy, concomitant medical conditions including frailty, cost considerations, and patient preference.	B	Jacobson et al., 2017

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. OSTEOPOROSIS

Signal Symptoms: Kyphosis, decreased height, vertebral or hip fractures, severe back pain.

Description: Osteoporosis is a systemic skeletal disease characterized by low bone mass and deterioration of bone tissue leading to bone fragility and an increased risk of fractures (National Osteoporosis Foundation [NOF], 2021). It is a major public health problem growing into a global epidemic. It has an impact on quality and quantity of life with medical, social, and economic consequences. It is seen in all age-groups, sexes, and races, but is more common in Whites, women, and older adults (Sözen et al., 2017). Patients with osteoporosis are at high risk for fractures and at moderate risk for low bone mass or osteopenia. Of those who have had at least one osteoporotic fracture, 80% are neither identified nor treated for osteoporosis (International Osteoporosis Foundation [IOF], 2021). Patients are either not being prescribed appropriate medications or, if prescribed, not taking them. Widespread media coverage of lawsuits over rare adverse events—atypical femur fractures and osteonecrosis of the jaw—has created fear among patients, leading to a decline in the use of osteoporosis drugs (*The Lancet*, 2018). Bone mineral density (BMD) screening rates within 6 months of a new osteoporotic fracture—when the need for treatment and action is higher—is only 8% for all Medicare beneficiaries (NOF, 2021). Earlier screening, diagnosis, and treatment of this disease before fractures occur can prevent osteoporosis with all its sequalae and cost burden.

Etiology: BMD results from both the peak bone mass achieved by the mid-twenties and the amount of bone loss after maturity. Men experience a gradual decline of bone mass into old age, whereas women experience a plateau followed by an accelerated period of bone loss for several years after menopause. Although osteoporosis is considered a disease of older adults, the origins of the disease begin in adolescence when there is a failure to achieve a high quality of bone. Peak bone mass is determined by genetic factors, with contributions from nutrition, endocrine status, physical activity, and health during growth. Once peak bone mass has been achieved in adulthood, the bone mass and structural integrity are maintained by a process called remodeling. Remodeling is the replacement of old tissue lost by resorption by new bone tissue and continues throughout life so that most of the adult skeleton is replaced every 10 years (IOF, 2021). Bone remodeling is used to repair microfractures and prevent them from becoming macrofractures, thereby assisting in maintaining a healthy skeleton. Osteoporosis results from an imbalance between bone resorption and bone formation, causing a reduction in bone tissue. Fractures occur because of both the qualitative and quantitative character of bone. Falls are the principal cause of fractures, which in older adults are related to a deteriorated sense of balance and low levels of muscular strength.

Occurrence: Per the IOF (2021), more than 200 million people are suffering from osteoporosis. Based on 2010 data, 54 million Americans aged 50 and older are impacted by osteoporosis (10.2 million) and low bone mass (39.8 million) with a risk for fracture (NOF, 2021). According to a Millman analysis commissioned by the NOF (2021), 1.8 million Medicare beneficiaries suffered 2.1 million osteoporotic fractures in 2016. More than 80% of those diagnosed with osteoporosis are women. One in three women and one in five men older than age 50 will suffer an osteoporotic fracture worldwide (IOF, 2021). Men aged 50 and older account for 25% of hip fractures but have a higher mortality rate after (IOF, 2021).

Age: Age is as great a risk factor for osteoporosis because of low BMD. A fracture at any major skeletal site in an adult older than 50 years should be considered a significant risk factor for osteoporosis, even when they occur without significant trauma. The most common fractures are those of the spine, hip, wrist, and distal forearm. Almost 75% of hip, spine, and distal forearm fractures occur among patients aged 65 and older (IOF, 2021).

Ethnicity: Peak bone mass and bone density are influenced by diet and lifestyle; however, genetics are the primary influence. The NOF (2021) report found substantial racial/ethnic disparities in fracture incidence, care, and deaths in Medicare beneficiaries. North American Natives suffered fractures at a rate 20% higher, Whites at 6% higher, Blacks 50% lower, Asians 32% lower, and Hispanics 19% lower than the national average. Rates of subsequent fractures within 12 months ranged from Blacks 11%; Whites 15%; Hispanic, Asian, and North American Natives all 14%. Tibia/fibula fractures were more common for Blacks; vertebral fractures were more common for Asians. Blacks had higher hospitalization rates, higher death rates, and lower BMD screening rates. Mortality rates were Blacks 22%, Whites 19%, Asians 16%, and Hispanic and North American Native 18%.

Contributing Factors: Many risk factors predispose individuals to osteoporosis. Some of these risk factors cannot be changed, including age, family history of the disease, low peak bone mass, female sex, race/ethnicity, small body structure, certain chronic disease states, and history of medication use. Chronic diseases that increase risk include hyperthyroidism, diabetes mellitus, rheumatoid arthritis, chronic kidney disease (CKD), Cushing's syndrome, previous gastric surgery, major organ transplantation, liver disease, epilepsy, alcoholism, malabsorption states, anorexia nervosa, hyperparathyroidism, and women having menopause before age 40 years without hormonal replacement. A history of falling puts a person at increased risk for sustaining an osteoporotic fracture. Patients taking medications such as corticosteroids, thyroid hormones, anticonvulsants, anticoagulants, lithium, chemotherapeutic agents, aluminum antacids, and tetracycline are at increased risk, and these medications need to be reviewed to determine whether alternatives are possible. A decrease in physical activity levels and aerobic capacity can result in changes in balance, increased susceptibility to falls, and impairment in functional capacity in older age. Other modifiable risk factors are tobacco use, excessive alcohol use, sedentary lifestyle, low gonadal hormone levels, low body mass index (BMI), and diet.

Signs and Symptoms: Osteoporosis is a silent disease, commonly displaying no signs or symptoms until a fracture occurs. Evaluate all postmenopausal women aged 50 years and older

© F.A. Davis Publishing

for osteoporosis risk. A detailed history, physical examination, and clinical fracture risk assessment with the Fracture Risk Assessment Tool (FRAX) should be included. Consider measuring bone strength using BMD testing based on FRAX profile. Patients need to be questioned about all the risk factors for osteoporosis. Inquire about a personal history of fractures. Inquire about a family history of hip fractures and obtain a thorough menstrual history in women. Dietary history, exercise patterns, and habits should be reviewed with patients. Physical examination may reveal loss of height with associated kyphosis of the spine. Height should be measured at the initial visit and yearly using a wall mounted stadiometer. Height loss (difference between the current height and peak height at age 20 years) of 1.5 inches (4 cm) or more is significant. If the patient is uncertain of what their peak height was, the arm span measurement is known to be an equivalent to adult height. Gait should be assessed, and the patient's body mechanics should be observed at the same time. It is helpful to do tests of basic functional mobility and balance such as the Timed Up and Go (https://www.cdc.gov/steadi/pdf/TUG_Test-print.pdf), Functional Reach (Duncan et al., 1990), Romberg, or the four-stage balance test (https://www.cdc.gov/steadi/pdf/4-Stage_Balance_Test-print.pdf). The mouth should be examined to assess oral hygiene, dentition, and any evidence of oral bone loss. The thyroid gland should be palpated. Observe for restrictive respiratory problems due to decreased volume of the thoracic cage and poor expansion with breathing. The spine should be examined in detail, including configuration. The most common site for vertebral fractures in patients with osteoporosis is the lower thoracic (T12) or upper lumbar (L1) region. Any tenderness to palpation over the spinous processes and evidence of swelling, tenderness, and ecchymosis present at the sight of an injury should be noted. Range of motion (ROM) should be determined, noting limitations or painful movement. An abdominal examination reveals whether the abdomen is protuberant from spinal changes. The distance between the rib cage and the anterior iliac crest should be recorded.

Diagnostic Tests: When BMD is measured, axial dual-energy x-ray absorptiometry (DXA) measurement (lumbar spine and hip; 1/3 radius) should be used. The World Health Organization (WHO) (1994) defines osteoporosis as a BMD less than 2.5 standard deviations (SDs) or more below the mean of a "young normal" adult (T-score of −2.5 or lower). When bone density is between 1.0 and 2.5 SD below the mean, the patient is said to have low bone mass or osteopenia (T-score between -1.0 and −2.5). The T-score is an important predictor of fracture risk, with the highest risk in those with the lowest BMD. Use of T-scores alone in the diagnosis of osteoporosis is inappropriate because age is as great a risk factor as BMD, and not all patients have access to a DXA (WHO, 1994). Results cannot be compared from different machines or following major software changes without appropriate adjustment or recalibration. Clinicians need to be able to accurately interpret DXA reports according to the criteria set forth by the International Society for Clinical Densitometry (ISCD). Clinicians can become a Certified Clinical Densitometrist (CCD) through the ISCD (https://ISCD.org). The percent change in BMD (from initial or previous) should be used to monitor treatment, not the T-score or FRAX (Camacho et al., 2020).

The FRAX Fracture Risk Assessment Tool developed by the WHO in 2008, accessible at www.shef.ac.uk/FRAX/tool.jsp, is the most widely used computer-based algorithm developed to assist clinicians in the identification of patients at high risk for fractures. The tool is intended to screen patients with low bone density who are not currently receiving treatment to help determine need for treatment. FRAX integrates validated clinical risk factors and BMD of the femoral neck to calculate the 10-year probability of hip fracture and the 10-year probability of a major osteoporotic fracture (clinical spine, forearm, hip, or humerus). Treatment of osteoporosis should be considered for patients with low BMD, as well as a 10-year risk of hip fracture of 3% or more or a 10-year risk of a major osteoporosis-related fracture of 20% or more. The FRAX is recommended for screening in most of the current clinical guidelines and the results are often incorporated into the standard bone density test results. FRAX may underestimate fracture risk among patients with diabetes, and the American Association of Clinical Endocrinologists (AACE) recommended rheumatoid arthritis be entered into the FRAX algorithm as a surrogate for fracture risk associated with diabetes (Camacho et al., 2020).

Using the FRAX algorithm, the AACE (Camacho et al., 2020) and the Endocrine Society's (Shoback et al., 2020) definitions of risk categories for fracture risk are listed in Table 18-6.

Lateral x-rays of the thoracic and lumbar spine or vertebral fracture assessment can assess the development or progression of asymptomatic vertebral fractures. Biomechanical computed tomography (BCT) analysis measures both bone strength and BMD at the hip or spine and is now available as a Medicare screening benefit (Keaveny et al., 2020). It is not ordered as a stand-alone test but for *opportunistic use* when the patient already has a hip or spine CT ordered for any medical condition and the software is available for this add-on test (VirtuOst BCT test). The BMD measurements from BCT can be used to identify osteoporosis, assess fracture risk, and monitor treatment. Laboratory testing should be considered for all women with postmenopausal osteoporosis and those at high fracture risk to identify coexisting medical conditions that cause or contribute to bone loss. Include a complete blood count (CBC), comprehensive metabolic profile, 25(OH)D, parathyroid hormone (PTH), phosphate, and a 24-hour urine collection for calcium, sodium, and creatinine. If medical history, physical findings, or laboratory test results suggest causes of secondary osteoporosis, additional laboratory evaluation may be warranted.

Differential Diagnosis: Osteoporosis is usually diagnosed based on low BMD in the absence of fracture but can also be diagnosed in patients with low bone mass at increased fracture risk using FRAX (Camacho et al., 2020). Clinically, osteoporosis can be diagnosed if there is a low-trauma/fragility fracture in the absence of other metabolic bone disease, independent of the BMD T-score (Camacho, et al., 2020). An osteoporotic or fragility fracture is defined as a fracture sustained from force similar to a fall from a standing height or less that would not have occurred in healthy bone, excepting fractures of the skull, face, fingers, and toes, which tend to occur due to trauma (Camacho et al., 2020). Vertebral fractures can occur during routine daily activities without a specific fall or injury. Other considerations are multiple myeloma, hyperparathyroidism,

TABLE 18-6 Stratification of Fracture Risk Categories

RISK CATEGORY	CRITERIA
Low Risk Normal	• No prior hip or spine fractures • Bone mineral density (BMD) T-score at the hip and spine above –1.0 • 10-year hip fracture risk <3% • 10-year risk of major osteoporotic fracture (OF) <20%
Moderate Risk Low bone mass	• No prior hip or spine fractures • BMD T-score at the hip & spine both between –1 to –2.5 • 10-year fracture risk <3% • 10-year risk of major OF <20%
High Risk Osteoporosis	• Prior spine or hip fragility fracture • BMD T-score at the hip or spine –2.5 or below • 10-year hip fracture risk ≥3% • Risk of major osteoporotic fracture risk ≥20%
Very High Risk Severe Osteoporosis	• Multiple spine fractures • BMD T-score at the hip or spine of –2.5 or below • Recent hip, spine fracture within the past 12 months* • High risk of falls or history of injurious falls* • Those who experience fractures while receiving approved osteoporosis therapy* • Those who experience multiple fractures* • Those who experience fractures while receiving drugs that cause skeletal harm, e.g., long-term corticosteroids* • BMD T-score <–3, 10-year risk of major osteoporosis fracture >30%, hip fracture >4.5%*

**Criteria by American Association of Clinical Endocrinologists only*

osteomalacia, hyperthyroidism, Cushing's syndrome, Paget's disease, and hypogonadism, based on abnormal laboratory results.

Treatment: Management of osteoporosis requires a comprehensive approach. The goal of treatment is to prevent fractures. Adequate intake of calcium is a fundamental aspect of any osteoporosis prevention or treatment program and part of a healthy lifestyle for all ages. Vitamin D is important for calcium absorption and bone health, and is important for muscle performance, balance, and falling risk. Women and men 50 years and older need 1,200 mg of calcium a day to maintain bone health (Camacho et al., 2020). There is limited benefit in increasing calcium intake above 1,500 mg, and the risk of renal stones is increased. Safety questions have been raised about the use of calcium supplements with or without vitamin D because of a potential increased cardiovascular risk. Reports have been conflicting and currently, there is no conclusive evidence that calcium supplements increase cardiovascular risk (Vandenbroucke et al., 2017). Food sources of calcium are preferable because they provide other nutrients as well. Vitamin D deficiency due to insufficient skin exposure to sunlight or reduced efficacy of vitamin D synthesis is common in patients with osteoporosis and may hinder the effectiveness of treatment if not corrected. Patient factors such as obesity, race or ethnicity, malabsorption, those on medications affecting vitamin D metabolism, and history of transplant may increase the necessary vitamin D dose to achieve adequate levels (Camacho et al., 2020). Vitamin D replacement is available as ergocalciferol (vitamin D_2) or cholecalciferol (vitamin D_3). Both are effective in raising the level of serum vitamin D, but Binkley and Wiebe (2018) only recommend vitamin D_3 for replacement. Ergocalciferol is a prescription preparation and carries the potential advantage of insurance coverage. Determining the proper vitamin D requirement for a given patient is based on expert recommendations in conjunction with clinical judgment. The AACE and the Endocrine Society recommend basing a dose required to maintain a 25 (OH) level at 30 to 50 ng/ml for an optimal and safe range (Camacho et al., 2020; Shoback et al., 2020). This often requires at least 1,000 to 2,000 IU of vitamin D daily. The combined supplementation of calcium and vitamin D is preferred because it has shown to have more benefit in reducing fractures than either component alone (Chen et al., 2019; Vandebroucke et al., 2017). Calcium and vitamin D supplementation are an essential but not sufficient component of osteoporosis treatment. Indications for pharmacological therapy are low T-score, increased fracture risk based on FRAX, or fragility fracture. Recommendations for pharmacological therapy are based on the risk of fracture, individual drug considerations, and patient medical history. Patient acceptance of treatment, insurance coverage, and out-of-pocket costs all play a role. Full prescribing information should be reviewed before recommending any specific agent. Currently available osteoporosis therapies are relatively safe with no significant differences in the incidence of most adverse events in even very old adults compared to the general population (Vandenbroucke et al., 2017). The AACE's (Camacho et al., 2020) and the Endocrine Society's (Shoback et al., 2020) recommendations for pharmacological treatment for prevention and treatment of osteoporosis based on fracture risk are found in Table 18-7. Table 18-8 lists available pharmacological treatments for osteoporosis with dosing based on prevention or treatment. Many random controlled trials have given evidence supporting the superiority of anabolic agents over antiresorptive agents in reducing vertebral fracture risk in patients at very high risk for fractures, causing some experts to

TABLE 18-7 Initial Pharmacological Treatment Based on Risk of Fracture

Low Risk	Reassess fracture risk in 2–4 years
Moderate Risk*	Bisphosphonates
High Risk*	Alendronate, denosumab, risedronate, zoledronic acid
Very High Risk*	Abaloparatide, denosumab, romosozumab, teriparatide, zoledronic acid

* *calcium + vitamin D as adjunct therapy*

advocate for this treatment approach (Camacho et al., 2020). Although at one time a treatment of choice for postmenopausal treatment, estrogen has only ever been approved by the U.S. Food and Drug Administration (FDA) for prevention and is to only be considered for women at significant risk of osteoporosis and for whom non-estrogen medications are not considered to be appropriate. Given the concerns regarding the increased risk of cardiovascular disease and breast cancer with estrogen use, AACE only recommends estrogen for the relief of menopausal symptoms in the lowest dose necessary and for the shortest time possible (Camacho et al., 2020).

Concomitant use of two or more osteoporosis drugs has not been shown to have a greater impact on fracture reduction, increases the cost of care and possibly side effects and is not routinely recommended by AACE (Camacho et al., 2020). However, drug combinations have been used when fracture risk is especially high or there is demonstrated suboptimal effects of certain drugs. For example, patients at high risk of hip fracture who are taking raloxifene to reduce their risk of breast cancer can add a bisphosphonate or denosumab (Camacho et al., 2020). Administration of denosumab with 20 mcg teriparatide resulted in a larger increase in BMD than either drug alone; results were even better using 40 mcg (Tsai et al., 2019). Two rare events have been associated mostly with long-term bisphosphonate therapy (more than 5 years duration), but causality has not been determined. Osteonecrosis of the jaw (ONJ) was first reported in patients with advanced cancer receiving high-dose zoledronic acid and denosumab, but the incidence is rare/much lower with drug doses for osteoporosis (Camacho et al., 2020). Risk factors are dental pathological conditions, invasive dental procedures, and poor dental hygiene. Delay initiation of treatment until dental issues are corrected. If a patient already receiving bisphosphonates or denosaumab needs invasive dental procedures, there is no evidence that discontinuing or interrupting treatment will change the outcome or reduce the risk of ONJ, but you can consider stopping treatment (Camacho et al., 2020). Atypical femur fracture (AFF) of the subtrochanteric area occurs with little or no trauma. Patients may present with a history of prodromal groin or thigh pain, bilateral fractures and bilateral radiographic abnormalities, and delayed healing (Camacho et al., 2020). These fractures are also seen in patients with low BMD who are not on any osteoporotic treatment. The number of fractures prevented with osteoporotic treatment far outweighs the risk of ONJ and AFF. Because bisphosphonates accumulate, they may have a prolonged residence time in bone and a residual therapeutic effect after stopping. A drug holiday may be considered to decrease risk of AFF and ONJ. A drug holiday is commonly believed to be 5 years; decision for initiation and duration must be individualized (not yet evidenced-based). Table 18-9 gives the AACE and Endocrine Society's guidelines on duration of pharmacological treatment, drug holidays, and (only for bisphosphonates) and drugs for transition.

Lifestyle: Nutritional recommendations include adequate intake of protein in the diet (0.8 to 1 g/kg) and reduction of excessive alcohol (3 or more drinks/day), caffeine (more than 2 servings/day), and high-phosphorus foods and carbonated beverages. Tobacco should be stopped. Patients should engage in regular weight-bearing exercises (e.g., walking, jogging, tai chi, stair climbing, dancing), which help to reduce the rate of bone loss and increase strength. Muscle-strengthening exercises (weight training and other resistive movements) improve strength, balance, and flexibility, which are important in preventing falls. The most effective exercise interventions associated with BMD changes and fracture reduction are those that include multiple exercise types and resistance exercise undertaken for 60+ minutes, 2 to 3 times/week for 7+ months (Pinheiro et al., 2020). All patients should be counseled on fall prevention. Measures to enhance safety in the home and environment should be emphasized. Personal risk factors should be minimized, such as compromised vision, orthostatic blood pressure drop, wearing high-heeled shoes, and drug or alcohol use. Individuals with severe osteoporosis should use caution when engaging in activities that involve forward spine flexion and rotation, lifting heavy weights, or even side bending of the trunk because these maneuvers exert compressive forces on the spine and may lead to fracture (Camacho et al., 2020). The NOF offers advice on exercise at www.nof.org.

Follow-Up: Serial BMD testing can be done to monitor the response to treatment, or the need for treatment. Frequency is clinically individualized, but in treated patients, BMD testing every 1 to 2 years may be appropriate (Camacho et al., 2020). In treated patients, if BMD decreases significantly, evaluate patients for nonadherence, secondary causes of osteoporosis, or use of drugs that might cause bone loss. Treatment failure can be a significant decrease in BMD or recurrent fractures in a patient who is adherent to therapy. Bone turnover markers (BTM) are useful for assessing patient adherence and efficacy of therapy (Camacho et al., 2020). Significant reductions in BTMs are seen with antiresorptive therapy and have been associated with fracture reduction, and significant increases indicate good response to anabolic therapy.

Sequelae: Any previous fracture is associated with an 86% increased risk of a future fracture (*The Lancet*, 2018). In the Millman Analysis of Medicare beneficiaries (NOF, 2021), more than 40% were hospitalized across all types of fractures, but 90% of those with hip fractures were hospitalized. Of those with a new osteoporotic fracture, 19% (154,000 women, 91,000 men) died within 12 months, 421,900 of them became institutionalized in nursing homes and 56,000 became eligible for Medicaid within

TABLE 18-8 Pharmaceutical Prevention and Treatment of Osteoporosis

MEDICATION	DIRECTIONS	PREVENTION	TREATMENT
Antiresorptives			
Bisphosphonates			
Alendronate	Take first thing in the morning with a full glass of plain water at least 30 minutes before eating, drinking anything else, or taking any other medication	5 mg PO daily 35 mg PO weekly	10 mg PO daily 70 mg PO weekly 70 mg + D (2,800 IU or 5,600 IU) weekly
Ibandronate	*PO:* Take first thing in the morning with a full glass of plain water at least 30 minutes (2.5 mg) or 60 minutes (150 mg) before eating, drinking anything else, or taking any other medication *IV:* Administered by a health-care provider	2.5 mg PO daily 150 mg PO monthly	2.5 mg PO daily 150 mg PO monthly 3 mg IV every 3 months
Risedronate	Take first thing in the morning with a full glass of plain water at least 30 minutes (5, 35 mg) or 60 minutes (150 mg) before eating, drinking anything else, or taking any other medication	5 mg PO daily 35 mg PO weekly 150 mg PO monthly	5 mg PO daily 35 mg PO weekly 150 mg PO monthly
Zoledronic acid	Over no less than 15 minutes	5 mg IV every second year	5 mg/100 mL IV once yearly
Selective Estrogen Receptor Modulator			
Raloxifene		60 mg PO daily	60 mg PO daily
RANKL (Osteoclast) Inhibitor			
Denosumab	Administered by the health-care provider in the upper arm, upper thigh, or abdomen	—	60 mg/mL subcutaneous injection every 6 months
Sclerostin Inhibitor			
Romosozumab	Administered by a health-care provider in the abdomen, thigh, or upper arm; give as 2 separate injections consecutively	—	Two prefilled syringes 210 mg subcutaneously once monthly
Calcium Metabolism Modifier			
Calcitonin		—	100 IU daily subcutaneously or IM or 200 IU (1 spray, one nostril) daily
Anabolic (also includes romosozumab, which has dual action)			
Teriparatide	Into thigh or abdominal wall, requires refrigeration	—	20 mcg subcutaneously once daily
Abaloparatide	Into thigh or abdominal wall; no refrigeration required	—	80 mcg subcutaneously daily
Over the Counter			
Calcium Dietary calcium preferred; total calcium intake should not exceed 1,500 mg/day. Calcium citrate is more expensive but better tolerated than calcium carbonate; if tablets are difficult to swallow, soft chews and gummies are available	If calcium carbonate, take with food; do not take >500–600 mg/dose for optimal absorption	Part of a healthy lifestyle for any age; recommended daily allowance for calcium is age dependent	Ages ≥50: 1,200 mg/day
Vitamin D	Take with a meal with some fat in it to aid absorption	1,000 IU–2,000 IU daily or an appropriate dose to maintain adequate 25(OH)D level	Dose needed to correct deficiency varies based on 25(OH)D level; if <30, try 50,000 IU once weekly or 5,000 IU daily of vitamin D_2 or D_3 daily for 8–12 weeks

© F.A. Davis Publishing

TABLE 18-9 Duration of Pharmacological Treatment for Osteoporosis and Transition

DRUG	DURATION OF TREATMENT	DRUG HOLIDAY	TRANSITION TO
Bisphosphonates	Risk-benefit ratio for treatment >10 years unknown (Camacho et al., 2020)	Low risk: Consider after 3–5 years of stability on oral or 3 years on IV zoledronic acid	Low risk: No other treatment but reassess fracture risk at 2- to 4-year intervals and consider resuming treatment if fracture or significant bone mineral density loss occurs
		High risk: 10 years for oral, 6 years for IV zoledronic acid	High risk: Parathyroid hormone or raloxifene
Calcitonin	Safety data available through 5 years	No	When stopped, skeletal benefits are quickly lost over next 1–2 years
Denosumab	Reassess fracture risk after 5–10 years; if patient remains at high risk continue or change as long as clinically appropriate	No	Start an antiresorptive to prevent accelerated bone loss that occurs with stopping anabolic treatments
Parathyroid hormones	18–24 months	No	Bisphosphonate or denosumab to prevent accelerated bone loss that occurs with stopping anabolic treatments; can use romosozumab if patient remains high risk
Raloxifene	As long as clinically appropriate	No	When stopped, skeletal benefits are quickly lost over next 1–2 years
Romosozumab	1 year	No	Bisphosphonate or denosumab to prevent accelerated bone loss that occurs with stopping anabolic treatments
Zoledronic acid	Up to 6 years in very-high-risk patients	Consider after 3 years in high-risk patients or until fracture risk is no longer high	Not applicable

Source: Camacho et al., 2020; Arceo-Mendoza & Camacho, 2021

3 years. Those with a hip fracture had the highest mortality rate at 30%. Within a 3-year follow-up period, 14% had a subsequent fracture. For those who suffered subsequent fractures, the total estimated allowed medical cost in the 6-month period following was $5.7 billion in 2018. This estimate did not cover costs related to the loss of productivity, absenteeism, nonskilled home and nursing home costs, or pharmaceutical drugs. After a vertebral fracture, there may be acute pain that may resolve or may become chronic.

Prevention/Prophylaxis: The basic level of prevention and treatment includes diet, exercise, and fall prevention strategies.

Referral: Primary care providers may be knowledgeable about prevention and screening of fractures but may refer to an orthopedic surgeon for management of a fracture or to an osteoporosis specialist or clinical endocrinologist for management of osteoporosis. Fracture liaison services programs, a model of coordinated care where patients with recent fractures may be referred for secondary fracture prevention, have successfully reduced repeat fractures and lowered costs (NOF, 2021). Referral to such osteoporosis specialists is important in patients with fragility fractures, those with normal BMD and fracture without major trauma, those with recurrent fractures or continued bone loss while receiving therapy without obvious treatable causes of bone loss, those with less common secondary conditions (e.g., hyperthyroidism, hyperparathyroidism, hypercalciuria or elevated prolactin). those with osteoporosis with unexpectantly severe or unusual features, those with a condition that complicates management like CKD (glomerular filtration rate [GFR] <35) or malabsorption (Camacho, 2020). Consider a referral to physical or occupational therapy for significant kyphosis, back discomfort, and gait instability to improve gait and strength, reduce the risk of falling, and instruct the patient on proper body mechanics to prevent fractures and the use of adaptive treatment.

Education: Providers need time with a patient for a balanced discussion about their risks of probable osteoporosis, the risks and benefits of treatment options, reducing behavioral risks, diet, exercise and a fall reduction program, the risks of fracture and their consequences, and risks and benefits of discontinuing therapy. It is important to learn from the patient about their cultural beliefs, previous treatment experiences, fears, and concerns. The provider needs to present data in simple language that is understandable to the patient, sometimes with the use of decision aids such as brochures, cartoons, graphs, videos, and skeleton models. These are all important in patient-centered, shared decision making and should result in a management plan that is acceptable to the patient as well as better clinical outcomes.

PANCREATIC DISORDERS

PANCREATIC CANCER

Signal Symptoms: Pancreatic cancer is called the "silent disease" because often the disease is advanced before any symptoms begin. Symptoms include weight loss, pain in the upper abdomen spreading to the back that may come and go and be worse after eating and at night, jaundice of the skin or eyes, dark urine and light-colored stools, bowel movements that look greasy and float in the toilet, weakness, loss of appetite, and nausea and vomiting (Fernandez del-Castillo, 2021).

Description: Pancreatic cancer is difficult to detect, hard to diagnose, early to metastasize, and resistant to treatment. Pancreatic tumors can be characterized as either endocrine or exocrine, depending on the cells of origin. Exocrine pancreatic tumors are the most common, with adenocarcinoma being the most common subtype (American Cancer Society [ACS], 2021a). Cancers can arise from both exocrine and endocrine portions of the pancreas, though 95% develop in the exocrine portion. Approximately 75% of pancreatic cancers occur within the head or neck, 20% in the body, and 5% to 10% in the tail of the pancreas. The most common type of pancreatic cancer is pancreatic duct adenocarcinoma. Generally, it metastasizes to regional lymph nodes, then to the liver or, less commonly, the lungs (National Comprehensive Cancer Network [NCCN], 2021).

Etiology: Pancreatic cancer is fundamentally a disease caused by damage to the DNA. These mutations can be inherited, or they can be acquired as one ages. DNA can also be damaged by certain behaviors, such as smoking, or simply by chance (ACS, 2021b).

Occurrence: More than 60,000 cases of pancreatic cancer are diagnosed annually in the United States. Pancreatic cancer accounts for over 48,000 deaths annually (NCCN, 2021; National Cancer Institute [NCI], 2021). The overall 5-year survival rate for pancreatic cancer is 10.8%. Incidence is slightly higher in men than in women (NCI, 2021).

Age: The disease is rare in patients younger than 45 years. The median age of diagnosis is 70 years. Approximately two-thirds of patients are at least 65 years old (NCI, 2021).

Ethnicity: Blacks are only slightly more likely to have pancreatic cancer compared with Whites. Asian/Pacific Islanders have the lowest incidence rate (NCI, 2021).

Contributing Factors: Pancreatic cancer has been linked to smoking, obesity, diabetes, and chronic pancreatitis. Exposure to chemicals and heavy metals including beta-naphthylamine, benzidine, pesticides, asbestos, benzene, and chlorinated hydrocarbons is associated with pancreatic cancer (ACS, 2021b). Certain hereditary conditions are associated with pancreatic cancer, including hereditary breast and ovarian cancer syndrome (*BRCA1* and *BRCA2* genes), hereditary breast cancer (*PALB* gene), familial atypical multiple mole melanoma (FAMM) syndrome (*p16/CDKN2A* gene), familial pancreatitis (*PRSS1* gene), Lynch's syndrome or hereditary nonpolyposis colon cancer (*MLH1* or *MSH2* genes), and Peutz-Jeghers' syndrome (*STK11* gene) (ACS, 2021b; NCCN, 2021).

Signs and Symptoms: Patients should be questioned about abdominal and midback pain, anorexia, depression, nausea, vomiting, and changes in bowel movements. Along with significant weight loss and moderate epigastric tenderness, the patient may have a palpable gallbladder (Courvoisier sign) and skin excoriation from pruritus. One of the most characteristic signs of pancreatic cancer of the head of the pancreas is painless obstructive jaundice (Fernandez del-Castillo, 2021). However, patients may notice a darkening of the urine and lightening of stools before the jaundice is visually evident. When questioned, they may indicate that their stools float. They may also have ascites, and an abdominal mass may be noted in those with advanced pancreatic cancer. Left supraclavicular lymphadenopathy (Virchow's node) may be palpated in some patients with widespread disease. Many

© F.A. Davis Publishing

patients with advanced disease have Trousseau's syndrome (a hypercoagulable state) and there is a high incidence of thromboembolic events as well (Fernandez del-Castillo, 2021).

Diagnostic Tests: Liver function testing may show an elevated bilirubin and alkaline phosphatase. Bilirubin may be noted in urine and stool samples as well. The most useful tumor marker for pancreatic cancer is the ca19.9 antigen. A pancreatic protocol computed tomography (CT) scan of the abdomen is recommended when pancreatic cancer is suspected. Cases should be reviewed by an experienced multidisciplinary team to determine whether the disease is resectable, borderline resectable, locally advanced, or metastatic. Additional testing may include a CT scan of the chest, endoscopic ultrasound (EUS), magnetic resonance imaging (MRI) of the abdomen, endoscopic retrograde cholangiopancreatography (ERCP) with stent placement, and positron emission tomography (PET) scan. A biopsy will be done using fine-needle aspiration after a CT scan or EUS is done (NCCN, 2021).

Differential Diagnosis:

- Aortic aneurysm
- Duodenal or gastric ulcers
- Ampullary carcinoma
- Bile duct strictures or tumors
- Cholangitis
- Cholecystitis
- Choledocholithiasis
- Cholelithiasis (Fernandez del-Castillo, 2021; NCCN, 2021)

Treatment: The extent of surgery depends on the location and size of the tumor, the stage of the disease, and the patient's general health. The Whipple's procedure is the most common surgery for pancreatic cancer, especially if the tumor is in the head of the pancreas. A distal pancreatectomy removes the body and the tail of the pancreas, and a total pancreatectomy removes the entire pancreas, part of the small intestine, a portion of the stomach, the common bile duct, the gallbladder, the spleen, and nearby lymph nodes. After surgery the patient may have radiation therapy, chemotherapy, or a combination of both. FOLFIRINOX (chemotherapy regimen made up of the following: folinic acid [FOL], fluorouracil [F], irinotecan [IRIN], and oxaliplatin [OX]) or a regimen that contains gemcitabine are the recommended systemic treatment options (NCCN, 2021). Pain relief is crucial in palliative care. This can be done with narcotic analgesics alone or by combining them with tricyclic antidepressants or antiemetics. Radiation therapy can also palliate pain but does not affect patient survival. Obstructive jaundice warrants relief if the patient has pruritus or right upper quadrant pain. Anorexia may also improve after relief of biliary obstruction. Pancreatic insufficiency and subsequent malabsorption are treated with pancreatic enzyme replacement.

Follow-Up: Follow-up after surgery and/or treatment modalities is important to ensure that any changes are seen and dealt with as early as possible. This will include visits to the primary care provider, the surgeon (if surgery was done), and oncologist if that treatment modality was selected (NCCN, 2021).

Sequelae: Patients with pancreatic carcinoma are often anorexic. Patients with malabsorption diarrhea and weight loss may benefit from pancreatic enzyme supplementation. Visits to a dietitian may also be useful for nutritional assistance (NCCN, 2021).

Prevention/Prophylaxis: Although pancreatic cancer is not completely preventable, patients need to be aware of probable modifiable risks associated with the development of pancreatic cancer, such as smoking and excessive alcohol intake (a contributor to chronic pancreatitis). It remains controversial whether people with given risk factors should be screened for pancreatic cancer.

Referral: Current guidelines recommend that decisions about treatment and resectability involve input from a multidisciplinary group of specialists. Patients selected for surgery should be based on the probability of cure (NCCN, 2021). Other factors include comorbidities, overall performance, and age. In advanced pancreatic cancer, patients and family should be informed of availability of palliative care measures and hospice as indicated by the patient's progression of disease.

Education: The best decisions are made with a solid knowledge base, so one needs to learn as much about pancreatic cancer as possible. The patient and family will need end-of-life education. Although some patients may live up to 2 years or more, most with advanced pancreatic cancer die within months of diagnosis. There are support groups that can give information on possible clinical trials pertinent to the patient's condition (NCCN, 2021).

PANCREATITIS, ACUTE

Signal Symptoms: Mild-to-severe sharp epigastric pain with possible radiation to the back, chest, or flanks; pain can be exacerbated by eating, drinking, or lying flat. Nausea and vomiting often accompany the abdominal pain, as does mild to moderate fever.

Description: Acute pancreatitis is the result of acute inflammation of the pancreas, an organ that produces enzymes such as amylase, lipase, trypsin, and chymotrypsin to aid in digestion, as well as the hormone insulin, which controls the level of glucose in the blood. It is located in the upper abdomen, behind the stomach. The enzymes are secreted into the duodenum through the pancreatic duct and join with bile produced by the liver to digest food. Generally, these enzymes do not become active until they reach the small intestine. However, with a precipitating event the acinar cells within the pancreas can become damaged triggering a cascade activation of digestive enzymes within the pancreas causing pancreatic autodigestion which leads to pancreatic damage and inflammation (Mederos et al., 2021). Acute pancreatitis typically has a sudden onset and in a majority of patients resolves in 3 to 5 days with treatment and without complications. However, some patients progress to developing complications, which can include chronic pancreatitis, pancreatic pseudocyst, necrosis, organ failure, and death with a mortality rate of up to 30% in patients with severe acute pancreatitis (Quinlan, 2014).

Etiology: The two most common causes of acute pancreatitis are obstruction by gallstones, accounting for 21% to 33% of cases, and alcohol, accounting for 16% to 27% of cases (Zilio et al., 2019). If not due to gallstones or alcohol use, two less common but useful causes to investigate in the older adult are drug-induced pancreatitis and hypertriglyceridemia-induced pancreatitis, typically with serum triglycerides over 1,000 mg/dL (Gapp et al., 2019; Goyal et al., 2016; Papachristou et al., 2017; Simons-Linares et al., 2019). Other possible causes of acute pancreatitis are many and include viral infections (mumps, coxsackie B, mycoplasma pneumonia, and campylobacter), abnormalities of the pancreas itself, obstruction by pancreatic neoplasm, hereditary diseases such as cystic fibrosis, autoimmune disorders such as systemic lupus erythematosus, complication of endoscopic retrograde cholangiopancreatography (ERCP) (occurs in approximately 3% of post-ERCP patients), and trauma to the abdomen (Forsmark, Baillie, AGA Institute Clinical Practice and Economics Committee, & AGA Institute Governing Board, 2007). More than 500 drugs have been implicated in acute pancreatitis including acetaminophen, enalapril, furosemide, losartan, nadolol, statins, antibiotics such as tetracycline, and many others (Nitsche et al., 2010; Simons-Linares et al., 2019).

Cigarette smoking has been identified as a risk factor for both recurrent acute pancreatitis and progression to chronic pancreatitis (Ahmed Ali et al., 2016; Magnusdottir et al., 2019). In addition to smoking, older age, obesity, and HIV-positive status have been identified as risk factors for acute pancreatitis (Forsmark et al., 2016). Despite numerous etiologies, it should be noted that many cases of acute pancreatitis are idiopathic with no identifiable cause (Mederos et al., 2021).

Occurrence: Acute pancreatitis is the leading gastroenterological cause of hospitalization with nearly 275,000 hospitalizations annually (Forsmark et al., 2016). Eighty percent of pancreatitis is considered mild, and those persons generally recover without complication. The other 20% have severe disease with local and systemic complications. The mortality rate for acute pancreatitis varies based on severity but can range from approximately 1%, to over 30% in the most severe cases (Working Group IAP/APA Acute Pancreatitis Guidelines, 2013). Disease severity scoring systems have been developed to attempt to predict patient mortality rate based on variables that influence disease severity such as age, presenting signs/symptoms, and laboratory values (Mederos et al., 2021). Acute pancreatitis affects males and females nearly equally (Yadav & Lowenfels, 2013); however, alcohol-related etiology is more common in men than in women, although the rates equalize when level of alcohol consumption is equal. Gallstone etiology is more common in women compared to men.

Age: Acute pancreatitis is more common in older adults, with the incidence rate (per 100,000 population) for those age 75 years and older double that of those age 35 to 44 years in males and nearly triple that in females for the same age comparison groups (Yadav & Lowenfels, 2013). Mortality, likewise, increases with age. A study by Fan and associates (1988) found mortality for acute pancreatitis at 5.9% for those age 50 years and younger and 21.3% for those age 75 years and older. The reasons are attributed to diminished organ function, comorbid illnesses, increased susceptibility to infection and ischemia, and age-associated changes in the pancreas and biliary system (Skolnick et al., 2008).

Ethnicity: In the United States, Blacks have a two to three times higher risk of acute pancreatitis than do Whites (Yadav & Lowenfels, 2013). The hospitalization rates of Blacks are three times higher than for Whites and are more pronounced for males than females.

Contributing Factors: Biliary tract disease, binge alcohol use, recent surgery, family history of high triglycerides (typically over 1,000 mg/dL), and increasing age are some of the contributing factors. There is some disagreement on other potentially contributing factors. Some studies cite medications as causing up to 2% of acute pancreatitis cases (Quinlan, 2014); others assert that factors such as medications, hypercalcemia, hyperparathyroidism, and infection are falsely attributed as causative factors to acute pancreatitis because the evidence supporting these is lacking and therefore causative links are only theoretical (Tenner et al., 2013).

Signs and Symptoms: Examination findings will vary depending on severity of the attack. With a mild attack, the epigastric area may be minimally tender; however, with severe episodes, there may be abdominal distention, tenderness, guarding, and decreased bowel sounds (Mederos et al., 2021). Respirations may be shallow due to diaphragmatic irritation. There may be ecchymotic discoloration of the flank (Grey-Turner's sign) or in the periumbilical area (Cullen's sign), which occurs in less than 1% of cases, reflects intra-abdominal hemorrhage

© F.A. Davis Publishing

typically associated with severe necrotizing acute pancreatitis, and is associated with a high mortality (Pannu et al., 2017).

Diagnostic Tests: Amylase and lipase amounts are elevated during acute pancreatitis and are the most common laboratory markers used to establish a diagnosis of acute pancreatitis. While these tests tend to be ordered together in about 90% of cases, there is research demonstrating lipase as a superior test (Barbieri et al., 2016). Continued use of amylase is often attributed to more familiarity with the test, belief that both tests are necessary to establish a diagnosis, and order sets that bundle the tests together. However, lipase has been shown to have higher sensitivity and specificity, increased ability to detect both early- and late-stage cases of pancreatitis, and more specificity to the pancreas compared to amylase. Because of this, it has been suggested that amylase offers no increased diagnostic value and lipase should be ordered alone (Barbieri et al., 2016; Ismail & Bhayana, 2017). Another potential marker of acute pancreatitis is trypsinogen activation peptide (TAP) that becomes markedly increased and may be useful in detection of early acute pancreatitis. Additional useful laboratory tests include the metabolic panel to look at blood urea nitrogen (BUN), creatinine, glucose, and calcium levels, as well as liver function tests, triglycerides, a complete blood count (CBC), arterial blood gases (ABGs), and a urinalysis, all of which can help establish disease severity, help predict outcomes, and identify complications (Mederos et al., 2021).

Radiological evidence is used to confirm or exclude the clinical diagnosis, establish a cause, assess severity, and provide guidance for therapy. An abdominal x-ray is generally done first and helps to exclude other causes of abdominal pain, such as an obstruction or bowel perforation. A finding in more severe disease is an ileus or "colon cut-off sign," reflecting paucity of air in the colon due to spasm of the descending colon. This may be followed by an abdominal ultrasound, which is 87% to 98% sensitive for detection of gallstones, as well as for showing a diffusely enlarged hypoechoic pancreas. Abdominal computed tomography (CT) scan or magnetic resonance imaging (MRI) can be performed to confirm the diagnosis of acute pancreatitis, especially with normal lipase and/or amylase levels, or to evaluate patients who fail to show improvement after 72 hours (Vivian et al., 2019). However, it is not necessary at initial presentation and management unless diagnosis is unclear (Mederos et al., 2021).

Endoscopic ultrasonography (EUS) and magnetic resonance cholangiopancreatography (MRCP) can be especially helpful in documenting stones, tumors, changes in pancreatic ducts and anatomic structural abnormalities. It can also be useful in determining which patients with acute pancreatitis would benefit from a therapeutic ERCP (100% sensitive and 91% specific for gallstones). MRCP is a newer, noninvasive technique and is comparable to ERCP for cholelithiasis detection but does not have the interventional capacity for stone extraction, stent insertion, or biopsy, as the ERCP does. Additionally, advantages of MRCP include no radiation exposure compared to CT scan; gadolinium contrast in MRI has a lower risk of renal complications than iodine contrast in CT scan; and for patients with contraindication to contrast, nonenhanced MRI can still detect pancreatic necrosis. ERCP may be used for the less common causes of pancreatitis such as sphincter of Oddi dysfunction or pancreatic duct strictures. It is indicated for those persons who have not passed a stone during the acute attack and those with evidence of sepsis, biliary obstruction, cholangitis, elevated bilirubin worsening, or persistent jaundice or worsening pain in the presence of an abnormal ultrasound (Carroll et al., 2007; Cherian et al., 2007). For patients with acute cholangitis and persistent obstruction, ERCP should be performed in less than 24 hours to lessen disease severity (Working Group IAP/APA Acute Pancreatitis Guidelines, 2013).

Most patients will have mild disease; however, it is important to know as early as possible whether the attack is mild or severe for purposes of management and use of resources. There are several scoring systems used to identify early prognostic signs to predict the severity of pancreatitis, including the Revised Atlanta Classification (REC), Ranson criteria, the Acute Physiology and Chronic Health Evaluation (APACHE II) model, the Systemic Inflammatory Response Syndrome (SIRS) Score, and the Computed Tomography Severity Index (CTSI). Each has its pros and cons. With all scoring systems, the higher the prognostic score, the poorer the clinical outcome will be.

The REC is both used to diagnose acute pancreatitis and rate the severity of pancreatitis. Diagnosis is made based on the REC when two of three criteria are met: abdominal pain consistent with acute pancreatitis, serum amylase and/or lipase three times the normal limit, and cross-sectional (CT or MRI) imaging findings consistent with acute pancreatitis. To rate severity, the RAC uses the Modified Marshall Score to grade existence and duration of organ failure, as well as the presence of localized (pancreatic) complications. Patients with mild disease typically have a short, self-limiting course and hospital discharge within 7 days; moderate pancreatitis has a more prolonged course for weeks or even months due to organ dysfunction and localized complications (such as pseudocyst or necrosis) (Mederos et al., 2021).

Several scores can be used to predict outcome, such as mortality; they can also be used to guide management such as level of care and required resources. The Ranson criteria was the first system and remains the best known and most widely used. However, drawbacks include the need for information both at diagnosis and within the first 48 hours of admission and that it can be difficult to use (Mederos et al., 2021). The sensitivity and specificity for disease severity is 0.79 and 0.78, respectively; for mortality sensitivity and specificity are 0.91, 0.72 (Mikó et al., 2019). The criteria include:

On Admission:

- Age of more than 55 years
- White blood cell (WBC) count greater than 16,000/mm^3 (16.0×10^9/L)
- Blood glucose greater than 200 mg/dL (11.1 mmol/L)
- Serum lactate dehydrogenase (LDH) greater than 350 U/L
- Aspartate aminotransferase (AST) greater than 250 U/L

During the Initial 48 Hours:

- Hematocrit decrease greater than 10%
- BUN increases greater than 5 mg/dL (1.8 mmol/L)
- Serum calcium less than 8 mg/dL (2 mmol/L)
- Base deficit greater than 4 mmol/L (4 mEq/L)
- Fluid sequestration greater than 6,000/mL
- PaO_2 less than 60 mm Hg

© F.A. Davis Publishing

Scoring: One point for each criterion met. The prognostic implication is as follows: 0 to 2 means 2% mortality; 3 to 4 means 15% mortality; 5 to 6 means 40% mortality; and 7 to 8 means 100% mortality.

The APACHE II score can be used to assess the patient at any point during the illness, but it is cumbersome to use. Sensitivity is 71% and specificity is 80% for disease severity and 92% and 79% for mortality (Mikó et al., 2019). The equation includes multiple factors, including history of severe organ insufficiency or immunocompromised state, age, rectal temperature, measures of respiratory status, heart rate, serum electrolytes, serum creatinine, hematocrit, WBC count, Glasgow Coma Scale score, FIO_2, and others. Scoring can be calculated at https://www.mdcalc.com/apache-ii-score.

The CT Severity Index (CTSI) developed by Balthazar (2002) is the only scoring system to use evidence of necrotic pancreas as criteria. A key criterion for identification of patients at higher risk for fatal pancreatitis is pancreatic necrosis. Although the CTSI requires a CT scan to be performed, it is both easy to calculate and provides reliable information on both disease severity and mortality (Mikó et al., 2019).

CT Grade:
- A is normal pancreas (0 points)
- B is edematous pancreas (1 point)
- C is B plus mild extrapancreatic changes (2 points)
- D is severe extrapancreatic changes plus one fluid collection (3 points)
- E is multiple or extensive fluid collections (4 points)

Necrosis Score:
- None (0 points)
- Less than 30% (2 points)
- Greater than 30% but less than 50% (4 points)
- Greater than 50% (6 points)

Scoring: CT grade plus necrosis score. Scores range from 0 to 10 with 0 to 2 equated to mild disease, 4 to 6 moderate disease, and 8 to 10 severe disease (Mortele et al., 2004).

The presence of systemic inflammatory response syndrome (SIRS) has been associated with an increase in mortality from acute pancreatitis. A score based on the presence of SIRS can be used daily to reliably predict acute pancreatitis severity. When SIRS is persistent for 48 hours despite the patient being adequately hydrated, a poor prognosis may be indicated (Forsmark et al., 2016). One study found that patients with persistent SIRS from admission, presence of SIRS on admission that was not persistent, and no SIRS had mortality rates of 25%, 8%, and 0%, respectively (Mofidi et al., 2006). SIRS is present if the patient meets two or more of the following criteria:

- Temperature greater than 38.3°C (100.4°F) or less than 36.0°C (96.8°F)
- Heart rate greater than 90 beats/minute
- Respiratory rate greater than 20 breaths/minute or $PaCO_2$ less than 32 mm Hg
- WBC count greater than 12,000 cells/mL, less than 4,000 cells/mL, or greater than 10% immature (band) cells

At initial presentation, pancreatitis severity should be estimated using an established classification method, such as the Atlanta classification system, rather than clinical judgment alone. Additionally, hemodynamic status should be assessed immediately on presentation, and fluid resuscitation should be started at the time of diagnosis even in the emergency department (Crockett et al., 2018; Ketwaroo et al., 2019; Vivian et al., 2019).

Differential Diagnosis:
- Cholangitis
- Cholecystitis
- Choledocholithiasis
- Cholelithiasis
- Colon cancer
- Colonic obstruction
- Diabetic ketoacidosis
- Dissecting aneurysm
- Diverticulitis with/without perforation
- Duodenal or gastric ulcers
- Gastric or pancreatic cancer
- Gastric outlet obstruction
- Gastric volvulus
- Hepatitis
- Intestinal infarction
- Mesenteric ischemia
- MI
- Perforated peptic ulcer
- Pneumonia
- Tubo-ovarian abscess (Quinlan, 2014)

Treatment: The acronym PANCREAS can be used to remember management particulars: **P**erfusion, **A**nalgesia, **N**utrition, **C**linical management, **R**adiology, **E**RCP, **A**ntibiotics, and **S**urgery (Khaliq et al., 2010). For acute pancreatitis, a short stay in the hospital is generally required for IV fluid replacement and pain management. Persons admitted with severe acute pancreatitis or certain high-risk patients (older adults, gross obesity, diabetes) may require intensive care because multiple complications can develop within hours or days. In rare cases, acute pancreatitis can cause hypoxia, and this is more common in the older adult. If there is vomiting, a nasogastric tube may be inserted to remove fluid and air (Neoptolemos, 2009).

Fluid resuscitation is key to treatment of acute pancreatitis. Previous recommendations included aggressive fluid resuscitation of 5 to 10 mL kg/hr, unless contraindicated due to cardiac, renal, or other conditions (Working Group IAP/APA Acute Pancreatitis Guidelines, 2013). However, more recent research has dialed this back to less than 3 mL/kg/hr or has recommended against specific, blanket recommendations in favor of goal-directed therapy based on laboratory values and physiological data (Ketwaroo et al., 2019; Vivian et al., 2019). Fluid status should be frequently reassessed based on BUN and hematocrit. Clinical signs and adequate fluid resuscitation have been linked to reduced mortality (Working Group IAP/APA Acute Pancreatitis Guidelines, 2013).

Antibiotics are generally not indicated for most cases of pancreatitis, even with findings of necrosis unless fever and/or leukocytosis are present (Ketwaroo et al., 2019). For patients with gallstone pancreatitis, a cholecystectomy should be performed during the hospital stay, generally after at least 24 hours of treatment but within 2 weeks (Ketwaroo et al., 2019). Acute cholangitis resulting from biliary pancreatitis is potentially life threatening and should be treated with antibiotics; an ERCP may be required as well in these cases (Vivian et al., 2019).

© F.A. Davis Publishing

Patients with mild disease can begin on a low-fat, low-residue, soft diet within 24 hours of symptom control; with severe disease precluding an oral diet, parenteral nutrition should begin within 3 days of diagnosis (Vivian et al., 2019). Enteral nutrition (via oral, nasogastric, or nasojejunal route) is the preferred route of nutrition due to lower cost, decreased length of stay, and prevention of complications, organ failure, and mortality in acute pancreatitis (Ketwaroo et al., 2019; Vivian et al., 2019).

Follow-Up: Treatment of the patient must address underlying causes of pancreatitis and should follow a health-care team approach. If the culprit is alcohol consumption, treatment should go beyond just telling the patient to quit drinking and rather focus on a multidisciplinary team approach to alcohol cessation including medical care, behavioral health, and counseling. An endocrinology consultation may be assistive for those with hypertriglyceridemia or hypercalcemia-induced pancreatitis. Multidisciplinary care should also address triglycerides with lifestyle modification, weight control, and diet in addition to pharmacological therapy. Those with medication-induced pancreatitis may benefit from a pharmacology consultation to identify possible offenders and reasonable alternatives.

Sequelae: Gallstones may be the cause of acute pancreatitis and will need to be removed, which may be done by cholecystectomy if the pancreatitis is mild. However, surgery should occur within 2 weeks to prevent recurrent gallstone pancreatitis (Ketwaroo et al., 2019). If the pancreatitis is more severe, the gallstones may be removed using ERCP and a cholecystectomy performed after a full recovery from acute pancreatitis. Other possible complications can be an abscess or pseudocysts. Newly diagnosed patients with acute pancreatitis have a twofold increased risk of developing prediabetes or diabetes in the 5 years following acute pancreatitis (Das et al., 2014). Primary care providers should be vigilant with aggressive monitoring and prevention strategies in these patients. Acute pancreatitis can also cause kidney failure through acute tubular necrosis, although this risk can be lessened with adequate hydration during hospitalization. However, impaired kidney function after acute pancreatitis is possible, and a nephrology consultation may be beneficial. Finally, repeated episodes of acute pancreatitis can lead to chronic pancreatitis and the sequelae of this including pancreatic insufficiency, pseudocysts, and chronic pain.

Prevention/Prophylaxis: Depending on the cause of the acute pancreatitis episode, the person needs to be counseled on the cause, such as hypertriglyceridemia, alcoholism, hypercalcemia, or gallstone pancreatitis. The patient should be educated on steps related to prevention strategies such as alcohol cessation, evaluation for causes of hypercalcemia like hyperparathyroidism, and lifestyle modification for hypertriglyceridemia (Mederos et al., 2021). Additionally, triglyceride management with fibrates, statins, or omega-3 fatty acids (O3FAs) would be beneficial.

Referral: A dietary consultation and endocrinology referral may be helpful for the patient with acute pancreatitis that is due to high triglycerides or calcium. Endocrinology may also assist in management of diabetes that can result from pancreatitis. A referral for behavior modification, behavioral health, or a treatment program can be useful for the person who continues to drink alcohol. Nephrology can assist in any renal complications that result from acute pancreatitis.

Education: It is necessary for persons who have had an episode of acute pancreatitis to understand the mechanism behind the episode of pancreatitis to promote necessary changes including lifestyle management, diet, exercise, alcohol cessation, and others. Alcohol, specifically, increases the likelihood of recurrent attacks and development of chronic pancreatitis; education should be initiated in the hospital and occur as an outpatient at 6-month intervals for a minimum of 2 years (Mederos et al., 2021).

PANCREATITIS, CHRONIC

Signal Symptoms: As many as 80% of people experience upper abdominal pain, described as dull, and often in the epigastric area with radiation to the back (Barry, 2018; Singh et al., 2019; Wilcox et al., 2015). The pain may feel worse after eating or drinking and is sometimes relieved by leaning forward. The pain can be intermittent or constant. Overall, the severity, duration, character, and timing are variable between patients. Pain may also be accompanied by nausea and/or vomiting. The majority of patients experience intermittent attacks of pain at unpredictable intervals over years. Other associated symptoms can include fatigue, weight loss, steatorrhea, diarrhea, and decreased appetite (Kemalasari et al., 2018; Singh et al., 2019).

Description: Chronic pancreatitis is a chronic inflammatory condition as a result of pancreatic insult(s) resulting in irreversible structural and functional damage (Hart & Conwell, 2020; Kemalasari et al., 2018; Singh et al., 2019). It occurs due to the same underlying causes of acute pancreatitis and can be a consequence of recurrent acute pancreatitis episodes. In the presence of a trigger, such as alcohol, acinar cells are damaged and release digestive enzymes and inflammatory cytokines causing parenchymal damage that progresses to inflammation, fibrosis, and calcification; over time pancreatic ducts can become stenosed and obstructed, resulting in tissue loss and pancreatic atrophy (Kemalasari et al., 2018; Singh et al., 2019).This, in turn, results in exocrine and endocrine insufficiency, which can lead to diabetes mellitus, steatorrhea, chronic pain, malabsorption, vitamin deficiency, weight loss, osteoporosis, and pancreatic adenocarcinoma (Barry, 2018). The TIGAR-O (Toxic-metabolic, Idiopathic, Genetic, Autoimmune, Recurrent/severe acute pancreatitis, and Obstructive) classification system is based on risk factors for chronic pancreatitis (Barry, 2018).

Etiology: The three most common causes of chronic pancreatitis are alcohol and idiopathic and genetic causes (Singh et al., 2019). The majority of chronic pancreatitis cases have been attributed to excessive alcohol use and can account for approximately 50% of cases, or as many as 77% of cases (Singh et al., 2019). One study found the relative risk of chronic pancreatitis in patients who consume either 35 drinks a week or 48 drinks a week to be 2.7 and 3.3, respectively (Kristiansen et al., 2008). Idiopathic etiology simply means that after testing and work-up, no specific cause could be found; anywhere from 28% to 80% of cases have been found to be idiopathic, and this is generally considered the second most common etiology (Kemalasari et al., 2018; Singh et al., 2019). Genetic causes are the third most common etiology. Recently, several pathological genetic variants have been identified linked to pancreatitis and may be responsible for more cases than initially thought. A study in the United States found pathological variants of four specific genes in 47.8% of the study's patients previously diagnosed with idiopathic pancreatitis (Jalaly et al., 2017). In a study of Chinese patients with idiopathic pancreatitis, similar variants of the same genes were found in 50% of patients compared to 5.9% in the control group (odds ratio [OR] 16.1, $p < 0.001$) (Zou et al., 2018). Alcohol plays a larger role in chronic pancreatitis in men; women tend to have chronic pancreatitis of idiopathic, autoimmune, or gallstone origin.

Other, less common, etiologies of chronic pancreatitis include ductal obstruction (such as from stones, stricture, or tumor), hypercalcemia, severe hypertriglyceridemia, autoimmune diseases (such as inflammatory bowel disease, celiac disease, systemic lupus erythematosus, Sjögren syndrome), other chronic diseases (such as cystic fibrosis), and pancreatic anatomical abnormalities (such as annular pancreas) (Kemalasari et al., 2018; Singh et al., 2019).

Occurrence: Overall, chronic pancreatitis is a relatively rare disease, with prevalence having been estimated by several studies of between 35 to 73/100,000 in the United States and incidence ranging from 4 to 12/100,000/year, which translates to <200,000 U.S. patients living with chronic pancreatitis (Hart & Conwell, 2020; Singh et al., 2019). Chronic pancreatitis is more common in men then in women, although the degree of difference varies. Some newer studies find minimal difference in genders of about a 5% increased frequency in men than women (Machicado et al., 2019; Yadav et al., 2011). Others have found men 1.5 to 3 times more likely to have chronic pancreatitis, although these are typically older studies (Etemad & Whitcomb, 2001).

Age: Patients with chronic pancreatitis have an average age of 35 to 55 years old at diagnosis. However, there are age variations dependent on etiology. Average diagnostic age in alcohol-associated pancreatitis is 40 to 60 years old; genetic etiology is

© F.A. Davis Publishing

10 to 40 years old. Idiopathic pancreatitis can be classified as early-onset (average 19 years old at diagnosis) and late-onset (56 years old) (Layer et al., 1994; Singh et al., 2019). However, because of the lifelong nature of chronic pancreatitis, older patients are simply less likely to be newly diagnosed.

Ethnicity: As with age, ethnicity tends to affect variations in etiology. Blacks are more likely to have alcohol-related chronic pancreatitis than Whites; more broadly, non-Whites have higher rates of alcohol-related chronic pancreatitis than Whites (68% versus 42% in one study) (Beyer et al., 2020; Conwell et al., 2017; Singh et al., 2019). Additionally, Blacks with chronic pancreatitis have been shown to be more likely to be male, current or former smokers, and have etiology related to alcohol consumption (Wilcox et al., 2016). Finally, Blacks were more likely to have more advanced pancreatic morphological changes on imaging than Whites (Hart & Conwell, 2020).

Contributing Factors: Alcohol use remains the most common contributing factor (Barry, 2018; Kemalasari et al., 2018; O'Brien & Omer, 2019; Singh et al., 2019); it has been attributed to as much as 70% of cases (Barry, 2018). Idiopathic "late-onset" pancreatitis is more common in older adults. Obstructive chronic pancreatitis can be caused by an ampullary tumor or adenocarcinoma of the pancreas as well as pancreatic duct stricture (Barry, 2018; Kemalasari et al., 2018). Pancreatic stones also have been known to develop in older adults (Shah et al., 2008). Polypharmacy, common in older adults, raises the risk of pancreatitis-inducing medication use. Cigarette smoking has also been identified as a risk factor for chronic pancreatitis and accelerates disease progression (Barry, 2018; Hart & Conwell, 2020; Kemalasari et al., 2018; Singh et al., 2019). Other contributing factors include concomitant autoimmune diseases (such as inflammatory bowel disease, celiac disease, primary biliary cholangitis, and Sjögren syndrome) and genetic links with four recently identified gene variants linked to chronic pancreatitis development (Barry, 2018; Hart & Conwell, 2020; Kemalasari et al., 2018; Singh et al., 2019).

Signs and Symptoms: The most important clue to a proper diagnosis of chronic pancreatitis is an accurate medical history and subjective interview. The most common symptoms for chronic pancreatitis include abdominal pain, typically dull, epigastric, and with radiation to the back, neck, or flank, that can be worsened by food intake (Barry, 2018; Drewes et al., 2017; Hart & Conwell, 2020; Kemalasari et al., 2018; Singh et al., 2019). The pain is typically variable between patients but can be debilitating, result in social impairment, and significantly impact quality of life. Other symptoms can accompany pain including nausea, vomiting, weight loss/malnutrition, and steatorrhea (Kemalasari et al., 2018; O'Brien & Omer, 2019; Singh et al., 2019). Although pain is the most common symptom of chronic pancreatitis, as many as 20% of patient may have "silent" pancreatitis; additionally, pain can subside in patients as the pancreas fails (Barry, 2018).

The pancreatic enzymes (lipase and amylase) that are grossly elevated in acute pancreatitis may be normal or only mildly elevated and are considered nonspecific for chronic pancreatitis. Liver function tests may be elevated in obstructive pancreatitis such as with chronic strictures or mass. Serum triglycerides may be significantly elevated if related to the etiology, although this is rare. There may also be abnormal pancreatic function tests, such as fecal elastase, fecal fat, and serum trypsinogen (Barry, 2018).

As discussed, pain may subside as the pancreas fails; when 90% of pancreatic function is lost, exocrine dysfunction may result and impede the body's ability to break down complex foods and properly absorb products of digestions (Barry, 2018). Symptoms in these cases may include weight loss, diarrhea, steatorrhea, fat-soluble vitamin deficiencies, and osteopenia/osteoporosis. Even if the patient's appetite is unaffected by abdominal pain, patients with chronic pancreatitis may suffer weight loss due to these malabsorption deficiencies (Barry, 2018; O'Brien & Omer, 2019; Singh et al., 2019).

Occasionally on physical examination a tender fullness or mass may be palpated in the epigastric area, suggesting a pseudocyst or an inflammatory mass in the abdomen. Patients who have protein and fat deficiencies associated with advanced disease may exhibit decreased subcutaneous fat, temporal wasting, sunken supraclavicular fossa, and other signs of malnutrition. Severe or rapid weight loss should be a red flag for the health-care provider because it is generally worrisome for pancreatic cancer, which has a 15% to 40% incidence in patients with chronic pancreatitis (Barry, 2018).

Diagnostic Tests: Symptoms between acute and chronic pancreatitis can be similar. Serum amylase and lipase levels may be slightly elevated in chronic pancreatitis but are often normal or even decreased with the atrophy of the gland itself. If there is obstruction of the biliary tract, one may see elevated bilirubin, serum alkaline phosphatase, and hepatic transaminase levels (liver function tests). In the more advanced stages of pancreatitis, when malabsorption is present, the health-care provider may order blood, urine, and stool tests (testing fecal fat content) to help diagnose and monitor progression. However, maldigestion and malabsorption do not occur until more than 90% of the pancreas is destroyed (Barry, 2018).

Pancreatic function tests at present are direct tests, such as determining duodenal aspirates, but although they are sensitive, they are invasive and expensive. Generally, x-rays of the abdomen may show pancreatic duct calcifications in 30% of patients with chronic pancreatitis, although this is not diagnostic. In patients with suspected chronic pancreatitis, the first imaging modality for diagnosis is computed tomography (CT scan). If diagnosis is not established, the next imaging choice is magnetic resonance imaging (MRI). If diagnostic criteria are still not met, then endoscopic ultrasound (EUS) may be further used and may show calcifications, pancreatic enlargement, pancreatic pseudocysts, or pancreatic ductal dilation. Finally, endoscopic retrograde cholangiopancreatography (ERCP) can be performed. It must be considered that both EUS and ERCP are invasive tests and carry risks, such as acute pancreatitis (Mederos et al., 2021). The sensitivity/specificity for chronic pancreatitis are 75%/91% for CT, 78%/96% for MRI, and 81%/90% for EUS (Barry, 2018).

Although EUS has the highest possible sensitivity and specificity, it is invasive, has associated risks, and its accuracy is limited by the skill of the ultrasonographer/endoscopist with high interrater variability. Magnetic resonance imaging/magnetic resonance cholangiopancreatography (MRI/magnetic resonance cholangiopancreatography [MRCP]) is becoming the choice test for diagnosing chronic pancreatitis because of its ability to identify calcifications and duct obstructions in the disease without the radiation exposure associated with CT scan imaging and invasive procedural risks of EUS and ERCP.

© F.A. Davis Publishing

However, there is still low sensitivity for small calcifications and small duct calculi. Although CT has similar sensitivity and specificity to MRI/MRCP, there is low sensitivity for early disease, nonoptimal pancreatic duct visualization, and high levels of radiation exposure (Barry, 2018).

Differential Diagnosis:

- Pancreatic cancer
- Intestinal ischemia/infarct
- Cholecystitis
- Chronic gastritis
- Peptic ulcer disease (PUD)
- Biliary obstruction
- Crohn's disease
- Intestinal obstruction
- Ovarian cyst
- Myocardial infarction (MI)
- Irritable bowel syndrome (IBS)
- Ectopic pregnancy
- Acute appendicitis (Barry, 2018)

Treatment: Optimal management of chronic pancreatitis includes lifestyle changes, pain management, improvement of exocrine pancreatic insufficiency leading to malabsorption, and management of any complications. Lifestyle modifications that should be cornerstone to chronic pancreatitis treatment include smoking cessation and alcohol abstinence (Barry, 2018; Drewes et al., 2017; Gardner et al., 2020; Singh et al., 2019). Continued smoking and alcohol have been associated with continued disease progression; cessation can lead to decreased complications such as pancreatic cancer (Barry, 2018). Smoking may also be associated with decreased efficacy of endoscopic and surgical treatments (Singh et al., 2019). However, there is limited evidence associating smoking cessation and reduction in pain (Drewes et al., 2017). Alcohol abstinence in patients with chronic pancreatitis can improve pain, reduce frequency of recurrent acute pancreatitis, and limit hospitalizations (Drewes et al., 2017; Gardner et al., 2020). Both smoking and alcohol cessation should be addressed using a multidisciplinary approach, including pharmacological and nonpharmacological interventions such as support groups and behavior health/counseling.

Treatment of pain generally follows a stepwise approach, starting with nonopioid medications, such as nonsteroidal anti-inflammatory drugs and acetaminophen, with escalation based on clinical response (Barry, 2018; Beyer et al., 2020; Gardner et al., 2020; Hart & Conwell, 2020; Singh et al., 2019). If nonopioids are not effective in managing the patient's pain, then the next option would include weak opioids such as tramadol, followed by strong opioids such as oxycodone or morphine (Barry, 2018; Singh et al., 2019). If there is a need for opioid therapy, long-acting formulations should be strongly considered and appropriate attention should be paid to the risks of opioid use; follow tenants of safe prescribing (Beyer et al., 2020; Gardner et al., 2020). Another potential treatment option for pain includes antioxidants, especially in early disease, although research is limited and results are mixed (Barry, 2018; Gardner et al., 2020). Additionally, coanalgesics, such as antidepressants (e.g., gabapentin) and anticonvulsants (e.g., pregabalin), may reduce the need for opioids, although caution should be used with anticonvulsants (Beyer et al., 2020). Pancreatic enzymes, often used for malnutrition and pancreatic exocrine insufficiency, have limited data on effectiveness in pain management, although for patients who report pain improvement these can be continued given their low risks (Gardner et al., 2020). Finally, endoscopic, and surgical options (such as celiac plexus block) can be used to aid in pain management, although studies are conflicting in regard to timing and effectiveness (Beyer et al., 2020; Gardner et al., 2020). As noted by the complexity of pain management in these patients, it should be approached by a team including primary care, gastroenterology, and pain management specialists.

Patients with chronic pancreatitis are at risk for subsequent exocrine pancreatic insufficiency, malabsorption, and malnutrition and need to be appropriately managed. All patients with chronic pancreatitis should undergo regular nutrition assessment (Beyer et al., 2020; Gardner et al., 2020; O'Brien & Omer, 2019). Most patients' nutrition can be managed orally with supplementation, although some may require tube feeding (O'Brien & Omer, 2019). All patients with documented exocrine pancreatic insufficiency and/or malnutrition should receive pancreatic enzyme supplementation with weight-based dosing per treatment guidelines (Beyer et al., 2020; Gardner et al., 2020; Hart & Conwell, 2020). Enzyme supplementation may even improve or reduce complications from chronic pancreatitis (Gardner et al., 2020). Many organizations recommend a healthy diet that is low fat and consists of small, frequent meals to reduce risk of pain and complications (Barry, 2018; Beyer et al., 2020). Finally, assessment of fat-soluble vitamin deficiencies should be periodically done, with supplementation added as needed (Gardner et al., 2020; O'Brien & Omer, 2019).

Finally, as previously discussed, patients with chronic pancreatitis are at increased risk for several complications including diabetes, bone density loss and osteopenia/osteoporosis, and risks for pancreatic cancer, and should be subsequently monitored and treated (Gardner et al., 2020; Hart & Conwell, 2020). For patients who develop diabetes as a complication of chronic pancreatitis, management recommendations include metformin as the first-line treatment followed by insulin (Hart & Conwell, 2020). Use of insulin has also been thought to potentially reduce catabolic side effects of chronic pancreatitis (Hart & Conwell, 2020). It is reasonable that patients with chronic pancreatitis should undergo baseline dual x-ray absorptiometry (DEXA) scanning for bone mineral density (BMD) to evaluate for bone density losses because of the risk of osteopenia/osteoporosis. Subsequent screening and treatments, including weight-bearing exercises, supplementation with calcium and vitamin D, smoking cessation, and cautious use of bisphosphonates (if needed) should follow established general guidelines (Hart & Conwell, 2020). Finally, patients with chronic pancreatitis have an increased risk of pancreatic cancer (Barry, 2018). However, routine pancreatic cancer screening with imaging is not recommended for multiple reasons, although care providers should be vigilant in evaluating for warning signs that may raise suspicion for pancreatic cancer (Gardner et al., 2020; Hart & Conwell, 2020).

Follow-Up: If alcohol use and/or smoking are among the habits of the patient, these are best treated by a team approach using a chemical dependency counselor, psychologist, or mental health nurse practitioner. An alcohol treatment program may be appropriate. The patient will be seen back for follow-up on symptoms and clinical progression of

© F.A. Davis Publishing

the disease, with any treatment modifications needed, based on symptoms and presentation. Involvement of the multidisciplinary team, possibly including gastroenterology, pancreatic disease specialist, pain management, and endocrine, can be initiated for more complex patients.

Sequelae: There are several possible complications of chronic pancreatitis (Beyer et al., 2020; Gardner et al., 2020; Hart & Conwell, 2020; O'Brien & Omer, 2019; Singh et al., 2019). Chronic pancreatitis can also lead to calcification of the pancreas, where the tissue hardens, and surgery may be necessary to remove part of the pancreas. Long-standing inflammation in the pancreas caused by chronic pancreatitis is a risk factor for developing pancreatic cancer. Benign cysts, called pseudocysts, are formed of pancreatic fluid and surrounded by a fibrous wall. However, these cysts can also fill with fluid and debris, become infected, and rupture (Barry, 2018). Biliary obstruction and gastric outlet obstruction may occur because of compression of the bile duct necessitating endoscopic or surgical intervention (Barry, 2018). If the beta cells of the pancreas are destroyed, diabetes may develop, and insulin and diet will be recommended along with frequent blood glucose monitoring. Other risks include osteoporosis and risk of bone fracture, fat-soluble vitamin deficiency.

Other complications of chronic pancreatitis include development of duodenal obstruction, pancreatic ascites, and pleural effusion from fluid accumulation, pseudoaneurysms, and splenic vein thrombosis (Barry, 2018). When medical management no longer relieves pain, when patients are significantly malnourished, or when quality of life is decreased greatly, surgical intervention should be considered (Kemalasari et al., 2018; O'Brien & Omer, 2019). To date, the most recent Cochrane review of surgical intervention in obstructive chronic pancreatitis found that early surgical intervention seemed beneficial but could not be definitively demonstrated (Ahmed Ali et al., 2012). Caution is advised when regulating glycemic control in older adults to prevent episodes of hypoglycemia regardless of diabetic etiology.

Prevention/Prophylaxis: A cornerstone of prevention of chronic pancreatitis is smoking cessation and alcohol abstinence (Gardner et al., 2020). For patients already diagnosed with the disease, a diet low in fat with frequent small meals is generally recommended (Barry, 2018; Beyer et al., 2020). Additionally, patients with exocrine pancreatic insufficiency (EPI) should be placed on pancreatic enzymes for treatment/prevention of malabsorption and worsening malnutrition (Beyer et al., 2020; Gardner et al., 2020). The dosing is generally 500 units lipase/kg/meal and half that for snacks, and attempts should be made to ensure patient takes the supplements correctly to promote intended effect (O'Brien & Omer, 2019). The enzymes should be taken with every meal and snack (not before or long after) and should be taken whole with adequate fluids. A diet low in fiber may help, as dietary fiber can reduce the effectiveness of pancreatic enzymes (O'Brien & Omer, 2019). Various other supplements may be considered to help prevent nutritional issues due to malabsorption and malnutrition. A daily proton pump inhibitor may be added for those with refractory therapy because gastric acid may denature exogenous enzymes. Those persons with a known reason for chronic pancreatitis, other than smoking or alcohol, should have those reasons treated or corrected, if possible.

Referral: Surgical intervention is indicated when there is an anatomical complication correctable by mechanical intervention and includes an abscess, fistula, and fixed obstruction such as a stone, pseudocyst, stenosis, or a varietal hemorrhage due to splenic vein thrombosis. Additionally, surgery may be needed as a pain management intervention for some patients. Pancreatic resection with islet auto transplantation (TPIAT) is reserved for those with small duct disease or pain unresponsive to medical management, although this is only offered at a limited number of facilities and will likely require tertiary care referral (Barry, 2018; Beyer et al., 2020).

Education: All persons with chronic pancreatitis should have a consultation with a dietitian concerning a diet low in fat. They should also have instruction on how to cook low-fat meals and how to portion out small, frequent meals. Additionally, there should be education on smoking cessation, alcohol abstinence, risks of complications, and warning signs to be aware of.

THYROID DISORDERS

HYPERTHYROIDISM

Signal Symptoms: Apathy, fatigue, confusion, weakness, course tremors, anorexia, palpitations, orbitopathy, weight loss.

Description: Hyperthyroidism occurs when there is an excessive synthesis and secretion of thyroid hormone. Whereas the clinical signs and symptoms of hyperthyroidism are generally well recognized in younger patients, older adults may present atypically with symptoms such as mood, cognitive changes, or heart arrhythmias (Ross et al., 2016). Overt hyperthyroidism is defined as a suppressed thyroid-stimulating hormone (TSH) level and elevated free T4/T3 levels. Subclinical hyperthyroidism is defined as suppressed TSH levels and normal free T4/T3 levels. Subclinical thyroid disease is clinically relevant in older adults, potentially leading to progression to overt hyperthyroidism, along with multiple complications such as cardiac issues, bone loss, fractures, and dementia (Biondi & Cooper, 2018).

Etiology: The most common cause of hyperthyroidism in adults is Graves' disease; however, the proportion of patients with toxic multinodular goiter (Plummer's disease) and toxic adenoma increases with age and iodine deficiency. Graves' disease is a familial autoimmune disorder in which thyrotropin receptor antibodies stimulate the TSH receptor, resulting in increased thyroid hormone production (Ross et al., 2016). In toxic multinodular goiter or toxic adenoma, the nodules are thought to independently produce excess thyroid hormone. Thyroiditis may occur, which is caused by the release of thyroid hormone due to the autoimmune or viral destruction of the tissue (Hughes & Eastman, 2021).

Occurrence: Hyperthyroidism occurs in about 1.2% of the U.S. population (0.5% overt and 0.7% subclinical) (Ross et al., 2016). Women are 5 to 10 times more likely to develop Graves' disease than men (Antonelli, et al., 2020).

Age: Of all cases of hyperthyroidism, 15% to 25% occur in people 60 years and older (Papaleontiou & Haymart, 2012).

Contributing Factors: Patients with other autoimmune conditions, such as type 1 diabetes, rheumatoid arthritis, and myasthenia gravis, are at risk for developing hyperthyroidism. A familial tendency for developing hyperthyroidism exists (Antonelli et al., 2020). Patients prescribed amiodarone or radiographic contrast media can develop iodine-induced hyperthyroidism (Ross et al., 2016). Hyperthyroidism may occur rarely in patients with metastatic follicular thyroid cancer, certain ovarian tumors, and TSH-secreting pituitary tumors. Laboratory findings that suggest hyperthyroidism in a patient with known hypothyroidism is due to over-replacement with exogenous thyroid hormone. The dose of levothyroxine should be adjusted to ensure a euthyroid status. Environmental factors may include viruses, a high-iodine diet, smoking, and selenium and/or vitamin D deficiency (Antonelli et al., 2020).

Biotin is a common supplement that can lead to an error in the laboratory reporting of thyroid labs. High doses of biotin make TSH appear falsely suppressed and T4/T3 levels falsely elevated, which can lead clinicians down the incorrect path of a hyperthyroidism diagnosis. Biotin has also been shown to cause falsely positive thyroid antibodies (TRab) that suggest autoimmune hyperthyroidism. It is imperative that patients who take biotin supplements stop them at least 2 days before their laboratory draw to provide the most accurate report (Ardabilygazir et al., 2018).

Signs and Symptoms: For patients of all ages, weight loss, fatigue, heat intolerance, tremor, and palpitations are the most common symptoms (Smith & Hegedüs, 2016). Older patients commonly report weight loss, decreased appetite, and cardiac manifestations. Atrial fibrillation occurs in more than 10% of patients older than 60 years with hyperthyroidism (Smith & Hegedüs, 2016). Thyroid hormones play an essential role in mood and cognition, along with emotional regulation. A wide range of symptoms may occur, such as depression, anxiety, or apathy, particularly in untreated patients (Riguetto et al., 2019). Older adults may experience diarrhea; a prior history of constipation may resolve with the onset of undiagnosed hyperthyroidism. A reduction or increase in appetite may be revealed; patients with severe hyperthyroidism may become cachectic. Photophobia and blurred and/or double vision may be reported.

Known as apathetic thyrotoxicosis, patients and/or caregivers may report that the patient is withdrawn, anorexic, and experiencing new onset of proximal muscle weakness, all contributing to inactivity (Samuels & Franklyn, 2018).

On physical examination, ophthalmological changes in the older adult such as exophthalmos are not as common; however, the risk of opthalmopathy is higher in older men (Smith & Hegedüs, 2016). Physical examination findings related to the eye may include proptosis, eyelid swelling, eyelid retraction, exophthalmos, extraocular muscle dysfunction, or increased lacrimation (Smith & Hegedüs, 2016). Patients may report ocular pain.

The examiner needs to remember that the thyroid is found lower in the neck and substernal area in older adults than in a younger person. Palpate the thyroid to determine presence or absence of nodules and/or tenderness. Thyroiditis may or may not be painful (Hughes & Eastman, 2021).

Because cardiac findings are prevalent in older adults with hyperthyroidism, a thorough cardiac examination is essential. Accurate measurement of pulse and blood pressure is important for the initial work-up and ongoing surveillance of patients with hyperthyroidism. Tachycardia, angina, atrial fibrillation, heart failure, and cardiovascular death may occur in patients with hyperthyroidism, particularly if untreated (Lillevang-Johansen et al., 2019). New onset of atrial fibrillation is much more common in the older adult with thyrotoxicosis. Look for evidence of peripheral nonpitting edema with asymmetrical plaques or nodules (pretibial myxedema).

A reduction in muscle mass may be detected (proximal weakness is common in hyperthyroidism), so muscle strength should be tested. Ask patients to demonstrate their ability to stand up from a seated position. If patients report recent falls, observe gait and assess the patient's ability to maintain balance. A coarse tremor may be evident; note for presence in

© F.A. Davis Publishing

outstretched fingers. Brisk tendon reflexes may occur; however, this manifestation is less common in older adults.

Although the signs, symptoms, and physical examination of patients with hyperthyroidism may be dramatic, it is important to recognize that many older adults with subclinical hyperthyroidism may be asymptomatic (Biondi & Cooper, 2018).

Diagnostic Tests: The TSH level is decreased in patients with hyperthyroidism. If the serum-free T4 result is normal following a decreased TSH, a serum-total T3 should be ordered. This value is sometimes increased, indicating T3 toxicosis (Ross et al., 2016). If the T3 result is also normal, the patient is said to have subclinical hyperthyroid disease. Serum antibody tests are useful in determining the cause of hyperthyroidism. Testing should include TRabs, which have a 96% sensitivity for detecting Graves' disease (Ross et al., 2016). Antibody testing is the preferred initial approach to reduce overall cost of diagnostic testing (Ross et al., 2016). Radioactive iodide uptake (RAIU) may be ordered to differentiate the cause of the thyrotoxicosis. For patients with Graves' disease, toxic adenoma, or toxic multinodular goiter, the RAIU will indicate increased iodine uptake, whereas other causes will show a low uptake, including thyroiditis (Ross et al., 2016). There is a diffuse uptake of RAIU in Graves' disease, whereas there is focal uptake in toxic nodular disease. In older adults, an electrocardiography is warranted to rule out associated cardiac arrhythmias, particularly if there is clinical concern. The use of thyroid ultrasound is indicated if the patient requires evaluation for thyroid nodules as thyroid cancer may coexist in up to 10.6% of with hyperthyroidism and nodules (Ross et al., 2016). Additional baseline laboratory tests should include a complete blood count and liver enzymes. Routine laboratory tests of patients with hyperthyroidism may reveal impaired glucose tolerance, increase in serum calcium levels, and elevated liver enzymes.

Differential Diagnosis:

- Anxiety
- Depression
- Diabetes mellitus, type 1 or type 2
- Severe anemia
- Leukemia
- Atrial fibrillation
- Pheochromocytoma
- Medication side effects

Treatment: Hyperthyroidism needs immediate attention in older adults because it is commonly associated with involvement of other organ systems, especially cardiac. Long-acting beta blockers are indicated in the early treatment of hyperthyroidism to control palpitations and tachycardia, unless limited by other concomitant conditions such as asthma or heart failure (Ross et al., 2016).

The three main treatments for hyperthyroidism are antithyroidal agents (thioamides), radioactive iodine ablation, and thyroidectomy. Methimazole is the preferred antithyroidal agent for older adults with hyperthyroidism. Methimazole works by blocking thyroid hormone synthesis. Current guidelines recommend that adults can remain safely on methimazole for up to 18 months or longer with careful monitoring. Potential rare but serious side effects include agranulocytosis (<0.5% of patients) and hepatic injury (<0.1% of patients) (Biondi & Cooper, 2018). For patients who are high risk for surgery or who have a limited life expectancy, methimazole treatment is the preferred long-term treatment (Ross et al., 2016). Radioactive iodine ablation is a definitive treatment option for patients with Graves' disease or toxic nodules, with a cure rate of approximately 75% in the 6 months following treatment (Hughes & Eastman, 2021). Ablation therapy may be preferred for patients who are healthier with a longer life expectancy and patients should be euthyroid before proceeding for treatment. Thyroid ablation is not recommended for patients who have moderate or severe orbitopathy due to the potential for worsening of the eye disease (Ross et al., 2016). Thyroidectomy is a final option but is generally not recommended in older patients unless they have a large goiter causing compressive symptoms, have concomitant thyroid cancer, or other options have failed to control the hyperthyroidism (Hughes & Eastman, 2021).

The treatment of subclinical hyperthyroidism has long been an area of debate in endocrinology. Current recommendations support treating older adults with subclinical disease due to the potential for harm from cardiac involvement, bone loss, or cognitive decline (Biondi & Cooper, 2018).

Follow-Up: Patients with hyperthyroidism require monitoring during the course of treatment, including symptoms, thyroid levels, and cardiac status. The patient must be aware of the potential of converting to hypothyroidism due to overtreatment or reversal of the underlying condition. Diagnostic studies, including TSH, free T4 (with or without T3) should be monitored every 6 to 8 weeks following treatment for Graves' disease until a euthyroid state is achieved and the patient is stable (Ross et al., 2016). Following radioactive iodine ablation, most patients eventually develop hypothyroidism within 2 to 6 months and will require thyroid hormone replacement such as levothyroxine. For patients with autoimmune hyperthyroidism, it is possible that they will enter remission after taking thioamides. Patient counseling of signs and symptoms of both hypothyroidism and hyperthyroidism is important. Careful monitoring of thyroid function is required on a regular basis. In patients with subclinical hyperthyroidism who do not have obvious sequalae or symptoms such as arrhythmias, it is reasonable to wait and repeat thyroid labs in 2 to 3 months to assess trends before deciding on treatment (Biondi & Cooper, 2018). Subnormal TSH levels are transient in up to 50% of patients (Biondi & Cooper, 2018). Autoimmune hypothyroidism occurs in 10% to 20% of patients during long-term follow-up (Smith & Hegedüs, 2016).

Sequelae: Complications that can develop in hyperthyroidism include ischemic heart disease, angina, cardiac arrhythmia, atrial fibrillation, myocardial infarction (MI), and heart failure. Bone density may decrease, rendering the patient susceptible to the development of osteoporosis. For patients who remain on antithyroidal treatments, potential side effects of methimazole should be evaluated continually, including agranulocytosis and hepatic injury. It is generally not recommended to follow laboratory studies (complete blood count [CBC], hepatic panel) unless the patient presents with signs and symptoms (e.g., severe infection).

Prevention/Prophylaxis: Hyperthyroidism is not known to be preventable; however, because thyroid disease is prevalent in older adults, regular screening for signs and symptoms of

© F.A. Davis Publishing

hyperthyroidism in patients with a history of other autoimmune conditions and/or family history of thyroid disease should be considered.

Referral: Patients with complicated hyperthyroidism should be treated by an endocrinologist, especially in the presence of complications or multiple comorbid conditions. Patients who wish to discuss treatment options or long-term management may also benefit from referral to a provider experienced in the care of thyroid disease.

Education: Patients should have a discussion with their health-care provider outlining the signs and symptoms of both hyperthyroidism and hypothyroidism. All three treatment options should be discussed, along with pros and cons of each. Patients should understand that the treatment of hyperthyroidism will require ongoing monitoring and screening for potential complications such as cardiac issues. Prescribed medications should be taken daily. Weight gain is common in patients after being treated for hyperthyroidism as the euthyroid state is recovered (Hughes & Eastman, 2021). Patients should be counseled to take measures to ensure a well-rounded diet with an appropriate calorie amount for their activity level to avoid unnecessary weight regain.

HYPOTHYROIDISM

Signal Symptoms: Weakness, cold intolerance, myalgias, depression, apathy, impaired memory, fatigue, hair thinning and/or loss, weight gain.

Description: Hypothyroidism is classified as either primary hypothyroidism, which is the failure of the thyroid gland to produce hormones; or secondary hypothyroidism, which occurs when the pituitary gland fails to secrete adequate amounts of thyroid-stimulating hormone (TSH). Hypothyroidism can further be divided into either overt (elevated TSH and low free T4) or subclinical (elevated TSH and normal free T4).

Etiology: Autoimmune thyroiditis, known as Hashimoto's thyroiditis, is the most common cause of hypothyroidism in people of all ages, causing 90% of hypothyroidism (Calsolaro et al., 2019). Other causes of primary hypothyroidism include thyroidectomy, radioiodine treatment, infection, or infiltration of the thyroid gland. Hypothyroidism can be iatrogenic from medications such as amiodarone, lithium, or tyrosine-kinase inhibitors (Calsolaro et al., 2019). Severe iodine deficiency or mild to severe iodine excess can cause hypothyroidism (Taylor et al., 2018). Causes of secondary (central) hypothyroidism include hypothalamic failure, pituitary adenoma or apoplexy, or, rarely, thyroid hormone resistance (Taylor et al., 2018).

Occurrence: Hypothyroidism occurs in up to 3.7% of the population of the United States (Taylor et al., 2018)

Age: Hypothyroidism is more common in adults older than 65 years, affecting 5% to 10% of women and 3% to 8% of men (Duntas & Yen, 2019). Women are up to 10 times as likely to be diagnosed with the condition (Taylor et al., 2018). Subclinical hypothyroidism may be present in up to 15% of the older population (Jasim & Gharib, 2018).

Ethnicity: Hypothyroidism is most common in White populations compared to Black, Asian, or mixed-race populations (Taylor et al., 2018).

Contributing Factors: Patients with previous thyroid dysfunction or goiter may develop hypothyroidism. Patients who have had extensive neck surgery, radiation, or prior thyroid surgery may develop hypothyroidism. Hypothyroidism can result from pituitary disease and certain infiltrative diseases such as sarcoidosis and scleroderma. Patients with first-degree relatives with thyroid disease are at risk.

© F.A. Davis Publishing

Signs and Symptoms: The symptoms of hypothyroidism may be commonly mistaken for the normal aging process. Older adults with hypothyroidism are more likely to present with mild, absent, or even atypical symptoms (Leng & Razvi, 2019). The most common symptoms in older adults are constipation, psychiatric problems, balance problems, and joint/muscle pain (Duntas & Yen, 2019). Other signs and symptoms may include dry skin, cold intolerance, weight gain, puffiness, slow heart rate and slow thinking (Jonklaas et al., 2014). Older patients may experience cognitive changes that could include confusion, disorientation, impairment in word fluency, or even dementia (Leng & Razvi, 2019). Additionally, patients with undiagnosed hypothyroidism may experience dyspnea and sleep apnea (Jonklaas et al., 2014). Given that the signs and symptoms of hypothyroidism are neither sensitive nor specific, it is recommended that they be correlated with laboratory findings (Jonklaas et al., 2014).

On physical examination, the overall appearance of the patient may reveal brittle nails, puffiness of the face and eyelids, thinning of the outer halves of the eyebrows, and xerosis (Watson & Guilbeau, 2021). During the thyroid examination, the examiner should first observe the thyroid while the patient swallows and then proceed to hands-on examination. A goiter may be present that feels rubbery, is not tender, and is possibly nodular. Thyroiditis may cause a tender thyroid gland. Thyroid nodules, common in older adults, are more likely to be benign if they feel smooth and easy to manipulate, whereas malignant nodules are more likely to be hard, irregular, fixed, and tender on palpation.

Other physical examination findings may include macroglossia, bradycardia, elevated diastolic blood pressure, diminished bowel sounds, delayed relaxation of deep tendon reflexes, nonpitting edema in the lower extremities (pretibial myxedema), carpal tunnel disease, and ataxia (Watson & Guilbeau, 2021). A mental status screening examination should be performed.

Diagnostic Tests: Overt hypothyroidism is defined as an elevated TSH and a suppressed free T4. It is important to note that TSH levels increase with the normal aging process. Some studies suggest that TSH can rise to around 8 mU/L in adults older than 80 years who do not have underlying thyroid disease (Duntas & Yen, 2019). Using age-specific intervals for thyroid levels may be the most appropriate evaluation method in older adults. An elevated TSH and a normal free T4 occurs in subclinical hypothyroidism. Thyroid antibodies should be drawn to assess for autoimmune disease. Antithyroid peroxidase antibodies and anti-thyroglobulin (TgAbs) are the most sensitive and specific (Calsolaro et al., 2019). An electrocardiogram may indicate sinus bradycardia, prolonged QT intervals, and possibly atrioventricular block and conduction disturbances (Jonklaas et al., 2014). A thyroid ultrasound is warranted in patients with thyroid nodule(s) or goiter (Jonklaas et al., 2014).

Differential Diagnosis: A number of conditions can mimic hypothyroidism. It is imperative for clinicians to conduct a full history and physical to determine the potential for comorbid conditions. The following diagnoses should be considered in addition to hypothyroidism:

- Dementia
- Anemia
- Depression
- Heart failure
- Ascites
- Chronic fatigue syndrome
- Fibromyalgia
- Sleep disorder (insomnia or obstructive sleep apnea)

Treatment: The goals of treatment for hypothyroidism are to resolve symptoms, achieve normalization of thyroid hormones, and avoid overtreatment (Jonklaas et al., 2014). Older adults with an underactive thyroid should be prescribed levothyroxine. Although most younger patients are started on weight-based levothyroxine dosing (1.6 mcg/kg/day), older adults should typically start with more conservative dosing. Generally, levothyroxine can be initiated at 50 mcg/day. For those who are underweight, frail or who have underlying cardiovascular disease, the starting dose should be 12.5 to 25 mcg/day. Patients should be reevaluated in 4 to 6 weeks for assessment of clinical presentation and TSH level. The dose can then be adjusted upward by 12.5- to 25-mcg intervals every 4 to 6 weeks (Jonklaas et al., 2014).

A thorough medication history is necessary when prescribing levothyroxine. Cholestyramine, ferrous sulfate, sucralfate, and antacids containing aluminum hydroxide can reduce medication absorption and effectiveness. Phenytoin, carbamazepine, rifampin, and anticoagulants may increase the drug metabolism. Patients taking levothyroxine should allow a 4- to 6-hour interval between these medications (Jonklaas et al., 2014). Dietary fiber and soy can also interfere with absorption, so levothyroxine needs to be taken on an empty stomach in the morning, at least 30 minutes before any other food, medication, supplement, or even coffee.

There is ongoing debate about whether older adults with subclinical hypothyroidism should be treated. Some studies suggest that symptoms do not improve in patients treated with thyroid replacement (Saifi et al., 2017). Other studies suggest that subclinical hypothyroidism is a risk factor for the development or exacerbation of type 2 diabetes, hyperlipidemia, hyperuricemia, and hypertension (Jasim & Gharib, 2018). The American Association of Clinical Endocrinologists recommends treating patients with subclinical hypothyroidism who have a TSH >10, have a TSH between 5 to 10 with a goiter, cardiac symptoms, or positive antibodies, or if there is significant concern about the progression to overt hypothyroidism (Jasim & Gharib, 2018; Peeters, 2017).

Treatment with thyroid formulations other than levothyroxine is not recommended in older patients as alternate treatments can be difficult to titrate, are often associated with higher rates of side effects, and have a lack of long-term safety data (Jonklaas, et al., 2014).

Follow-Up: Patients who are still needing dose adjustments should have thyroid levels checked every 4 to 6 weeks until the TSH is normal. Once stable, patients should have a routine TSH evaluation every 6 to 12 months. Patients with secondary hypothyroidism need a free T4 test because the TSH will not be accurate given lack of pituitary function. Monitor clinical signs and symptoms in all patients. Patients with subclinical hypothyroidism should be reevaluated every 3 to 6 months to determine whether hypothyroidism treatment is clinically indicated (Jonklaas et al., 2014).

Sequelae: Patients with untreated (or undertreated) hypothyroidism may develop hyperlipidemia and/or coronary artery disease or heart failure (Jonklaas et al., 2014). Patients who are overtreated with too high of a levothyroxine dose may experience bone loss leading to fracture, weight loss, or atrial

© F.A. Davis Publishing

fibrillation (Jonklaas et al., 2014). Patients with subclinical hypothyroidism and positive antibodies (TRAb and/or TgAb) convert to overt hypothyroidism at a rate of 4.3% per year (Calsolaro et al., 2019).

Prevention/Prophylaxis: Although the value of regular screening for thyroid disease has been debated for the general population, it is advocated for older adults who have higher rates of thyroid disease (Duntas & Yen, 2019).

Referral: If the patient has numerous complications or is not responding to treatment despite compliance, referral to an endocrinologist is appropriate.

Education: Remind patients about the potential for drug interactions that have been shown to interfere with L-thyroxine absorption, including over-the-counter products that contain iron, aluminum-containing antacids, and calcium carbonate. Patients should not increase their dosage if they are experiencing symptoms of hypothyroidism; instead, they should contact their health-care provider. Alert patients to contact their health-care provider if they experience signs and symptoms of hypothyroidism or hyperthyroidism. In most cases, the diagnosis of hypothyroidism will require lifelong management and follow-up.

THYROID NODULES

Signal Symptoms: Neck mass, hyperthyroidism, thyroid cancer.

Description: A thyroid nodule is a lesion within the thyroid gland that is radiologically distinct from the surrounding thyroid parenchyma. There can be one or multiple thyroid nodules within the thyroid gland. The majority of thyroid nodules are benign, but each nodule holds independent risk for malignancy and should be evaluated individually (Durante et al., 2018).

Etiology: The majority of thyroid nodules are caused by overgrowth of normal thyroid tissue without a known cause. Iodine deficiency has been associated with increased risk of thyroid nodules (Kant et al., 2020). Ionizing radiation is a known risk factor for both benign and malignant nodules of the thyroid, with rates of nodule development up to 2% annually (Zamora et al., 2021). There can be a familial association in some disorders including multiple endocrine neoplasia type 2 leading to medullary thyroid cancer and familial adenomatous polyposis (Kant et al., 2020).

Occurrence: Thyroid nodules are very common; between 20% to 50% of asymptomatic patients examined with ultrasound or at autopsy have one or more thyroid nodules. Durante et al. (2018) state that about 16 million individuals in the United States have palpable thyroid nodules, whereas up to 219 million individuals have ultrasound detectible nodules. Most thyroid nodules, however, are small and not of clinical significance. Approximately 5% of women and 1% of men will come to clinical attention because of a thyroid nodule. Women are about four times more likely to have thyroid nodules than men (Castellnou et al., 2020).

The number of incidentally found thyroid nodules is growing with increased imaging modalities for other reasons not related to the thyroid. Although most thyroid nodules are benign, between 7% and 15% of thyroid nodules are found to be thyroid cancer of which the majority are differentiated thyroid cancer (Haugen et al., 2016). (This number may be higher with additional risk factors discussed below.)

© F.A. Davis Publishing

Age: The prevalence of thyroid nodules increases with age.

Ethnicity: Thyroid nodules are found in all ethnic groups, but most commonly in Whites. The rate of differentiated thyroid cancer is also highest in Whites. A study by Iwata et al. (2018) reported that 12.9% of incidentally discovered thyroid nodules were found to be differentiated thyroid cancer in Whites versus 4.9% in non-White patients.

Contributing Factors: There are multiple potential contributing factors to development of thyroid nodules. Iodine deficiency has been found to increase the risk of thyroid nodules, but this is now very rare in the United States after the introduction of iodized salt in 1924 (Kant et al., 2020). Increased age, obesity, and smoking are also potential contributing factors (Zamora et al., 2021). Head and neck radiation, occupational radiation exposure, or nuclear fallout increases the risk of thyroid nodule and thyroid cancer development. This is especially true if exposure occurred as a child (Durante et al., 2018). As stated above, family history of thyroid nodules and thyroid cancer can also contribute to increased risk (Haugen et al., 2016).

Signs and Symptoms: Most thyroid nodules are asymptomatic. If symptoms are present, they are typically related to size and location of the thyroid nodule. Globus sensation, dysphagia, dysphonia, and voice hoarseness can occur (Durante et al., 2018). Large goiters may lead to supine compression and fullness of the neck. Pemberton's sign is defined as facial plethora when the patient is instructed to lift both arms above their head. This is used to evaluate for venous obstruction of the thoracic outlet in large goiters (Pishdad, 2020). Reports of a rapidly growing nodule raises concern for more aggressive thyroid cancer and should be promptly evaluated (Haugen et al., 2016).

Diagnostic Tests: All patients with thyroid nodules should be evaluated with ultrasonography of the neck and a baseline thyroid-stimulating hormone (TSH) level. If the TSH is low, a radionuclide uptake scan should be performed to evaluate for a hyperfunctioning thyroid nodule. Thyroid nodules that are hyperfunctioning have a very low risk of malignancy and should not routinely be biopsied (Haugen, et al., 2016).

Thyroid ultrasound provides valuable information to stratify risk of malignancy based on nodule characteristics and size. There are multiple classification systems to stratify risk and determine when fine needle aspiration (FNA) should be performed. Many providers follow the American Thyroid Association (ATA) guidelines which vary slightly from the American College of Radiology (ACR) Thyroid Imaging Reporting & Data System (TI-RADS) that is frequently used by radiologists when reporting ultrasound results. Both systems label cystic nodules as benign and do not require an FNA. Very low risk nodules are partially cystic or spongiform nodules without other concerning features. A biopsy should be considered when then nodule is around 2 cm in size or larger. Low risk nodules are isoechoic (same color as the surrounding thyroid tissue) or hyperechoic (lighter than surrounding tissue) and solid. The size used to recommend an FNA varies among sources, but it is typically 1.5 cm in the largest dimension for nodules with low-risk characteristics. The estimated risk of malignancy for these nodules is about 5%. Hypoechoic nodules (darker than surrounding thyroid tissue) are considered intermediate risk for cancer, with about a 5% to 20% risk of malignancy. Thus, biopsy is usually recommended for hypoechoic nodules at 1 cm. The characteristics of nodules considered high risk include hypoechoic pattern and solid form with any of these additional features: microcalcifications, irregular borders, taller than wide, rim calcifications, or evidence of extension beyond the thyroid. These nodules should also be biopsied when they are 1 cm in the largest dimension and carry up to a 90% risk of malignancy according to the ATA (Durante et al., 2018). It is important to remember that each nodule carries independent risk for malignancy; therefore, multiple thyroid nodules may need to be biopsied in a particular patient with a multinodular goiter (Haugen et al., 2016).

The Bethesda Classification System is used to classify FNA results. Bethesda category 1 is nondiagnostic. This indicates there were insufficient cells to classify the sample and the patient will require a repeat FNA. Bethesda category 2 indicates a benign nodule. This holds a 0% to 3% predicted risk of malignancy. Bethesda category 3 is atypia of undetermined significance or follicular lesion of undetermined significance and holds a 5% to 15% risk of malignancy. Bethesda category 4 includes cytology results labeled follicular neoplasms or suspicious for follicular neoplasm and holds a 15% to 30% risk of malignancy. Both Bethesda category 3 and category 4 are considered indeterminate results and require repeat biopsy, usually 6 to 12 weeks after the initial biopsy. This is typically performed with the addition of molecular testing to help stratify risk by identifying genetic mutations or changes in gene expression associated with thyroid cancers. Bethesda category 5 indicates suspicious for malignancy with 60% to 75% risk and Bethesda category 6 show malignancy at 97% to 99% risk. Both Bethesda categories 5 and 6 should be referred to a surgeon with specialized training in thyroid surgery to discuss thyroidectomy or thyroid lobectomy (Haugen et al., 2016).

Differential Diagnosis: Other diagnoses to consider when evaluating a thyroid nodule include infectious or inflammatory diseases (including lymphadenopathy, sialadenitis, or neck abscess), congenital conditions (including brachial anomalies or thyroglossal duct cysts), goiter, or other head and neck malignancies (Durante et al., 2018).

Treatment: Treatment is determined based on thyroid nodule size and FNA biopsy results. Nodules that are benign or nodules that are too small to meet criteria for biopsy do not require any treatment. Nodules that have FNA results suspicious for malignancy or that are malignant should be referred to endocrine surgery for discussion of thyroid lobectomy or total thyroidectomy. Nodules that were indeterminate but with higher risk molecular testing results should also be referred for consideration of thyroidectomy. Other considerations for surgery include thyroid nodules that are causing aerodigestive compromise or nodules that are over 4 cm in size (Haugen et al., 2016).

Patients with hyperfunctioning thyroid nodules should be referred to endocrinology for treatment of hyperthyroidism through either radioactive iodine ablation, thioamide medication therapy, or surgery (Durante et al., 2018).

© F.A. Davis Publishing

Follow-Up: Follow-up is dependent on the risk of malignancy and if a biopsy has been performed. Nodules that have not been biopsied that are low risk should have a repeat ultrasound around 24 months. Intermediate to high-risk nodules that did not meet FNA size criteria should have a repeat ultrasound in 12 months (Haugen et al., 2016).

Thyroid nodules with benign pathology on FNA should still have repeat ultrasound monitoring in 12 months if they had high-risk features. Low- to intermediate-risk nodules should have repeat ultrasound monitoring in 12 to 24 months. Nodules that grow more than 20% (and at least 2 mm) in two dimensions or have an increase in total volume of 50% or more should have a repeat FNA given the potential for missed malignancy. If a nodule has had two benign biopsies, the nodule no longer needs ultrasound surveillance. Evidence is lacking for specific guideline recommendations for long term monitoring of thyroid nodules (Haugen et al., 2016).

Patients who have undergone a thyroid lobectomy should have TSH monitoring following surgery. About 22% of patients who had a thyroid lobectomy will have biochemical hypothyroidism and require thyroid hormone replacement therapy. The risk of postoperative hypothyroidism increases if the patient has positive thyroid antibodies or high normal TSH prior to surgery. All patients who have had a total thyroidectomy will require lifelong thyroid hormone replacement therapy (Haugen et al., 2016). Follow-up after surgery for thyroid cancer should initially be managed by an endocrinologist.

Sequelae: There are typically no long-term effects from thyroid nodules because most thyroid nodules are asymptomatic. Hyperfunctioning thyroid nodules that are untreated can lead to symptoms of hyperthyroidism, including tachycardia, palpitations, and diaphoresis. Long-term complications of untreated hyperthyroidism include atrial fibrillation, osteoporosis, and weight loss (Ross et al., 2016).

Prevention/Prophylaxis: The U.S. Preventive Services Task Force (USPSTF) does not recommend a screening ultrasound to evaluate for the presence of thyroid cancer in asymptomatic people because earlier detection did not lead to reduced mortality (2017). It is not recommended to routinely measure thyroglobulin or calcitonin in patients with thyroid nodules (Haugen et al., 2016).

Referral: Primary care providers should consider referral to endocrinology for management of thyroid nodules when there are high risk features for thyroid cancer including history of head/neck radiation, proximity to a nuclear fallout zone, or family history of thyroid cancer. All patients with a low TSH on initial screening should be referred to endocrinology for management of hyperthyroidism (Walker et al., 2019). Patient reports of a rapidly growing neck mass should prompt urgent referral for ultrasound and surgical evaluation. Surgical referrals can be determined based on pathology results (Bethesda 5 and 6 and high-risk molecular markers), large nodules (more than 4 cm), or thyroid nodules causing aerodigestive compromise (Haugen et al., 2016).

Education: It is important to reassure patients that most thyroid nodules are benign. The cornerstone of management includes ultrasound monitoring to assess size and characteristics of the thyroid nodule and will guide the decision for biopsy. A small percentage of thyroid nodules are toxic nodules, leading to hyperthyroidism. This is managed by either anti-thyroid medication, radioactive iodine ablation, or thyroidectomy (Kant et al., 2020).

Clinical Recommendation	Evidence Rating	References
Imaging with ultrasound remains an accurate method to guide recommendation for management of thyroid nodules.	A	Haugen et al., 2016
Initial evaluation of a thyroid nodule should include family history, evaluation of risk factors (including occupational exposures to radiation, radiation to the head or neck, and proximity to nuclear fallout zone), and symptoms of aerodigestive compromise or rapid nodule growth.	A	Haugen et al., 2016
A baseline thyroid-stimulating hormone (TSH) should be performed in all patients with a thyroid nodule to evaluate thyroid hormone function. If the TSH is low, a radionuclide uptake scan should be completed.	A	Kant et al., 2020
In the absence of concerning features or rapid growth, most nodules (including those that have been biopsied and are benign) can be followed with ultrasound annually. Low-risk nodules that have not been biopsied should have a follow up ultrasound in 24 months.	C	Haugen et al., 2016
The decision to biopsy a thyroid nodule should be based on the nodule's size and characteristics. The ATA classification or ACR TI-RADS system are commonly used to stratify nodule risk.	C	Durante et al., 2018
Surgical referral for thyroid lobectomy or total thyroidectomy should be considered for nodules >4 cm, symptoms of aerodigestive compromise, or thyroid nodules with cytopathology suspicious for malignancy (Bethesda 5), diagnostic malignancy (Bethesda 6), or high-risk molecular testing results.	C	Haugen et al., 2016

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. CASE STUDY

A 65-year-old man presents with pain in the left-upper quadrant and epigastric area of his abdomen. He states that he had an episode of acute pancreatitis 10 years ago without any real sequelae. He does say that he has had episodes of abdominal pain in the epigastric and upper abdominal area over the years, but generally over time it goes away within hours or days, and he does not seek medical care.

On further questioning, he admits to drinking anywhere from two to six beers at least 3 days a week. He does not feel this is a problem; he does remember being told to watch his alcohol intake when he had acute pancreatitis, but after several years without pain he decided that alcohol must not be a factor in his abdominal pain. Further questioning about his symptoms has him telling you that his pain radiates to the left scapular area of his back. He admits to being thirstier recently and has been urinating more frequently as well. He has had to notch his belt two holes within the last year. He has not been trying to lose weight. He denies diarrhea but has had nausea without vomiting. Eating aggravates the pain but bending over at the waist helps the pain lessen.

Objective: Blood pressure (BP) 135/80 mm Hg, heart rate (HR) 80 beats/min, BMI 21.

1. What additional subjective data are you seeking?
2. What additional objective data will you be assessing for?
3. What are the differential diagnoses that you are considering?
4. What laboratory tests will help you rule out some of the differential diagnoses?
5. What imaging studies are generally ordered for a patient with these symptoms?
6. What is your treatment plan for this patient?
7. Will you be looking for a consultation?

CHAPTER 19

Hematological Disorders

Evelyn Duffy

ASSESSMENT

Assessment of the hematological system needs to include a detailed history, physical examination, and diagnostic testing. The presenting symptoms of hematological deficiency can include excessive bruising, petechiae, unexplained bleeding, epistaxis, or inflamed lymph nodes. Older adult patients with severe anemia may complain of fatigue, dizziness, heart palpitations, headache, shortness of breath with exertion, and exercise intolerance (Ianni et al., 2021). Confusion, depression, and cold intolerance are also common. Some patients present with unusual food cravings, referred to as pica. In many cases, symptoms are absent, subtle, or erroneously attributed to the aging process, and anemia is identified on routine complete blood count (CBC). Identification is important because anemia in older adults has been associated with an increase in all-cause mortality (Lanier et al., 2018).

The medical history obtained from the patient should include history of anemia, hemoglobin abnormalities (sickle cell or thalassemia), recent surgery or blood transfusion, lymphadenopathy, clotting disorders, and occupational or other known exposure to toxic agents or radiation. Inquire about comorbid conditions and any family history of anemia. Review current medications both prescribed and over-the-counter. Particularly important are anticoagulants, including aspirin, chronic use of NSAIDs, metformin, levodopa, or the use of proton pump inhibitors (PPIs) or histamine-2 blockers.

Some of the most common causes of hematological disease in the older adult include iron-deficiency anemia, anemia of chronic disease, and nutritional deficiencies, which have an increased incidence in patients older than 60 years. Myelodysplastic syndromes and leukemias are also becoming more common. Systemic disease and severe clotting disorders need to be included in the differential diagnosis.

Physical Examination and Diagnostics

The physical examination should be complete and thorough. Assess the eyes for pale conjunctiva or icteric sclera, which occur with some anemias. Inspect the skin for pallor or jaundice and note the temperature of the skin (Ianni et al., 2021). Check for petechiae, bruising, and pale mucous membranes. Assess the nails for the presence of koilonychia (concave spoon nails), which is seen with chronic iron deficiency (Rathod & Sonthalia, 2021). Check for lymphadenopathy. On oral examination there may be several signs of possible anemia. A red, painful, beefy tongue can be present with pernicious anemia. In iron deficiency, angular cheilitis, atrophic glossitis, and erosion of the buccal mucosa may be evident (Halim et al., 2018). Tachypnea and tachycardia can be seen with severe anemia. Auscultate the heart for any systolic murmurs; severe anemia can cause a loud apical and mid-precordial murmur. An early diastolic murmur may also occur, heard best at the left sternal border. Palpate the abdomen for tenderness or hepatosplenomegaly. A rectal examination and stool guaiac should be completed if the history indicates possible gastrointestinal (GI) blood loss. Hematuria can be indicative of hemolytic anemia. Complete an assessment of mental status and, if indicated by the history, do a complete neurological examination. The absence or presence of physical findings on examination helps to narrow the clinical diagnosis. Ultimately hematological diagnoses cannot be made without laboratory work-up; they cannot be based on signs and symptoms alone.

Based on the history and physical examination, choose appropriate diagnostic tests to complete the hematological assessment:

- CBC with differential will guide additional choice of diagnostics
- Comprehensive metabolic panel (CMP)
- Hemoglobin A1c
- Urinalysis
- Erythrocyte sedimentation rate (ESR)
- Iron, total iron-binding capacity (TIBC), and ferritin if iron-deficiency or microcytic anemia is considered
- Vitamin B_{12} and folate levels to rule out pernicious anemia or other megablastic anemia
- Reticulocyte count to assess for blood loss or blood cell destruction
- Hemoglobin (Hgb) identification (electrophoresis) to assess for Hgb abnormalities or thalassemia

When the assessment is complete, plans will address the specific diagnosis. If etiology is unclear or the probable diagnosis is complex, consultation or referral to hematology is necessary to evaluate the older adult patient further.

© F.A. Davis Publishing

APPROACH TO INTERPRETING THE COMPLETE BLOOD COUNT

The CBC is essential to the diagnostic decision-making process when assessing the hematological system. Therefore, every advanced practice registered nurse (APRN) should be fluent in the language of the CBC. Although inexpensive and readily available, it should not be ordered routinely. Know the rationale for the choice of the test and how it will inform the care of the older adult.

The CBC provides information on three cell lines: white blood cells (WBCs), red blood cells (RBCs), and platelets. All three are the result of the differentiation of the hematopoietic stem cells in the bone marrow. Only mature blood cells are detected in a normal CBC. The CBC also includes a determination of hemoglobin (Hgb), hematocrit (Hct), and RBC indices. The differential, if added, includes identification of the different WBC types. Common abnormalities on the CBC include anemia, leukemia, polycythemia, thrombocytosis, and thrombocytopenia. Other abnormalities can occur because of infection, inflammation, coagulopathies, malignancies, and exposure to toxins. Abnormal results on the CBC may be the first sign of disease in an asymptomatic patient.

Red Blood Cells

The RBCs, or erythrocytes, supply oxygen to the tissues and remove carbon dioxide waste. Their biconcave shape provides for a large surface area to accomplish the gas exchange. RBCs survive in the circulation for about 120 days. They have no nucleus and cannot divide. To create a healthy RBC the older adult needs to have functioning bone marrow, adequate erythropoietin production by the kidneys, and adequate substrates (iron, cobalamin [vitamin B_{12}], and folate [vitamin B_9]).

In response to low oxygen states, rather than a decrease in RBCs, the kidneys produce erythropoietin, which in turn stimulates RBC production in the bone marrow. RBC production has the potential to increase to 10 times the normal rate. Renal disease decreases erythropoietin production and can be a cause of anemia. Inadequate substrates, iron, B_{12}, or folate also result in anemia. B_{12} and folate are needed for cell growth, DNA synthesis, and reproduction. Iron is needed for Hgb synthesis. Hgb is the iron-containing protein in red blood cells that carries oxygen. Hgb is about 90% of the weight of the RBC.

Reticulocytes are the immediate precursors to RBCs. In healthy patients they only remain in circulation for 1 day before becoming fully mature. An increase in reticulocytes occurs when there is an acute blood loss or if there is hemolysis. The reticulocyte is a percentage of RBCs, so in anemia it may be erroneously elevated. Calculating a reticulocyte production index (RPI), or corrected reticulocyte count, is indicated. The RPI is the reticulocyte percentage times the patient's Hct/normal Hct (normal value is usually 45%). A normal RPI is between 0.5% and 2.5%. An RPI less than 0.5% is a hypoproliferative state, whereas a value greater than 3% indicates a hyperproliferative state due to hemolysis or acute blood loss. If hemolysis is suspected, additional tests, including lactate dehydrogenase (LDH), total bilirubin, and haptoglobin, can confirm the diagnosis (Phillips & Henderson, 2018). After identifying the cause of anemia and treating it effectively, there will be an increase in reticulocytes as much as 20%. In the setting of bone marrow failure, reticulocytes are not adequately produced.

The CBC includes a report of the RBC count. The result is the number of RBCs per liter of blood in International Units, for example 5.43 × m/uL (a normal count). The Hgb and Hct add information to further define the result. Hgb is produced in the immature RBC and is complete when the RBC matures. Hgb is measured in grams per deciliter; for example, 14 g/dL (a normal result for both men and women). There are different types of Hgb: A (healthy adult), F (fetal and newborns), S (sickle cell), C, and E (those of Southeast Asian descent). The heme portion of Hgb provides the red color to the RBC, and binds the oxygen. The globin portion is made up of four amino acid chains, each of which is associated with a heme. The amino acid chains (also called globin chains) of a healthy adult (HgbA) include two alpha and two beta chains, whereas fetal Hgb (HgbF) has two alpha and two gamma chains. HgbA2, a normal variant of HgbA, has two alpha and two delta chains. HgbA2 is present in low levels in adults and is increased in beta thalassemia. In the disease alpha thalassemia, there is a lack or absence of alpha chains and excess beta chains. In beta thalassemia there is a lack or absence of beta chains and an excess of alpha chains. Both are the result of a genetic defect and can occur with either a major or minor presentation, which may severely affect health or have no symptoms at all. To determine the type of Hgb, a Hct identification or hemoglobin electrophoresis can be ordered.

The Hct represents the ratio of RBCs to total whole blood volume and is reported as a percent. Total whole blood volume includes RBCs, WBCs, platelets, and plasma. The Hct is normally about three times the Hgb level, which is about three times the number of RBCs; this is referred to as the rule of 3s. Hyperglycemia and hypernatremia can result in enlarged RBCs and will increase Hct. In dehydration, which is not uncommon in older adults, the RBCs, Hgb and Hct will all appear higher. Comparison with blood urea nitrogen level (BUN) can help to assess the accuracy of the result. In the situation of fluid overload, the opposite occurs.

Other RBC measures of significance include the reticulocyte count, the mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), and the often-overlooked red cell distribution width (RDW). The MCV should be assessed after the RBC, Hgb, and Hct. The normal MCV value is between 80 and 100 fL and is referred to as normocytic. Values below 80 fL are considered microcytic (smaller than normal), while values above 100 fL are considered macrocytic (larger than normal). The size of the RBC can be helpful in identifying the cause of any anemia as well as other hematological disorders.

MCH measures the average weight of the Hgb in the RBC—a ratio of Hgb/RBC. It may not be reported on current CBC results. Because the MCH is a calculated value, its value can decrease by the same conditions that elevate the RBCs. The MCHC can be helpful to judge contributing factors to the CBC results. It is a ratio of the Hgb to the Hct and should be about 1/3 (remember the rule of 3s). If the result is lower than the reference range, the cells are hypochromic or have less hemoglobin. Values greater than the norm are not referred to as hyperchromic because the RBCs cannot accumulate more than the normal concentration of Hgb. If cells have an elevated MCHC, it may be due to a change in the shape of the cell.

© F.A. Davis Publishing

The RDW describes the discrepancy in the size of the cells, anisocytosis, reported as the standard deviation. The greater the deviation in the RDW the greater the variation in cell size. The RDW-CV is the width of the frequency distribution of the cell volumes at one standard deviation from the mean divided by the MCV. Normal range is 13% + 1%. Variations can be another indication of the type of abnormality responsible for any irregular values.

White Blood Cells

The WBCs, or leukocytes, can be divided into two main categories: phagocytes and immunocytes. All WBCs have nuclei, and they may be categorized as myeloid or lymphoid depending on their origin. Myeloid cells, or myelocytes, include neutrophils, eosinophils, basophils, and monocytes. Monocytes and neutrophils are phagocytes that kill unwanted microorganisms.

Myelocytes that contain granules in their cytoplasm and are classified as granulocytes include neutrophils, eosinophils, and basophils. Granulocytes take about a week to develop in the bone marrow, remain in circulation for 6 to 12 hours, then are sequestered for 2 to 3 days in the spleen tissue before ultimately being eliminated. Neutrophils are mature granulocytes and make up 60% to 70% of WBC types. They are also called segmented neutrophils (segs) or polymorphonuclear neutrophils (PMNs) or polys. They are the most common cell type in the early stage of inflammation. With increased demand, additional neutrophils can be released from the bone marrow. In inflammation they migrate out of the capillaries and into the tissue where they digest organisms and debris and form pus. Eosinophils are about 2% to 4% of the WBC total. Eosinophils increase in response to allergies, collagen disease, and disease of the spleen and central nervous system. Eosinophils are also seen in mucous membranes. Basophils respond in allergies and in antigen responses by releasing histamine and dilating blood vessels. Basophils circulate in the bloodstream. They are less than 0.5% of WBC count.

Monocytes and lymphocytes do not contain granules. Monocytes are myelocytes and are the largest of the WBCs in size. They are young cells in the bloodstream then move to tissue where they become mature macrophages. Monocytes are the major cell population in the body tissues. Their levels increase in response to wounds, malignancy, and inflammation and form the mononuclear phagocytic system.

Lymphocytes are also nongranulocytes and are responsible for the immune response. They are the second most numerous WBC circulating in the bloodstream but are more common in the lymphatic system. Lymphocytes include two cell types: B cells, which make antibodies and enhance pathogen destruction, and T cells. T cells mature in the thymus and are responsible for cell-mediated immunity, which does not involve antibodies. T cells can stimulate B cells, which trigger humoral or antibody-mediated immunity.

An elevation of WBCs is called leukocytosis. It commonly occurs in infection, inflammation, or tissue necrosis that occurs in myocardial infarction, burns, leukemia, or lymphoma. Elevations in WBCs have also been noted after ischemic stroke. In leukemia, elevations in WBCs may be greater than 100,000. Stress can also cause an elevation in WBCs, but they should rapidly return to normal. After identification of an increase in WBCs, further review of the cell constituents can help clarify the diagnosis. Unsegmented neutrophils, or bands, are immature neutrophils that are released when there is an increased demand. This may be referred to as a *shift to the left* or bandemia. This result may be noted before there are other overt signs of infection.

Platelets

The smallest of the three population of cell types are the platelets or thrombocytes. They are nonnucleated disk-shaped cells with a life span of 9 to 12 days. Platelets are fragments of megakaryocytes that are located in the bone marrow. They are important in the clotting cascade. They are the initial reactants when there is damaged epithelium. Their response is rapid, occurring in 3 to 5 minutes. Excessive platelets, known as thrombocytosis, can result in clotting disorders. Very elevated platelet counts are present in myeloproliferative disorders. Thrombocytopenia is a low platelet count and can result in bleeding disorders.

Clarifying Complete Blood Count Results

After the CBC has been evaluated, several additional laboratory studies can further clarify the finding. If there is an unexpected result on the CBC that seems inconsistent with the patient's presentation, a reasonable response might be to order a repeat CBC. It is also possible to ask the laboratory to do a peripheral blood smear. A peripheral blood smear provides the opportunity for direct visualization of the cells. It is a sample of blood that is smeared on a microscope slide by a laboratory professional and examined under magnification to add more clarity regarding the size, shape, and number of cell types. The visualization allows for identification of other types of cells such as spherocytes or sideroblasts. An indication for a smear might be a wide RDW noted on the CBC.

ANEMIA

Anemia is a decrease in the whole-body red cell mass (RCM). It is not a disease; it is the sign of an underlying disease. Anemia is ultimately a laboratory diagnosis, with Hgb and Hct being representative of the RCM. However, these may not accurately represent RCM when there is a volume increase, such as in pregnancy or when patients have received IV fluids, referred to as relative anemia or dilutional anemia. Determining the cause of the anemia is the challenge for the provider. Treatment should not be introduced based on an abnormal laboratory value alone.

Anemia in older adults has a prevalence of 10% to 24% overall, including 7% to 11% in those living in the community, 47% of those in long-term care, and 40% of hospitalized older adults (Stauder et al., 2018). Even slightly low hemoglobin levels have been independently associated with increased morbidity and mortality, affecting functional ability and both cognitive status and mood (Lanier et al., 2018; Stauder et al., 2018). Anemias have been associated with cardiovascular disease, decrease in cognitive function, mood disorders, falls, and fractures. Patients with anemia have more frequent hospitalizations with longer stays.

The thresholds for definition of anemia were established by the World Health Organization study group on nutritional anemia in 1968 and remain the overall reference values. These values are a Hgb of less than 13 g/dL in an adult male and less than 12 g/dL in an adult female. Recent attempts to

© F.A. Davis Publishing

modify this definition based on race or age have not been universally adopted (Stauder et al., 2018).

Many patients with anemia are asymptomatic. The anemia is noted when the provider receives the abnormal result from a complete blood count (CBC). Lack of symptoms in an older adult is not uncommon, particularly if the anemia developed over time and the body has adjusted to the reduced number of red blood cells (RBCs) (Ianni et al., 2021). An older adult may attribute symptoms to their older age, and the provider may assume symptoms, such as fatigue or dyspnea, are due to an existing chronic illness. Even without concerns from the patient, a thorough review of systems should not be omitted.

Laboratory assessment of anemia begins with the CBC. A systematic approach to analysis of the CBC is critical to the accuracy of the final diagnosis. After determining that the Hgb is low, comparison to previous results adds additional data. A Hgb of 9.0 g/dL may not require an urgent response if it has been in that range historically. However, if recent Hgb results were all in the normal range, a Hgb of 9.0 g/dL would indicate a definite change in condition and an urgent response would be necessary. If the choice is to send the patient for a more urgent work-up, it is necessary to communicate the details of your concern to the acute care providers. In acute care settings a Hgb below 7.0 g/dL is the criteria most often used to order a blood transfusion, so anything higher may be dismissed as non-urgent unless there is evidence of an acute bleed. This is an example of the communication necessary for a successful handoff between primary and acute care providers.

After determining that the Hgb and Hct values are low, the next step is to review the mean corpuscular volume (MCV) and the red cell distribution width (RDW). The MCV is most informative, and its interpretation informs the follow-up analysis. Recall that the normal range for the MCV is 80 to 100 fL (normocytic). Results below 80 fL indicate that the RBCs are smaller than normal (microcytic). Results greater than 100 fL indicate that the RBC is larger than normal (macrocytic). The RDW is helpful, particularly in interpretation of values that are normocytic or macrocytic. A large RDW indicates a mixed cell population, and a normocytic result could occur if the patient has a combination of an iron and a B_{12} deficiency. In that circumstance, a large RDW identifies the variation in cell size and requires an expanded differential diagnosis (Ianni et al., 2021). After the anemia has been defined as normocytic, microcytic, or macrocytic, further diagnostic tests are required to clarify the cause and develop a treatment plan.

The following sections will address each of the abnormal presentations in detail, normocytic anemia, microcytic anemia, and macrocytic anemia. The sections include the common causes of each type, their treatment, as well as those less common hematological concerns that should not be missed.

NORMOCYTIC ANEMIA

Description: A low Hgb and Hct and a normal MCV between 80 and 100 fL on a CBC is classified as normocytic anemia. This means that the cells are the normal shape and size but have a low Hgb. To verify that the cells are all a normal size, check the RDW. If it is elevated, it indicates that the cells are a mixture of sizes, and a peripheral blood smear can be requested to further identify the cell types. In anemia of inflammation (AI) there may be a normal or even an increased amount of iron stores, but a low level of iron in the cells. The inflammation prevents the cells from using the stored iron.

Etiology: In the past normocytic anemia was often identified as the anemia of chronic disease (ACD). This label was not inaccurate, but it failed to identify the chronic diseases responsible and the potential treatments appropriate to the cause. Normocytic anemia often occurs due to chronic inflammation characteristic of chronic kidney disease, cancer, or autoimmune diseases (Stauder et al., 2018). A more appropriate label may be AI rather than ACD (National Institute of Diabetes and Digestive and Kidney Diseases [NIDDKD], 2018). Chronic kidney disease (CKD) is a primary contributor to AI. In CKD there is a decline in the synthesis of erythropoietin (EPO). EPO promotes the survival, proliferation, and differentiation of erythrocyte precursors. As the glomerular filtration rate decreases and CKD progresses, EPO is reduced and results in deficiency. If kidney function continues to decline, the progression of anemia may ultimately result in true microcytic iron-deficiency anemia. Even a mild decline in GFR can compromise a robust synthesis of EPO. Inflammation inhibits EPO function and may decrease hepcidin level, which influences iron metabolism (Begum & Latunde-Dada, 2019). Hepcidin is produced in the liver and regulates the metabolism and transport of iron. It has a major role in AI. AI can shorten the RBC survival, normally about 120 days.

Hemolytic anemia should also be included in the differential diagnosis of normocytic or macrocytic anemia (Phillips & Henderson, 2018). Hemolytic anemias can be intrinsic or extrinsic. Intrinsic destruction of the RBCs is due to a defect in the cells themselves such as in hereditary spherocytosis, or a problem with a red cell enzyme, as in G6PD deficiency. Extrinsic hemolytic anemia occurs when RBCs that are normal undergo destruction from direct trauma, infection, malignancies, autoimmune disorders, or medications. Another consideration is the cause of the hemolysis, which can be extravascular (most common) or intravascular. Extravascular hemolysis occurs when the RBCs are removed prematurely from circulation by the liver and spleen due to hemoglobinopathies such as sickle cell or thalassemia. Extravascular hemolysis can also be due to enzymopathies such as G6PD deficiency, membrane defects such as spherocytosis, or be a result of medications. Intravascular hemolysis occurs when the cells are broken up within the circulatory system which can result from a transfusion reaction or infection. Causes of hemolytic anemia are numerous. If identified referral to hematology for a complete work-up is the appropriate next step.

Occurrence: With their high burden of chronic conditions, AI is a common cause of anemia in older adults, accounting

© F.A. Davis Publishing

for more than one-third of the cases. The prevalence of anemia increases twofold over the general population in patients with CKD. In those with CKD, the prevalence of anemia increases with declining function, approaching 53.4% at Stage 5 (Portolés et al., 2021). About 1 million people older than 65 years have anemia due to inflammation (NIDDKD, 2018).

Age: Normocytic anemias due to inflammation or CKD can occur at any age, but older adults are more likely to have AI because they are more likely to have chronic diseases that cause inflammation (NIDDKD, 2018). Before age 75 women are more likely to have anemia than men, but after age 75 men are more likely to have anemia than women. Sex distribution varies based on the underlying cause of anemias. Some of the difference may be due to the World Health Organization's sex-specific value of less than 13 g/dL being used for males across all ages (as opposed to less than 12 g/dL for females). Because Hgb declines slightly and anemia prevalence rises with aging, the prevalence rate for men is higher with advancing age (Cappellini & Motta, 2015).

Contributing Factors: The presence of one or more chronic conditions, such as cancer, chronic infection, chronic inflammation, or autoimmune conditions, is a contributing factor to the development of AI and is also a factor in hemolytic anemia.

Signs and Symptoms: Onset of signs and symptoms in AI can be confounding and is usually masked by the underlying conditions. The typical symptoms of anemia, such as fatigue, weakness, dyspnea, and palpitations, may be present but are nonspecific. In older adult patients these symptoms tend to be attributed to the aging process. Additionally, many older patients adjust their activities as their bodies make physiological adaptations for the underlying disease. Signs specific to hemolytic anemia include jaundice or hematuria. With chronic hemolysis, lymphadenopathy or hepatosplenomegaly may be detected on physical examination (Phillips & Henderson, 2018). Although it may be difficult to assess in the older adult population, conjunctival pallor is a reliable sign. Its absence, however, cannot exclude anemia. Other signs may be discovered through incidental laboratory testing. Cognitive decline, depression, and decreased quality of life may also accompany AI. The clinician should have a high index of suspicion of AI in older adult patients with chronic conditions, and any presentation of the previous symptoms should prompt further evaluation.

Diagnostic Tests: A first step in confirming AI is to review the RDW to evaluate the possibility that the MCV includes a consistent cell size. A smear may be requested to determine more specifics regarding the cell population. Checking the reticulocyte count and calculating RPI can identify if the anemia is hypoproliferative or hyperproliferative. If hyperproliferative, additional laboratory work should be ordered to assess for hemolysis, including LDH, haptoglobin, total bilirubin and urinalysis. In hemolytic anemia, in addition to reticulocytosis, there will be an increased LDH, increased total bilirubin, and decreased haptoglobin levels. Ordering a direct antiglobulin test (Coombs') will evaluate for an autoimmune hemolytic anemia (Phillips & Henderson, 2018). To evaluate kidney function as a cause of normocytic anemia, check the blood urea nitrogen (BUN), creatinine and estimated glomerular filtration rate. To differentiate AI from iron-deficiency anemia (IDA), a serum ferritin is key. Serum ferritin is a measure of iron stores, and the main abnormality in AI is the impaired ability to use iron stores in the reticuloendothelial system (liver/spleen). Values in AI are reflected in a normal to high ferritin level (i.e., iron is present but inaccessible for use). In contrast, ferritin levels in IDA are low (below 30 ng/mL). Ferritin is an acute phase reactant and is increased in the presence of inflammation. That explains the higher levels in AI, but it is also less reliable as a measure to define IDA. Other measures such as serum transferrin can be helpful. If measurement of serum hepcidin becomes more readily available, it would be an excellent choice in the differential diagnostic process, as it is very low in IDA and elevated in AI.

Inflammatory markers of concern in AI include tumor necrosis factor alpha (TNF-alpha), interleukin-1 (IL-1), interferon gamma (IFN-gamma), and IL-6. Decision regarding these less-common tests could be deferred until initial assessment is complete. Referral to hematology for additional work-up is always an option.

Table 19-1 compares the laboratory data in AI and IDA. Research is being directed to look at new serological markers, such as hepcidin, that may be used in the future to better distinguish AI from IDA.

Differential Diagnosis: Differential diagnosis may include almost any cause of anemia. Early or partially treated IDA is the main differential diagnosis for AI because microcytosis may be present or absent in either disorder. Normocytic indices may be the result of a mixed anemia due to vitamin B_{12} and/or folate deficiency in addition to IDA. Due to potential neurological complications, it is important not to miss a vitamin B_{12} deficiency. Hypoproliferative anemias (e.g., renal disease, endocrine disorders) and thalassemia are also considerations. Blood loss and hemolysis are other optional causes.

Treatment: Treatment of AI focuses on management of the underlying disorder. Although there is no specific treatment for AI, if anemia is severe or underlying disease is resistant to treatment, erythropoiesis-stimulating agents (ESAs) (e.g., Epogen, Procrit) may be used (Begum & Latuda-Dada, 2019). Large trials highlighted the harm of using high-dose ESA with a goal of complete correction of anemia and raising the Hgb above 11 g/dL, which was associated with poor outcomes. The poor outcomes included increased risk of stroke, rapid progression of malignancies, and increased mortality. Current guidelines recommend the use of lower doses of ESA and only if Hgb is below 10 g/dL (Begum & Latuda-Dada, 2019). Coverage for ESAs by Medicare and other third-party reimbursement requires documentation of laboratory test findings indicative of AI. Current recommendations include the addition of iron, either oral or parenteral. Dosage for a patient with renal disease should be individualized and be as low as possible to reduce risk of poor outcomes while also reducing the need for transfusion.

Vitamin D reduces hepcidin gene transcription, lowers serum levels by 50%, enhances erythropoiesis, and reduces inflammation. It was not as effective in mild to moderate anemia. Cholecalciferol (vitamin D_3) is the formulation of choice and is also useful in the prevention of mineral and bone disorders common in CKD.

TABLE 19-1 Laboratory Data in AI and IDA[1]

LABORATORY TEST	AI	IDA
CBC		
• Hemoglobin	<12 g/dL (120 g/L) women <13 g/dL (130 g/L) men Rarely <10 g/dL (100 g/L)	<12 g/dL (120 g/L) women <13 g/dL (130 g/L) men
• Mean corpuscular volume: (MCV)[2]	80–96 mcm^3 (normocytic)	70–80 mcm^3 (microcytic)
• RBC distribution width: (RDW)	Normal	Increased
Serum ferritin	Normal or increased	Decreased
Serum iron	Decreased	Decreased
Total iron-binding capacity	Decreased	Increased
Transferrin	Normal to low	Increased
Transferrin saturation	Reduced	Reduced
Reticulocyte production index	Decreased	Decreased
Reticulocyte count	Decreased	Decreased
Peripheral smear	Normochromic	Microcytosis, hypochromic

[1] *Changes in relation to respective normal values*
[2] *Overlap, may be normal with AI + IDA*

Abbreviations: *AI = anemia of inflammation; CBC = complete blood count; IDA = iron deficiency anemia; RBC = red blood cell; g/dL = grams per deciliter, L = liter*

Follow-Up: Follow-up is individualized depending on underlying cause and extent of the anemia. A robust rise in a reticulocyte count completed 5 to 10 days after initiating treatment may confirm the correct course.

Sequelae: Variable depending on the underlying condition.

Prevention/Prophylaxis: Early education regarding healthy lifestyle may prevent or delay onset of some chronic conditions. Avoidance of renal toxic substances such as NSAIDs can protect the kidneys. Use of tobacco and frequent alcohol intake may also contribute to the development of AI or hemolytic anemia.

Referral: Referral is indicated for progression of anemia and/or resistance to treatment of underlying condition; significant anemia of unknown causation; and severe, symptomatic anemias.

Education: Teaching the patient and family about the importance of lifestyle modifications and adherence to a treatment plan for management of underlying conditions may be a factor in preventing or slowing the progression of chronic diseases. A healthy balanced diet is indicated to prevent or correct dietary deficiencies that can contribute to other forms of coexisting anemias.

MICROCYTIC ANEMIA

Signal Symptoms: Fatigue, weakness, pica, koilonychias (spoon nails), pale conjunctiva, cheilitis, glossitis. The patient may be completely asymptomatic.

Description: Microcytic anemias are identified by red cells that are smaller than normal. A mean corpuscular volume (MCV) less than 80 is indicative of microcytosis. However, microcytic anemias can occur concurrent with other anemias. When the MCV is 80 to 100 (normocytic) or above 100 (macrocytic) but the red cell distribution width (RDW) is wide, it can be an indication of a mixed anemia. In that presentation ordering a follow-up peripheral blood smear can help to identify the presence of microcytic cells.

Etiology: The small cell size is due to a decreased production of Hgb. In microcytic anemia the cells are also hypochromic. Causes of microcytic anemia include a lack of iron (iron-deficiency anemia), a problem of iron delivery (chronic kidney disease [CKD], inflammation) or a lack of globin production, the protein that binds iron (thalassemia).

Iron-deficiency anemia (IDA), the most common cause, can be a result of inadequate intake, decreased absorption, increased demand, or increased loss of iron. In the United States, IDA is less often a result of dietary deficiency because iron is added to many foods for enrichment and fortification. Because of this addition of iron in foods, iron deficiency is most often caused by blood loss (Lanier et al., 2018). Most older adults with IDA have an underlying gastrointestinal (GI) tract abnormality. A GI source of blood loss should be assumed until proven otherwise, it cannot afford to be missed. Anemia of inflammation (AI) may initially be normocytic, but as the disease process advances it can develop into a microcytic anemia.

Thalassemias are a group of inherited disorders resulting in a defect of the Hgb chains. The globin part of Hgb has four amino acid chains and in healthy adults there are two alpha and two beta chains. In alpha thalassemia there is a lack of alpha chains and an excess of beta chains. In beta thalassemia there is lack of beta chains and an excess of alpha chains. There is a reduced amount of HgbA on Hgb analysis. The extent of the reduction or absence determines whether the disease is major or represents thalassemia trait. The imbalance of globin chains can cause hemolysis or impair erythropoiesis and result in microcytosis and possibly anemia. Thalassemia major would be diagnosed in childhood; however, because of the subtle nature of thalassemia minor the patient may have been labeled as having iron-deficiency anemia and treated presumptively with iron replacement. This is a reason to include this diagnosis in your differential of microcytic anemia.

Occurrence: Anemia affects 27% of the population worldwide, with iron deficiency as the dominant cause (greater than 60%) (Kassebaum et al., 2016). Between 1% and 10% of these patients have undiagnosed GI cancer. Thalassemia occurs in about 5% of the world's population (Muncie & Campbell, 2009).

Age: IDA is most common in children and younger women of childbearing age; in older adults, incidence increases with age. AI/anemia of chronic disease (ACD) can occur at any age but increases with aging. Thalassemia is an inherited disorder and is present from birth. With aging, complications of thalassemia increase, such as vascular and hepatic disease. In addition, hepatic, hematological, and solid cancers have occurred related to the chronic stress on the bone marrow from thalassemia (Taher et al., 2021).

Ethnicity: Alpha thalassemia occurs most often in those with African or Southeast Asian heritage, and beta thalassemia is most common in those of Mediterranean, African, and Southeast Asian descent. Thalassemia trait is present in 5% to 30% of those in these ethnic groups (Muncie & Campbell, 2009).

Contributing Factors: In the older adult patient, decreased oral intake or inadequate diet, GI-related surgery, benign prostatic hypertrophy, malabsorption syndromes, low socioeconomic status, medications (i.e., salicylates, NSAIDs, proton pump inhibitors [PPIs], H_2 blockers, and antacids), combination of medication and alcohol, and chronic blood loss—most frequently from the GI tract—are contributing factors for IDA. Some GI causes include malignancy, esophagitis, peptic ulcer disease, gastritis, diverticular disease, or bleeding caused by inflammatory bowel disease. *Helicobacter pylori* infection can decrease iron absorption and can also lead to microerosions that cause bleeding. Surgeries such as gastrectomy, duodenal bypass, or bariatric surgery (Roux-en-Y gastric bypass) can result in decreased iron absorption (Camaschella, 2015).

Recent evidence suggests that obesity may also play a role in IDA due to inflammation that can cause impaired duodenal absorption and an increase in hepcidin, a peptide that regulates iron homeostasis. Higher hepcidin levels may reduce iron absorption and blunt the effects of iron fortification (Stoffel et al., 2020). In patients with prosthetic heart valves, intravascular hemolysis may lead to IDA related to increased hemosiderin loss in the urine. Epistaxis, hematuria, dysfunctional uterine bleeding, and bleeding diathesis are other possible contributing factors in older adults.

In thalassemia there is ineffective erythropoiesis and peripheral hemolysis that can cause a chronic microcytic anemia. A key diagnostic feature is the presence of a very low MCV in the presence of a mild decrease in Hgb. Many of these patients have been treated presumptively with iron for many years and face the very real possibility of iron overload. Proper identification of the patient who may have thalassemia can prevent overuse of iron replacement and risk of iron overload.

Signs and Symptoms: Diagnosis of IDA may be the result of an incidental finding on CBC, requiring further investigation. Clinical presentation of IDA can be vague, unreliable, and, in many cases, asymptomatic. In the older adult, symptoms may be incorrectly attributed to the aging process or chronic comorbid conditions. Anemia that develops slowly tends to present with fewer signs and symptoms then anemia that is of a rapid onset (e.g., acute bleeding). Fatigue, weakness, lethargy, tachycardia, palpitations, dyspnea on exertion,

© F.A. Davis Publishing

headache, irritability, inability to concentrate, neuralgia, sore tongue, paresthesia, restless legs syndrome, alopecia, and susceptibility to infection are possible symptoms. Dizziness, faintness, claudication, exercise intolerance, or angina also may be present.

Thalassemia, unless diagnosed in childhood, is generally asymptomatic. Patients may report a history of iron therapy for anemia without evidence of a specific cause of blood loss.

A thorough history should include questions about diet, symptoms (especially GI-related), signs or sources of blood loss, surgeries, and family history of GI malignancies such as stomach or colon cancer. Pica or pagophagia (i.e., compulsive consumption of ice or iced drinks) may be reported. Medication history, including over-the-counter (OTC) drugs, is especially important to rule out NSAID-induced bleeding.

Physical examination may be unremarkable. Pallor, common in patients with significant anemia, is also common in aging and may be discounted as a normal age-related finding. Conjunctival pallor is the only sign attributable specifically to anemia. Angular cheilitis, glossitis, brittle ridged nails, or "spoon" nails (koilonychia) may also be present. Cardiovascular and respiratory examination may reveal tachycardia, systolic murmur, or signs of heart failure (HF). In some patients, splenomegaly may be present, owing to hemolysis of iron-deficient RBCs. Lymphadenopathy, weight loss, bruising, and jaundice are physical signs that require further evaluation.

Diagnostic Tests:

- CBC will reveal Hgb of less than 12 g/dL in women and 13 g/dL in men. Note that patients who are smokers and those with chronic hypoxemia have a higher premorbid Hgb and therefore can be anemic at higher Hgb levels (Sharma et al., 2019).
- RBC indices reveal an MCV/RBC size that will be decreased to less than 80 fL in adults; MCH will be low, consistent with hypochromia. In thalassemia the MCV is usually less than 75 fL and MCH will be low.
- RDW-CV% may be increased in IDA indicating a mixture of mature and immature RBCs. In thalassemia the RDW is normal or may occasionally be increased.
- Serum ferritin level is the most accurate initial test for IDA; patients with IDA are expected to have low levels. It is important to consider that ferritin is an acute phase reactant and increases in the face of inflammation. Given the many chronic inflammatory diseases that are more common in older adults, a normal serum ferritin may be misleading. A ferritin level of less than 25 ng/mL is highly predicative of IDA, whereas a level of greater than 100 ng/mL indicates adequate iron stores with a decreased likelihood of IDA. In thalassemia serum ferritin is normal.
- TIBC: increased in IDA and is especially helpful in coordination with consideration of the possible falsely normal ferritin. TIBC is normal in thalassemia.
- Serum iron: decreased in IDA, also helpful if serum ferritin is normal. Serum iron is normal to increased in thalassemia.
- Transferrin saturation: decreased in IDA. This finding indicates that there is a decreased amount of iron available to bind to transferrin, which is an iron-carrying protein. Transferrin saturation is normal to increased in thalassemia.
- Peripheral smear in IDA reveals microcytosis, hypochromia, and poikilocytosis (abnormally shaped RBCs). In thalassemia nucleated red blood cells appear on the peripheral smear.
- Hgb identification for suspected thalassemia
- With referral to hematology, bone marrow iron stain: may be helpful in an unclear presentation

If IDA is confirmed, further diagnostic studies to determine the cause must be undertaken. The presence of IDA in adults, especially men and postmenopausal women, is presumed to be the result of blood loss in the GI tract, and the possibility of malignancy must be ruled out. Endoscopic evaluation usually begins with colonoscopy, if indicated, and when the patient is 50 years or older to identify any lower GI bleeding. Esophagogastroduodenoscopy (EGD) investigates for upper GI bleeding. Evaluation of mid and distal small bowel can be done through several methods, including capsule endoscopy, and should be done if the colonoscopy and EGD findings are negative (Joosten, 2018; Lanier et al., 2018). The choice and sequence of procedures is dependent on clinical suspicion and presenting signs and/or symptoms.

Differential Diagnosis: Differential diagnosis for microcytic, hypochromic anemias by etiology includes:

- Defective iron utilization: thalassemia trait, sideroblastosis, G6PD deficiency
- Defective iron reutilization: infection, inflammation, cancer, and other chronic diseases
- Hypoproliferation: decreased erythropoietin from renal failure, hypothyroidism, and other hypoproliferative states (Prath & Miller-Chism, 2019)

In adult men and postmenopausal women, differential diagnosis for microcytic anemia includes the following in decreasing order of frequency: IDA, AI, unexplained anemias, and thalassemia trait.

Treatment: Oral iron therapy is usually first-line treatment for patients with IDA. An initial medication of choice is ferrous sulfate 325 mg (65 mg of elemental iron) bid–tid. Depending on the severity of the IDA, adults will usually require a daily dose in the range of 100 to 200 mg of elemental iron (Lanier et al., 2018). This treatment is not well tolerated and associated with dark or black stools, constipation, diarrhea, abdominal discomfort, nausea, and vomiting. Interventions to reduce GI symptoms include dose reduction of iron or starting with one-half the dose and gradually increasing it. Switching from ferrous sulfate to better tolerated formulations, ferrous gluconate 325 mg (35 mg of elemental iron) or ferrous fumarate 325 mg (99 to 108 mg of elemental iron), may also help. Other options include taking iron with food, which may increase patient compliance with therapy but may also reduce absorption by 50%. Measures to alleviate constipating effects of iron therapy include gentle laxatives, stool softeners, fiber, and adequate liquid intake. There is some new evidence that iron given at lower doses and less frequently may reduce the adverse effects. Further research, especially with older adults, is needed to determine optimal dosing efficacy.

Ideally, a dose is administered on an empty stomach, 1 hour before meals. Absorption of iron is enhanced with ascorbic acid (vitamin C). Other measures to improve iron absorption include avoidance of foods high in tannate (tea,

© F.A. Davis Publishing

bran, cereal) and medications that increase gastric pH (milk, antacids, PPIs, H_2-histamine blockers, quinolones, and tetracycline). Liquid iron preparations are recommended for those who are unable to dissolve the coating of iron pills, which leads to decreased iron absorption. Sustained-release formulations (enteric coated) of iron for initial therapy should be avoided because they reduce the amount of iron presented for absorption by the GI tract (Pasricha et al., 2021).

Treatment effectiveness should be demonstrated after 3 to 4 weeks of therapy, and Hgb and Hct should be normalized in 6 to 8 weeks. The duration of therapy is not specifically identified, but it is generally continued for 3 to 6 months after Hgb and Hct are normalized (Lanier et al., 2018).

Parenteral iron therapy is indicated in the following situations: chronic uncorrectable bleeding, intestinal malabsorption, intolerance to oral therapy, nonadherence, or Hgb level less than 6 g/dL with signs of poor perfusion in those who would otherwise receive transfusions (e.g., those with religious objections), and coexisting inflammatory conditions that can interfere with iron homeostasis. Several different IV iron products are available in the United States.

Blood transfusions may be necessary initially (e.g., acute bleeding) and should be considered for patients who are symptomatic (i.e., fatigue, dyspnea on exertion), as well as for asymptomatic cardiac patients with an Hgb level less than 7 g/dL (Lanier et al., 2018). The decision to transfuse should consider the clinical status and comorbidities.

In addition to medical therapy, a healthy diet with foods rich in iron should be encouraged. Dietary sources of iron include meat, fish, poultry, fruits, green leafy vegetables, beans, nuts, and grain products.

Follow-Up: The restoration of iron stores is the primary goal of treatment. The Hgb level should increase by 1 g/dL every 2 to 3 weeks, but restoration of iron stores may take 3 months after Hgb is corrected, during which time iron therapy should be continued (Lanier et al., 2018). The patient should be seen at regular intervals to reassess symptoms or side effects from the treatment plan. Patients should be evaluated in 2 to 4 weeks for examination and repeat CBC after the initiation of therapy. Referral should be considered if failure to respond to a 4- to 6-week trial of oral iron occurs (Pasricha et al., 2021). Frequency of subsequent evaluations with repeat CBC should be based on the identified cause and whether it was reversed.

Sequelae: Possible complications in the evaluation of a microcytic anemia include failure to identify an occult bleeding source, particularly one related to malignancy. Failure to identify thalassemia can result in unnecessary treatment with iron and possible iron overload.

Prevention/Prophylaxis: IDA can be prevented by promoting proper nutrition with adequate iron intake, identifying those at high risk, and prompt evaluation and treatment of any symptoms or bleeding.

Referral: Referral to a specialist (e.g., gastroenterology for diagnostic studies, hematology, oncology if malignancy is suspected) is indicated to aid in the diagnosis and treatment of the causation. Collaborative management is appropriate for complex cases. Referral to a nutritionist can assist with the evaluation of dietary inadequacies and with meal planning or with congregate or home-delivered meals.

Education: The patient should be educated about the mechanism of anemia, the expected course of therapy with respect to frequency of office appointments and blood tests, any referrals, the importance of adhering to the treatment regimen, and the need to notify the patient's health-care provider about problems with the regimen. A guide to the dietary sources of iron to supplement oral iron medication is helpful to both the patient and any person responsible for meal planning and preparation. If iron is prescribed, inform the patient of possible side effects, including the black stools, and offer treatment options for GI side effects.

MACROCYTIC ANEMIA

Signal Symptoms: Weakness, shortness of breath, glossitis, dizziness, neuropathy. Often asymptomatic and only noted after receiving results of a routine CBC.

Description: Macrocytic anemia presents with macrocytosis (MCV greater than 100) on the CBC. Macrocytic anemia can be megaloblastic, a result of deficiency or impaired utilization of B_{12} (cobalamin) or folate (vitamin B_9), or non-megaloblastic due to disease such as myelodysplastic syndrome, liver disease, hypothyroidism, medications, or inherited disorders of DNA synthesis (Nagao & Hirokawa, 2017). The RBCs are the result of impaired DNA synthesis that inhibits nuclear division in the reticulocytes. The maturity of cytoplasm in RBCs is dependent

© F.A. Davis Publishing

on RNA and protein synthesis and continues normally. Adequate vitamin B_{12} and folate levels are necessary for DNA synthesis. When levels are inadequate, a nuclear-cytoplasmic asynchrony allows the cells to grow bigger before the nucleus signals division, resulting in large, nucleated RBCs, known as megaloblasts (Hariz & Bhattacharya, 2021).

Etiology: Megaloblastic anemia is primarily the result of a nutritional deficiency, particularly insufficient B_{12} and folate. Such deficiencies are often related to social determinants of health, such as lack of access to fresh food or alcohol abuse. Malabsorption of B_{12} and folate can be the result of the absence of intrinsic factor (IF) due to pernicious anemia or can occur after gastric surgery. Some medications interfere with the DNA synthesis, and some research has shown copper deficiency plays a role in megaloblastic anemia (Hariz & Bhattacharya, 2021).

Vitamin B_{12} is bound to IF produced by gastric parietal cells and then absorbed in the terminal ileum. Vitamin B_{12} is stored in the liver (about 2 to 3 mg total, which is an adequate supply for 2 to 4 years) (Hariz & Bhattacharya, 2021). The hepatic supply is one explanation for the length of time it can take for serious symptoms to develop. Pernicious anemia is an autoimmune condition resulting in a lack of IF causing poor vitamin B_{12} absorption from the ileum. Initially pernicious anemia was considered a primary cause of vitamin B_{12} deficiency, but more recent research has determined that it is relatively rare (Stauder et al., 2018). Other factors, such as *Helicobacter pylori* infections, acid-reducing agents, or atrophic gastritis that can cause hypochlorhydria, more frequently lead to cobalamin malabsorption syndrome (Stauder et al., 2018). Dietary sources of vitamin B_{12} include meats, fish, eggs, and dairy products. Strict vegetarian and vegan diets are low in vitamin B_{12}, and those patients should be screened for deficiency (Hariz & Bhattacharya, 2021).

Folate is from the Latin word *folium*, meaning "leaf." It is present in dark green leafy vegetables, legumes, fruits, grains, seafood, and liver. Folic acid is the synthetic form of folate and is a frequent additive in foods because of its role in prevention of neural tube defects in pregnancy. Folic acid is better absorbed than folate (85% vs. 50%). In addition to its role in RBC development, folate helps to break down homocysteine, which has harmful effects if elevated. About 5 mg of folate is stored in the liver—enough supply to meet the dietary requirement for 3-4 months (Hariz & Bhattacharya, 2021).

Macrocytic anemias that are non-megaloblastic can be due to liver disease, alcohol abuse, hypothyroidism, medications, myelodysplastic syndrome, and certain inherited disorders (Nagao & Hirokawa, 2017). One explanation of how liver disease without nutritional deficiency can cause macrocytosis is that increased deposition of cholesterol on the membranes of RBCs increases their surface area. Liver disease can also result in increased hemolysis. resulting in a hemolytic anemia (Yang et al., 2018).

Many medications can cause a megaloblastic anemia by impairing the availability or utilization of folate or vitamin B_{12}. Medications are also responsible for macrocytic non-megaloblastic anemias: Antineoplastics, folate antagonists, antimetabolite, antibacterial, antimalarial, anticonvulsant, anti-inflammatory, and antivirals.

Alcohol intake of greater than 85 ml a day can have a direct effect on the development of RBCs. Macrocytosis may be present in alcoholics before anemia develops (Nagao & Hirokawa, 2017). Abstinence may return the MCV to normal. Thyroid hormone helps to stimulate erythropoietin and hematopoiesis, so a low level of thyroid hormone may cause either normocytic or macrocytic anemia.

Myelodysplastic syndrome (MDS) is a hematopoietic stem and progenitor cell disorder identified by cytopenia, myelodysplasia, ineffective hematopoiesis, and risk of progression to acute myeloid leukemia (AML) (Hellström-Lindberg et al., 2020; Nagao & Hirokawa, 2017). In addition to cytopenia, MDS is defined by the presence of morphological dysplasia of precursor and mature bone marrow RBCs (Hellström-Lindberg et al., 2020). MDS is a variety of disorders that present with different degrees of anemia, dysplasia, and risk of AML. Subtypes include MDS with a single blood component (WBC, RBC, or platelet) that is low in number or abnormal. Another subtype may have two or three abnormal cell types. Ring sideroblasts, RBCs with rings of excess iron, are present in another subtype of MDS. MDS may include a subtype with a specific DNA mutation known as del(5q) chromosome abnormality. MDS with excess blasts includes any of the three types of blood cells and very immature blasts in the blood and bone marrow. Finally, there may not be a clear classification of the MDS.

Occurrence: Most sources acknowledge that megaloblastic anemia is common, but concrete data on prevalence are rare. One study published in 2017 found that megaloblastic anemia was present in 3.6% of all cases of anemia (Kaur et al., 2018). In the same study, no association between vegetarian diet and megaloblastic anemia was noted. Nagao and Hirokawa (2017) report that in family practice 2% to 4% of patients were found to have macrocytosis, and in older adults living at home macrocytosis was noted in 6.3% of men and 3.3% of women.

Age: The incidence of megaloblastic anemia increases with age. Older adults are at highest risk for pernicious anemia. Older adults are more likely to have a lack of stomach acid and intrinsic factor preventing the small intestine from absorbing vitamin B_{12}. Most patients presenting with MDS are older than 60 years.

Ethnicity: Vitamin B_{12} deficiency is more common in older White women than in Black women. Folate deficiency is more prevalent in Black than in White older women. Pernicious anemia is more common in people of Northern European and African descent (Ankar & Kumar, 2021).

Contributing Factors: Because megaloblastic anemia is often due to nutritional insufficiency, careful assessment of lifestyle and social habits are important. Alcoholism has been a chief component in both megaloblastic and non-megaloblastic macrocytic anemia. Any patient noted to have a macrocytosis with or without anemia should be assessed for alcohol misuse.

As noted above several classes of medications can contribute to the development of macrocytic anemia. These include some common medications such as allopurinol, disease-modifying antirheumatic drugs, hydroxyurea, 5 fluorouracil, trimethoprim, penicillin antibiotics, erythromycin, metformin, and triamterene. These medications can cause changes in the bone marrow or reduce the intestinal absorption of folic acid or vitamin B_{12} or metabolism of these vitamins (Hariz & Bhattacharya, 2021). A recent focus on a link between metformin and vitamin B_{12} deficiency has

© F.A. Davis Publishing

resulted in patients questioning the use of this first-line treatment for diabetes.

Patients with previous chemotherapy or radiation are at an increased risk of MDS. Exposure to benzene has been linked to MDS.

Signs and Symptoms: Most often there are no concerns expressed by the patient, but the abnormality is noted on routine laboratory findings. Because most macrocytic anemia is megaloblastic and caused by nutritional deficiency, and the liver has stores of vitamin B_{12} and folate, the anemia may take years to develop, and any insidious symptoms go unrecognized. The neurological manifestations of vitamin B_{12} deficiency are most concerning. Paresthesia and balance disorders are common, but the deficiency can also result in peripheral neuropathy, visual disturbances caused by optic atrophy, or dementia. Vitamin B_{12} is included in any laboratory evaluation of possible contributing factors to dementia.

Patients with MDS may have no symptoms until the disease advances. Complaints that can occur with any anemia include fatigue, shortness of breath, and pallor. Patients with MDS may develop a pancytopenia and, due to thrombocytopenia (low platelets), present with bruising, bleeding, or petechiae. With leukopenia (low WBCs) they may experience frequent infections.

On physical examination the provider may note a decrease in vibratory sensation, proprioception, or (in extreme cases) a positive Romberg test in patients with a B_{12} deficiency. Although less common, a Babinski reflex, hyporeflexia, and clonus may be noted in advanced neurological decline (Hariz & Bhattacharya, 2021). Depending on how long the deficiency has been present and the severity of the symptoms, the disorders may not be completely reversible.

The astute provider will recognize that comorbidities are common in older adults and expand the assessment to include concurrent factors such as hypothyroidism or hepatic dysfunction.

Diagnostic Tests:

- CBC will reveal Hgb of less than 12 g/dL in women and 13g/dL in men. Note that patients who are smokers and those with chronic hypoxemia have a higher premorbid Hgb and therefore can be anemic at higher Hgb levels (Sharma et al., 2019).
- RBC indices reveal an MCV/RBC size that will be increased to more than 100 fL in adults; MCH will be high, consistent with hyperchromia.
- Reticulocyte count, if elevated, may indicate hemolysis, which can occur in advanced liver disease. If low, serum vitamin B_{12} and folate levels will be the only additional tests needed.
- Vitamin B_{12} above 300 pg/mL is considered normal. If the level is between 200 and 300 pg/mL, additional testing with methylmalonic acid and homocysteine levels should be obtained.
- Folate levels of 2 to 4 ng/mL are considered borderline; levels below 2 ng/mL are diagnostic of folate deficiency.
- Methylmalonic acid can help to differentiate between vitamin B_{12} and folate deficiency. It is only elevated in vitamin B_{12} deficiency. In severe renal disease, methylmalonic acid levels are unreliable.
- Homocysteine is elevated in both vitamin B_{12} and folate deficiencies.
- In patients diagnosed with vitamin B_{12} deficiency, consider antibody assays against intrinsic factors.
- To evaluate for hypothyroidism, thyroid-stimulating hormone (TSH) level with reflex to T4 if abnormal.
- Hypersegmented neutrophils may be present on a stained peripheral smear in megaloblastic anemia.
- Poikilocytosis (RBCs of varying shapes) and anisocytosis (RBCs of varying sizes) are common due to ineffective erythropoiesis.
- Referral to hematology for bone marrow biopsy is essential in a patient suspected of having MDS.
- Ring sideroblasts, excess blasts, and chromosomal abnormalities on bone marrow biopsy are consistent with the diagnosis of MDS.

Differential Diagnosis: Differential diagnosis for macrocytic, hyperchromic anemia includes:

- Alcoholic hepatitis
- Atrophic gastritis
- Hypothyroidism
- Gastric cancer
- Celiac sprue
- Liver disease
- Tropical sprue
- MDS
- Aplastic anemia
- Acquired sideroblastic anemia
- Homocystinuria

Treatment: Vitamin B_{12} and folic acid can be given orally or parenterally. Vitamin B_{12} is absorbed in the terminal ileum and is dependent on intrinsic factor; however, oral vitamin B_{12} can be absorbed passively independent of intrinsic factor (Chan et al., 2016). The preferred route is oral unless there are malabsorption issues. Oral treatment takes time, so when severe neurological symptoms are present, a more rapid treatment response with parenteral vitamin B_{12} is required. If anemia is symptomatic, a blood transfusion may be necessary because vitamin B_{12} and folate, even given parenterally, will not correct anemia rapidly (Hariz & Bhattacharya, 2021).

The recommended dose of vitamin B_{12} is 1,000 mcg parenterally once a week until the deficiency is corrected, or an oral dose of 1,000 mcg daily. Duration of treatment depends on the cause. If the cause is corrected, diet improved, alcohol intake addressed, the supplement can be stopped when vitamin B_{12} levels are normal. When comorbidities such as history of gastric bypass or pernicious anemia exist, supplementation needs to be ongoing.

Folic acid supplement to correct a folate deficiency is 1 mg orally once a day until the deficiency is corrected or in the case of an ongoing condition, indefinite supplementation is needed. For non-megaloblastic causes of anemia, treatment needs to address the underlying cause. Treatment for alcohol misuse syndrome involves initiating thyroid replacement hormone and deprescribing medications that cause macrocytosis if possible. For MDS, refer to hematology and follow-up with the patient for support and management of other comorbidities.

Follow-Up: With treatment for vitamin B_{12} or folic acid deficiency, bone marrow should respond within 1 week and Hgb and Hct will normalize in 1 to 2 months

© F.A. Davis Publishing

(Hariz & Bhattacharya, 2021). The neurological effects of vitamin B_{12} deficiency will take longer to correct and may be permanent depending on how long the deficiency occurred undetected.

Follow-up for patients with non-megaloblastic macrocytic anemia is dictated by the identified cause. Care is often comanaged with specialists.

Prevention/Prophylaxis: A diet with leafy greens, meats, fish, and fresh fruits helps prevent folate deficiency. Diets that include meat, fish, eggs, and dairy products are important to provide adequate vitamin B_{12}. To reduce alcohol-related complications, patients should consume two or less drinks a day for men or one or less drinks a day for women. A drink is considered 12 ounces of a beer with 5% alcohol content, 5 ounces of wine (which is typically 12% alcohol content), or 1.5 ounces of distilled spirits (which are typically 40% alcohol content) (National Institute on Alcohol Abuse and Alcoholism [NIAAA], 2021). Remember that in alcohol misuse syndrome and hypothyroidism, patients may have macrocytosis without anemia. Perform a careful medication review to evaluate for medications that can contribute to the development of macrocytic anemia and deprescribe if possible.

Sequelae: Support patients who have severe neurological effects from chronic vitamin B_{12} deficiency to understand that while symptoms may not completely resolve, treatment success is measured is resolution of anemia and preventing further decline. Patients with MDS need to follow with hematology and consider referral to palliative care. Many of these patients will go on to develop AML.

Referral: If cause is not clear or the patient does not respond to treatment, referral to hematology is indicated to aid in the diagnosis and treatment. Collaborative management is appropriate for complex cases. Referral to a nutritionist can assist with the evaluation of dietary inadequacies and with meal planning or with congregate or home-delivered meals. Patients with alcohol misuse syndrome should be referred for counseling.

Education: The patient should be educated about the mechanism of anemia, the expected course of therapy with respect to frequency of office appointments and blood tests, any referrals, the importance of adhering to the treatment regimen, and the need to notify the patient's health-care provider about problems with the regimen. A guide to the dietary sources of vitamin B_{12} and folate are helpful to both the patient and any person responsible for meal planning and preparation. If vitamin B_{12} or folic acid are prescribed, inform the patient of expected length of treatment. Patients who are strict vegetarians or vegans need to understand the rationale for including vitamin B_{12} as a supplement.

PLATELET DISORDERS

As noted earlier in this chapter, platelets are the smallest population of blood cells. They are nonnucleated and disk-shaped fragments of megakaryocytes located in the bone marrow, with a life span of 9 to 12 days. Platelets are important in the clotting cascade. When damage occurs to a vessel wall, they form a hemostatic plug to close the leak. Their response is rapid, occurring in 3 to 5 minutes. Thrombopoietin regulates the production of platelets just as erythropoietin regulates production of RBCs. Thrombocytopenia is defined as a platelet count below 150×10^9/L. Thrombocytopenia can result in bleeding disorders due to the lack of platelets available to respond to injury. Thrombocytosis is defined as a platelet count above 450×10^9/L. Thrombocytosis may result in clotting disorders but in some cases can paradoxically cause bleeding.

© F.A. Davis Publishing

THROMBOCYTOPENIA

Signal Symptoms: There may be no symptoms and the low platelet count may be an incidental finding on the CBC. Before they become symptomatic, a patient's platelet count is typically less than 30×10^9/L, at which point minimal trauma may cause bleeding. A patient with a very low platelet count, less than 10×10^9/L, may present with petechiae, bruising, or oral mucocutaneous bleeding.

Description: Thrombocytopenia is classified as mild when the platelet count is between 100 and 150×10^9/L, moderate between 50 and 99×10^9 /L, and severe if less than 50×10^9/L. Sources may define these classifications differently, with some labeling a platelet count between 70 and 150×10^9/L as mild and severe as less than 20×10^9/L. With counts greater than 50×10^9/L, patients are rarely symptomatic unless they suffer a major trauma. Platelet counts can vary with age, sex, and race. Younger adults have higher counts than older adults, women have higher counts than men, and platelet counts in non-Hispanic Blacks are higher than in Whites. The baseline platelet count is important because if a patient has a high normal platelet count, 450×10^9/L for example, and it declines by greater than 50%, 247.5×10^9/L, it would still be well within the normal range but could indicate a clinically significant problem that should be evaluated.

Etiology: Thrombocytopenia can result from decreased platelet production, sequestration, or increased platelet destruction.

Decreased Platelet Production: Decreased platelet production can result from bone marrow disorders due to deficient nutrients, myeloid disorders (MDS, myeloproliferative syndromes), lymphoid malignancies, and metastasis from other cancers. Infection can cause thrombocytopenia.

Medications that can cause platelet destruction include antibiotics, antiepileptics, and (of classic concern), heparin. Treatment with radiotherapy or high-dose chemotherapy can affect the production of platelets in the bone marrow.

Thrombocytopenia can occur in chronic liver diseases including drug-induced, infectious hepatitis, and nonalcoholic liver disease. Liver disease or chronic alcohol abuse can affect both production of platelets as well as sequestration of platelets in the spleen. Production of platelets can be affected because thrombopoietin, which regulates platelet production, is produced in the liver.

Sequestration: Monocytes in the spleen are called reticular cells and act to remove old cells from circulation and act as phagocytes for inflammatory and immune responses. When platelets circulate through the spleen they may be identified by the reticular cells as abnormal and remove them. This may be due to portal hypertension, sarcoidosis, lymphomas, or chronic lymphocytic leukemia.

Platelets can also shift into the spleen, resulting in a low platelet count, even though the total number of platelets is actually normal or increased. Dilution occurs when there is a massive fluid resuscitation or transfusion. Redistribution/hypersplenism occurs when the normal one-third of platelet mass is altered either due to an increase in spleen size or congestion due to portal hypertension due to alcoholic liver disease. As noted above platelet sequestration can occur because of alcohol abuse even without liver disease.

Increased Platelet Destruction: Platelet destruction or consumption can be the result of idiopathic thrombocytopenic purpura (ITP), medications, disseminated intravascular coagulation (DIC) or hemolytic uremic syndrome which can be autoimmune or due to a bacterial infection.

Occurrence: Immune thrombocytopenia occurs in 2 to 4 cases per 100,000 person years (Cooper & Ghanima, 2019).

Age: Immune thrombocytopenia has two age peaks. The first is between 20 and 30 years and disproportionately affects females, due to causes resulting from pregnancy. The second much larger peak occurs after the age of 60 when autoimmune diseases of all types are more likely to occur (Cooper & Ghanima, 2019).

Ethnicity: Not significant.

Contributing Factors: Viral infections, such as HIV, Epstein-Barr, rubella, mumps, varicella, hepatitis-C, and COVID-19, result in thrombocytopenia due to bone marrow suppression. Bacterial infections, including malaria and tuberculosis (TB) cause low platelet counts through immune-mediated destruction, sequestration, and a shortened platelet survival time. TB can infiltrate the bone marrow and decrease platelet production or cause immune thrombocytopenia. *Heliobacter pylori* infection has also been associated with both ITP or as a secondary cause of immune thrombocytopenia.

Thrombocytopenia can occur due to alcohol abuse, even in the absence of liver disease. It may be associated with megaloblastic anemia due to vitamin B_{12} and folic acid deficiency, but those deficiencies may not be present. Discontinuing alcohol use can restore the platelet count. Other autoimmune diseases, such as systemic lupus erythematosus, Grave's disease, and sarcoidosis, can cause secondary immune thrombocytopenia.

Signs and Symptoms: Bleeding, petechiae, purpura, ecchymosis, enlarged liver or spleen. There may be no symptoms, but a routine blood test may show thrombocytopenia with no other abnormalities. Severe bleeding is usually only a concern if platelet count falls under 10×10^9/L (Cooper & Ghanima, 2019). The concurrent presence of an autoimmune disorder favors secondary ITP (Cooper & Ghanima, 2019).

Diagnostic Tests: CBC with peripheral blood smear (PBS) will reflect thrombocytopenia but otherwise be normal. PBS may show larger than normal platelets but normal RBC and WBC morphology. If there are other abnormalities in the PBS, a bone marrow biopsy is required to rule out other problems. In patients older than 60 years, bone marrow biopsy is realistic due to an increase in MDS.

Differential Diagnosis:

- Pseudothrombocytopenia
- Renal or liver disease
- Acute leukemia
- Chronic lymphocytic leukemia
- MDS

© F.A. Davis Publishing

- Aplastic anemia
- Thrombotic thrombocytopenic purpura
- Other autoimmune diseases
- Infection (HIV, Epstein-Barr, hepatitis, cytomegalovirus)
- Vasculitis
- Vitamin K deficiency
- DIC
- Hemolytic uremic syndrome (HUS)
- Hypersplenism

Treatment: The goal of treatment is to sustain a safe (not normal) platelet count to avoid bleeding. This may include withholding certain drug therapy, where risks outweigh benefits. If counts are above 80×10^9/L and the patient is asymptomatic, repeating the CBC and evaluating factors that may contribute to the thrombocytopenia is a reasonable first step. One study of the long-term outcomes of patients with incidental thrombocytopenia with platelet counts from 100 to 150×10^9/L followed for 10 years found that 64% normalized or remained stable (Gauer & Braun, 2012). Only 7% developed ITP, and 12% developed an autoimmune disorder. Four cases of MDS were diagnosed—all in older adults. A hematology referral should be initiated for assessment and management of patients with platelet counts less than 80×10^9/L, for those who have bleeding on examination, or for any patient for whom the advanced practice registered nurse (APRN) is not confident regarding the diagnosis and treatment. Treatments are indicated for those with 20 to 30×10^9/L who present with bleeding or plan surgical procedures (Al-Samkari & Kuter, 2020). Emergent conditions include those with new-onset acute thrombocytopenia. ITP only occurs in 100 cases per 1 million each year and half of these are in children, but immediate referral for management is critical (Gauer & Braun, 2012). For patients with platelet counts less than 10,000/mm^3, platelet transfusions may be indicated. For ITP, prednisone 1 mg/kg/day orally or IV immunoglobulin (IVIG) is used initially; a 4-day burst of dexamethasone (40 mg/day) may also be initiated or used in lieu of steroid treatment. In cases where platelet counts are less than 20,000/mm^3 with severe mucocutaneous bleeding or any significant bleeding, hospitalization is indicated to stabilize the patient. For RhD-positive patients who have not had a splenectomy, anti-D products, such as WinRho and Rhophylac, are as effective as IVIG in refractory cases (Cooper & Ghanima, 2019).

Splenectomy is a second-line option; the risks and benefits of surgery must be weighed (Cooper & Ghanima, 2019). Newer therapies include the monoclonal antibody rituximab and thrombopoietic growth factors for recalcitrant cases (Lambert & Gernsheimer, 2017). Other drugs that have been used successfully include cyclosporine, antifibrinolytics, and certain chemotherapy agents.

For many adult patients with ITP and a platelet count 30,000 to 40,000, watchful monitoring is all that is required if they are asymptomatic. The course of ITP in older adults tends to be chronic with initial responses to treatment, with a reversal back to baseline after a few months.

Follow-Up: Follow-up is variable depending on symptoms, platelet levels, causative agent, and response to treatment (if initiated). Patients with moderate or severe ITP will be followed by hematology and comanagement will be helpful in support of the patient.

Sequelae: Mortality rate is less than 1%, usually related to infections, bleeding, or refractory disease. There are some spontaneous remissions.

Prevention/Prophylaxis: Causes of thrombocytopenia are numerous and many of them can be addressed and treated. Adequate treatment of viral or bacterial causes can result in resolution of the low platelet count. Alcohol abuse needs to be addressed and support for recovery provided. Medications or the use of nutraceuticals or street drugs should be carefully assessed and properly managed with deprescribing, encouraging elimination, or referral for treatment.

Referral: Consultation with or referral to hematology is indicated in cases of severe bleeding or cases refractory to treatment. If malignancies are identified, refer to oncology. Autoimmune diseases may be best managed by rheumatology. The goal is accurate diagnosis and treatment.

Education: Patients should be instructed to avoid invasive dental procedures and other activities that could precipitate bleeding episodes. Low-impact exercise is recommended. Aspirin and NSAIDs should be avoided; alcohol intake should be limited to an occasional drink. Patients with hypertension should be encouraged to take their medications as ordered and to have frequent monitoring of their blood pressure to avoid a stroke. Periodic monitoring of platelets will be necessary.

THROMBOCYTOSIS

Signal Symptoms: Thrombocytosis is often asymptomatic and is initially noted on the CBC. If symptoms are present, they are generally related to the secondary cause of the elevated platelets. In patients with primary thrombocytosis, symptoms may be due to blood clots or bleeding.

Description: Thrombocytosis is defined as a platelet count exceeding 450×10^9/L in adults. The problem can be primary (essential thrombocythemia), caused by alterations in the genes of the main regulators of thrombopoietin, which affects the development of hematopoietic cells. Essential thrombocytosis is a subform of myeloproliferative neoplasms. Most often thrombocytosis is the result of a secondary cause (reactive thrombocytosis).

Etiology: Essential thrombocytosis can be familial or sporadic. There may be similarities in the cellular mutations in both forms of the disease, but it is not clear cut. Even those with sporadic disease may have a hereditary component. Myeloproliferative disorder is often a diagnosis of exclusion, meaning that other differentials must first be ruled out as a cause of the elevated platelet count. Reactive thrombocytosis occurs because of elevated levels of thrombopoietin, interleukin-6, other cytokines or catecholamines because of an external cause such as cancer, chronic inflammation, iron deficiency, in situations of stress. or a rebound after splenectomy. When thrombocytosis is noted without clear causation, it is important to consider an occult malignancy.

© F.A. Davis Publishing

Occurrence: The most common cause of thrombocytosis is a reactive process, greater than 90% (Galvez & Stein, 2020). Essential thrombocytosis occurs in the remaining cases. Women are one and a half times more likely than men to develop essential thrombocytosis.

Age: People older than age 60 years are more likely to develop essential thrombocytosis and are also more susceptible to the diseases likely to cause reactive thrombocytosis.

Contributing Factors: May be genetic or due to the disease resulting in reactive thrombocytosis.

Signs and Symptoms: Some symptoms may be due to clotting, such as headaches, dizziness, chest pain, weakness, or numbness and tingling of the hands and feet. Ischemia of the hands or feet may be present with essential thrombocytopenia. There may be paradoxical bleeding complications in essential thrombocytopenia. Forty percent of patients with essential thrombocytopenia have splenomegaly. On peripheral blood smear there may be giant platelets in essential thrombocytopenia which would not be present in reactive thrombocytopenia.

Diagnostic Tests: Screening tests appropriate to rule out the common causes of secondary or reactive thrombocytopenia. Laboratory tests do not offer clear differential diagnosis. Referral to hematology is appropriate for bone marrow biopsy and possible genetic testing.

Differential Diagnosis:
- Other myeloproliferative disorders
- Acute blood loss
- Recovery from thrombocytopenia
- Acute infection or inflammation
- Response to exercise
- Iron deficiency
- Hemolytic anemia
- Cancer
- Chronic inflammatory disease
- Drug reactions
  - Vincristine
  - Cytokines
  - Growth factors

Treatment: In patients with reactive thrombocytosis, platelet-lowering medications are not required because the abnormal platelet count does not increase the risk of vascular events (Galvez & Stein, 2020). The critical concern is identifying the cause of the reactive thrombocytosis and treating the underlying disease.

In essential thrombocytosis treatment to lower the platelet count may be needed. Referral to hematology to guide decision making regarding treatment is the best strategy. Adults over the age of 60 and those with cardiovascular risk factors are at the highest risk for thrombotic and vascular events. Those at high risk may benefit from platelet lowering medication and aspirin. When cerebrovascular events or digital ischemia has already occurred platelet-cytoreductive agents and aspirin may be indicated. All the available treatment options include the potential for serious side effects and ongoing studies are being conducted to determine the best alternatives.

Follow-Up: Regardless of etiology, essential or reactive thrombocytosis, the patient will most likely be comanaged with a specialist. Coordination of care will be of utmost importance and maintaining high degree of vigilance for complications.

Sequelae: Depends on the underlying cause of the elevated platelet count. Gene therapy for essential thrombocytosis may be an option in the future. Adherence to treatment and ongoing monitoring.

Clinical Recommendation	Evidence Rating	References
Treatment decisions are influenced by platelet count and degree of bleeding; therapy is seldom required for platelet counts >30,000/mm^3.	C	Lambert & Gernsheimer, 2017
The goal of treatment is to prevent bleeding, not necessarily to return platelet count to normal.	C	Lambert & Gernsheimer, 2017 Cooper & Ghanima, 2019
Initial management includes treatment with oral prednisone. Other choices for treatment include high-dose dexamethasone, IVIG, and WinRho.	C	Lambert & Gernsheimer, 2017 Cooper & Ghanima, 2019
Chronic refractory ITP is defined as persistence for >3 months, lack of response to splenectomy, and platelet count <50,000/mm^3. Treatment options include glucocorticoids, rituximab, vincristine, cyclophosphamide, and methylprednisolone.	C	Cooper & Ghanima, 2019

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. For information about the SORT evidence rating system, go to https://www.aafp.org/afp/2004/0201/p548.html.

LEUKEMIA

Leukemia is a hematological malignancy of the blood and bone marrow and arises from the hematopoietic stem cell line. Blood cell development undergoes several steps to mature to erythrocytes (red blood cells), megakaryocytes (platelets), or granulocytes and lymphocytes (white blood cells).

Leukemia develops because of genetic changes in the hematopoietic precursor cell. Abnormal and immature blood cells replicate and invade bone marrow and peripheral blood and impede the normal function of all hematopoietic cell lines (erythrocytes, granulocytes, lymphocytes, and megakaryocytes).

The four main types of leukemia are acute lymphoblastic leukemia (ALL), acute myeloid leukemia (AML), chronic lymphocytic leukemia (CLL), and chronic myeloid leukemia (CML). Adult leukemias represent 3% of all adult cancers (NCI, 2021). In the adult population, AML and CLL are the most prevalent types of leukemia.

© F.A. Davis Publishing

ACUTE MYELOID LEUKEMIA

Description: In acute myeloid leukemia (AML), myeloid cells grow into leukemia blasts, crowding out the healthy myeloid cell precursors in the marrow, which may result in pancytopenia (low blood counts) (Srinivas, 2021). AML is categorized into subtypes M0 to M7 based on the type of cell it develops from and the maturity of the cell (American Cancer Society [ACS], 2021b). Acute promyelocytic leukemia (APL) is a particularly aggressive subtype of AML with distinct morphology and clinical presentation. APL accounts for 10% of AML cases. There is high risk for early mortality due to coagulopathy (National Comprehensive Cancer Network [NCCN], 2021a).

Occurrence: In 2021, there will be an estimated 20,240 new cases and 11,400 deaths in the United States. Based on SEER program data from 2011 to 2017, 29.5% of patients with AML were alive 5 years after diagnosis (NCI, 2021a).

Age: The median age at diagnosis is 68 years. The median age at diagnosis of APL is 47 years (NCCN, 2021a).

Ethnicity: Not significant.

Signs and Symptoms: Patients present with fever, pallor, fatigue, shortness of breath, bleeding, or bruising due to pancytopenia (Srinivas, 2021).

Diagnostic Tests:

- History and physical examination
- CBC with differential, CMP, lactate dehydrogenase (LDH), uric acid, prothrombin time (PT), partial thromboplastin time (PTT), International Normalized Ratio (INR), fibrinogen
- Additional work-up to be initiated by a hematologist
- Bone marrow aspirate and biopsy (NCCN, 2021a)

The presence of 20% blasts in peripheral blood or bone marrow is diagnostic of AML. Patients are divided into three risk categories based on cytogenetics—favorable, intermediate, and poor risk. Molecular profiling is now a standard diagnostic tool for AML because it further refines prognostic risk groups (NCCN, 2021a).

Differential Diagnosis:

- Acute lymphocytic leukemia
- Anemia
- Aplastic anemia
- B-cell lymphoma
- Bone marrow failure

Treatment: AML treatment is rapidly evolving, with eight new targeted therapy drugs approved since 2017. The options used to be intense chemotherapy with curative intent versus low-intensity palliation (Table 19-2). For the past several decades, the treatment discussion focused on the fitness for intensive therapy. Now, there are new factors: ensuring prompt identification of molecular mutations at diagnosis and relapse, choosing an appropriate therapy, and safe management of adverse effects. Ongoing clinical trials will better define drug response and toxicities (Dinardo & Wei, 2020).

The treatment of AML is divided into induction and post-remission (consolidation) therapy. The goal of induction is to reduce tumor burden and restore hematopoiesis. Induction chemotherapy must be started before cytogenetic and molecular information is known. Therapy is based on age, history of myelodysplasia or cytotoxic therapy, and performance status.

Cytogenetic and molecular analysis provide the best prognostic information for induction and post-remission chemotherapy (NCI, 2021a). There is no standard or ideal salvage chemotherapy regimen for relapsed/refractory AML. For older adults who are frail and with significant comorbidities, a less intense regimen is preferred to control disease and minimize treatment-related mortality (Megías-Vericat et al., 2018). Supportive care with blood product transfusions and hydroxyurea is an appropriate option for patients who are not fit for induction therapy or who choose supportive care and forego chemotherapy (NCCN, 2021a). Supportive care with blood product transfusions and hydroxyurea is an appropriate option for patients who are not fit for treatment or choose not to receive chemotherapy (NCCN, 2021a).

Response to Treatment: Sixty to seventy percent of adults obtain complete remission after induction. Older patients have increased morbidity and mortality during induction. The 3-year survival rate for adults with AML is 25%. Negative prognostic factors include age, central nervous system (CNS) involvement, infection at diagnosis, WBC >100,000/mm^3 at diagnosis, therapy-related malignancy, history of myelodysplastic syndrome (NCCN, 2021a).

TABLE 19-2 Treatment Phases for Acute Myeloid Leukemia

TREATMENT PHASE	GOALS OF TREATMENT PHASE	CONSIDERATIONS
Induction	Reduce leukemic blast burden	Prognostic/genomic features determine treatment plan
	Restore hematopoiesis	
	Achieve clinical remission	If remission is not achieved, a re-induction is initiated.
Post-Remission (Consolidation)	Eradicate remaining leukemia	Move to hematopoietic stem cell transplantation evaluation based on prognostic/genomic features
	Prevent relapse	
Supportive Therapy	Support through myelosuppression caused by treatment	Blood products, anti-infectives, growth factors

© F.A. Davis Publishing

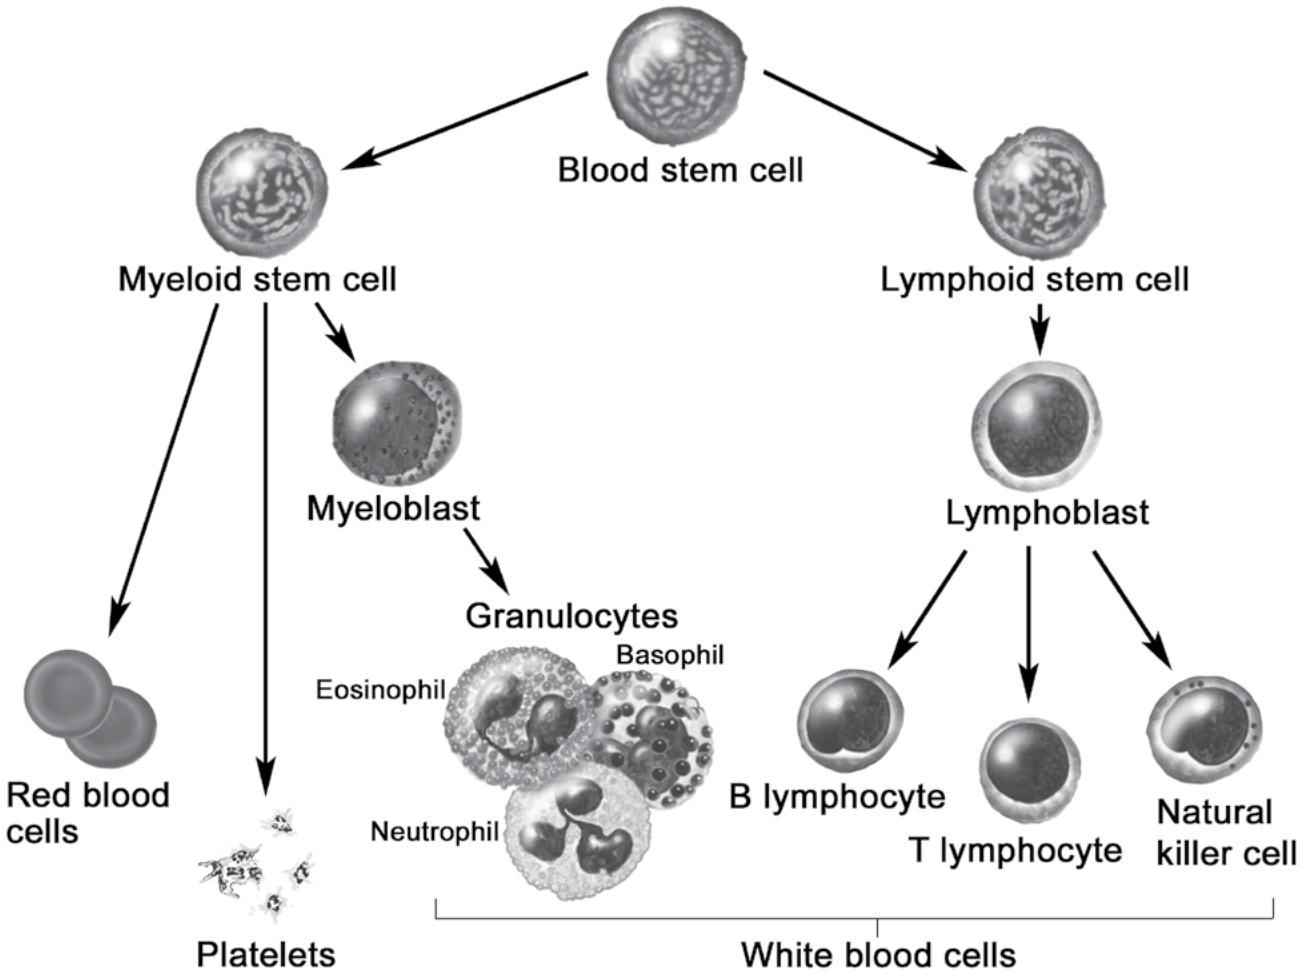
Supportive Care: Patients require CBC every 1 to 3 months for the first 2 years after consolidation and every 3 to 6 months for up to 5 years. Bone marrow biopsies are only performed if the CBC is abnormal.

Patients require antimicrobial prophylaxis, tumor lysis prophylaxis, growth factor support, blood product transfusions, correction of coagulopathies, and electrolyte replacement (NCCN, 2021a). Patients are at increased risk of secondary malignancy and HF due to treatment with anthracycline chemotherapeutic agents. Patients who undergo hematopoietic stem cell transplant (HSCT) may experience acute and chronic graft versus host disease, chronic infections due to immunosuppression, infertility, osteopenia, cataracts, iron overload, chronic fatigue, and secondary malignancies (NCI, 2021a).

Considerations for the Primary Care Physician (PCP): Obtain a CBC in patients who appear anemic and/or have extreme fatigue, unexplained high fevers, infections that are difficult to control or recur, lymphadenopathy, bruising/bleeding, petechiae, or an enlarged spleen. If symptoms persist or blood counts are abnormal, refer to a hematologist for further work-up. In any individual with an abnormal CBC, rapid referral to a hematologist should be considered. Treatment of an individual with AML is considered critically urgent and patients will be admitted to the hospital as soon as the potential diagnosis is made.

CHRONIC LYMPHOCYTIC LEUKEMIA

Description: Chronic lymphocytic leukemia (CLL) is one of the chronic lymphoproliferative neoplastic disorders and is characterized by the progressive accumulation of abnormal and incompetent lymphocytes (Fig. 19-1). Small lymphocytic lymphoma (SLL) is an indolent non-Hodgkin's lymphoma (primarily seen in nodal disease), yet is identical to CLL. However, CLL abnormal lymphocytes are in the blood and bone marrow and SLL is found in lymph nodes and bone marrow.



© 2007 Terese Winslow LLC
U.S. Govt. has certain rights

FIGURE 19-1 Blood cell development.

© F.A. Davis Publishing

Occurrence: CLL is a disease of older adults. It makes up 25% of new leukemia cases. In 2021, there will be an estimated 21,250 new cases and 4,320 deaths in the United States.

Age: Average age at diagnosis is 70 years. It is rarely seen in people younger than 40 (American Cancer Society [ACS], 2021b).

Ethnicity: More common in North America and Europe than in Asia. Asian people who live in the United States do not have a higher risk than those living in Asia (ACS, 2021b).

Signs and Symptoms: Patients are usually asymptomatic in early CLL. Based on the heterogenous nature of CLL, certain subsets of patients have survival rates like the normal population. Symptoms that occur later in CLL progressive disease include painless swelling of lymph nodes, fatigue, weakness, pain, or fullness below ribs (splenomegaly), fever, infection, bruising/bleeding, petechiae, weight loss, night sweats (NCI, 2021b).

Diagnostic Tests:
- History and physical examination
- Measurement of lymph nodes, spleen, and liver
- CBC with differential, chemistry panel, LDH, beta-2 microglobulin
- Reticulocyte count, indirect bilirubin, serum haptoglobin, direct Coombs', and cold agglutinin (if concern for autoimmune hemolytic anemia)
- Additional tests/genetic analysis completed by a hematology/oncology specialist (NCI, 2021b)

CLL diagnosis requires monoclonal B lymphocytes present at 5×10^9/L and clonality of B cells confirmed by peripheral blood flow cytometry. SLL diagnosis requires lymphadenopathy and/or splenomegaly with B lymphocytes of less than 5×10^9/L in the peripheral blood and confirmation with lymph node biopsy.

Differential Diagnosis:
- Infection resulting in lymphocytosis
- Monoclonal B cell lymphocytosis
- Prolymphocytic leukemia
- Mangle cell lymphoma
- Lymphoplasmacytic leukemia
- Hairy cell leukemia
- Follicular lymphoma
- Splenic marginal zone lymphoma

Treatment: Treatment of CLL ranges from observation (providing treatment of infectious, hemorrhagic, or immunological complications) to a variety of therapeutic options administered as targeted single agents or combination therapy. In asymptomatic patients, treatment may be deferred until the disease progresses and symptoms occur. Frequent and careful observation is required to monitor the clinical course, and the patient may experience a long period of stability. Treatment is indicated for patients with disease-related complications, including worsening anemia and/or thrombocytopenia, symptomatic splenomegaly, or constitutional symptoms (significant fatigue/inability to perform usual activities, fevers and/or night sweats greater than 2 to 4 weeks without evidence of infection, and/or unintentional weight loss >10% within the previous 6 months).

Response to Treatment: Targeted therapy treatment regimens have altered the treatment landscape for CLL, providing treatment response/remission without need of traditional chemotherapeutic agents. Apart from allogeneic hematopoietic stem cell transplant (HSCT), however, CLL remains incurable with current treatment options.

Supportive Care: Patients with relapsed CLL are severely immunocompromised. They must receive the influenza vaccine annually and pneumococcal vaccine every 5 years. Herpes virus prophylaxis with acyclovir and PJP prophylaxis with sulfamethoxazole/trimethoprim is indicated. IV immunoglobulin (IVIG) can be effective to prevent recurrent infections. Hepatitis B, cytomegalovirus, and Epstein-Barr virus can be reactivated. Autoimmune hemolytic anemia (AIHA) and idiopathic thrombocytopenic purpura (ITP) are commonly seen in CLL (NCCN, 2021b).

CHRONIC MYELOCYTIC LEUKEMIA

Description: Chronic myelocytic leukemia (CML) is a myeloproliferative neoplasm defined by the Philadelphia chromosome, translocation (9;22), which creates the BCR-ABL1 fusion gene. It is classified into three phases: chronic phase (CP-CML), accelerated phase (AP), and blast phase (BP). Ninety to ninety-five percent of patients present in CP-CML. CP-CML may transform to a more aggressive form of disease (AP or BP) within 3 to 5 years. Increased peripheral blood blast count and cytogenetic changes, as well as fever, bone pain, and change in spleen size can be seen during transformation (NCCN, 2021c).

Occurrence: Fifteen percent of adult leukemias are CML. In 2021, there will be an estimated new 9,110 cases and 1,220 deaths in the United States (ACS, 2021c). Targeted therapy has changed the treatment landscape for Ph-positive CML. Today CML is classified as a chronic disease (Vener et al., 2020). Unfortunately, patients with Ph-negative CML do not respond well to treatment and have a shorter overall survival (NCI, 2021c).

Age: The median age at diagnosis is 67 years.

Ethnicity: Most common in non-Hispanic Whites and least common in non-Hispanic Asian/Pacific Islanders (NCI, 2021c).

Signs and Symptoms: Symptoms of CML are often dependent on the stage of the disease. Chronic phase CML symptoms result from anemia and splenomegaly, including fatigue, weight loss, malaise, early satiety, and left upper quadrant fullness. Bleeding, thrombosis, gouty arthritis, priapism, retinal hemorrhages, and upper gastrointestinal (GI) ulceration are rare symptoms. Headaches, fevers, bone and joint pain, bleeding, infections, and lymphadenopathy are signs that CP-CML is transforming into an AP or BP, which very much resembles AML (Eden & Coviello, 2022).

© F.A. Davis Publishing

Diagnostic Tests:

- History and physical
- Spleen size by palpation
- CBC with differential and chemistry (NCCN, 2021c)

CP-CML is diagnosed when there are less than 10% blasts and promyelocytes in the peripheral blood and bone marrow; AP-CML 10% to 19% blasts; BP-CML 20% or more blasts. When patients with 20% or more blasts also present with fever, malaise, and splenomegaly they are in blast crisis (NCI, 2021c). Transformation between phases is characterized by leukocytosis, thrombocytosis, thrombocytopenia, anemia, splenomegaly, hepatomegaly, fever, bone pain, bone lesions, and thrombotic or bleeding complications (NCI, 2021c).

Differential Diagnosis:

- Leukemoid reactions
- Effect from corticosteroids
- MDS
- Polycythemia vera with iron deficiency
- Philadelphia-negative CML
- Myeloid hyperplasia
- Thrombocythemia

Treatment: There are several first-line targeted therapies (tyrosine kinase inhibitors [TKIs]) for CP-CML. Therapies are chosen based on the patient's comorbidities. (Vener et al., 2020). TKIs are generally well tolerated, but each has a unique side-effect profile ranging from fatigue to renal, pulmonology, hepatic, and cardiology toxicities. All TKIs can cause cytopenias (NCCN, 2021c). Patients with advanced phase CML (AP and BP) should enroll in a clinical trial, if available, as well as be worked up for hematopoietic stem cell transplant (HSCT).

Response to Treatment: Hematological, cytogenetic, and molecular responses to treatment with TKIs are evaluated to assess response (Table 19-3). If patients do not achieve a molecular response at 3, 6, or 12 months after subsequent TKI therapy, they need to be evaluated for appropriateness of HSCT (NCCN, 2021c).

Supportive Care: Compliance with oral TKIs can be a barrier to treatment. Patient education and side effect management is key to adherence. TKIs can interact with many medications and dosing needs to be reviewed with a pharmacist. A multidisciplinary team is best suited to coordinate care for patients with CML (Eden & Coviello, 2022).

TABLE 19-3 Measurement of Treatment Response With TKI for CML

LEVEL OF RESPONSE	DEFINITION	TEST
Hematological	Complete hematological response is noted when the peripheral blood counts are normal with no immature blood cells, leukocyte count is less than 10×10^9/L, and platelet count is less than $450{,}000 \times 10^9$/L.	CBC
Cytogenetic	Cytogenetic response is noted when there is a decrease in the number of Philadelphia-positive metaphases, as determined by bone marrow aspirate and cytogenetics.	Bone marrow cytogenetics
Molecular	Decrease in the amount of BCR-ABL1 chimeric mRNA as measured by the RT-PCR.	Quantitative real time-polymerase chain reaction (RT-PCR)

CASE STUDY

Mrs. L., a 68-year-old woman, presents to your office today with a complaint of feeling tired all the time and now, more recently, feeling weak and like "I can't catch my breath sometimes." She has been healthy except for high cholesterol, managed by Lipitor. Her husband died 9 months ago, and she has attributed her fatigue to dealing with his death, but realizes that she is feeling worse and not better as time passes.

No known drug allergies, takes only Lipitor. Past surgical history: Appendectomy in childhood; hysterectomy for uterine myoma 10 years ago. No significant medical history. Has two daughters living nearby. Blood pressure (BP) 106/70 mm Hg, heart rate (HR) 98 beats/min and regular, respiratory rate 18 breaths/min and afebrile, body mass index (BMI) 22 (10-lb weight loss since death of husband).

Slender, quiet-spoken older woman appearing tired. Conjunctiva pale, mucous membranes moist. No lymphadenopathy of neck or femoral area. Chest CT angiogram (CTA), good air movement. Heart tachyarrhythmic with regular rate, soft midsystolic murmur. Abdomen soft, bowel sounds × 4. Urine dipstick negative.

1. What additional subjective data are you seeking?
2. What additional objective data will you be assessing for?
3. What national guidelines are appropriate to consider?
4. What tests will you order?
5. Are there any screening tools that you want to use?
6. What are the differential diagnoses that you are considering?
7. What is your plan of care?
8. Are there any *Healthy People 2020* objectives that you should consider?
9. What additional patient teaching may be needed?
10. Will you be looking for a consultation?

CHAPTER 20

Psychosocial Disorders

Laurie Kennedy-Malone

ASSESSMENT

Psychosocial assessment of the older adult requires a holistic, systematic review and evaluation of the patient, their family, and their environment. The psychosocial assessment provides the foundation for developing and implementing a comprehensive plan of care and a means for evaluating its effectiveness. The psychosocial assessment needs to consider not only the patient's mental health but also their social well-being. The practitioner must understand what happens during the aging process because this knowledge allows differentiation between normal and abnormal symptoms. For the older adult, physical health, mental health, spirituality, and environmental and social problems all interact to complicate the life and function of the older patient, their caregivers, and their family. Differentiating between medical and psychological disorders can be difficult for any clinician due to the possibility of multimorbidity (Varghese & Dahale, 2018).

The assessment of older adults is quite challenging considering the many age-related physiological and metabolic changes, increased number of chronic diseases with potential psychiatric manifestations, medications and their side effects, and often atypical presentation of illness (Meeks et al., 2009).

The psychosocial assessment of the older adult includes evaluation of the following basic needs:

- Autonomy and independence
- Dignity, credibility, and respect
- Identity and individuality
- Communication and belonging
- Touch

A positive correlation exists between social supports and the use of health-care services by older adults. Older adults who are alone and lonely, depressed, or having difficulty adapting to change appear in their practitioner's office more frequently than those with adequate support systems. Social networks are an important aspect of a patient's social functions, as are work, hobbies, and interests. Older adults may be reluctant to reveal social or emotional concerns and, in some cultures, may feel that it is unacceptable to share personal problems with outsiders. However, they may feel comfortable discussing a physical manifestation, such as pain or sleeplessness, with a health-care provider (Kendall, 2019; Varghese & Dahale, 2018).

The older adult population is not a homogeneous group; rather, the population demonstrates a diversity in health, social and environmental supports, financial security, and cultural and personal philosophies. Some distinctive occurrences in the lives of older adults may include:

- Developmental milestones that have an impact on most older adults (e.g., retirement, loss of a spouse)
- Changes in financial and social resources that allow the older adult to cope effectively with age-related phenomena

Relocation, financial concerns, and lack of social supports may be the impetus for physical and mental health problems. The most common life events that place the older adult at risk for psychosocial dysfunction include:

- Retirement/role loss
- Loss of spouse
- Deaths of close friends
- Family problems
- Relocation
- Financial problems (Meeks et al., 2009)

Psychological Health

Because older adult patients may hesitate to discuss social or emotional problems with a health-care provider, physical symptoms may be the chief expression of underlying psychosocial dysfunction. Therefore, measurement of psychological health adds an important component to the older adult assessment. Psychological health is measured based on the two subdomains of cognition (mental status) and affect (anxiety and depression). A variety of tools, mentioned throughout this text, can be used for cognitive and emotional health assessment. Although helpful, screening tools should not replace the interactive relationship between practitioner and patient (Kendall, 2019). The heterogeneity of socioenvironmental factors precludes the use of a single tool for evaluating the older adult; however, to evaluate this domain, an environmental and safety checklist may be helpful, and it may also be used for patient and family

© F.A. Davis Publishing

education. The information derived from this evaluation will direct the practitioner in areas of education for the patient and family.

Chronic disease, physical disability, pain and suffering, cognitive impairment, accumulated losses, and social isolation may occur when an individual is least able to cope with change. Therefore, a psychosocial assessment provides a foundation for developing and implementing a comprehensive plan of care. The expected outcome for the older adult is an enhanced quality of life.

Components of the Psychosocial Assessment

An accurate psychosocial assessment is an interactive process between the practitioner and the older adult that creates an awareness of risks, limitations, and functional changes (Varghese & Dahale, 2018). This enables the older adult to make appropriate lifestyle changes and accommodations to maintain their autonomy, independence, and dignity. The psychosocial assessment should be performed at the initial encounter and annually thereafter for all older adults. Reassessment is appropriate whenever a patient's health status changes. You may want to consider at some time assessing the older adult with and without a family member or caregiver present.

Components of the psychosocial assessment are included in the Welcome to Medicare Examination and the Annual Wellness Visit (Camacho et al., 2017; Pfoh et al., 2015; Simpson et al., 2021), providing the clinician time to review their psychosocial status even if the patient is not forthcoming with their concerns (Lucas et al., 2022).

When considering the approach to the psychosocial assessment in an older adult, use terminology that can be understood by the older adult. It may be a struggle for an older adult to commit to a visit that pertains to mental health issues, so focus on their overall well-being. Address the patient's overall medical information, including presenting problems, history of past conditions, medications (prescription and over-the-counter), known psychiatric history, present level of cognition, screening for changes in behavior or mood, and any psychotic or anxiety symptoms. Ascertain from the patient, family member, or caregiver information about any past treatments (medications, psychological therapy, and electroconvulsive therapy [ECT]) and for a history of psychiatric disorders. Conduct a brief suicide assessment. Evaluate for signs and symptoms of abuse or neglect, current and past use of alcohol and other illicit drugs, changes to functional status. Also ask about the patient's current living environment, family status/history (especially of psychiatric or neurological disorders), friends, and social support network (Varghese & Dahale, 2018).

Review current and past occupational, military, and education history. Determine the patient's engagement in spirituality, leisure activities and hobbies, and what gives them pleasure and meaning in life. Assess the patient's coping skills. If an older adult has experienced significant loss, consider assessing for bereavement overload.

The overall assessment should begin with a test of cognition; however, it is crucial to first establish a rapport and a secure trust with the patient before using a specific screening instrument. The complete mental status assessment includes the appearance, motor movement, speech, affect/mood, thought content, process, perception, cognition, insight, and judgment (Libby et al., 2021; Snyderman & Rovner, 2009). When positive findings of any of the components of the mental status examination are reported or observed, further probing is needed and information should be verified by the patient, family members, or caregivers (Kendall, 2019; Varghese & Dahale, 2018).

Evaluation for Neuropsychiatric Conditions

When considering assessing psychosocial conditions in older adults, the clinician knows that older adults are often not forthcoming about a change in their overall condition or even why they might be experiencing symptoms (medication-related or disease-process–related). Questions about prevalent psychosocial symptoms commonly experienced by older adults, such as apathy, sadness, depressive symptoms (lack of energy, loss of interest, deceased ability to concentrate), agitation, and sleep disturbance, may need to be probed by the clinician if these symptoms are suspected or anticipated because of changes in function, medications, or experienced loss (Kendall, 2019; Meeks et al., 2009). If patients respond to having experienced any of these symptoms, it is important to quantify the duration of the symptom, any known precepting factors and any self-care measures or treatments that the patient has initiated. A more in-depth neuropsychological evaluation can be considered for an objective assessment of multiple cognitive and complicated emotional functions that may require complex treatment plans (Schroeder et al., 2019).

Determining Capacity in Older Adults

Whether or not impaired cognition or progressive psychiatric illness is determined, older adults may be found to have impaired decisional capacity and competency (Meeks et al., 2009; Varghese & Dahale, 2018). *Capacity* is defined as a functional determination that an individual is or is not capable of making a medical decision within a given situation, whereas *competency* is defined as the ability of an individual to participate in legal proceedings (Darby & Dickenson, 2017). Nurse practitioners can determine decision-making capacity in patients (Libby et al., 2020). Establishing capacity is viewed as a complex computation involving a complete mental status assessment and an appraisal of the patient's culture, education level, health literacy skills, and ability to articulate the issues of concern (Goldfrank & Wittman, 2017). A patient has capacity if they:

- Understand information relevant to the decision in question
- Have the ability to weigh risks and benefits and to assess alternative options
- Communicate clearly with medical providers about the decision in question, and verbalize the ultimate decision
- Demonstrate consistency of logic and decision making throughout the encounter (Libby et al., 2021, para 26)

It is highly recommended that older adults be proactive in establishing advance directives before the need to determine capacity and competency (Meeks et al., 2009).

AGITATION

Signal Symptoms: Change in behavior, also known as *neuropsychiatric symptoms of dementia.*

Description: Various terms are used to describe agitation. These include *aggression, hyperactivity*, and *irritability*. The International Psychogeriatric Association defines *agitation* as manifesting excessive motor activity or verbal or physical aggression that is associated with emotional stress for the person concerned (Schmudderich et al., 2021).

Etiology: Symptoms are related to the changes in the brain structure and function, particularly in the brain circuits and networks that are involved in motivated behavior, emotions, and cognitive processing (Nowrangi et al., 2015).

Occurrence: Agitation occurs most frequently in those with cognitive impairment or dementia, with a higher incidence in females. Ninety percent of people with dementia develop at least one clinically significant neuropsychiatric symptom. The prevalence of agitation can reach 85% based on the assessment tool utilized (Schmudderich et al., 2021).

Age: Predominantly in older adults

Ethnicity: Patients with moderate to severe dementia who are Black or Latino have a higher prevalence of dementia-related behaviors than Whites (Freedman et al., 2018).

Contributing Factors: Cognitive impairment, sensory impairment, social isolation, chronic bedrest, pain, and hunger can precipitate episodes of agitation. Environmental triggers, such as noise, light, and visual cues from television and physical surroundings, can also lead to agitation. Psychosocial triggers, such as the approach taken by staff, interaction with other residents, and anxiety during personal care, may cause a person to become agitated (Schmudderich et al., 2021).

Signs and Symptoms: Behaviors may be displayed in multiple ways. Common behaviors include repeating questions, arguing, pacing, screaming, crying out, making disruptive sounds, physical or verbal aggression, and shadowing a caregiver. When assessing the older adult with agitation, primary psychiatric causes should not be overlooked. Anxiety disorders are the most prevalent psychiatric disorder among older adults. Acute anxiety can present with signs of agitation including restlessness, pacing, irritability and agitation. Individuals with psychotic symptoms such as delusions, paranoia, hallucinations, or disorganized behavior may also be agitated (Kennedy et al., 2020).

Diagnostic Tests: Assessment should include ruling out conditions that can cause agitation. These include hypoxia, hyperglycemia, ST-elevation myocardial infarction (STEMI), electrolyte imbalance, infection, and medication side effects. Obtain complete blood count (CBC), comprehensive metabolic panel (CMP), urinalysis, and electrocardiogram (EKG) (Shenvi et al., 2021).

Differential Diagnosis:

- Delirium
- Psychosis
- Mania
- Infection
- Medication side effects
- Late-life delusional disorder
- Depression
- Pain
- Seizures

Treatment: Depending on the manifestations of agitation, evidence supports the use of antidepressants, antipsychotics, or antiepileptics in conjunction with cholinesterase inhibitors (Table 20-1). Cholinesterase inhibitors have a favorable safety

TABLE 20-1 Psychotropic Drug Management for Agitation

DRUG	DOSE	FORM	CAUTIONS
Antipsychotics (Always Start at Lowest Dose)			
aripiprazole (Abilify)	2.5 mg	Tab, dissolvable	Decreased white blood cells
	Max 30 mg	Liquid, IM	Potentiates antihypertensives
risperidone (Risperdal)	0.25–1.0 mg	Tab, liquid, IM	Dose-related EPS
			Potentiated by proton inhibitors
			May be affected by fluoxetine (Prozac), paroxetine (Paxil)
asenapine (Saphris)	5–10 mg	SL	Weight gain, anxiety, depression
Antiseizure Agents (Off-Label Use)			
carbamazepine (Tegretol)	200–1,000 mg	Tab	Poor tolerability in older adults
			Monitor complete blood count, electrolytes, liver profile
lamotrigine (Lamictal)	25–200 mg	Tab	Slow dose titration
			Stevens-Johnson syndrome
divalproex sodium (Depakote)	250–2,000 mg	Tab, liquid, sprinkles	Monitor complete blood count, platelets, liver function
			Better tolerated by the older adults

Abbreviations: CBC = complete blood count; EPS = extrapyramidal symptoms; IM = intramuscular; SL = sublingual; WBCs = white blood cells.

profile and are generally well tolerated. They may be used long term. An antidepressant may help decrease agitation among those exhibiting depressed mood, anxiety, or paranoia. Start antidepressants at a lower dose and titrate slowly because they are associated with increased fall risk.

Antipsychotics, especially risperidone, aripiprazole, and olanzapine, have been evaluated in multiple studies and demonstrated improvement in severe agitation and aggression. Effects and durations of antiepileptics vary widely. It is recommended they be used for short duration. Valproate has a higher incidence of toxicity. Carbamazepine can cause side effects, requiring liver enzymes and CBC to be monitored. Gabapentin is better tolerated and shows a modest decrease in aggression (McDermott & Grvenewald, 2019).

Follow-Up: Review laboratory reports, treat any infections or acute medical conditions, and review medications. If antipsychotics were prescribed, monitor for extrapyramidal symptoms, falls, and lethargy. If indicated, attempt a gradual dose reduction of any psychotropic medications after the acute episode and further reduction at least once every 3 months.

Sequelae: Falls, sedation, hypotension, gait disturbances, weight gain, gastrointestinal problems (McDermott & Gruenewald, 2019).

Prevention/Prophylaxis: Identify antecedents, avoid triggers, educate staff and caregivers, and introduce behavior modification. Data also support the use of the person-centered care model in long-term care facilities and assisted living communities, along with the use of the nonpharmacological interventions listed in Table 20-2 and Table 20-3. The main focus should include tailored activities based on ability and interest, addressing individual needs, reducing environmental stimuli and improving staff interaction. An overarching activity noted in multiple studies is the use of individualized music (Isaac et al., 2021).

Referral: In refractory cases, a specialist, such as a geriatric psychiatrist, a geriatrician, or a neurologist with specific expertise in pharmacological management, should be consulted.

Education: Education should include patient safety and fall prevention, identification of triggers, reassurance and redirection techniques, simplification of activities, establishment of routine and structure, promotion of rest and sleep, and consistent caregiver assignments.

ANXIETY

Signal Symptoms: Anxiety in older adults involves excessive worrying that is difficult to control and interferes with daily functioning (American Psychiatric Association [APA], 2013). Anxiety is characterized by restlessness, fatigue, difficulty concentrating, irritability, muscle tension, and sleep disturbance (APA, 2013). Older adults with anxiety may present with physical or somatic symptoms, such as headaches, chest pain, palpitations, shortness of breath, dizziness, sweating, or gastrointestinal upset.

Description: Anxiety disorders are common among older adults and continue to require increased efforts in screening, diagnosis, and treatment as the older adult population rises in the United States. The U.S. Census Bureau (2020) reported that the population of older adults aged 65 years and older rose by more than a third since 2010. Most older adults with anxiety initially present to their primary care providers instead of psychiatric providers in mental health-care settings (Brahmbhatt et al., 2021). However, anxiety disorders are often undertreated, underrecognized, underdiagnosed, or misdiagnosed in primary care settings (Bandelow et al., 2017; Brahmbhatt et al., 2021). This lack of diagnosis and treatment of anxiety could be related to comorbid conditions, such as depression, neurocognitive disorder, and other medical conditions, as well as lack of recognition of anxiety by some older adults (Aggarwal et al., 2017).

Anxiety in older adults can present as an exacerbation of anxiety diagnosed earlier in life. However, some older adults experience new-onset late-life anxiety related to pain, loss, physical limitations, and other challenges in later life. According to the *Diagnostic and Statistical Manual of Mental Disorders* (5th ed.; *DSM*-5; APA, 2013), anxiety disorders commonly diagnosed in older adults include generalized anxiety disorder (GAD), social anxiety, specific phobia, agoraphobia, panic disorder, and anxiety disorder related to substance use, medication, or another medical condition. One of the most common anxiety disorders diagnosed in older adult populations overall is GAD (Subramanyan et al., 2018). Among older adults in residential care facilities, GAD and specific phobias were found to be the most common anxiety disorders diagnosed (Creighton et al., 2016). Medical conditions should be considered and ruled out before making a diagnosis of an anxiety disorder.

Etiology: Although anxiety is common among older adults, anxiety is not a normal result of the aging process. The pathogenesis of late-life anxiety likely involves interactions between biological, psychological, and environmental risk factors (Hellwig & Domschke, 2019). Risk factors include genetic factors, structural brain changes, hypothalamic-pituitary-adrenal axis changes, cognitive impairment, loss, social isolation, and other age-related changes (Hellwig & Domschke, 2019). Worry was found to be associated with activation of the frontal brain, amygdala, and insula in older adults with GAD (Mohlman et al., 2017).

Occurrence: Estimates of anxiety disorder prevalence among older adults are unclear due to underdiagnosis, undertreatment, and lack of utilization of reliable diagnostic tools. Anxiety disorders are estimated to be diagnosed in 14% to 17% of older adults (Canuto et al., 2018; Welzel et al., 2019). Older adults in aged care facilities were estimated to experience higher prevalence of anxiety disorders compared to older adults in community settings (Creighton et al., 2016). Researchers discovered that some anxiety disorders have been found to occur more often among older women compared to older men (Canuto et al., 2018; Grenier et al., 2019). Grenier and associates (2019) found that prevalence rates for GAD and social anxiety disorder (SAD) were increased for older women compared to older men. Canuto and associates (2018) concluded that older women were twice as likely to receive a diagnosis of agoraphobia or GAD compared to older men.

Age: Anxiety disorders are common among older adults, but prevalence generally decreases as age increases (Reynolds et al., 2015). Among adults aged 82 years and older, anxiety prevalence is estimated to be 14.5% (Welzel et al., 2019).

Ethnicity: There are limited data available regarding differences in anxiety disorder prevalence between various ethnic groups. Vilsaint and associates (2019) found that non-Latino White Americans experienced higher unadjusted prevalence of anxiety disorders compared to African Americans, Hispanic Americans, and Asian Americans. Nativity and lower education were found to be relevant risk factors for anxiety disorders, especially among racial/ethnic minorities compared to non-Latino White Americans (Vilsaint et al., 2019).

Contributing Factors: Anxiety among older adults is frequently related to functional decline, recent loss, depression, and experience of major stressors during the aging process (World Health Organization, 2017). Occurrence of a past anxiety episode increases risk of anxiety in older adults (Grenier et al., 2019). Anxiety among older adults living in residential aged care was associated with pain, depression, and lower perceived quality of life (Creighton et al., 2017). Among individuals aged 82 years and older, depression, impaired cognitive ability, and recent loss are associated with anxiety and related distress (Welzel et al., 2019).

© F.A. Davis Publishing

Signs and Symptoms: Anxiety among older adults may be manifested by excessive worry, restlessness, and somatic problems, such as gastrointestinal upset, chest pain, or headaches. Older adults with anxiety commonly experience comorbid depression and somatic symptoms (Bakkane et al., 2018; Grover et al., 2019). Older adults commonly experience fear or worry related to falling, pain, death, burdensomeness, physical limitations, health problems, and financial challenges. Worry symptoms may negatively impact neurocognitive performance (De Vito et al., 2019). Clinically significant anxiety in late life has been associated with increased risk of Alzheimer's disease (Santabárbara et al., 2019). Anxiety was also found to be a common symptom among older adults with dementia (Kwak et al., 2017). In older adults with depression, the severity of anxiety symptoms was found to be associated with the severity of depression symptoms and suicidality (Bakkane et al., 2018).

Diagnostic Tests: To diagnose anxiety in older adults, it is important to complete a history and physical examination. Laboratory tests can rule out medical conditions that may be related to anxiety, including a complete blood count (CBC), comprehensive metabolic panel (CMP), and thyroid-stimulating hormone (TSH) test. Additional laboratory tests may be needed based on findings from the history and physical examination. Valid and reliable self-report scales to help diagnosis and assess older adults for anxiety include the Geriatric Anxiety Inventory (GAI) and the Geriatric Anxiety Scale (GAS) (Segal & Mueller, 2019; Szalek et al., 2021). Assess the extent of distress, suicide risk, and functional impairment in addition to considering scores from self-report scales (Szalek et al., 2021). A diagnosis of GAD according to the *DSM-5* requires excessive anxiety, difficulty controlling worry, and associated symptoms (at least three), including restlessness, easy fatigability, difficulty concentrating, irritability, muscle tension, or difficulty falling or staying asleep (APA, 2013).

Differential Diagnosis: When diagnosing an anxiety disorder in an older adult, it is important to rule out medical conditions with similar symptoms, other psychiatric disorders, medication effects, or substance use disorders. Examples of medical conditions that could be ruled out when diagnosing anxiety include thyroid conditions (hyperthyroidism or hyperparathyroidism), cardiac diseases (angina, myocardial infarction, or arrythmias), pulmonary diseases (asthma or obstructive pulmonary diseases), neurological conditions (seizure disorders or transient ischemic attacks), adrenal diseases (pheochromocytoma), and other medical conditions (Craske & Stein, 2016). Anxiety could be induced by substance intoxication or withdrawal. Examples of related substances and medications include alcohol, caffeine, cannabis, opioids, amphetamines, cocaine, phencyclidine, decongestants, albuterol, and levothyroxine, among other substances (APA, 2013). Anxiety symptoms in older adults may overlap with symptoms of depression and dementia (Kwak et al., 2017).

Treatment: Goals for treatment for anxiety in older adults include improved functioning, decreased distress, and relief of anxiety symptoms. Therapeutic communication, active listening, compassion, and respect can help to improve the therapeutic relationship during the treatment of anxiety. Comorbid depression, dementia, and other medical or psychiatric conditions should be treated. Research studies have demonstrated that pharmacological and psychological interventions are effective for treating adults with GAD, but younger adults are more likely to experience anxiety symptom relief compared to older adults (Carl et al., 2020).

First-line treatment for generalized anxiety disorder in older adults includes use of selective serotonin reuptake inhibitors (SSRIs) or serotonin and norepinephrine reuptake inhibitors (SNRIs) due to overall effectiveness, improved tolerance, and a more favorable safety profile compared to other anxiety medications (Crocco et al., 2017). Sertraline, escitalopram, and citalopram are SSRIs that are frequently used in older adults with anxiety (Szalek et al., 2021). Higher doses of SSRIs within therapeutic dosage ranges increased benefit in relieving anxiety (Jakubovski et al., 2019). Gastrointestinal disturbances, sexual dysfunction, insomnia, somnolence, and hyponatremia may occur with SSRI use in older adults, and QTc interval prolongation may occur with doses of citalopram above 40 mg (Crocco et al., 2017; U.S. Food and Drug Administration [FDA], 2017). SNRIs, including venlafaxine and duloxetine, have been shown to be effective in older adults with anxiety, but blood pressure may be increased when taking SNRIs, especially venlafaxine (Crocco et al., 2017; Jakubovski et al., 2019). Tricyclic/tetracyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) are not considered first-line or primary treatments for anxiety disorders in older adults due to risks of adverse effects, including orthostatic hypotension, falls, and confusion (Crocco et al., 2017). Benzodiazepines, such as lorazepam, could be used for the short term, as older adults' initiate treatment with an SSRI or SNRI; long-term use in older adults is not advised (Crocco et al., 2017). There is limited evidence regarding the use of buspirone for anxiety disorders in older adults, but buspirone is a safer adjunct treatment alternative to benzodiazepines (Crocco et al., 2017).

Psychological interventions, especially cognitive behavioral therapy (CBT), can be effective for treating GAD as well as coexisting anxiety and depression in older adults (Hall et al., 2016; Wuthrich et al., 2021). CBT in older adults has been found to be as effective as CBT in working-age adults (Kishita & Laidlaw, 2017). For older adults with GAD, CBT augmentation to treatment with SSRIs could decrease cortisol levels (Rosnick et al., 2016). There is modest evidence that exposure therapy can be effective in decreasing anxiety symptoms in older adults (Jayasinghe et al., 2017). There is limited evidence that mindfulness-based cognitive therapy can be effective for treating anxiety symptoms (Helmes & Ward, 2017). Life review could also be valuable for older adults to improve quality of life, well-being, and other psychosocial outcomes (Lan et al., 2017).

Follow-Up: Evaluation of the effectiveness and tolerability of anxiety treatment depends on the severity of symptoms, impairment in functioning, and use of pharmacotherapy or psychotherapy. Trials of SSRIs may last 6 weeks, and maintenance treatment can last at least 6 months to prevent relapse of anxiety symptoms in older adults (Szalek et al., 2021). Antidepressant use among older adults is associated with hyponatremia, so if antidepressants (especially mirtazapine, escitalopram, or venlafaxine) are prescribed, then the patient should be monitored for possible hyponatremia 2 to 3 weeks after the medication is initiated (Grover et al., 2018; Szalek et al., 2021). Provide education about anxiety for the patient and caregiver, use simple terminology, allow adequate time

© F.A. Davis Publishing

for addressing questions, and allow for description of symptoms in their own words (Subramanyam et al., 2018).

Sequelae: Anxiety disorders have been linked to cognitive impairment, disability, and decreased quality of life (Bower et al., 2015). Anxiety in older adults was also found to be associated with incident impairment in self-care functioning (Simning & Seplaki, 2020).

Prevention/Prophylaxis: Although it may be difficult or not possible to prevent anxiety disorders in older adults, distress and relapse of anxiety symptoms could be mitigated by managing stress, maintaining a support network, sleeping and eating adequately, and exercising regularly.

Referral: Patients expressing suicidal ideation or those at high risk for harming themselves or others should be referred immediately to a psychiatric provider or inpatient psychiatric facility. Psychiatric evaluation by a mental health provider may be beneficial if impaired functioning or anxiety symptoms persist after multiple trials of treatment or if comorbid psychiatric conditions are suspected (Szalek et al., 2021). Refer to a neurological specialist if dementia is suspected (Szalek et al., 2021).

Education: Compared to younger adults, older adults may have decreased knowledge about anxiety disorders (Beaunoyer et al., 2019), so psychoeducation is critical. Educate patients and caregivers to recognize and manage anxiety symptoms and triggers and to understand the connection between anxiety and physical symptoms (Szalek et al., 2021). Discuss physical activity, social networks, nutritional status, and sleep hygiene with the patient.

BIPOLAR DISORDER

Signal Symptoms: Patients may present with clusters of symptoms and in various phases of mood changes. Phases include depressive, hypomanic, manic, or rapid cycling (called the *cyclothymic phase*). In the manic phase, individuals may feel energized or have pressured speech or grandiosity or thoughts of grandeur, delusions, distractibility, or fluctuations in mood with persistent insomnia of 4 to 7 nights in a row that impact the domains of social, environmental, occupational, and/or other areas of daily functioning. Bipolar depressive symptoms include trouble with appetite and sleep (*Diagnostic and Statistical Manual of Mental Disorders*, 5th ed.; *DSM*-5; American Psychiatric Association [APA], 2013; Dols & Beekman, 2020).

Description: Bipolar disorder, also called bipolar affective disorder, is a mood spectrum disorder that presents similar to unipolar major depressive disorder until a first manic episode. According to the APA (2013), bipolar disorders are classified as bipolar I, bipolar II, cyclothymic disorder, and other specified bipolar related disorders. Each presentation has a hallmark of intensity and time frame of symptoms. A diagnosis of bipolar I disorder requires an individual to have experienced at least one full manic episode. A manic episode involves changes in mood that are expansive, euphoric, grandiose, or irritable, accompanied by an increase in energy levels despite poor sleep of only 3 hours or less per night for 7 nights in a row. Most patients also have depressive episodes, and although this may be precluded or followed by a manic episode, it is not a required for the diagnosis of bipolar I disorder; only one manic episode is required. A diagnosis of bipolar II disorder requires at least one prior episode of major depression and at least one hypomanic episode, although hypomania lasts at least 4 days/nights and fewer than 7 days/nights (APA, 2013). Cyclothymic disorder is characterized by milder mood fluctuations that occur over a longer period, more specifically 2 years of cycling phases with symptoms that cause clinical impairment, and it does not meet criteria for a full hypomanic episode (APA, 2013). It is important to distinguish bipolar disorder from major depressive disorder, also known as *unipolar depression*, because treatment differs (National Institute of Mental Health [NIMH], 2020).

© F.A. Davis Publishing

Etiology: Scientists have not discovered one precise etiology of bipolar disorder, but factors include brain structure and function, genetics, and stress (National Alliance on Mental Illness [NAMI], 2017). Neurocognitive changes and cerebral vascular comorbidities are more common causes in older-age bipolar disorder (OABD) (Dols & Beekman, 2020). Additional research indicates that progressive central nervous system degenerative changes caused by inflammation, mitochondrial dysfunction, and oxidative stress may influence late onset of bipolar disorder (Madireddy & Madireddy, 2022). Patients with OABD presenting with a new onset of mania should be assessed for a cerebral vascular accident or brain tumor (Dols & Beekman, 2020). Misdiagnosis in older adults is common, although 10% of individuals aged 50 or older will have a first manic episode (Marzani & Neff, 2021).

Occurrence: According to the APA, 6 million Americans have bipolar affective disorder and 1 million of those are 60 years old or older (2013). Epidemiological studies have found the prevalence of new-onset cases of bipolar disorder I, in which individuals experience their first manic episode as an older adult and receive a diagnosis, to be 1% of older adults (Carlino et al., 2013). Overall cases of OABD in older adults who are 60 years old or older is expected to increase by 50% in 2030 (Marzani & Neff, 2021). Over 60% of patients with late-life onset of bipolar disorder are female (Ljubic et al., 2021). More females experience rapid cycling, more depressive episodes, and more comorbidities than males.

Age: Bipolar disorder can occur at any age, with the average age of onset being 20 years (APA, 2013). About 90% of older adults with bipolar disorder experience bipolar disorder symptoms as an adolescent and have a continuation of the disorder lifelong. Less commonly, the condition is diagnosed after the age of 50 years old, although the patient may be diagnosed and treated for unipolar depression for decades and tend to do fair ((Ljubic et al., 2021).

Ethnicity: Bipolar disorder manifests across all ethnic and cultural groups although is lower in Afro-Caribbean than Black or White populations (APA, 2013).

Contributing Factors: According to the Depression and Bipolar Support Alliance statistics (2021), two-thirds of people with bipolar disorder have at least one close relative with bipolar disorder or unipolar depression; however, OABD has less of a genetic link to a family history of bipolar disorder (Tampi et al., 2021). For older adults with new-onset bipolar disorder, stressors from life are postulated to be a contributing factor, including adverse childhood events and traumatic brain injuries (Dols & Beekman, 2020; Tampi et al., 2021).

Signs and Symptoms: Classic symptoms that bring individuals in for treatment are the depressive episodes, and an antidepressant may be prescribed. The danger of antidepressant medication is that it may activate a first manic episode. Elevated mood, presenting as euphoria or irritability, is common in OABD. Dysphoric depression alone may be a common presentation. Rapid cycling includes back-and-forth shifts from subhypomania to depression over longer periods of time or phases. All phases have insomnia (hypomania, mania) or hypersomnia (depressive) implications. Inquiring about suicide ideation or intent should be assessed at every visit. Psychotic symptoms may present in either manic or depressive phases, and cognitive impairment is common in dual diagnoses of substance use disorders (APA, 2013; Dols & Beekman, 2020).

The acronym DIGFAST has been used to describe signs and symptoms during a manic or hypomanic phase (Kadiyala, 2020):

- **D**istractibility
- **I**ndiscretions
- **G**randiosity
- **F**light of ideas
- **A**ctivities are increased (hyperactive, does not feel they need rest)
- **S**leep deficits (and do not miss the sleep)
- **T**alkative (pressured or rapid speech)

According to the *DSM*-5, the individual must also experience increased energy and poor sleep while having DIGFAST symptoms (APA, 2013).

Symptoms during the depressive phase are similar to those of major depressive disorder. Use the acronym SIGECAPS, which requires only 5 symptoms over 2 weeks:

- **S**leep disturbance (although they miss the sleep with unipolar major depressive disorder)
- **I**nterest is lost/anhedonia
- **G**uilt feelings, thoughts of worthlessness or helplessness
- **E**nergy changes/fatigue

Diagnostic Tests: The Mood Disorder Questionnaire (MDQ) is a validated (Hirschfeld et al., 2005) screening tool to assess for bipolar disorder; however, it is not specific to older adults. For patients with depressive features, the Geriatric Depression Scale (GDS), is recommended as a screening tool for unipolar major depressive disorder. Risk factors for the depressive phase include potential risk for suicide, which should be assessed at each visit because OABD have a much higher risk than younger adults.

Diagnostic studies to rule out a medical etiology of mood changes include a complete blood count (CBC), comprehensive metabolic panel (CMP), toxicology drug screen, urinalysis, thyroid function tests, rapid plasma reagin (RPR), venereal disease research laboratory (VDRL) testing, B_{12} and folate levels, electrocardiogram, and other individualized testing as indicated by the individual patient presentation and anticipation of treatment modalities (Shah et al., 2017). In patients with new onset of psychosis, an electroencephalogram (EEG), magnetic resonance imaging (MRI), or computed tomography (CT) scan of the brain may be appropriate to rule out medical pathologies. Other screening tests for cognitive disorders, such as the Mini-Mental State Examination (MMSE) (Folstein et al., 1975) or the Saint Louis University Mental Status (SLUMS), are more sensitive to detecting cognitive impairment, and may be useful in assessing comorbid neurocognitive deficits (Yoelin, & Saunders, 2017).

Differential Diagnosis: Bipolar disorder in older individuals is often undetected or misdiagnosed for decades. The etiology of new-onset mania may be secondary to an underlying

© F.A. Davis Publishing

medical illness. Medical conditions include stroke, brain tumor, multiple sclerosis, hyperthyroidism, traumatic brain injury, medication reaction, vascular dementia, or most commonly delirium (Tampi et al., 2021). Substance use disorder, schizophrenia, schizoaffective disorder, major depressive disorder (MDD) (unipolar), and anxiety disorders are included in comorbid psychiatric diagnoses (APA, 2013; Ott, 2018). A complete medication list review should be assessed to rule out medication-induced mania and to assess polypharmacy.

Treatment: The goal is remission of symptoms and improvement in functionality. There are no guidelines specific to older adults; however, clinical practice guidelines generally suggest similar pharmacological treatment for older adults as used in younger adults (National Institute for Health and Care Excellence [NICE], 2020; Shah et al., 2017). These medications include divalproex sodium (or valproic acid), lithium, carbamazepine, lamotrigine, some atypical antipsychotics, and antidepressants. Patients with bipolar disorder are often challenging to manage because of the fluctuating and chronic nature of bipolar disorder. Depending on the presentation and severity, inpatient treatment may be required to stabilize the patient.

First-line treatment for late-life onset of mania includes the mood stabilizers lithium and valproic acid, or the antipsychotics risperidone, quetiapine, or olanzapine (Dols & Beekman, 2020; Ljubic et al., 2021)). Because older adults are frequently on multiple medications for comorbid conditions, monotherapy has been recommended as a starting point with a backup plan for adding other medications if clinically indicated (Sajatovic & Chen, 2021; Tampi et al., 2021). Patients with coexisting dementia require individualized treatment and comanagement by a geriatric psychiatrist or psychiatric mental health nurse practitioner. There is early evidence of a neuro-protective affects for comorbid dementia in those prescribed lithium (Stahl, 2021). Drug therapy is specific to different bipolar disorder phases, symptoms, and comorbidities (Marzani & Neff, 2021).

Dosing should begin at the lowest dose and be slowly increased, while monitoring comorbidities and potential adverse side effects. Benzodiazepines are sometimes used for adjunct, or acute agitation in mania.

Selective serotonin reuptake inhibitors (SSRIs) are generally not recommended for monotherapy in bipolar depression, because they are often ineffective or may induce mania unless added concurrently with an anticonvulsant and/or an antipsychotic medication (Sajatovic & Chen, 2021); however, they are prescribed in select, resistant depressive cases. Treatment may require a combination of the previously mentioned medications (Stahl, 2021). Electroconvulsive therapy (ECT) is highly effective in resistant cases of bipolar depression, psychosis, or catatonia and should be considered if drug therapy is ineffective (Ljubic et al., 2021).

An integrated care model has been successful for patients with combined chronic medical and mental health disorders. Establishing a therapeutic alliance, including psychotherapy and psychoeducation, is key to management (APA, 2021).

Follow-Up: Regular follow-up, particularly during active periods of mania or depression, is essential and should include monitoring for suicide. Family members or life partners are usually included because bipolar disorder affects the entire family. Patients on lithium require initial evaluation of renal, cardiac, and thyroid function before initiating therapy, and then periodically during treatment. Lithium levels need close monitoring during the initial period and periodic monitoring once stabilized. Concurrent use of NSAIDs, thiazide or loop diuretics, and angiotensin-converting enzyme (ACE) inhibitors may adversely affect lithium levels or impair renal function (Stahl, 2021). Adverse effects of lithium include tremor, hypothyroidism, rash, weight gain, and renal impairment. Patients being treated with valproic acid require close monitoring of serum levels, liver function tests (LFTs), and CBC. Adverse effects include weight gain, hepatotoxicity, pancreatitis, sedation, and thrombocytopenia.

Those on atypical antipsychotics should have weight, glucose, and lipid monitoring. QTc interval prolongation can also occur, especially in comorbid cardiovascular disease. Atypical antipsychotics prescribed for older adults with dementia have been found to increase mortality and should be avoided, if possible, in those with bipolar I disorder (Stahl, 2021).

Sequelae: Bipolar disorder is a chronic mental health disorder with both physical and mental health sequelae. Medications used to treat bipolar disorder often cause adverse effects. Concurrent substance use or sexual hyperactivity or foolish financial sprees may result in legal consequences and can complicate the treatment of bipolar disorder. Individuals with bipolar disorder have a 45% lifetime prevalence of comorbid anxiety disorders such as generalized anxiety disorder (GAD), post-traumatic stress disorder, and obsessive-compulsive disorder (APA, 2013; Ott, 2018). Comorbidities often confound and determine the course of treatment for bipolar disorder in older adults (Marzani, & Neff, 2021).

Prevention/Prophylaxis: Teach patients, caregivers, and families to avoid unnecessary stress that could precipitate an acute manic episode. Promote sleep hygiene and routine activity. Educate caregivers and families to recognize early signs of mania to avoid a full-blown episode. Work with the patient and the family to develop a safety plan strategy if the patient demonstrates injurious behavior directed toward self or others. Educate the patient and family on the importance of regular sleep patterns, medication adherence, and routine follow-up with a designated health-care practitioner (Marzani & Neff, 2021).

Referral: Initial referral to a psychiatrist or an advanced practice psychiatric mental health nurse practitioner experienced in the assessment and management of bipolar disorder is important, particularly in older adults with cognitive deficits or medical comorbidities. Any patient with suicide intent should be referred immediately to psychiatry at an inpatient facility if safety is a concern. Referral of the patient and the family to support services is important.

Education: Those with new-onset bipolar disorder require extensive education on the disorder. Poor insight may be part of the clinical picture, thus frequent re-education is indicated. For patients who are in a group living setting, education of

© F.A. Davis Publishing

caregiving staff is essential so that manic and hypomanic episodes in particular are not misinterpreted as deliberate aggression. Spouse and family, if present, also require education in the disorder phases, triggers, the chronic nature of symptoms, and the importance of medication adherence. Avoidance of alcohol and other addictive substances is an important part of the education.

DELIRIUM

Signal Symptoms: Change in mental status, confusion, disorientation (time, place, person), agitation.

Description: According to the American Psychiatric Association's (APA, 2013) *Diagnostic and Statistical Manual of Mental Disorders* (5th ed.; *DSM*-5), delirium is a neurocognitive disorder that presents as a disturbance "in attention (i.e., reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment)" (DSM-5 Criterion A). The onset of the disturbance is rapid (hours to days) and typically fluctuates over the course of the day (DSM-5 Criterion B). Cognitive changes (poor memory, disorientation, speech disturbance) and/or perceptual disturbances are distinct

© F.A. Davis Publishing

from a preexisting, established, or evolving neurocognitive disorder (DSM-5 Criterion C and Criterion D). Delirium frequently represents a sudden and significant decline from a previous level of functioning, and there is usually evidence from the history, physical examination, or laboratory tests of a direct physiological etiology of a general medical condition, substance intoxication or withdrawal, use of a medication, toxin exposure, or a combination of these factors (DSM-5 Criterion D and Criterion E; APA, 2013).

The *DSM-5* differentiates delirium into the following categories:

1. Substance intoxication delirium
2. Substance withdrawal delirium
3. Medication-induced delirium
4. Delirium due to another medical condition
5. Delirium due to multiple etiologies (APA, 2013).

Delirium should also be specified as acute or persistent, as well as hyperactive, hypoactive, or mixed level activity. The duration of delirium can range from less than 1 week to more than 2 months and typically resolves within 10 to 12 days. However, for some older persons persistent delirium can last for years. Although delirium was once thought to be reversible, evidence supports that delirium may result in permanent neuronal damage to the brain and increased mortality (APA, 2013; Hshieh et al., 2018a).

Etiology: Causes of delirium are numerous, and in older adult hospitalized patients there are often multiple etiologies (Hshieh et al., 2018a; Percisco et al., 2018):

- Metabolic: renal failure, hepatic failure, anemia, hypoxia, hypoglycemia, thiamine deficiency, electrolyte abnormalities
- Infection: meningitis, encephalitis, sepsis, urinary tract infection (UTI), respiratory infection
- Cardiac: myocardial infarction, heart failure, arrhythmia
- Neurological: stroke, intracranial hemorrhage, head trauma, seizures, undiagnosed pain
- Pulmonary: respiratory failure, chronic obstructive pulmonary disease (COPD) causing hypoxia
- Sensory impairment: visual and/or hearing deficits
- Medications: benzodiazepines, sedative-hypnotics, opioids, anticholinergics, antihypertensives, corticosteroids, lithium
- Toxins: alcohol, amphetamines, cocaine, substance intoxication or withdrawal

Because the cause of delirium is multifactorial, no single neuropathology of delirium has been identified (Oh et al., 2017; Hshieh et al., 2018a). Possible neurological pathways may involve oxidative stress, inflammatory responses, and neurotransmitter deficiencies in acetylcholine and melatonin; excesses of norepinephrine, dopamine, and glutamate; and abnormalities in serotonin, histamine, and gamma-aminobutyric acid (GABA) (Maldonado, 2017; Mulkey et al., 2018). The role of inflammatory biomarkers is thought to be implicated in the pathophysiology of delirium (Hshieh et al., 2018a; Oh et al., 2017).

Changes in brain function, multiple general medical problems, polypharmacy, reduced hepatic metabolism of medications, multisensory declines, and brain disorders such as dementia make older adults particularly vulnerable to delirium (Hsheith et al., 2018a). Reviewing all medications is part of a complete evaluation. Although many medications can be a causative factor, those with anticholinergic effects are frequently responsible (American Geriatrics Society 2015 Beers Criteria Update Expert Panel, 2015; Mulkey et al., 2018).

Occurrence: Prevalence in the community is 1% to 2% but increases to 14% in those aged 85 years and older. The prevalence of delirium ranges from 10% to 30% of older persons in the emergency department, 15% to 53% postoperatively, and 70% to 87% in the intensive care unit. In long-term care residents aged 75 years and older, the prevalence of delirium may be as high as 60% at any given time. Approximately 14% to 24% of persons exhibit delirium on admission to the hospital, and 6% to 56% may develop delirium during their stay. Prevalence varies depending on the underlying condition(s), procedures and surgeries performed, and other medical interventions provided (APA, 2013).

Age: Any medically ill patient can develop delirium; however, older adults are more prone to delirium due to preexisting conditions, aging processes, and greater vulnerability to multiple precipitating factors (Hshieh et al., 2018a; Petrie & Kirschner, 2021).

Ethnicity: Culture and ethnicity should be taken into consideration when evaluating an individual's mental status and capacity. Some patients may not be familiar with information used in cognitive rating scales (general knowledge, geographical information, memory, and orientation/location), and many scales adjust for these factors, as well as educational level, in the interpretation of scores (APA, 2013).

Contributing Factors: See Etiology, Occurrence, and Age. Frailty and delirium are related entities (Hshieh et al., 2018a; Percisco et al., 2018). Approximately half of postoperative patients develop delirium, and the majority of those with terminal illness (up to 83%) develop delirium as they approach death (APA, 2013).

Signs and Symptoms: Symptoms of subclinical delirium, such as restlessness, anxiety, irritability, distractibility, or sleep disturbance, may be manifested in the days before the onset of overt delirium and may progress to full-blown delirium over the course of a few days. The clinical presentation may include confusion; difficulty sustaining and shifting attention; extreme distractibility; reduced or inability to focus, disorientation to time and place; impairment of recent memory; misperceptions about the environment, including illusions and hallucinations; emotional instability; and psychomotor activity that fluctuates between agitation and vegetative state (APA, 2013; Maldonado, 2017; Sherer et al., 2020). Disorientation to other persons occurs commonly. Dysarthria is a frequent speech and language disturbance, and dysnomia (impaired ability to name objects), dysgraphia (impaired ability to write), or aphasia may be observed.

Commonly associated features of delirium include disturbances in the sleep–wake cycle, such as daytime sleepiness, nighttime agitation, and disturbances in sleep continuity. Complete reversal of the sleep–wake cycle or fragmentation of the circadian sleep–wake pattern can occur. Emotional disturbances may include anxiety, fear, depression, irritability, anger, euphoria, and apathy. Affective lability (rapid and unpredictable shifts from one emotional state to another) may occur. Possible autonomic signs associated with delirium include nausea, vomiting, diarrhea, tachycardia, sweating, chest pain, hypoventilation, and elevated blood pressure (Suneja et al., 2020).

© F.A. Davis Publishing

The diagnosis of delirium superimposed on dementia presents challenges for clinicians (Morandi et al., 2017) and results in poor outcomes for older persons, including increased cognitive decline, institutionalization, and mortality (Fick et al., 2013; Inouye et al., 2014b). Delirium is an independent risk factor for dementia and dementia is the leading risk factor for delirium (Fong et al., 2015).

Diagnostic Tests: Laboratory work will assist in identifying potential causative factors, as will rating scales that measure cognition and establish diagnostic data such as the Confusion Assessment Method (CAM), the Delirium Rating Scale – Revised (DRS-R-98), or the Delirium Observation Screening Scale. These scales assist in tracking progress and in the patient's return to baseline functioning (Hshieh et al., 2018a). However, because of fluctuating levels of consciousness and cognition, it may be difficult to assess mental status and cognitive function. When possible, obtain information from the medical record, medical staff, and others, especially family members.

Differential Diagnosis: See Etiology. The most common differential diagnostic challenge is whether the patient has dementia or delirium, has delirium alone, or has a delirium superimposed on a preexisting dementia. Although there are common cognitive disturbances in delirium and dementia, a primary difference is that the patient with dementia usually is alert, whereas the patient with delirium manifests overt disturbances of consciousness or arousal. The rapid onset and course of cognitive impairments and the reversibility of symptoms are helpful in distinguishing between delirium and dementia. The severity of delirium symptoms typically fluctuates over the course of a day, whereas dementia symptoms generally do not fluctuate (Inouye et al., 2014a). Information from medical records, caregivers, and family members may help determine whether dementia was present before the onset of delirium. Depression is another differential diagnosis, because patients often manifest cognitive and psychomotor symptoms common to dementia and delirium (Oh et al., 2017).

Treatment: Nonpharmacological interventions are used as well as treatment for the underlying cause (Hshieh et al., 2018a; Wan & Chase, 2017). Appropriate treatment for delirium involves discovering the causes, many of which are reversible, and preventing complications through prompt treatment of specific, identified disorders. A thorough, comprehensive assessment; evaluation of medications, interactions, and contraindications; and ordering of laboratory work will assist in ruling out/in the many etiologies of delirium. While assessing for probable etiology and definitive treatment, management should focus on ensuring safety from behavioral disturbances by combining environmental, behavioral, and pharmacological therapies.

Nonpharmacological Interventions: Nurses are instrumental in directing the course of treatment for older adults with nonpharmacological interventions (Wan & Chase, 2017). A therapeutic environment would include reassurance and reality orientation by family members; clear communication; caregiver consistency; decreased stimuli (noise reduction, adequate lighting, sufficient time to perform tasks); decreased stress and anxiety through frequent reassurance and provision of a daily routine; comfort maintenance (eyeglasses, hearing aids, personal belongings); reestablishment of a sleep–wake cycle by controlling nighttime noise and unnecessary disruptions; guarantee of adequate daily fluid intake; assurance that elimination needs are met; provision of space and programs for physical activity, ambulation, and range of motion; and avoidance of chemical or physical restraint (Marcantonio, 2017; Marra et al., 2017; Oh et al., 2017). Medication should be used as a last resort (Bellelli et al., 2021). In one observational prospective study (Blandfort et al., 2019), hospitalized adults aged 75 years and older in single-bed rooms experienced a reduced risk for delirium when compared with double room occupancy.

Pharmacotherapy: Data support the use of first generation (e.g., haloperidol) and second generation (e.g., olanzapine, risperidone, ziprasidone, and quetiapine) antipsychotic medications to control behavioral symptoms of delirium and prevent injury to self or others. Antipsychotic medications have significant side effects, especially for older persons with dementia, and should be prescribed at the lowest effective dose and only 1 to 2 days or the shortest interval possible depending upon the setting, such as surgery or intensive care (American Geriatrics Society Expert Panel on Postoperative Delirium in Older Adults, 2015; Marcantonio, 2017; Reus et al., 2016;). The avoidance of benzodiazepines except for specific indications (e.g., alcohol or *gamma*-hydroxybutyric acid [GHB] withdrawal delirium, delirium related to seizures) continues to be a recommendation (American Geriatrics Society Expert Panel on Postoperative Delirium in Older Adults, 2015; Marcantonio, 2017).

It is important to reassess the patient's mental status and any other prevailing psychiatric symptoms. Regular monitoring and periodic assessments of mental status and symptoms will allow for the adjustment of treatment strategies and may indicate the effectiveness of interventions and new or worsening medical conditions (American Geriatrics Society Expert Panel on Postoperative Delirium in Older Adults, 2015; Morandi et al., 2017).

Follow-Up: Close follow-up for treatment efficacy, appropriate laboratory and diagnostic studies to monitor resolution of the underlying cause, and monitoring of mental status and cognitive functioning are essential to ensure full recovery.

Sequelae: During overt periods of delirium, there is risk of injury to self or others due to confusion, altered perception, and impaired insight and judgment. Fear is often a precipitant to injury in patients with delirium and may result in attacking others; falling out of bed; or pulling on IV lines, oxygen tubing, tracheotomy or gastrointestinal (GI) tubes, urinary catheters, or other medical equipment. Although the majority of patients recover fully, delirium may progress to stupor, coma, seizures, or death. Full recovery is less likely in older adults, and persistent cognitive deficits are common (Fong et al., 2015). Such deficits may be due to preexisting dementia that was not clearly established.

Older adults have a significantly increased risk of developing complications, such as pneumonia and decubitus ulcers, which may result in longer hospital stays. In postoperative patients, delirium may limit recovery and contribute to poorer long-term outcomes. Increased risk for postoperative complications, longer postoperative recuperation periods, longer hospital stays, and long-term disability are associated with delirium. Delirious patients with alcohol or sedative-hypnotic withdrawal, cocaine intoxication, head trauma, hypoglycemia, strokes, or extensive burns are at increased risk for seizures.

© F.A. Davis Publishing

Delirium in the medically ill is associated with an increased mortality rate, and patients who develop delirium during a hospitalization also have a very high rate of death during the months following discharge (Hshieh et al., 2018a).

Prevention/Prophylaxis: Preventive measures to lessen the likelihood of delirium include elimination or minimization of risk factors. These measures include judicious use of high-risk medications (Beers criteria; STOPP/START), timely management and good control of acute and chronic medical disease processes, correction of sensory deficits (eyeglasses, magnifying glasses, adequate lighting, hearing aids, cerumen removal), promotion of normal sleep patterns through good sleep hygiene measures, provision of adequate nutrition and hydration with oral/parenteral supplementation as necessary, prompt attention to elimination needs, participation in activities that maintain and stimulate cognitive and physical functioning, and provision of general supportive measures (environmental modifications, reality orientation, control of external stimuli) (Marcantonio, 2017). For hospitalized older adults and long-term care residents, encourage frequent visits by family members to provide familiarity, reality orientation, reassurance, and comfort. Quality improvement models of care and protocols specific to older adults that address hospitalized older adults can also improve outcomes, but further research on their efficacy is needed (Hsieh et al., 2018b; Scheunemann et al., 2018).

Referral: Patients with delirium should be hospitalized so that diagnostic testing, identification of underlying causes, and management can occur in a rapid, coordinated manner during concurrent treatment of acute symptoms to ensure patient safety and comfort. Care of the patient with delirium should be coordinated by the primary care provider and managed jointly with internal medicine, psychiatry, neurology, and other specialty physicians to ensure appropriate comprehensive evaluation and care.

Education: Patients and families should be educated about the etiology of delirium and the expected course of illness, while being provided reassurance that delirium is usually temporary and that the symptoms are part of a medical condition. The American Delirium Society (www.americandeliriumsociety.org) is a multidisciplinary professional group dedicated to delirium research and the education of professionals and families of patients with delirium.

DEMENTIA

Alzheimer's disease (AD) is the most common cause of dementia and is the primary focus of this section. According to the American Psychiatric Association's (APA, 2013) *Diagnostic and Statistical Manual of Mental Disorders* (5th ed.; *DSM*-5), dementia is a neurocognitive disorder and is defined as a clinical syndrome with global cognitive decline from a previous level of baseline function that interferes with activities of daily living (ADLs). In the differential diagnosis, it is important to ascertain whether an individual has cognitive impairment or an illness with similar or overlapping signs and symptoms such as delirium, depression, schizophrenia, bipolar disorder, or other neurological disorder (APA, 2013). If there is cognitive impairment, then developmental delay, borderline intellectual functioning, mild cognitive impairment, and other related diagnoses must be ruled out (APA, 2013). To meet the criteria for minor or major neurocognitive disorders according to the *DSM*-5 (APA, 2013), cognitive decline must be in at least one of the following cognitive domains including "complex attention, executive function, learning and memory, language, perceptual motor or social cognition" (APA, 2013). Once dementia is ruled in, the type of dementia can then be determined (APA, 2013).

Signal Symptoms: Cognitive changes including confusion, disorientation (as to time, place, person), and impaired short-term memory. Personality changes, psychiatric symptoms, problem behaviors, and changes in daily functioning (APA, 2013).

Description: Clinicians must consider normal aging processes and factors that may contribute to the overall clinical picture when assessing a patient who presents with signs or symptoms of dementia (Arvanitakis et al., 2019). AD has a gradual onset, and the course of illness and progression is typically slow (Arvanitakis et al., 2019). The duration of AD ranges from 3 to 20 years and averages 10 years as comorbidities complicate the course of illness (APA, 2013). Symptoms vary from person to person, and cognitive deficits cause significant impairment in social and occupational functioning, impaired ability to care for oneself, and altered behavioral patterns. Signs and symptoms progress from memory loss to impaired executive functioning, language deficits, coordination, and perception with total or partial loss of the ability to recognize familiar people or objects. Impairment in memory and learning (amnestic) is the typical presentation for AD (APA, 2013) and neuropsychiatric symptoms almost always occur (Phan et al., 2019).

The National Institute on Aging (NIA) and the Alzheimer's Association workgroup introduced diagnostic staging for AD, including preclinical, mild cognitive impairment due to AD, and dementia due to AD (Albert et al., 2011; Jack et al., 2011; McKhann et al., 2011; Sperling et al., 2011). An update (Jack et al., 2018) from the 2011 NIA and Alzheimer's Association workgroup includes the framework for the three clinical stages and a numeric staging along the Alzheimer's disease continuum.

Etiology: The etiology of dementia includes numerous systemic disorders; however, most cases of dementia are irreversible because dementia is a progressive disease process unto itself.

- Central nervous system (CNS) disorders: mild cognitive impairment (MCI), AD (most common type of dementia [Alzheimer's Association, 2021a, b], 60% to 80%; one-half of cases are mixed dementia related to other pathology), Lewy body dementia (10% to 25%), vascular dementia (10%), primary degenerative dementia, frontotemporal dementia or Pick's disease (10% of persons 45 to 60 years old), Huntington's disease, normal pressure hydrocephalus (5%)
- Cardiovascular disease: cerebral hypoxia/anoxia, vascular insults to brain, cardiac arrhythmias, inflammatory blood vessel disease
- Infectious processes: AIDS, Creutzfeldt-Jakob's syndrome, neurosyphilis
- Liver disease: chronic progressive hepatic encephalopathy
- Neoplastic conditions: intracranial lesions, primary or metastasis
- Pulmonary disease: respiratory encephalopathy, chronic obstructive pulmonary disease (COPD)/CO_2 toxicity
- Urinary tract disease: urinary tract infection (UTI), chronic or progressive uremic encephalopathy

Occurrence: Currently, 6.2 million Americans are living with AD, and 11% people age 65 years and older have AD (Alzheimer's Association, 2021b). By 2060, the number of older persons 65 years and older with AD is expected reach 13.8 million (Alzheimer's Association, 2021b). More women than men have dementia, primarily because women live longer.

Age: Most people have a diagnosis of late-onset AD. In late-onset AD, symptoms are experienced after age 65 years and older (Alzheimer's Association, 2021b).

Ethnicity: African Americans and Hispanics are at highest risk of developing AD. African Americans are approximately twice as likely to develop AD than Whites, and Hispanics have approximately one and one-half times the risk of their White counterparts.

Contributing Factors: Risk factors for AD are designated as actual and probable.

Actual Risk Factors:

- Age
- Genetics/family history (NIA, 2019)
- Gene mutations chromosomes 1, 14, 21
- A 50/50 chance of developing early-onset AD if one parent had AD
- Apolipoprotein E (ApoE) gene on chromosome 19
- ApoE alleles e2, e3, e4
- Possibly chromosomes 9, 10, 12
- Microglial *TREM2* gene increases the risk of AD (Zheng et al., 2018)
- Down's syndrome
- Less than 5% of AD cases are caused by rare genetic variations found in a small number of families worldwide. In these inherited forms of AD, the disease tends to develop before age 65 years, sometimes in people as young as 30 years old. The genetic mutations involve the following chromosomes:
  - Chromosome 21 on the gene for the amyloid precursor protein

© F.A. Davis Publishing

- Chromosome 14 on the gene for the presenilin 1 protein
- Chromosome 1 on the gene for presenilin 2 (APA, 2013; NIA, 2019)

Probable Risk Factors:

- Low educational level, low lifetime achievements
- More years of education (versus fewer years) provides a "cognitive reserve" that enables compensation for symptoms of AD/other dementia
- Differences in education and dementia risk may reflect increased risk for disease in general and less access to medical care in lower socioeconomic groups
- Female gender, low estrogen levels
- Framingham Study: Lifetime risk for any dementia in females who reached age 55 years = 21% and for males = 14%
- Depression, brain injury
- Cardiovascular disease, hypertension, type 2 diabetes mellitus, smoking, obesity

Signs and Symptoms: Signs and symptoms vary according to the stage of dementia and disease progression. AD is a multiyear brain disease; it is thought to begin well before clinical manifestations appear. Preclinical changes in the brain can begin 10 to 20 years before symptoms present. These changes include diffuse cerebral plaques, neuritic plaques and tangles, neuron and synapse loss, and some cognitive impairment (Edwards, 2019; Sperling et al., 2011). The onset of clinical symptoms typically begins with memory loss. The duration of each stage of the disease varies, and functional changes usually occur late in the disease process (see Table 20-4).

Many patients manifest neuropsychiatric symptoms, such as apathy, agitation and aggression, combativeness, delusions, hallucination, depression and anxiety, sleep disturbances, and wandering, years before being diagnosed with dementia. Once dementia is diagnosed, neuropsychiatric symptoms may continue to manifest similarly or progress to symptoms more difficult to manage.

Diagnostic Tests: A thorough diagnostic evaluation aimed at identifying the specific etiology of dementia is necessary and will guide treatment decisions. The evaluation should determine whether any treatable psychiatric or general medical conditions might be causing or exacerbating the symptoms manifested by the patient. The clinician must obtain a comprehensive history, and because of questionable reliability secondary to cognitive deficits, a family member or caregiver should be present to validate and obtain collateral information. Take care to note the patient's attitude toward the family member (e.g., friendly, positive, suspicious, paranoid, angry, hostile) who is answering the examiner's questions. If the family member is frequently "correcting" the patient's answer to a question, consider patient and/or family denial, compensation, inconsistency, and fabrication of information (Arvanitakis et al., 2019). The history should include:

- Family history, past medical history, occupation, current health status
- Onset and frequency of memory and cognitive lapses
- Word-finding difficulties
- Ability to perform ADLs, instrumental ADLs
- Sleep patterns
- Ability to drive without getting lost
- Recognition of known others and recall of names
- Wandering

TABLE 20-4 Stages of Alzheimer's Disease and Associated Symptoms

STAGE	ASSOCIATED SYMPTOMS	DURATION
Preclinical	Impaired memory, excused or covered	2–4 years or longer
	Insidious instrumental activities of daily living (ADLs) losses (money handling, bills)	
	Preserved basic ADLs	
	Poor judgment and decisions	
	Subtle personality changes	
	Decreased spontaneity, sense of initiative	
	Increased anxiety, socially normal	
Mild–moderate	Obvious memory impairment	2–10 years
	Overt instrumental ADL impairment	
	Basic ADLs failing	
	Prominent behavioral difficulties	
	Shortened attention span	
	Language difficulty	
	Variable social skills	
	Supervision required	
Severe	Memory fragments only	1–2 years or longer
	No recognition of familiar people	
	Assistance with basic ADLs required	
	Fewer troublesome behaviors	
	Reduced mobility	
	Weight loss, infections	
	Seizures, dysphagia	
	Incontinence	
	Groaning, moaning, grunting	

Diagnostic and Screening Tests: Evidence-based studies support the following routine laboratory studies: complete blood count (CBC), electrolytes, glucose, blood urea nitrogen (BUN), creatinine, liver function tests (LFTs), thyroid-stimulating hormone (TSH), serum B_{12}, folate, syphilis serology, and urinalysis (American Geriatrics Society, 2021). A noncontrast computed tomography (CT) scan will detect vascular insults (infarcts, stroke), and based on history and physical findings and clinical suspicion, magnetic resonance imaging (MRI) may assist in ruling out medical/neurological processes and assist in differential diagnosis. Tests for early diagnosis of AD or for low diagnostic uncertainty are in investigative stages and include a positron emission tomography (PET) scan and biological markers (American Geriatrics Society, 2021; Arvanitakis et al., 2019).

Mental Status Examination and Cognitive Testing: A full mental status examination may uncover mood and neurovegetative symptoms that indicate treatable comorbid psychiatric conditions (e.g., depression, anxiety) that may contribute to cognitive difficulties. Instruments that assess orientation, attention,

© F.A. Davis Publishing

calculation, and memory should be initiated early to assist in diagnosis and establish baseline and should be routinely repeated to objectively document and measure changes over time.

Although commonly used, the Mini-Mental State Examination (MMSE) has poor specificity for dementia and may exhibit poor sensitivity in highly intelligent or well-educated patients; copyright limitations also apply. Additionally, sensory loss and physical frailty may lower scores. Other cognitive instruments may unmask deficits in executive function, abstraction, praxis, visuospatial performance, and test clock-drawing ability, word fluency, proverb interpretation, and praxis (e.g., ability to brush teeth or comb hair). The Montreal Cognitive Assessment (MoCA) and the St. Louis University Mental Status Exam (SLUMS) are well-validated instruments that may be used in the assessment of dementia. The MoCA is a screening test to detect MCI and has greater sensitivity and specificity in distinguishing normal controls from MCI when compared to the MMSE. The MoCA assesses attention and concentration, executive functions, memory, language, visuoconstructional skills, conceptual thinking, calculations, and orientation (Carlson et al., 2017). The SLUMS is useful for detecting MCI and dementia, is more sensitive than the MMSE, and tests orientation, short-term memory, word fluency, attention, concentration and recall, clock drawing, and identification (Yoelin & Saunders, 2017).

The Clock Drawing Test (CDT) can be administered alone or within other cognitive screening instruments (e.g., SLUMS) and screens for AD and other types of dementia. The CDT offers clues regarding areas of cognitive change or damage and provides information about general cognitive and adaptive functioning (memory, information processing, vision, visual-spatial skills). Of note, the CDT lacks sensitivity for MCI. The patient is asked to draw a clock with all of the numbers and to set the hands to read a certain time (Palsetia et al., 2018).

Physical Examination: A general medical assessment should be completed with emphasis on the cardiovascular, respiratory, neurological, and musculoskeletal systems. Assess for endocrine, inflammatory, and infectious processes that may contribute to cognitive symptoms, and note focal motor or sensory signs and altered reflexes, gait, or coordination. The presence of tremor, rigidity, or cogwheeling may indicate a parkinsonian process and vertical gaze paralysis may suggest supranuclear palsy. Look for funduscopic changes that may indicate vascular damage or intracranial pressure, and vision and hearing loss that can mimic or worsen cognitive decline. Unless there are comorbid medical disease processes, the physical examination does not typically reveal many findings.

Diagnosis: Definitive diagnosis of AD is only possible on autopsy and upon finding disease-specific pathology in the brain. As such, the diagnosis of AD is presumptive and based upon the following diagnostic criteria:

Major or Mild Neurocognitive Disorder Due to AD*

DIAGNOSTIC CRITERIA

A. The criteria are met for major or mild neurocognitive disorder.

B. There is insidious onset and gradual progression of impairment in one or more cognitive domains (for major neurocognitive disorder, at least two domains must be impaired).

C. Criteria are met for either probable or possible AD disease as follows:

For Major Neurocognitive Disorder:

Probable Alzheimer's disease is diagnosed if either of the following is present; otherwise, **possible Alzheimer's disease** should be diagnosed.

1. Evidence of a causative AD genetic mutation from family history or genetic testing.
2. All three of the following are present:
   - **a.** Clear evidence of decline in memory and learning and at least one other cognitive domain (based on detailed history or serial neuropsychological testing)
   - **b.** Steadily progressive, gradual decline in cognition, without extended plateaus
   - **c.** No evidence of mixed etiology (i.e., absence of other neurodegenerative or cerebrovascular disease, or another neurological, mental, or systemic disease or condition likely contributing to cognitive decline)

For Mild Neurocognitive Disorder:

Probable Alzheimer's disease is diagnosed if there is evidence of a causative AD genetic mutation from either genetic testing or family history.

Possible Alzheimer's disease is diagnosed if there is no evidence of a causative AD genetic mutation from either genetic testing or family history, and all three of the following are present:

1. Clear evidence of decline in memory and learning
2. Steadily progressive, gradual decline in cognition, without extended plateaus
3. No evidence of mixed etiology (i.e., absence of other neurodegenerative or cerebrovascular disease, or another neurological or systemic disease or condition likely contributing to cognitive decline)

D. The disturbance is not better explained by cerebrovascular disease, another neurodegenerative disease, the effects of a substance, or another mental, neurological, or systemic disorder.

*Reprinted with permission from the DSM-5 (2013). American Psychiatric Association. All rights reserved.

Differential Diagnosis: Numerous disorders and disease processes have similar or overlapping symptoms to dementia, and a comprehensive assessment is necessary for accurate diagnosis. The primary focus of differential diagnoses for dementia is depression and delirium because symptoms may be very difficult to differentiate in an acutely ill patient (see Table 20-5). Additional differential diagnoses include:

- Psychiatric: depression, delirium, mild cognitive impairment, vascular cognitive impairment, amnesic disorder
- Neurological: multiple sclerosis, normal-pressure hydrocephalus, intracranial tumors, subdural hematoma, dementia pugilistica
- Infection: HIV, neurosyphilis
- Inflammatory: rheumatoid cerebrovasculitis, lupus cerebrovasculitis, neurosarcoidosis
- Endocrine: hypothyroidism, hypoparathyroidism, Cushing's disease, Addison's disease, hyperthyroidism, hyperparathyroidism

© F.A. Davis Publishing

TABLE 20-5 Differential Diagnosis of Dementia, Delirium, and Depression

CLINICAL FEATURES	DEMENTIA	DELIRIUM	DEPRESSION
Onset	Insidious	Rapid	May be abrupt, with life changes
Course	Long, progressive	Short, diurnal variation	Situational
Duration	Months to years	Hours to 1 month	2 weeks, months, years
Awareness	Clear	Reduced	Clear
Alertness	Normal	Impaired	Normal
Orientation	Impaired	Impaired	Selective
Thought process	Poor abstract thinking; diminished thoughts; poor judgment; difficulty with word finding/verbalizing	Disorganized, distorted, fragmented, diminished, or expansive thoughts, incoherence	Intact, linear; themes of hopelessness, helplessness, poor self-esteem
Perception	Frequent misperceptions	Distorted with illusions, delusions, hallucinations	Intact
Psychomotor behavior	Normal, apraxia	Varies/mixed; hypokinetic, hyperkinetic	Varies with restlessness, agitation, retardation
Sleep–wake cycle	Fragmented, disturbed, reversed	Disturbed, reversed	Disturbed sleep patterns (increased/decreased); early, mid-, late insomnia; napping
Associated features	Affect superficial, labile, inappropriate; may be in attempt to conceal deficits	Variable affective changes, increased arousal, personality exaggeration	Affect and mood depressed, increased somatic complaints, preoccupation, rumination
Mental status testing	Increased effort to find appropriate replies, frequent near-miss answers, word searching	Distracted from task, inability to focus	Inability to focus/concentrate; makes little effort; gives up; shows indifference, apathy

- Metabolic: vitamin B deficiency
- Toxins: alcohol/substance abuse/dependence

Once depression, delirium, and systemic causes of dementia are eliminated from the differential, it is important to differentiate the type of dementia manifested by the patient. Dementia that is primarily caused by degenerative CNS processes or sequelae includes vascular dementia, Lewy body dementia (associated with Parkinson's disease), frontotemporal lobe dementia (Pick's disease), AD, and mixed dementia. There are similar/overlapping symptoms and distinct symptoms of each type, which help with the differential diagnosis.

Differentiation of Dementia: Dementia can be classified as vascular, Lewy body/Parkinson's, frontotemporal lobe/Pick's disease, or mixed (Alzheimer's Association, 2021b; APA, 2013).

Vascular Dementia:
- Sequelae from transient ischemic attacks, mini-strokes, cerebrovascular accidents
- No or little cortical shrinkage
- Cognitive, behavioral, and functional losses defined by area of infarct
- Stepwise deterioration over time

Clinical Presentation:
- Abnormal executive functioning
- Impaired psychomotor performance
- Changes in personality and mood
- Disturbances in gait (slow and unsteady)
- Hyper-reflexia, extensor plantar response
- Urinary incontinence
- Hemiparesis, including lower facial weakness
- Hemisensory deficits
- Visual problems (field defect, diplopia)
- Pseudobulbar syndrome (e.g., dysarthria, dysphagia, emotional incontinence)
- Focal deficits

Lewy Body/Parkinson's Dementia:
- Diffuse presence of Lewy body proteins in brain, including cerebral cortex
- Lewy bodies deplete dopamine
- Acetylcholine is depleted, causing disruption of perception, thinking, and behavior
- Resultant parkinsonian symptoms: stiff, shuffling gait, stiffness in arms and legs, tremors, frequent falls, mask-like facies with blank stare, flat affect, stooped posture, drooling, runny nose

Clinical Presentation:
- Parkinsonian signs
- Symptoms may fluctuate as often as moment to moment, hour to hour, or day to day
- Fluctuating cognition, varying degrees of alertness and attention
- Progressive memory loss
- Visual hallucinations
- Rapid eye movement (REM) sleep difficulties

© F.A. Davis Publishing

Frontotemporal Lobe Dementia/Pick's Disease:

- Gradual and progressive changes in behavior—socially inappropriate, disinhibition, easily frustrated, impulsive, compulsive behaviors
- Gradual and progressive language dysfunction—problems with expression of language, incorrect words, naming objects
- Difficulties with reading and writing

Mixed Dementia:

- More than one type of dementia (e.g., combination of AD and vascular dementia)

Treatment: A comprehensive, multidimensional treatment plan for dementia includes biological, psychotherapeutic, social, family, and pharmacological interventions (American Geriatrics Society, 2021).

Biological Interventions: Treat underlying medical disorders with medications, medical or surgical procedures, and ongoing evaluation and management as indicated.

Psychotherapeutic Interventions: Include behavioral management, reminiscence therapy, validation therapy, supportive psychotherapy, sensory integration, simulated presence therapy, reality orientation, skills training, recreation and art therapy, exercise, and aromatherapy.

Social Interventions: Include a functional and safety assessment, environmental modifications, assessment for abuse and neglect, provision of supervision and home health care, cleaning and meal services, assessment for appropriate level of care, financial and estate planning, and legal provisions for power of attorney.

Family Interventions: Include caregiver education, training and support, respite care, and support groups.

Pharmacotherapy: Cholinesterase inhibitors (ChEIs) are the cornerstone of pharmacological therapy, with the aim to enhance or preserve cognitive and behavioral status. Acetylcholine is important for the functioning of brain cells involved in memory, thought, and judgment, and brain levels are significantly decreased in those with AD. ChEIs inhibit breakdown of acetylcholine, which increases levels within the brain; this mechanism of action may improve or delay a decline in memory. ChEIs are effective in approximately 30% of patients and are not curative, preventive, or disease-reversing agents. The choice of ChEI is based on the patient's clinical presentation and comorbid conditions.

The three commonly prescribed ChEIs are donepezil, rivastigmine, and galantamine (NIA, 2018). Clinical and safety issues for ChEIs include medical and psychosocial factors before drug initiation, consideration of when to initiate the medication, and side effects, which are fewer with slower dose titration. Careful monitoring for efficacy and side effects is necessary. Common side effects of ChEIs are nausea, vomiting, dyspepsia, anorexia, diarrhea, insomnia, vivid dreams, fatigue, increased urination, and cramps. Uncommon side effects of ChEIs are syncope, bradycardia, confusion, depression, and agitation. Use cautiously in patients with liver or gastric disease, COPD, bradycardia, and inadequate supervision.

Considerations regarding when to stop ChEIs may include intolerable side effects, new medical contraindications, poor compliance, lack of supervision, and rapid cognitive and/or functional decline. Any benefits of treatment are rapidly lost upon discontinuation. Long-term treatment may continue to offer advantages such as slowing of cognitive decline, continued ability to perform ADLs, fewer noncognitive behavioral symptoms, and decreased caregiver burden (NIA, 2018).

Another medication approved to treat dementia is memantine (Namenda), an *N*-methyl-D-aspartate (NMDA) receptor antagonist. Memantine assists in regulating high levels of glutamate in the brain, typically found in AD. Common side effects include headache and constipation, and an uncommon side effect is confusion. Memantine is excreted through the kidneys, and caution is advised in patients with renal impairment. Combination therapy of memantine with a ChEI is a good strategy, because these medications work differently (NIA, 2018). Usually, medications are started when AD severity is moderate, but they can be initiated earlier depending on individual patient clinical presentations (see Table 20-6).

Management of Neuropsychiatric Symptoms: Includes determination and management of other potential or influencing factors, including (International Psychogeriatrics Association [IPA], 2015):

- Environmental: external (noise) or internal (UTI, constipation)
- Situational: time of day, unknown trigger
- Psychiatric: depression, anxiety, panic, fear
- Medical: medication, pain, metabolic, infection, sensory deficits, cardiopulmonary

Nonpharmacological Approaches Include (IPA, 2015):

- Ensure safety and provision of adequate supervision.
- Analyze behavior(s) for clues to potential causes.
- Use environmental interventions.
- Provide structure—usual routines and predictability are important to allay anxiety.
- Provide pleasurable experiences.
- Do not rely on learning or memory.
- Educate caregivers and other support systems.
- Use of physical or chemical restraint is discouraged and may be used only as a last resort in order to ensure safety to self and others.
- Provide caregiver education for managing agitation (see Table 20-7).

Treatment Strategies and Pharmacotherapy for Neuropsychiatric Symptoms and Psychiatric Comorbidities: It is estimated that up to 90% of patients living with dementia will experience neuropsychiatric symptoms during the course of the disease trajectory (Bessey & Walaszek, 2019). One observational study (Tori et al., 2020) estimated that 65.1% of long-term care residents have psychiatric diagnosis.

One systematic review (Leung et al., 2021) showed the prevalence of depression in persons living with dementia ranges from 10% to 78% with a pooled prevalence of 39%. The prevalence of depression in mild (38%), moderate (41% and severe (37%) dementia is very close (Leung et al., 2021). Depressive symptoms may present as initial manifestations of dementia and may fluctuate over time. There are more reports of decreased ability to concentrate and indecisiveness, and fewer reports of insomnia or hypersomnia, feelings of worthlessness and guilt, or thoughts of suicide and death. Diagnostic criteria for comorbid depression in dementia

TABLE 20-6 FDA-Approved Medications for Alzheimer's Disease

	DONEPEZIL (ARICEPT) CHEI	RIVASTIGMINE (EXCELON) CHEI	GALANTAMINE (REMINYL) AND EXTENDED RELEASE (RAZADYNE) CHEI	MEMANTINE (NAMENDA) (NMDA RECEPTOR AGONIST)
FDA approval	1996; mild, moderate, severe AD	2000; mild, moderate AD	2001; mild, moderate AD	2004; moderate, severe AD
Benefit	Typically, well tolerated; improves cognitive and behavioral status, caregiver burden, and capacity for ADLs	Improves cognitive, behavioral, and functional impairments; is more selective for central processes and regions critical for cognition and memory	Significantly improves cognitive, behavioral, and functional symptoms of AD	Delays loss of daily functions, cognition, and global performance; decreases agitation
Dosage strengths (mg)	5, 10	1.5, 3, 4.5, 6	4, 8, 12 Extended Release: 8, 16, 24	Titrate to 10 mg bid over 4 wk
Oral solution	1 mg/mL	2 mg/mL	4 mg/mL	
Starting dose	5 mg qd	1.5 mg bid	4 mg bid	
Maximum recommended dose	10 mg qd	6 mg bid	8–10 mg bid Extended Release: 16–24 mg qd	10 mg bid
T1/2 (hours)	73	5	6–8	60–80
Plasma protein binding	96%	40%	18%	
CYP450 substrate of	2D63A4	NA	2D63A4	
CYP450 inhibitor of	NA	NA	NA	NA

TABLE 20-7 Managing Agitation: Caregiver Education

DO	DON'T	PREVENTION	SAFETY
Ask permission to approach/provide assistance.	Raise voice.	Create a calm environment.	Use alarms and/or locks on doors and gates.
Use a calm approach.	Take offense.	Follow a routine with set structure and tasks.	Remove or secure firearms.
Slow down (do not rush patient or self).	Corner or crowd.	Use verbal cueing.	
Use visual and verbal cues.	Rush or pressure.	Redirect attention.	
Provide time and space.	Criticize or condescend.	Use a clock and calendar.	
Limit stimuli.	Argue or attempt reason.	Monitor heat, cold, hunger, sleep, elimination, and comfort.	
	Shame or ignore.		
	Demand, force.		
	Make sudden movements.		
	Restrain.		

include the addition of irritability, social withdrawal, and isolation with frequent, concurrent apathy and anxiety.

The Cornell Scale for Depression in Dementia (CSDD) is a validated screening tool designed for use in the assessment of those who can communicate basic needs (Goodarzi et al., 2017). Other diagnostic instruments include the PHQ-9 and the Geriatric Depression Scale (GDS) (see Depression). First-line treatment strategies for comorbid depression include supportive psychotherapy and a selective serotonin reuptake inhibitor (SSRI) such as citalopram (Celexa), fluoxetine (Prozac), or sertraline (Zoloft). If interventions are ineffective and/or suffering is severe and persistent, patients may be referred to psychiatry for consideration of electroconvulsive therapy (ECT), a well-established and effective treatment option.

The prevalence of anxiety in persons living with dementia varies from 27.7% to 63.4% (Goodarzi et al., 2017). In one meta-analysis anxiety occurs in 5% ($N_{studies}$ = 9) of patients with AD and 14% ($N_{studies}$ = 4) in vascular dementia (Kuring

© F.A. Davis Publishing

et al., 2018). One meta-analysis (Leung et al., 2021) reports the prevalence of anxiety is 38% in mild dementia, 41% in moderate dementia and 37% in severe dementia. Manifestations of anxiety in dementia include restlessness, irritability, muscle tension, and fear. Respiratory symptoms, such as hyperventilation or difficulty catching one's breath, correlate with excessive anxiety and worry. Diagnostic instruments to assist in diagnosing anxiety in those with dementia include the Worry Scale and the Rating Anxiety in Dementia Scale. First-line treatment options include psychosocial interventions and an SSRI or buspirone (Buspar). Use of benzodiazepines (e.g., lorazepam) is discouraged due to sedating side effects and increased risk of falls.

Psychosis in AD is frequently present with other cognitive symptoms (global deficits, anosognosia), affective symptoms (depression, elevated mood), and behavioral symptoms (agitation and overt aggression). Approximately 18% of dementia patients present with delusions that typically manifest as persecutory and misidentification delusions (IOM, 2012). Hallucinations are present in approximately 14% of dementia patients, with the occurrence of visual hallucinations more than twice that of auditory hallucinations (IOM, 2012). Capgras syndrome (belief that a close relative or friend has been replaced by an impostor) and "phantom boarder syndrome" (belief that strangers are living in the home) may be associated with agnosia. Instruments to assist in diagnosing psychosis in dementia include the Behavioral Pathology in Alzheimer's Disease (BEHAVE-AD) Scale and the Dementia Psychosis Scale. Behavioral and environmental interventions are first-line treatment strategies.

Before initiating pharmacological treatment with antipsychotic medications, the clinician should carefully analyze the risks and benefits of the use of such medications for each patient. Based on studies demonstrating increased risk for stroke and mortality in older adults, the U.S. Food and Drug Administration (FDA) has issued multiple black box warnings for use of antipsychotic medications in this population (Maust et. al., 2015). Judicial and cautious use of antipsychotic medication should be reserved for hallucinations, delusions, aggression, agitation, hostility, and uncooperative behavior that significantly interferes with care. Antipsychotics effective at low doses include aripiprazole (Abilify), haloperidol (Haldol), olanzapine (Zyprexa), quetiapine (Seroquel), risperidone (Risperdal), and ziprasidone (Geodon). Research evidence, FDA warnings, and clinical guidelines recommend use of antipsychotic medication only when (1) behavioral symptoms are due to mania or psychosis, (2) symptoms present a danger to the patient or others, or (3) the patient is experiencing inconsolable or persistent distress, a significant decline in function, or substantial difficulty receiving needed care (Reus et al., 2016).

Antipsychotic medication should not be used for sedation or restraint and should be used at the minimum dosage for the minimum amount of time possible. Careful monitoring for efficacy and side effects is required (Reus et al., 2016).

Approximately 27% of dementia patients exhibit agitation and/or aggression. Prevalence increases as dementia progresses (13% in mild dementia, 24% in moderate dementia, and 29% in severe dementia). *Agitation* is defined as intermittent psychomotor hyperactivity, disinhibition, screaming, physical aggression, and combativeness. There are many potential causes for agitation, including the underlying pathophysiology of dementia (e.g., serotonergic deficiency) and an inability to communicate needs (e.g., hunger) or physical discomfort (e.g., pain, constipation). Psychosocial stressors that may induce agitation include changes in one's living situation, caregiver(s), or environment. Medical evaluation is needed to rule out occult medical problems, medication side effects, and delirium. Instruments that may assist in accurate diagnosis are the BEHAVE-AD Scale, and the Cohen-Mansfield Agitation Inventory (IPA, 2015).

Interventions include evaluation and management of antecedents and/or causes of agitation, behavioral approaches (e.g., distraction, pleasurable activities), and calming activities or gentle sensory stimulation (e.g., music, art, routine/known physical activities such as folding towels). Pharmacotherapy options might include off-label use of mood stabilizers, such as carbamazepine or Depakote, to effectively manage agitation. Antipsychotic medications are not considered to be first-line treatment, because they are less effective than first believed; however, they should be considered when behaviors present a safety risk to self or others (Reus et al., 2016). For sleep problems, low-dose doxepin may be effective and is FDA approved for insomnia.

Follow-Up: After the presumptive diagnosis of AD is made, the patient should be followed closely with pharmacotherapy initiation and following any adjustments for efficacy and side effects. Thereafter, follow-up visits every 3 to 6 months to assess physical, mental, and emotional status should be individualized to the patient. Reevaluation of cognitive function with the same scale used at diagnosis/baseline is useful to track cognitive stability or decline. The patient's functional status, ability to perform ADLs and instrumental ADLs, behavior, sleep, appetite, weight, elimination, communication, and signs of anxiety or depression should routinely be evaluated at follow-up visits. The physical examination is individualized to the patient and any episodic or chronic illnesses should be well managed to maintain optimum quality of life and avoid complications or worsening of cognitive function.

The ability to drive competently and safely is a frequent concern of family members, and clinicians are often asked to assist in making the difficult decision to revoke the patient's driver's license. Dementia exacerbates age-related changes in driving ability and poses a substantial risk to safe driving. The American Medical Association National Highway Safety Administration guidelines state that a dementia diagnosis is not sufficient to withdraw driving privileges and recommend basing decisions on an individual's driving ability. Determining whether a patient with mild dementia is fit to drive presents a challenge to the clinician and begins with discussion of driving history, safety, and cessation with the patient. Data from physical and cognitive assessments, family and caregiver reports, and, when available, on-road testing will assist in the decision-making process. For patients deemed to be safe, discuss the necessity of future driving cessation and suggest driving training and self-limitation. A history of significant traffic problems, inability to find the way home, inattention, and psychosis are indications of progressive cognitive decline and driving skill deterioration. When driving safety is uncertain and the patient wishes to continue driving, a referral for on-road driving evaluation is needed. Those with mild dementia who pass an on-road driving test should be reevaluated and retested at least every 6 months. If driving safety is uncertain and the patient decides to stop driving, or if the patient is deemed unsafe to drive, the

© F.A. Davis Publishing

Department of Motor Vehicles and the patient should be notified by letter, and a copy of the letter should be placed in the patient's medical record. International consensus groups agree that a diagnosis of moderate-to-severe dementia precludes driving, and the driver's license should be revoked. Driving is essential to autonomy, and the vast majority of older adults rely on driving as their primary mode of transportation. Although the clinician's recommendation for driving cessation is distressing to patients and families, it is critical for patient and public safety (Pomidor, 2019).

Caregiver burden regarding patient care, household and financial responsibilities, and ability to provide adequate supervision and care at home should be determined at each follow-up visit. When the patient loses bowel and/or bladder control, their behavior becomes too difficult to manage, or the patient's or caregiver's safety is compromised, institutional care should be discussed.

Sequelae: Complications from severe dementia include immobility, swallowing disorders, malnutrition, and significantly increased risk of developing pneumonia, which is the most commonly identified cause of death among the elderly with AD and other dementias. Although there is a blurred distinction between death *with dementia* and death *from dementia*, since 2000 the AD mortality rate has been on the rise. AD is the sixth leading cause of death in the United States and the fifth leading cause of death among those 65 years of age and older. Death due to AD increased 16% with the COVID-19 pandemic (Alzheimer's Association, 2021b).

Prevention/Prophylaxis: A comprehensive evidence review commissioned by the Agency for Healthcare Research and Quality (AHRQ) included 25 systematic reviews and 250 primary research studies, both observational and randomized clinical trials (RCTs) on preventive interventions for AD. The primary conclusion was that there was a dearth of evidence for any strong recommendations for preventive interventions for AD (Williams et al., 2010). Physical activity and cognitive engagement were factors that demonstrated fairly constant association with prevention of cognitive decline and AD; diabetes, depression, smoking, and APOE e4 were associated with increased risk of cognitive impairment and AD. The National Academies of Sciences, Engineering, and Medicine (2017) conducted a follow-up study using RCTs, the gold standard for evidence. In spite of using RCTs, there remains inconclusive evidence for interventions including cognitive training, blood pressure management and increasing physical exercise to delay or prevent cognitive decline of dementia. Instead, multimodal interventions are thought to hold promise for preventing cognitive impairment and dementia.

Referral: Neurology, geriatric psychiatrist, geriatric nurse practitioner, psychiatric mental health nurse practitioner or clinical nurse specialist, psychology, support groups for patients and caregivers.

Education: The impact of AD on caregivers expands as the course of illness progresses. Caregivers, family, and friends of those with AD experience new or changing responsibilities such as shopping, meal preparation, cleaning, financial management, provision of ADLs, and managing behavioral issues. Caregivers also experience financial burden, physical and emotional stress, fatigue, and depression. It is estimated that 34% of caregivers are 65 years or older (Alzheimer's Association, 2015), and 23% are within the "sandwich" generation, providing care for family members (Alzheimer's Association, 2021b).

Patient and caregiver education and support needs include:

- Disease process, course of illness, staging
- Anticipatory guidance, life planning, advance directives, power of attorney (POA)

Preservation of the following:

- Safety at all times
- Dignity, respect, and self-esteem
- Independence and autonomy for as long as possible/practical/safe
- Daily schedules and routines
- Least restrictive environment
- Cognitive, behavioral, and pharmacological therapies

DEPRESSION

Signal Symptoms: Depression in older adults may be manifested by pervasive and sustained depressed mood, discouragement, lack of pleasure in usual activities, guilt, loss of motivation, low energy, and sleep and/or appetite disturbances (American Psychiatric Association [APA], 2013).

Description: Transient symptoms of depression are expected and healthy responses to life stressors and disappointments. Pathological depression manifests when a patient's coping skills are inadequate for adaptation to stressful life events or loss. Depression in older adults can be life threatening and associated with increased risk of suicide (Van Orden & Deming, 2018). Depression is characterized by a pervasive feeling of sadness or a lack of interest or pleasure in previously enjoyed or usual activities (APA, 2013). Feelings of guilt, low self-esteem, sleep and appetite disturbances, psychomotor changes, low energy, and decreased concentration are common symptoms (APA, 2013). Late-life depression involves new onset of depression occurring after age 60. Depression may be categorized as a single episode or recurrent, and further qualified as mild, moderate, or severe, with or without features such as melancholy, mood congruence, catatonia, peripartum onset, or with a seasonal pattern (APA, 2013).

Etiology: Although depression is common among older adults, depression is not a normal result of the aging process. Late-life depression involves combinations of physiological, environmental, and psychosocial risk factors (Van Damme et al., 2018).

Psychosocial factors contributing to late-life depression can include unemployment, loss of a spouse or partner, pain, social isolation, poverty, and limited access to mental health care (Alexopoulos, 2019; Van Damme et al., 2018). Difficulty accomplishing developmental tasks associated with life stages may contribute to and/or be a consequence of depression. Depression in older adults could be triggered by a single major life event or a combination of events and stressors. Loss of any kind may contribute to depression, and in the older adult, loss may include loss of a loved one or loss of functional abilities, relationships, mobility, independence, one's home, and financial security, along with social isolation and deterioration of physical health.

Biological risk factors are theorized to include genetic vulnerabilities, frailty, nutritional deficiencies, neurodegenerative disease, neuroplasticity problems, dysregulation of hypothalamic-pituitary-adrenocortical axis, deficiencies or dysregulation of monoamines (particularly serotonin, norepinephrine, and dopamine), stress, and vascular disease (Liu et al., 2017; Van Damme et al., 2018). Researchers discovered that genetic components that impact hippocampal plasticity and stress reactivity may be related to late-life depression (Tsang et al., 2017).

Occurrence: Depression is one of the most common psychiatric illnesses experienced by older adults, but prevalence data are not certain due to undertreatment, misdiagnosis, or underdiagnosis of depression in this population. Older adults may experience comorbidities and somatic symptoms that could prevent the diagnosis of depression in this population. Older adults may encounter help-seeking barriers related to stigma, access to care, self-motivation, and ageism (Polacsek et al., 2019). Researchers found that cognitive symptoms are common among older adults, but these problems are not frequently recognized or treated, and depression could have a key role in misdiagnosis of dementia (Voros et al., 2020). Higher depression prevalence is associated with impaired physical functioning, lack of a spouse or partner, and dementia (Sjöberg et al., 2017). Late-life depression in long-term care may be more prevalent than late-life depression in community settings, but prevalence data vary greatly, and depression is believed to be underrecognized among older adults in both settings (Simning & Simons, 2017). Older adults in long-term care are at particularly high risk of depression, especially when experiencing pain, sleep disturbance, lack of social support, and problems with person-environment fit (Chau et al., 2021). Researchers observed that high rates of depressive symptoms may occur in the last year of life, especially during the last 4 months (Kozlov et al., 2020).

Age: Depression occurring initially after age 60 is classified as late-life depression. In the United States, older adults aged 65 years and older were more likely than adults in other age-groups to experience mild depression symptoms in 2019 (Villarroel & Terlizzi, 2020).

Ethnicity: According to the National Institute of Mental Health (2019), prevalence of major depressive disorders (MDD) was highest among adults reporting two or more races. Researchers found that non-Hispanic White and non-Hispanic Black adults were most likely to experience mild depression symptoms when compared to Hispanic and non-Hispanic Asian adults (Villarroel & Terlizzi (2020). Non-Hispanic Asian adults were least likely to experience mild to severe depression symptoms when compared with Hispanic, non-Hispanic White, and non-Hispanic Black adults (Villarroel & Terlizzi, 2020). When considering older adults as a population, the chance of screening positively for depression was higher among study participants self-reporting as Mexican, Puerto Rican, Cuban, another Hispanic/Latino, multiple Hispanic/Latino ethnicities, Black/African American, Asian Indian, Filipino, Native Hawaiian/Pacific Islander, and two or more races, when compared with non-Hispanic White adults (Hooker et al., 2019).

Contributing Factors:

Genetics: Gene studies revealed that *APOE, BDNF*, and *SLC6A4* are associated with late-life depression (Tsang et al., 2017).

Psychosocial: Researchers identified unemployment, loss of spouse, pain, social isolation or loneliness, poverty, and limited access to mental health care as psychosocial risk factors for late-life depression (Alexopoulos, 2019; Van Damme et al., 2018). Persistent sleep disturbances in older adults were found to increase risk of depression development, recurrence, and worsening (Bao et al., 2017).

Biological/Physical Illnesses: Researchers discovered that frailty and depression had a reciprocal relationship, with each increasing prevalence and incidence of the other (Soysal et al., 2017). Multiple comorbidities, multiple medications,

© F.A. Davis Publishing

poor nutritional status, vitamin deficiencies (vitamin D, vitamin B_{12}, and folate), neurodegenerative disease, and cardiovascular disease are potential biological risk factors (Van Damme et al., 2018).

Signs and Symptoms: Depression among older adults may be manifested by depressed mood, anhedonia, apathy, helplessness, hopelessness, worthlessness, and loneliness as affective symptoms. Potential cognitive symptoms include ambivalence, uncertainty, inability to concentrate, confusion, poor memory, slowed speech, lack of motivation, a pessimistic outlook, negative thoughts, self-criticism, and poor self-esteem. Assess for perceptual disturbances, such as hallucinations, illusions, and delusions, to determine whether psychotic features are present.

Physiological changes may include sleep, appetite, and energy disturbances, weight change, constipation, pain, headache, decreased libido, multiple unexplained somatic complaints, or refusal to eat or drink (Kok & Reynolds, 2017). Assess for behavioral symptoms, such as psychomotor retardation or agitation, irritability, poor personal hygiene, tearfulness, and social withdrawal. It is vitally important to question the patient about suicidal ideation and/or plans, as well as assess for access to lethal weapons. Some patients experience excessive worry, preoccupation, and generalized anxiety. Major depression involving anxiety and somatic symptoms could increase disability (Morin et al., 2020). Some older adults may not associate behavioral or physiological symptoms with depression, so it is important for clinicians to suspect depression as an underlying cause (Kok & Reynolds, 2017).

The *DSM*-5 (APA, 2013) diagnostic criteria for MDD include sustained, disruptive, and pervasive depressed mood or loss of interest or pleasure. With the exception of suicidal ideation and weight change, five or more of the following symptoms must be present for most of the day, on most days, over a 2-week period:

- Depressed mood as reported in subjective report or as observed by others
- Obsessive rumination or worry
- Change in appetite and significant change in weight
- Change in sleep pattern: insomnia (difficulty falling asleep or staying asleep, waking earlier than necessary, inability to fall back asleep), hypersomnia, frequent napping
- Psychomotor agitation or retardation (including as observed by others)
- Fatigue or loss of energy
- Feelings of hopelessness
- Feelings of worthlessness, excessive guilt
- Diminished concentration, indecisiveness
- Recurrent thoughts of death, suicidal ideation or gestures, suicide attempt, suicide plan

Distinct clinical manifestations in older adults include:

- Report of lack of emotions (versus depressed mood)
- Excessive concern with bodily functions
- Seeking reassurance and support
- Isolative, withdrawn behavior
- Change in previous level of function, decline in activities of daily living (ADLs)
- Feeling overwhelmed, easily frustrated, excessive crying
- Irritability, fearfulness, agitation, anxiety
- Transient, recurring symptoms; diurnal fluctuations or pattern
- Minimizing expressed death wishes or passive suicidal behavior

If possible, at the first encounter, the patient should be interviewed individually. Goals of the interaction should include establishing a therapeutic, trusting alliance, which can then enhance the discussion of potentially sensitive topics, such as abuse and suicidal thoughts. The subjective history could begin with open-ended questions, which could then be followed by specific and focused questions. The history should include present illness, past psychiatric history, family history including mental health, medical history, prescription and over-the-counter (OTC) medication use, social history (education, work history, important relationships, sexual activity, spirituality, and current living arrangements), and functional assessment. Assessment should include a comprehensive physical examination to look for secondary causes of depressive symptoms, a full mental health assessment, and a mental status examination if confusion or cognitive impairment are present.

Diagnostic Tests: Diagnostic tests to assess for underlying or undiagnosed medical causes of depressive symptoms should be ordered. Standard blood work includes complete blood count with differential, comprehensive metabolic panel, lipid panel, thyroid function studies (thyroid-stimulating hormone [TSH] with reflex T_4), and serum vitamin B_{12} and vitamin D levels. Clinical evaluation instruments and scales are useful in assessing symptoms and severity of depression, cognitive impairment, and disability. Such instruments provide objective measures of signs and symptoms of illness and help in establishing baseline information with which future assessments can be compared in evaluating efficacy of treatment and interventions. Instruments also provide guides to dialogue, and they allow the practitioner to further discuss key concerns with the patient. Researchers found that the Geriatric Depression Scale, especially shorter versions, had high sensitivity and specificity for detecting depression in older adults (Krishnamoorthy et al., 2020),

Depression Scales:

- Geriatric Depression Scale (GDS, long and short forms)
- Beck Depression Inventory (BDI)
- Patient Health Questionnaire (PHQ–9)
- Hamilton Depression Scale (HAM-D)
- Two-Question Screen

Overall Cognitive Functioning:

- Montreal Cognitive Assessment (MoCA)

Differential Diagnosis:

- Mood disorder due to general medical condition such as thyroid disease, diabetes, cancer, epilepsy, stroke, multiple sclerosis, Parkinson's disease, cardiac disease, acute illness, or injury
- Substance-induced or medication-induced mood disorder related to alcohol use, illicit drug use, cardiac medications, steroids, sedatives, or other medications or substances
- Dysthymic disorder that manifests symptoms of mild depression and may have an early or late onset, is chronic in nature, and lasts more than 2 years

© F.A. Davis Publishing

- Bipolar affective disorder, in which bipolar depression may be misdiagnosed as unipolar depression
- Delirium
- Dementia
- Life circumstances, grief, bereavement, loss, financial challenges
- Somatization disorder
- Sleep disorder, obstructive sleep apnea

Treatment: Goals of treating late-life depression include preventing or reducing relapse or recurrence, improving quality of life and functioning, improving medical health, and reducing mortality. Compassion, therapeutic communication approaches, active listening, and respect can help to improve the therapeutic relationship during treatment of depression. It is important to evaluate the present medication regimen and remove or change any medications that may contribute to depression symptoms. Treat any medical condition that may have predisposed the patient to depression. Provide education or treatment for sleep disturbances and nutritional or vitamin deficiencies that may contribute to depression symptoms. A stepped-care approach based upon patient preference, severity of late-life depression, and functional impairment can improve treatment outcomes, especially in rural areas that may lack access to mental health care (Meuldijk & Wuthrich, 2019; Van Damme et al., 2018). Researchers found that depression severity, comorbid anxiety, executive dysfunction, episode duration, early improvement, physical illnesses, and age were predictors of treatment outcomes for depression in older adults (Tunvirachaisakul et al., 2018). In addition to treatment with pharmacotherapy, evidence-based psychotherapy may also be effective for late-life depression (Kok & Reynolds, 2017).

TABLE 20-8 First-Line Treatment with Antidepressant Medications

TYPE OF ANTIDEPRESSANT	MEDICATION—GENERIC NAME (TRADE NAME)
Selective serotonin reuptake inhibitor	citalopram (Celexa)
	escitalopram (Lexapro)
	fluoxetine (Prozac, Sarafem)
	fluvoxamine (Luvox)
	paroxetine (Paxil, Pexeva, Brisdelle)
	sertraline (Zoloft)
Serotonin and norepinephrine reuptake inhibitor	desvenlafaxine (Pristiq, Khedezla)
	duloxetine (Cymbalta)
	milnacipran (Savella)
	levomilnacipran (Fetzima)
	venlaxafine (Effexor, Effexor XR)
Norepinephrine-dopamine reuptake inhibitors	bupropion (Wellbutrin)
Serotonin modulator	nefazodone (Serzone)
	trazodone (Desyrel, Oleptro)
Norepinephrine-serotonin modulator	mirtazapine (Remeron)

Pharmacotherapy: The strategy for pharmacological management of late-life depression is to achieve complete and sustained relief or remission of depressive symptoms with the least amount of distressing adverse effects. If utilizing pharmacological interventions for older adults with depression, it is important to initiate pharmacotherapy with a "start low and go slow" approach to avoid risks of adverse effects in this population. The most widely prescribed antidepressants and with greatest evidence for achieving remission are selective serotonin reuptake inhibitors (SSRIs) (Gutsmiedl et al., 2020). Other types of antidepressants that are recommended treatment for late-life depression include serotonin-norepinephrine reuptake inhibitors (SNRIs), serotonin partial agonist/reuptake inhibitors, norepinephrine-dopamine reuptake inhibitors, selective norepinephrine reuptake inhibitors, and alpha-2 antagonists (see Table 20-8). SNRIs can be helpful when treating both depression and peripheral neuropathic pain in older adults (Van Damme et al., 2018). Mirtazapine can be effective for treating depression, insomnia, and appetite loss (Van Damme et al., 2018).

Although tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs) are available, they are no longer considered first-line recommendations due to increased risk of adverse effects compared to SSRIs. TCAs should be used with caution in older adults due to risk of anticholinergic effects, confusion, arrhythmias (Beyer & Johnson, 2018). Frequent adverse effects for older adults with depression who are taking SSRIs include gastrointestinal disturbances, sexual dysfunction, insomnia, and hyponatremia (Kok & Reynolds, 2017; Van Damme et al., 2018). QT interval prolongation may occur with doses of citalopram above 40 mg (U.S. Food and Drug Administration [FDA], 2017; Van Damme et al., 2018). The SNRIs, including venlafaxine and duloxetine, have been shown to be effective in older adults with depression, but blood pressure may be increased when taking SNRIs (Van Damme et al., 2018). Considerations when choosing an antidepressant for treatment of late-life depression include short- and long-term adverse effects, least-desirable adverse effects, safety, comorbid conditions, and cognition. Additional factors in antidepressant selection include the patient's primary symptoms, symptom clusters, current medications, history of medications used, efficacy and adverse effect tolerance, and family history of effective medication use.

It is important to monitor and evaluate therapeutic response to antidepressant therapy, as well as observe for side effects, tolerance, and unremitting symptoms of depression. Researchers estimate that approximately half of older adults with MDD taking antidepressants for 4- to 12-week trials experience improvement in depression symptoms (Gutsmiedl et al., 2020). For older adults, 2 to 3 months may be required to achieve the full benefit of antidepressant treatment (Avasthi & Grover, 2018). For patients who do not respond adequately to monotherapy after 4 to 8 weeks, consider reevaluating the diagnosis, evaluating treatment adherence, and assessing for other medical or psychosocial factors that could impact pharmacotherapy treatment (Avasthi & Grover, 2018). If monotherapy is not effective, consider maximizing the antidepressant, switching to a different antidepressant (of the same or different class), or augmenting an antidepressant with another medication, psychotherapy, or electroconvulsive therapy (ECT) (Avasthi & Grover, 2018).

© F.A. Davis Publishing

Second generation antipsychotics, such as aripiprazole, quetiapine, and olanzapine, can be effective in low doses and for short-term treatment when augmented with antidepressants for treatment-resistant depression (Cakir & Senkal, 2016). However, second generation antipsychotics should be used with caution in older adults because there is risk of cerebrovascular events and other adverse effects with these medications (Cakir & Senkal, 2016).

Partnering with the patient through inquiry into prior antidepressant use, shared decision making, and education regarding expected therapeutic response time could positively affect patient adherence to the therapeutic regimen. Discussion regarding common and potentially bothersome side effects, as well as the likelihood that they will wane over time, can promote medication adherence. Educate patients about serious or potentially dangerous effects of antidepressant medication and instruct them when it is necessary to notify their prescriber (see Table 20-9). As patients begin to feel better, advise them to continue taking the medication, and explain the risk of stopping medication abruptly or too early. Patients should be educated about the dangers of combining herbal remedies such as St. John's wort (hypericum) with SSRIs, because this combination raises the risk of serotonin syndrome.

Length of Pharmacotherapy Treatment and Follow-Up: When initiating or changing the dose of antidepressant medication, it is critical to monitor the patient closely for efficacy and adverse effects. Observe for worsening of depression, suicidal thoughts or actions, unusual changes in behavior, agitation, and irritability. Educate patients, families, and caregivers to pay close attention to sudden changes in mood, behaviors, thoughts, or feelings, as well as suicidal thoughts, and to report these concerns immediately to the provider. As depression symptoms begin to decrease, patients may become more energized and may be able to follow through on prevailing suicidal ideation and plans. Factors that increase risk for suicide in late life include cognitive control deficits, current depression, and impulsivity (Szanto et al., 2020). Patients should be screened for suicidal thoughts during pharmacological initiation, at dosing phases, and at every subsequent follow-up visit.

Length of antidepressant treatment varies depending on whether it is a first or recurrent episode. With each recurrence, there is an increased risk of future recurrence if medication is discontinued, and as a result, antidepressant therapy must be maintained for longer periods of time. The *acute phase* of treatment lasts up to 3 months after the start of medication, with the goal to achieve remission. Close follow-up is critical and highly individualized; however, there should be patient contact within the first month and additional contact every four weeks or sooner with dosage adjustments, switching, combination, or augmentation. Researchers concluded that in older adults with major depression and dementia, adherence to antidepressant treatment during the acute phase was associated with decreased all-cause hospitalization risk (Bhattacharjee et al., 2020). The *continuation phase* of treatment begins once remission is achieved, and medication should be continued for at least another 4 to 12 months. Patients in the continuation phase of treatment should be seen every 6 months or earlier. The *maintenance phase* of antidepressant therapy is specifically for patients with two or more lifetime episodes of major depressive disorder. These patients should be maintained on medication at the same dosage for another 15 months to 5 years. Patients in the maintenance phase of treatment should be seen every 6 to 12 months or earlier.

TABLE 20-9 Common Side Effects and Potentially Serious/Dangerous Side Effects of Antidepressants

SSRIs, NDRIs, SNRIs: common side effects	Mild nausea, loose bowel movements, anxiety, headache, insomnia, increased sweating, weight gain/loss, sexual dysfunction, vivid dreams, rash, SIADH
Serotonin modulators: side effects	Sedation, weight gain, mild anticholinergic symptoms; priapism, a side effect of trazodone, is a medical emergency
Serotonin syndrome (excessive serotonin)	Agitation, restlessness, diarrhea, diaphoresis, muscle twitching or rigidity, confusion, hyperpyrexia, seizures, tachycardia, death
SSRI discontinuation syndrome	Dizziness, headache, paresthesia, nausea, diarrhea, insomnia, and irritability; seen with missed doses and abrupt discontinuation of antidepressants with a short half-life

Abbreviations: NDRIs = norepinephrine-dopamine reuptake inhibitors; SSRIs = selective serotonin reuptake inhibitors; SNRIs= serotonin–norepinephrine reuptake inhibitors. SIADH = syndrome of inappropriate antidiuretic hormone secretion

Psychotherapy and Nonpharmacological Interventions: Research studies demonstrated that psychotherapeutic approaches, including cognitive behavioral therapy, problem-solving therapy, interpersonal psychotherapy, and life review therapy, could decrease depression symptoms in older adults (Kok & Reynolds, 2017; Renn & Areán, 2017; Van Damme et al., 2018). For patients with mild to moderate depression, psychotherapy may be sufficient as a treatment strategy, especially if the patient prefers to participate in psychotherapy instead of pharmacotherapy, or experiences nonadherence or adverse effects with medications (Renn & Areán, 2017). Combined psychotherapy and pharmacotherapy for older adults with depression may be more effective than use of monotherapy (Avasthi & Grover, 2018).

Older adults with severe depression or depression with psychotic features may benefit from ECT (Van Dierman et al., 2018). Most older adults with depression can tolerate treatment with ECT, but cognitive adverse effects are possible in this population (Obbels et al., 2018).

Activities that promote physical and mental wellness, including exercise and mindfulness-based activities, can reduce depression symptoms for some older adults. Mind-body, resistance, and aerobic exercises, especially when self-selected by patients according to preference, can improve outcomes for older adults participating in pharmacological treatment for depression (Miller et al., 2020). Although evidence is limited, mindfulness-based stress reduction has been found to reduce depression symptoms in older adults immediately after the intervention (Ho Li & Bressington, 2019). Some older adults may prefer or benefit from spiritual or religious support.

Integrated Care: Integrating mental health care into primary care has been found to increase quality of treatment for

© F.A. Davis Publishing

depression in older adults (Bruce & Sirey, 2018). Effective integrated care interventions include multidisciplinary care coordination, monitoring and screening for depression, treatment teams that include primary care and mental healthcare providers, and the use of guidelines for depression treatment in older adults (Bruce & Sirey, 2018).

Follow-Up:

- Use diagnostic scales/instruments (symptom and severity tools) to objectively assess progress compared to baseline evaluation.
- Assess for therapy and medication adherence, response, and adverse effects.
- Assess for suicidal ideation.
- Titrate medication dose for total remission.
- If medication trial is discontinued, then taper over 2 to 4 weeks.
- Monitor for early signs of recurrence.

Sequelae: Depression that is not identified and treated appropriately in older adults can be life threatening and debilitating. Late-life depression can increase risk of mortality in older adults, especially with older age, physical disability, and impairment in ability to perform activities of daily living (Cai et al., 2020). Complications of depression include impaired interpersonal relationships, interpersonal problems, increased medical comorbidity and medical risk factors over time, worsening of cognitive impairment, self-neglect, decreased mobility, increased disability, and increased mortality from suicide and interactions with medical conditions, such as cardiovascular and cerebrovascular disease. Depression can diminish health and overall life span.

Prevention/Prophylaxis: Minimizing risk factors can help to prevent incidence or exacerbation of late-life depression symptoms. Modifiable risk factors include nutritional deficiencies and cardiovascular disease (Van Damme et al., 2018). Interventions for these modifiable risk factors may include improvements in diet, exercise, sleep hygiene, nutritional supplementation, and smoking cessation (Van Damme et al., 2018). Stress reduction, strengthening support systems, and treatment of underlying medical conditions may also minimize depression risk in older adults.

Referral: Patients who should be referred to psychiatric providers include those experiencing prominent suicidal/self-harm thoughts or previous suicide attempts, a questionable diagnosis, suspected bipolar disorder or comorbid psychiatric conditions, persistent residual symptoms, and partial or no response to monotherapy, combination, augmentation, or adjunctive medications. For counseling, consider referring the patient to a psychiatric mental health nurse practitioner, a psychiatric clinical nurse specialist, licensed clinical psychologist, or other licensed therapist, and provide resources for support groups and appropriate service professionals and agencies.

Education: Patient and family education should include information about the disease process, risk factors, heritability, risk of relapse or recurrence, suicide risk, treatment strategies and recommendations, psychotropic medication use, side effects, length of time for medication efficacy, and use of herbs, vitamins, and supplements.

DIOGENES SYNDROME

Signal Symptoms: Social withdrawal, hoarding, neglected self-care and refusal of help

Description: Named after Greek philosopher Diogenes, known for his cynicism and contempt for social organization and his lack of shame, this complex syndrome occurs primarily in older adults. It is a constellation of symptoms that includes poor insight or understanding of self-hygiene and public health and safety; distrust of society and strangers, paranoia,

© F.A. Davis Publishing

or general suspiciousness; aloofness or detachment; extreme social anxiety; excessive hoarding; unsafe living conditions; poor nutrition; unwillingness to accept outside help; fear or distrust of medical professionals; hostility and aggression toward others; distorted concept of reality; and dermatitis passivate (Cipriani et al., 2012; Sacchi et al., 2021).

Occurrence: Fifteen percent of the population; 36% of those with Diogenes syndrome have frontotemporal dementia (Irvine & Nwachukwu, 2014;; Sacchi et al., 2021).

Age: Older than 60 years; average 79 years of age

Ethnicity: No significant difference.

Contributing Factors: Living alone, death of a spouse. Often initially confused for abuse or neglect, dementia, hoarding disorder, or severe depression (Sacchi et al., 2021).

Etiology: The pathogenesis is hypothetical. It does contain elements of acquired hoarding disorder. There does appear to be a higher incidence in those with frontotemporal dementia. This is believed to be a result of vascular lesions in the medial prefrontal or bilateral orbitofrontal cortex. Left lateral temporal lobe atrophy in frontotemporal dementia and obsessive-compulsive disorder may impair categorization of objects as unique and predispose individual to hoarding behavior (Sacchi et al., 2021).

Signs and Symptoms: Social withdrawal, depression, hoarding, self-neglect, and exacerbation of underlying medical conditions due to lack of care. Skin lesions and dermatitis passivate due to lack of washing, which forms a horny crust on the torso and extremities (Biswas et al., 2013; Cipriani et al., 2012; Irvine & Nwachukwu, 2014; Sacchi et al., 2021).

Diagnostic Tests: General panel of complete blood count (CBC), comprehensive metabolic panel (CMP) to rule out underlying medical problems. No specific tests for this syndrome because it primarily involves psychological conditions.

Differential Diagnosis:

- Dementia
- Paranoia
- Mood disorder
- Schizophrenia
- Hoarding disorder

Treatment: Medications for depression and hoarding have been found to be helpful. Paroxetine in doses of 20 to 40 mg has shown results in decreasing obsessive-compulsive disorder (OCD) symptoms. Recent studies have shown high-dose sertraline (100 to 150 mg) has decreased mood and behavioral symptoms. If psychotic symptoms are present, risperidone and quetiapine have shown positive results. Counseling and care management are recommended to deal with hoarding behavior. Skin lesions need to be manually removed. The patient may need to be treated for secondary cellulitis (Sacchi et al., 2021).

Follow-Up: As indicated for treatment of underlying medical conditions and skin management. Monitoring of medications and follow-up with referrals.

Prevention/Prophylaxis: None known because this is a complex and misdiagnosed condition.

Referral: Psychological counseling, cleaning and biohazard services, care management.

ELDER ABUSE

Signal Symptoms: Tell-tale signs indicative of abuse may include bruises, broken bones, poor personal hygiene, abrupt changes in finances, sudden withdrawal in normal activities, unexplained weight loss, and excessive power or control by a close family member or friend (Friedman et al., 2017).

© F.A. Davis Publishing

Description: The National Adult Protective Services Association identifies elder abuse as a form of mistreatment resulting in harm to a vulnerable person (Ejaz et al., 2022). It is a global public health problem that can be difficult to detect (Dong, 2015). *Elder abuse* is defined as any knowing, intentional, or negligent act performed by a caregiver or another person that may cause harm or risk of harm to an older adult who is vulnerable (NAPSA, 2021). Types of abuse include:

- Physical abuse: causing physical pain or injuring a vulnerable elder
- Sexual abuse: sexual contact with a vulnerable elder without their consent
- Neglect: failing to provide food, shelter, health care, or protection for a vulnerable elder
- Exploitation: the taking of funds, property, or any assets of a vulnerable elder without legal consent and not for the benefit of the elder
- Emotional abuse: using verbal or nonverbal means to cause mental pain, anguish, or distress in an elder
- Abandonment: deserting the vulnerable elder after someone has assumed responsibility for that individual
- Self-neglect: the elder fails to perform the needed activities to protect their own health and safety (lacks food/utilities, refuses medications, hoards, lives in unsafe conditions, neglects their grooming/appearance, is unable to handle finances, is isolated, is disoriented, develops a dependence on drugs and/or alcohol) (Pickens et al., 2021)

Elder abuse is highly underreported to authorities and is more common in the community setting compared to institutional settings. It is estimated that 0.6% to 5.2% of the older adult population experiences some form of abuse (U.S. Department of Justice, n.d.).

Etiology: Abuse of vulnerable older adults can happen in many settings, from private homes to long-term care facilities and hospital settings. The days when the family lived close by and took responsibility for its members are dwindling. Families are spread out and lack the close communication of past years. This separation leaves loved ones in closest proximity to older adults to be fully responsible for their oversight and care thus creating unforeseen stressors to the responsible family member. A lack of adequate support in these situations hampers individual's efforts in providing care and may play a role in perpetrating elder abuse. Common features of perpetrators committing elder abuse are partners or spouses living with the victim, history of alcohol or drug abuse, history of mental illness, history of unemployment, and being socially isolated (Amstadter et al., 2011).

Storey (2020) suggest that the abused older adult is more likely an older female. She generally has a physical impairment and is in poor health. She may either live alone, with the abuser, or in a household with many members. The perpetrator is generally found to be a male who has a history of past or current substance abuse, has mental health issues, is socially isolated, and has a history of past trouble with law enforcement. He may be financially dependent on the older adult and be under major stress.. According to Weissberger and colleagues, family members were the most common perpetrators in cases of elder abuse reported to National Center on Elder Abuse (2020). These cases result in an increased risk of death for the vulnerable older adult involved in the abusive situation.

Occurrence: The actual numbers of cases of elder abuse are difficult to quantify due to the variance in mandatory state reporting laws. Estimates include 1 in 10 Americans 60 years of age and older have experienced abuse, although others estimate the number to be 5 million. One study reported only 1 in 24 cases of elder abuse are reported to authorities (World Health Organization, n.d.). The National Elder Abuse Incidence Study states that for every one reported case of abuse there are about five that go unreported (Administration for Community Living, 1998). These numbers are expected to increase with the burgeoning of the older population.

Age: One out of every 10 older adults older than 60 years is a victim of elder abuse. Sixty percent of abusers are close family members.

Ethnicity: Occurs in all ethnic groups and socioeconomic classes.

Contributing Factors: Social isolation, frailty, physical or mental disability, and dependency are some of the contributing factors. Living with others can also be a risk factor for elder abuse.

Signs and Symptoms: The Administration on Aging provides several examples of potential abuse to observe in older patients. Physical signs include slap marks and unexplained burns or blisters, especially circular, as from a cigarette or other familiar object. Unusual bruising in areas that are not usually thought to be accidental can raise suspicion of possible abuse. Any bruising around breasts or genital area and/or unexplained sexually transmitted infections might indicate sexual abuse. Emotional abuse can be suspected if a patient withdraws from their normal activities or has an unusual change in their level of alertness or any other change in behavior that has not been previously observed. Furthermore, the inability to interview the individual alone may provide suspicion of elder abuse. Often, the affected victim fears placement in long-term care or being abandoned and, thus, tolerates the abuse (Powers, 2014).

The National Institute of Justice warns sudden changes in finances, unexplained changes to wills or trusts, unexplained bank withdrawals, and loss of property may indicate financial exploitation of an older adult. Signs of caregiver or self-neglect can be decubiti that are untreated, evidence of restraint use, suspicious bruising, medication nonadherence, lack of medical devices such as hearing aids or dentures, missed medical appointments, untreated medical conditions, unkempt appearance, refusal of care, and unusual weight loss (Boyle, 2020). These are all concerns that need to be followed up as possible signs of caregiver neglect or in cases of self-neglect, when no caregiver is involved (Ayalon, 2015; Pickens, 2021; Wong & Waite, 2017).

Diagnostic Tests: The basis to establishing a baseline of health is a head-to-toe examination of the patient in question. Having the patient unclothe to a patient gown will allow full examination of areas that may otherwise be hidden by clothing, socks, or shoes. It is important to examine the patient alone without the caregiver present. This individual time allows the practitioner to ask indirect and nonthreatening questions regarding abuse (because most older adults do not self-report abuse) followed by more direct questioning (Burnett et al., 2014; Lachs & Pillemer, 2015). Interviewing the caregiver separately may provide clues to

© F.A. Davis Publishing

differences in the victim and the alleged perpetrator's story regarding suspicious physical findings. The baseline examination will dictate the needed adjunct laboratory and imaging tests required to establish a diagnosis. If impairment in memory or alertness is suspected, a formal assessment of cognition and mood needs to be performed (Lachs & Pillemer, 2015; Pickens, 2021). In complex cases of suspected elder abuse, a referral to a geriatric team for a comprehensive geriatric assessment may be warranted (Burnett et al., 2014).

Differential Diagnosis:

- Unintentional injury
- Falls
  - Alcohol or substance abuse
  - Cancer
- Thin, friable skin with easy bruising

Treatment: If elder abuse is suspected, it is the health-care professional's responsibility—and in most cases a legal obligation—to report this to either 911 or the state elder abuse hotline (Boyle, 2020). Carefully collect information regarding the patient, using physical findings, cognitive screening, patient's functional abilities, testing results, and verbal information from the patient and their caregivers. Use an interdisciplinary team and speak with social workers, nursing staff, and others who may have interacted with the patient and caregiver (Ejaz et al., 2020; Rosen et al., 2019). Document all findings because they may be required to be presented in court later. Especially document any differences in verbal accounts between the patient and their caregiver. It is also prudent to photograph suspicious injuries, as well as measure or compare size of an injury with a familiar object if a ruler is not available (Cooper et al., 2009; Yonashiro-Cho et al., 2019). When a patient has dementia, a history can be difficult to evaluate. This collection of information will assist the adult protective services case workers in their case investigation. The information may protect the patient from further exploitation, neglect, or abuse. Be sure to follow up with the case workers to determine the outcome of the case. It sometimes takes several reports before the true picture of neglect, exploitation, or abuse can be investigated thoroughly, and the elder individual moved to a safe environment.

Follow-Up: After the elder abuse is reported, adult protective services will become involved and take action to protect the patient from further abuse. Contact them to obtain information on the outcome.

Sequelae: The older adult may need to be moved to a safe environment, such as a long-term care setting or the residence of another family member. There may be legal proceedings that can involve the health-care professional's testimony based on the observations and findings that have been carefully documented. The abuser may be incarcerated for their acts. Sometimes what is required is an evaluation of support in resources to assist the caregiver in improving their knowledge of the caregiving role. This requires education and counseling from community resources (Mosqueda et al., 2020). Unfortunately, risk of death increases in elder abuse cases (Lachs & Pillemer, 2015).

Prevention/Prophylaxis: Prevention can come in the form of education at multiple levels. The caregiver especially requires education on the patient's care. This can be done in part on regular clinical visits with the primary care provider, in community offerings, at Area Agency on Aging seminars, and with other local resources. In some communities, there are social workers and nurses who provide support services to families through private agencies. Respite programs can be accessed to lessen the stress on the caregiver by providing much-needed time for themselves. Adult day-care services are available in larger communities, as are meal services and other resources that can assist the caregiver in lessening the burden of providing care.

Health-care professionals need to incorporate routine screening of elder abuse in at-risk populations (Dong, 2015).

Referral: See Treatment for immediate referral. Access to information on National Adult Protective Services Association and resources available in your community can be found at NAPSA-Now.org.

Education: Education of health-care professionals also needed so that there is an understanding of those responsible for the care of older adults. Providing education on normal aging body expectations found in the older patient and what to do when there are red flags that require further investigation can help professionals provide better care for older adults.

Clinical Recommendation	Evidence Rating	References
Findings of this systematic review of elder abuse suggest elder abuse is common, particularly in underrepresented community-dwelling older adults. This review also confirms knowledge gaps, inconsistent definitions, and insufficient findings regarding intervention and prevention research in cases of elder abuse.	A	Dong, 2015
The state of current elder abuse research is comprised primarily of descriptive, observational case studies, no meta-analyses, and a few intervention trials. Little evidence is available that supports any intervention to prevent elder abuse. More rigorous elder abuse research and more investigators are needed.	A	Baker et al., 2016

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. For information about the SORT evidence rating system, go to https://www.aafp.org/afp/2004/0201/p548.html.

GRIEF AND BEREAVEMENT

Signal Symptoms: Societal and cultural terms of grief vary and must be taken into consideration when determining appropriate length of time for one to grieve. This is not standard for everyone, every culture, or every society; even though diagnostic criteria give a time frame, it should be used only as a guide. Most people will go through Elisabeth Kübler-Ross's five stages of grief: (1) denial, (2) anger, (3) bargaining, (4) depression, and (5) acceptance (Corr, 2020). The stages are not always linear, and a person can emotionally be in two stages at the same time; however, this has become widely accepted as the grief process. Deviations from this lasting longer than 6 months are considered abnormal (Meichsner et al., 2020).

Description: Unfortunately, grief is encountered frequently for older adults and is a natural response emotionally, behaviorally, and cognitively to a loss (Bui & Robert, 2020; Meichsner et al., 2020). According to the most recent edition of the *Diagnostic and Statistical Manual of Mental Disorders* (5th ed.; *DSM-5*; American Psychiatric Association [APA], 2013), bereavement is an intense sorrow and yearning for the deceased that can cause emotional pain. Complicated grief refers to the inability to cope with the loss or becoming "stuck" in the grief process. When the patient is unable to work through their grief, it intensifies and physical or psychological illness may occur; this type of grief is more intense and prolonged (Diolaiuti et al., 2021). Persistent complex bereavement, also known as prolonged grief disorder, can be diagnosed after more than 6 months of bereavement with persistent symptoms (APA, 2013).

Etiology: Loss or a significant change perceived as a loss. For older adults, the loss of a spouse or life partner is the most common and significant event (Diolaiuti et al., 2021). Other losses include loss of a parent, child, sibling, or close friend.

Occurrence: Almost one-third (32.5%) of persons aged 65 and older have been widowed (Medicine Encyclopedia, 2021). Among older adults aged 75 and older, 58% of women and 28% of men have been widowed at some point (Gurrentz & Mayol-Garcia, 2021). Grief and bereavement affect more women than men because life expectancy for women is higher (at 81.4 years prior to the COVID-19 pandemic and 80.2 years after 2020). It stands to reason that the longer one lives, the more loss one will endure.

Age: May occur at any age but becomes more repetitive as we age.

Ethnicity: The Hispanic population has a life expectancy of 78.8 years after 2020. The non-Hispanic White population has a life expectancy of 77.6 years after 2020. The non-Hispanic Black population has a life expectancy of 71.8 years after 2020 (Arias et al., 2021).

Contributing Factors: Length of illness, amount of suffering, relationship quality, survivor guilt, financial burden of illness, caregiver burden, personality attributes of deceased and survivor, and religious and cultural expectations all may be related to the variety of grief responses (Diolaiuti et al., 2021). Losing a loved one during the COVID-19 pandemic has caused increased grief symptoms in the bereaved individuals (Diolaiuti et al., 2021; Szuhany et al., 2021). When an older adult loses a family member that they were a caregiver for, their grief may be twofold, not only of the loss of a loved one but grieve the loss of the role of caregiver (Mason et. al., 2022).

The provider needs to inquire about substance use such as alcohol or marijuana. Alcohol is the most commonly used and abused substance among older adults and the use of marijuana is significantly increasing among older adults (National Institute on Drug Abuse [NIDA], 2020). Sometimes, grief turns into addiction when the grieving person uses a substance to avoid or distract them from feeling the severity of a loss (Juergens, 2020). Providers must be aware of this possibility and be able to pick up on signs and symptoms.

Signs and Symptoms: Grief is characterized by anxious and depressive symptoms including the inability to relax, feelings of impending doom, poor appetite and weight loss or compulsive eating and weight gain, sleep disturbance, tearfulness, anhedonia, avolition, difficulty concentrating, withdrawal and isolation, emptiness, indecisiveness, guilt feelings, and possibly suicidal ideation.

Diagnostic Tests: Patient interview and obtaining collateral information form sources who know the patient best, if possible. The Generalized Anxiety Disorder – 7 Scale and the Patient Health Questionnaire – 9 (PHQ-9) should be used to assess symptoms of anxiety and depression. The Brief Grief Questionnaire (BGQ) is a very quick and easy tool to use to assess for complicated grief and can be found at https://complicatedgrief.columbia.edu/professionals/complicated-grief-professionals/overview/. The Grief Intensity Scale is a free online tool that is diagnostic for prolonged grief disorder and can be found at https://endoflife.weill.cornell.edu/research/grief-intensity-scale.

Differential Diagnosis:

- Generalized anxiety disorder (GAD)
- Major depressive disorder (MDD)
- Adjustment disorder
- Post-traumatic stress disorder (PTSD)
- Persistent complex bereavement disorder

Treatment: If the person meets diagnostic criteria for any of the above, then starting appropriate medications is warranted. The provider and patient should have a discussion and determine whether medications are needed and decide on the best medication for the individual person. Appropriate classes of medications to consider are selective serotonin reuptake inhibitors (SSRIs), serotonin-norephinephrine reuptake inhibitors (SNRIs), or buspirone. Tricyclic antidepressants (TCAs) are fatal in overdose and should not be used in these cases.

Referral: Provide emotional support and refer for therapy. Patients should understand therapy and medications together have the best outcomes (Szuhany et al., 2021). Referral to support groups should be considered. A card or letter from

© F.A. Davis Publishing

professionals who cared for the deceased is also recommended. Reaching out to the surviving spouse in the early bereavement period is also helpful. Complicated grief treatment is an evidenced-based treatment that has seven themes focused on adaption to loss and resolving impediments. The themes are "accepting grief, managing emotional pain, thinking about the future, strengthening relationships, telling the story of the death, living with reminders, and connecting with memories" (Meichsner et al., 2020, p. 564). Encourage patients to return to their normal routine as soon as possible. Daily physical exercise can help patients cope with the depression that accompanies grief. If the primary care provider does not feel comfortable in treating the grieving older adult, then a referral to a psychiatric mental health nurse practitioner or psychiatrist should happen sooner rather than later.

Follow-Up: This person needs close and careful monitoring with weekly to monthly visits and phone calls in between visits.

Sequelae: In the first 3 months after the death of a spouse, older adults are prone to the *widowhood effect*, which is the increased mortality risk of being a widow. Some studies show men having a higher mortality risk and some show women having a higher mortality risk, but a systematic review indicated the risk of mortality to be between 19.2% and 48% regardless of the cause of death. Mortality can be as high as 90% immediately following bereavement. Men are at a higher risk of cardiovascular issues, and men with preexisting cardiac conditions have an even higher mortality rate (Ennis & Majid, 2021). Persons with mental health conditions may experience a relapse of symptoms during bereavement (Meichsner et al., 2020).

Prevention/Prophylaxis: If the loss can be anticipated, the goal is to encourage and support the patient in the normal grieving process and prevent dysfunctional grieving. Activation of social and spiritual support networks, discussion of anticipated loss, and involvement in support group activities or volunteerism may be helpful. If the patient was in palliative care, bereavement support and grief counseling are available to the family for 13 months. Often, this process begins before the death of the loved one.

Education: Make patients and their support networks aware of the variability of normal grieving; alert them to signs of dysfunctional grieving and resources for help. A helpful resource for survivors and families is www.nlm.nih.gov/medlineplus/bereavement.html. This site has information on usual and complicated grief written for the general public.

INSOMNIA

Signal Symptoms: Patient report of not sleeping, excessive daytime sleepiness, loud snoring (potential sleep apnea), restless legs, difficulty falling asleep, difficulty staying asleep, early morning awakening, sleep that is not refreshing and restful (Winkleman et al., 2021).

Description: Normal age-related changes have significant effects on sleep. Sleeping states and sleep schedules change with age. For example, peak sleepiness happens earlier in the evening for the older adult, but this time for bed does not fit societal norms, so the person often ignores this. In older adults, sleep during early morning hours is reduced. As we age, time to sleep, sleep efficiency, rapid eye movement (REM) sleep, slow-wave sleep (the deepest, most restorative sleep), and REM latency are all reduced. Sleep latency is slightly increased, and wake after sleep onset is increased in older adults. Sleep efficiency (time sleeping versus time in bed) is less than 80% in older adults, and time to fall asleep is extended (Feinsilver, 2021).

© F.A. Davis Publishing

Etiology: Insomnia can have several etiologies, including medical conditions, side effects of medications, substance use disorders, circadian rhythm disorders, or psychiatric conditions. Chronic insomnia lasts more than 1 month and results from age-related changes in sleep and chronic stressors (Bonnet & Arand, 2021).

Occurrence: Sleep disturbances increase with age (Feinsilver, 2021). Insomnia symptoms are present in as much as 65% of people aged 65 and older (Matheson & Hainer, 2017). Approximately 30% to 48% of older adults have insomnia (Patel et al., 2018) and 57% are affected by chronic insomnia (Abad & Guilleminault, 2018). Insomnia is more prevalent in women; older adults; those who have lost a family member; those who are unemployed, divorced, widowed, or separated; those of lower socioeconomic status or no higher education; or in those going through withdrawal from alcohol or opiates (Matheson & Hainer, 2017; Tsaras et al., 2021). Additionally, researchers have already linked the COVID-19 pandemic to insomnia and sleep-related disorders in older adults. It is also plausible that decreased sleep may increase one's vulnerability to be infected with SARS-COV-2 and for them to have a poorer prognosis (Pires et al., 2021).

Age: More common in older adults than any other age-group and continues to increase as one ages from the 65+ age-group to the 85+ age-group (Matheson & Hainer, 2017; Pires et al., 2021). Persons with chronic comorbidities (medical and psychiatric) are also at higher risk (Matheson & Hainer, 2017; Pires et al., 2021). Women are more likely to have insomnia and twice as likely to be diagnosed (Matheson & Hainer, 2017) but men have more insomnia in the over-85-years age-group (Bonnet & Arand, 2021).

Ethnicity: Starting with the least amount of sleep per night is Native Hawaiian/Pacific Islanders then Black, multiracial, American Indian/Alaskan Native, then Hispanic. Individuals who are White report having the most amount of sleep per night (Centers for Disease Control [CDC], 2017).

Contributing Factors:

- Sleep disorders such as restless legs syndrome or periodic limb movement disorder
- Sleep apnea
- Dementia
- Mood disorders (depression, anxiety)
- Bipolar disorders
- Substances such as caffeine, alcohol, nicotine, and stimulants
- Medications such as stimulants, antidepressants, glucocorticoids, NSAIDs, opioids, and diuretics can affect sleep (Murphy et al., 1994; Winkleman et al., 2021)
- Comorbid chronic medical conditions
- Poor sleep habits and poor sleep hygiene (Winkleman et al., 2021).
- Screen time: stop using electronic devices at least 30 minutes before bedtime (National Sleep Foundation, 2021)

Signs and Symptoms: A complete history should reveal a full description of the problems. Questions to be included include how often has the patient experienced insomnia (number of nights a week and for how long?). Patients may complain about difficulty falling asleep (a sign of anxiety) and staying asleep, frequent awakenings, early morning awakening (a sign of depression) and inability to return to sleep, daytime fatigue with unwanted naps, irritability, or difficulty concentrating. Patients should be questioned about their use of caffeine to include amount of caffeine consumed and time of day. Medications should be reviewed to determine whether insomnia could be medication related, especially if a new medication was prescribed or there has been an adjustment in dosage. Additionally, an older adult may spend 10 to 12 hours in bed at night trying to sleep. A pertinent physical examination should evaluate the systems associated with any medical conditions listed here. Falling may be a sign of insomnia. A mental status examination is useful in detecting cognitive or psychiatric disease (Bonnet & Arand, 2021).

Diagnostic Tests: Diagnosis is usually made on patient interview and obtaining sleep history. The sleep history should include an assessment of daytime sleepiness, fatigue, or sleep disturbance; the sleep environment; and the duration of symptoms. Additionally, information on frequency and duration of awakenings, sleep times, nap times, and lengths is important (Bonnet & Arand, 2021). Insomnia is a clinical diagnosis (Patel et al., 2018), verified by a sleep log. The Epworth Sleepiness Questionnaire can be used for patient's complaining of daytime sleepiness; however, it is not well validated in older adults (Feinsilver, 2021). The University of Pittsburgh has five different validated sleep questionnaires that a provider must obtain permission to use (https://www.sleep.pitt.edu/instruments/). The American Thoracic Society also has the insomnia severity index, which also requires permission to use. The Patient-Reported Outcomes Information System (PROMIS) sleep disturbance tool is a free and validated self-report tool for sleep–wake function (Northwestern University, 2021).

Wrist actigraphy monitors and stores data for up to 28 days and can be used to assess treatment response (Patel et al., 2018). Persons with insomnia tend to overestimate the time it takes them to get to sleep and underestimate their total sleep time (Bonnet & Arand, 2021). Polysomnography is not needed in the evaluation and diagnosis of insomnia, but it is used in the evaluation of sleep apnea or parasomnias (Patel et al., 2018).

Differential Diagnosis:

- Mood disorders such as depression and/or anxiety
- Inadequate sleep hygiene
- Medical problems
- Medication-related sleep disorder
- Substance-related sleep disorder

Treatment: Treat underlying or coexisting disorders. Changes in one's sleep habits and maintaining good sleep hygiene is the first step. Then, cognitive behavioral therapy for insomnia is considered first-line treatment (Pires et al., 2021). Mindfulness meditation is a successful treatment in motivated patients (Perini et al., 2021).

Medications for insomnia should be considered the last resort, not the first option. Melatonin, which is over the counter, is the safest medication to begin with and should be tried first. Over-the-counter (OTC) antihistamines are not considered safe for older adults due to their anticholinergic effects. They are also on the potentially inappropriate medication (PIM) list and should not be used for insomnia. Ramelteon (Rozerem), a melatonin receptor agonist, should be used for sleep onset insomnia (Neubauer, 2021). Lemborexant and suvorexant are

© F.A. Davis Publishing

orexin-receptor antagonists and should be used for sleep onset and sleep maintenance (Neubauer, 2021). Antidepressants are listed on the PIM list (Roux et al., 2020); however, low-dose mirtazapine is known to be sedating, but it may also increase appetite. Trazodone is used for insomnia, and it works for sleep onset and maintenance. Doxepin works on sleep maintenance. In older adults, avoid benzodiazepine hypnotics (estazolam, flurazepam, temazepam, triazolam, and quazepam) if possible because these have significant side effects in the older adult, are addictive, and are on the PIM list (Neubauer, 2021; Roux et al., 2020). The benzodiazepine receptor agonists (eszopiclone, zaleplon, and zolpidem in all forms) also have adverse risks for older adults, are also on the PIM list, and should not be used unless necessary (Neubauer, 2021; Roux et al., 2020). All these medications have interactions among substrate systems and the provider must be aware of that prior to prescribing.

Safe prescribing practices include (Neubauer, 2021):

- Prescribe the lowest possible effective dose.
- Do not prescribe more than the maximum dose.
- Educate the patient on not combining with substances such as alcohol or other sedatives.
- Do not provide refills until continued use has been deemed necessary.
- In older adults, use all these medications with caution.
- Assess for suicidal ideation in persons with comorbid depression.
- Educate the patient on proper timing of medication and half-life properties and when not to use.
- Discuss risk of next day impairment.
- Discuss risks of taking these types of medications and driving.
- Know the substrate systems and any potential interaction.

Follow-Up: Patients should return in 2 weeks. If the patient has a bed partner, this person should be interviewed as well. Examine the patient's sleep diary and evaluate the effectiveness of the treatment. If indicated, reevaluate the diagnosis and restructure the treatment. Pharmacological therapy should be considered a last choice and every effort should be made to wean the patient from these as soon as possible and/or avoid long-term use.

Sequelae: Includes reduced quality of life, depression, increased risk for falls/injury, and potential for drug dependence or drug interactions resulting from use of OTC sleep aids.

Prevention/Prophylaxis: The tips for better sleep from World Sleep Society (2020) include:

- Establish a regular bedtime and wake-up time.
- Avoid napping in excess of 45 minutes.
- Avoid alcohol and nicotine.
- Avoid caffeine 6 hours before bedtime.
- Exercise on a regular basis but not right before bed.
- Create an optimal sleep environment: temperature between 60°F and 67°F, comfortable bedding, turn off all lights and distracting noises, charge phones outside of the bedroom.
- Reserve your bed for sleep and sex.
- Avoid heavy, spicy, or sugary foods 4 hours before bedtime. A light snack is preferred.
- Maximize daytime exposure to bright light.
- Set aside a time each evening for relaxation and thinking.
- Maintain a sleep log or diary if having difficulty with sleep.

Referral: If therapy brings no improvement and other underlying causes have been eliminated, refer the patient to a sleep laboratory for evaluation.

Education: The National Sleep Foundation recommends 7 to 8 hours of sleep being optimal for older adults with a range of 5 to 9 hours being acceptable (2021). Explain age-related sleep changes to the patient and their family. Teach the patient to follow the guidelines listed under prevention/prophylaxis.

SUBSTANCE-RELATED AND ADDICTIVE DISORDERS

Signal Symptoms: Variable due to the substance-related disorders, craving, pinpoint pupils, constipation, confusion, drowsiness, anxiety, behavioral changes, impulsivity, personality changes

Description: These disorders, gambling disorder (GD), alcohol use disorder (AUD), and substance use disorder (SUD), commonly occur together.

According to the general criteria put forth by the *Diagnostic and Statistical Manual of Mental Disorders* (5th ed.; *DSM-5*; American Psychiatric Association [APA], 2013), diagnoses of SUD, AUD, and GD are closely related and include impaired control, social impairment, and risky use. The individual may drink more than intended, use substances more often than intended, or spend more money

© F.A. Davis Publishing

than intended. The individual may have tried to cut down or stop using substances or stop gambling without success. They spend an inordinate amount of time obtaining access to the substances or behaviors, using, and recovering from using or participating in these behaviors. Sometimes, when the cravings are so intense and the use disorder is severe, all activities in the day are directed at obtaining the substances or the gambling applications. All these disorders also manifest as a social impairment in one way or another, either isolation or entering relationships that are uncommon for that person. Risky use implies that use of the substance, alcohol, or gambling causes the individual discomfort in some way, either physically, socially, mentally, or financially. Cravings are defined as intense desire for the substance, alcohol, or gambling behavior and may occur anytime, but generally occur where the behavior usually occurs.

SUBSTANCE USE DISORDER

The *DSM*-5 definition (APA, 2013) of SUD includes the following substances: amphetamines, cocaine and other stimulants and combined stimulants, caffeine (intoxication and withdrawal), cannabis (with withdrawal symptoms), phencyclidine and other hallucinogens, inhalants (no withdrawal syndrome), tobacco, opioids, sedatives, hypnotics, and anxiolytics. Other substances included in this category include psilocybin, MDMA (Ecstasy/Molly), ketamine, Kratom, synthetic cathinone (bath salts), and synthetic cannabinoids. The use of prescription medications for reasons other than intended and "borrowing" a medication or other substance such as loperamide (used as an opioid alternative and has been linked to overdose) for pain or insomnia, are also included in SUD (Bulloch, 2018).

Substance use disorder in older adults is increasing, in part because many substances were not classified as dangerous or addicting in older generations. For example, heroin, whose name came from the sense of feeling "heroic," was used in the civil war and used in cough preparations and over-the-counter (OTC) products until it was clear that the product was addictive. It became a Class I controlled substance in 1924. Benzodiazepines were widely prescribed in the 1960s to help women cope with the stressors of raising children (Pyle, 2020). Until the addiction potential was discovered and the *DSM*-5 included Sedative, Hypnotic and Anxiolytic Use Disorder DSM-5 304.1 F13.1 (APA, 2013), which identified substance use resulting in distress or functional impairment, specified by the drug, and graded on a continuum from mild to severe, benzodiazepines have been considered a useful and commonly used treatment.

Cannabis is now a legalized entity for recreational use in many states, and many have changed their attitudes toward its use. Prior to that, use of medical marijuana was legalized in most states for multiple issues including chronic pain, seizure disorders, cancer, multiple sclerosis, fibromyalgia, and other chronic pain issues that would be anticipated to last a significant period. According to the National Survey on Drug Use and Health (NSDUH), use of marijuana among older adults is on the increase since over a decade ago (Han & Palamar, 2020).

GAMBLING DISORDER

Frequent trips to the casino, gambling on smartphones and online, the need to bet higher amounts of money, believing that the next bet will be "the winner" (also known as chasing one's losses) are some symptoms of GD. Other characteristics identified in the *DSM*-5 include preoccupation with gambling, persistent thoughts about past experiences, planning the next trip or how to download an app, gambling when feeling distressed, lying to conceal the extent of involvement with gambling, and jeopardizing or losing a significant relationship, job, or career opportunity because of gambling. Relying on others to provide money to relieve a difficult financial situation because of gambling is also part of the criterion for GD.

Individuals older than the age of 65 tend to have a lifelong history of problem gambling. The population at risk for GD is heterogenous and is at risk secondary to multiple motivations for beginning or maintaining gambling. Laws regarding gambling have loosened in the past 5 to 10 years in multiple states. Gambling programs can be accessed online and, in some states, advertisements for gambling programs are prevalent. Risks for gambling behaviors include retirement, social isolation, reduced social contact, physical-mental disease, or the loss of a partner.

Abbott and associates (2018) looked at the two types of gambling preferences. Nonstrategic games involve little or no decision making or skill and where the participant cannot influence the outcome. These include slot machines, bingo, scratch tickets, keno, and lottery games. The second game type includes those in which gamblers attempt to use their knowledge to influence the outcome. Some examples include poker, sports betting, craps, and blackjack.

Granero and associates (2020) identified two clusters of gamblers. Cluster 1 had a low risk of problem gambling and participated in nonstrategic games of chance or did not gamble at all. This group included women: older, lower education and income levels, fewer total number of life events, better psychopathological state, and lower prevalence of substance use. Cluster 2 included the higher proportion of men: married, higher levels of education, higher incomes, higher mean number of cumulative events, worse psychopathological states, and higher prevalence of substance use. All the members of cluster 2 met criteria for GD. Members of cluster 2 also had a higher propensity for AUD and SUD.

ALCOHOL USE DISORDER

A common controversy in AUD is the claim that moderate consumption of alcohol is healthy and is associated with decreases in mortality and morbidity. Yet studies have shown that the risk of mortality increases with heavier drinking (Hartz et al., 2018). The definition of moderate alcohol use is usually ≤1 drink per day (Kueber et al. 2014).

Etiology: Dopamine is a key chemical in the pleasure center of the brain. Substances, rewards, even sitting down at a screen can stimulate the release of dopamine, which then stimulates the reward center in the brain. The frontal lobes of the brain are involved in executive functioning and oversee voluntary actions such as reasoning, thinking, movement, decision making and planning. The amygdala is a cluster of cells involved in the limbic system of the brain that is responsible for the emotional and behavioral responses to stressors and events as well substances. The amygdala is responsible for preserving memories and specific emotions. It is also responsible for initiating the fight-or-flight response. On occasion, the frontal lobes are disabled in an event called an "amygdala hijack" where reasoning and executive function is diminished.

© F.A. Davis Publishing

Occurrence: According to the National Institutes of Health (NIH, 2020), nearly 1 million adults aged 65 and older live with SUD as reported in the 2018 data. The number of older adults who engage in unhealthy behaviors is expected to increase significantly as Baby Boomers age. Alcohol is the most used drug among older adults, with about 65% of people 65 and older reporting high-risk drinking, defined as exceeding daily guidelines at least weekly in the past year (NIH, 2020). Binge drinking is also of concern. More than a tenth of adults aged 65 and older currently binge drink (NIH, 2020). During the early months of the COVID-19 pandemic, 1 in 10 older adults reported an increase in their drinking (Eastman et al., 2021).

Smoking cigarettes is still the most common form of tobacco use. The highest rates of smoking occur for those 45 to 65 years old. In those persons older than 65, only 8.2% reported smoking in 2020. Currently, LGBTQ+ adults were more likely to be current smokers than heterosexual adults. Current smoking by adults is higher in the Midwest and lowest in the West (Centers for Disease Control and Prevention [CDC], 2020).

The prevalence of problem gambling among older people ranges from 0.3% to 10.4% in studies of those older than 55 years of age (Guillou Landreat et al., 2019).

Age: An evaluation of death certificates in the United States (White et al., 2020) reveals that the overall rates of alcohol-related deaths are more than four times higher among middle-aged and older adults aged 45 to 74 than those in an age bracket of 25 to 34. The baby boomer generation (those born between 1946 and 1964) has significant differences in attitudes and uses of alcohol and recreational use of illicit substances (Han & Moore, 2018).

Contributing Factors: Being male, being a woman who identifies as lesbian or as a woman who has sex with women, major life changes, and losses are contributing factors to AUD and SUD (Selix et al., 2020). Additionally, aging itself is often associated with an increased risk of medical conditions involving pain, and alcohol and other substances are often used to cope with pain. This practice itself results in poorer health outcomes. Other contributing factors include:

- Cultural attitudes toward drinking and intoxication
- Happy hour
- Free casino bus trips
- The availability of alcohol and substances
- Acquired personal experiences with alcohol
- Exaggerated positive expectations of the effects of alcohol and substances
- Persistent stress levels
- LGBTQ+

It is unclear whether risky drinking in older people represents a pattern of continued use, a return to use after a period of abstinence, new onset of use, or a combination of all these patterns. As adults move into the retirement years, many life changes occur. For instance, stressful late-life events, loss of productive social roles, loneliness, and the absence of supportive social relationships, to name a few. Additionally, drinking habits acquired in early life continue to be maintained through the life span. Several genetic markers have been studied, and a clear case for biological heritability has been established as one factor. Neurotransmitter effects from alcohol and alterations in brain anatomy in patients with alcohol use disorders as well as genetic makeup serve to reinforce the biological connection (Setka, 2018). Consistent with the complexity of substance use disorders, multiple pathways appear to contribute to substance use disorder.

Concerns about alcohol consumption in the older adult are directed primarily toward the physiological changes that accompany aging and the problems posed by regular alcohol consumption. Chemical breakdown of alcohol does not seem to change with aging; however, the changes associated with aging may increase the concentration of alcohol in the blood. These age-related changes include decreased lean muscle mass, decreased amount of body water, changes in liver function, and increased nervous system sensitivity to alcohol. After drinking one ounce of 80-proof alcohol, a 60-year-old would have a 20% higher blood alcohol level than a 20-year-old, and a 90-year-old would have a 50% higher blood alcohol level than a 20-year-old (Gilbertson et al., 2009). Patterns of AUD in older adults have been divided into two categories: early onset and late onset. See Table 20-10 for a comparison of the two categories.

Lower socioeconomic status is a frequently associated with gambling. Additionally, alcohol use, living in a neighborhood with limited resources, and being African American or Native American are common contributing factors in those with GD (Barnes et al., 2017). Pathological gambling has been observed in patients with Parkinson's disease, particularly those who are younger and that have a personal or family history of alcohol abuse (Heiden et al., 2017). Case reports have described patients diagnosed with frontotemporal dementia as exhibiting pathological gambling behaviors (Battista et al., 2019; Tondo et al., 2017).

Signs and Symptoms:

SUD: Many older adults are solitary, so problematic use is hidden. One way that substance misuse comes to light is when older adults are brought to the emergency department due to events related to their problem behavior. Other

TABLE 20-10 Patterns of Alcohol Use Disorder

VARIABLE	EARLY ONSET	LATE ONSET
Age at onset	Teens and twenties	Later life
Sex	Male	Female
Socioeconomic status	Low	High
Family history of alcoholism	Yes	Less likely
Physical dependence and withdrawal	Typically, have	May never become physically dependent
Cognitive damage	Less reversible	More reversible
Death related to alcohol	More likely	Less likely

© F.A. Davis Publishing

symptoms possibly related to substance misuse include falls, confusion, anxiety, insomnia, paranoid ideation, stroke, pneumonia, pancreatitis without stones, respiratory depression, hypotension, and delirium (National Institute on Alcohol Abuse and Alcoholism [NIAAA], n.d.).

GD: Symptoms may include suicide attempts, homelessness, depression, anxiety, paranoia, and other psychiatric disturbances. Physical signs that may be present on examination include tachycardia, atrial fibrillation, peripheral neuropathy, physical trauma, tremulousness, hepatosplenomegaly, rhinophyma, inconsistent or mild hypertension, and telangiectasias.

AUD: For older adults with AUD, physical examination findings may include hepatomegaly, ascites (late stage), jaundice (with pancreatitis), anemia, electrolyte imbalance, tremors, tachycardia, nausea, vomiting, insomnia, and spider angiomas; men may have gynecomastia, testicular atrophy, and loss of pubic and axillary hair. A complete neurological examination that includes cranial nerves, gait, sensory, motor, reflexes, Romberg sign, and tandem walking should be included.

Diagnostic Tests: The contemporary approach to the screening and intervention with individuals who may have at-risk, or problem use of substances is called Screening, Brief Interventions, and Referral to Treatment (SBIRT), which is an evidence-based practice used to identify, reduce, and prevent problematic use, abuse, and dependence on alcohol and illicit drugs (Hargraves et al., 2017). Diagnostic assessment depends on a thorough history.

As a part of screening, several tools can be used. Probably the most familiar screening test is the CAGE questionnaire originally developed, tested, and reported in 2001 by Hinkin and colleagues. This questionnaire has excellent sensitivity but poor specificity. However, the ease of use in the older adult for both alcohol and drug abuse make this a valuable screening tool. Primary prevention also includes the use of the Michigan Alcoholism Screening Test – Geriatric version (MAST-G). The MAST-G varies from the MAST in that questions are modified in relation to social and retirement situations. The MAST-G has a sensitivity of 93% and a specificity of 65%. Use of this tool can then direct the clinician in the screening, brief intervention, and referral to treatment also known as SBIRT. A GD tool has been developed by Molander and colleagues (2019). Labeled the G-DIT, the screening test is based on 47 gambling measures and is being tested clinically.

A psychosocial assessment that includes a mental status examination and a geriatric depression scale should also be performed. Additionally, consider a cultural assessment if appropriate.

Drug screening has evolved significantly over the years. Drug testing can not only identify the presence or absence of the drug and metabolite, but drug screening can also be used to monitor success in treatment programs. A broad definition is used to confirm the recent use of a substance and various sources can be used such as hair, nails, blood, breath, and saliva. Confirmatory assays have matured to increase confidence in the result of the testing.

Differential Diagnosis:

- Nonpathological use of alcohol; drinking, even daily, in low doses and occasional intoxication does not by itself identify misuse.
- Recreational use of marijuana in states where it is legal
- Misuse or a use disorder of other psychoactive substances such as opiates, benzodiazepines, or other psychoactive drugs
- Dementia
- Cerebrovascular accident
- Urinary tract infection
- Gastritis
- Pancreatitis also should be considered

Treatment: According to the USDA and HHS Dietary Guidelines for Americans 2020-2025, healthy adults older than the age of 65 (who do not take medications) should limit their daily alcohol consumption to one drink a day or less for women and two drinks or less for men in older adults. Older adults with health problems or who take medications that may interact with alcohol or substances should abstain from using alcohol or substances altogether. Going to casinos should be limited and attending events where liberal use of alcohol may be an issue should be of concern. The level and severity of alcohol use and misuse as well as substance use and misuse determine the treatment. Patients in physical distress such as alcohol withdrawal, respiratory depression or those who are hemodynamically unstable should be admitted to the hospital. Uncomplicated or mild alcohol use disorder can be treated in the outpatient setting.

The Substance Abuse and Mental Health Services Administration (SAMHSA) provides an in-depth guide to treating SUD in older adults with evidence-based interventions. It is available for download at https://store.samhsa.gov/sites/default/files/SAMHSA_Digital_Download/PEP20-02-01-011%20PDF%20508c.pdf

Alcoholics Anonymous (AA) and Narcotics Anonymous (NA) are the most successful groups in encouraging ongoing sobriety; however, the self-sufficient spirit, often characteristic of older adults, reduces the probability of participation. An AA/NA volunteer of the same gender and of an age comparable to the patient's age is usually available to meet with an individual at the clinic site and can assume the role of the patient's sponsor, reducing fear and providing the support that may encourage group participation. For older adults, people who are important in their lives need to be instructed by counselors in ways to encourage the treatment process and decrease behaviors that enable the older adult to misuse alcohol.

After consultation with an addiction specialist, naltrexone may be given to help maintain abstinence in healthy patients; naltrexone can be used in patients with opioid use disorder, not currently using opioids, and requires proper supervision, and intensive therapies. For chronic alcoholism, the diet should be supplemented with multivitamins containing folic acid and thiamine, 100 mg/day. The patient should also be evaluated for electrolyte problems and anemia.

Opioid use disorder is a frequent problem after years of prescription of opioid use for the management of chronic pain. Dalal and colleagues report that buprenorphine is an effective treatment for chronic pain in patients aged 65 to 84 years (2021). Buprenorphine also decreased sleep disturbances but was associated with constipation, nausea, dizziness, vomiting and in some more frail patients, respiratory depression.

Follow-Up: Alcohol diminishes the effect of many medications and unpredictably strengthens the effects of sedatives. Certain medications are known as alcohol-interactive (AI) drugs that can be problematic: benzodiazepines, antidepressants, sleep

© F.A. Davis Publishing

medications, muscle relaxants, antipsychotics, anticholinergics, prescription narcotics, antihypertensives, antidiabetic, and cholesterol medications (Weathermon & Crabb, 1999). It is critical that patients with AUD are aware of these potential interactions and avoid the use of alcohol if prescribed these medications.

Following when treatment has begun for the substance related and addictive disorder, the older adult should be seen weekly to provide continuity in the practitioner–patient relationship and to monitor treatment effectiveness. When the patient is participating in the treatment protocol, monthly visits should be adequate to monitor progress.

Sequelae: A major concern associated with SUD in the older adult is the increased occurrence of drug-alcohol and drug-drug interactions. The decreased metabolism of drugs by the liver in older adults yields significantly higher-than-normal drug levels, and alcohol increases this effect. Alcohol is metabolized by the CYP2E1 enzyme. Consequently, drugs metabolized by that enzyme pathway will be affected. Alcohol also blocks an enzyme in the liver known as CYP2C9 (Lu & Cederbaum, 2018). Alcohol misuse can lead to gastrointestinal bleeding, especially if the patient is taking aspirin or arthritis medications. More than two alcoholic drinks daily can contribute to hypertension. Gait disturbances, peripheral neuropathy, and decreased functional ability are consequences of alcohol misuse. Malnutrition, cirrhosis, urinary incontinence, decline in cognitive status, insomnia, anxiety, addiction, and tolerance with concomitant withdrawal symptoms may occur. Substance misuse is very serious in that many forms of heroin and narcotics are mixed with manufactured fentanyl which is extremely dangerous secondary to overdose.

Suicide is associated with self-destructive behaviors at any point in the trajectory of SUD, AUD, and GD. Frequently, alcohol and substances are used to self-medicate for depression, anxiety, and other mental health issues. Gambling can contribute to the depression and can worsen anxiety and depression.

Prevention/Prophylaxis: Older adults have age-related risks for continued use that should be considered. Several risk factors have already been identified in this section. Alcohol and substance use/misuse as well as risky behaviors such as gambling are frequently used to combat feelings of loss, grief, depression, and social isolation. On the other hand, social interactions, happy hour, and group activities that also incorporate alcohol and substance use may not be negative. The severity of the implications of substance use/misuse in a person's life dictates the treatment.

Referral: Referral must be completed thoughtfully. Referral to AA or NA is common. The SAMHSA national hotline is 1-800-662-HELP and is a way to explain to families and patients how substance and alcohol treatment works. Refer to in-person or virtual counseling. Gamblers Anonymous is a newer organization to help men and women deal with gambling. Like AA, they have a 20-question survey to identify problem gambling. It is critical for the practitioner to be familiar with these services as well as services in the community so that referral is appropriate and functional.

Education: Education regarding substance use and abuse, alcohol use and abuse, and gambling behaviors all have similar challenges. It is crucial to use a nonjudgmental attitude and avoid stigmatizing terms. Treat people with substance use disorders with respect, caring and compassion. When people with addiction are stigmatized and rejected, it only contributes to the vicious cycle of substance abuse (Volkow, 2020).

Clinical Recommendation	Evidence Rating	References
The U.S. Preventive Services Task Force (USPSTF) Screening for Unhealthy Drug Use recommends screening by asking questions about unhealthy drug use in adults aged 18 years or older. Screening should be implemented when services for accurate diagnosis, effective treatment, and appropriate care can be offered or referred.	B	USPSTF, 2020
The USPSTF recommends screening for unhealthy alcohol use in primary care settings in adults 18 years or older, including pregnant women, and providing persons engaged in risky or hazardous drinking with brief behavioral counseling interventions to reduce unhealthy alcohol use.	B	USPSTF, 2020
APA recommends that patients be assessed for co-occurring conditions (including substance use disorders, other psychiatric disorders, and other medical disorders) that may influence the selection of pharmacotherapy for alcohol use disorder.	C	Reus et al., 2019
APA recommends that patients with alcohol use disorder have a documented comprehensive and person-centered treatment plan that includes evidence-based nonpharmacological and pharmacological treatments.	C	Reus et al., 2019
For patients with opioid use disorder, recommendations are buprenorphine/naloxone in any setting or methadone or buprenorphine/naloxone provided through an accredited opioid treatment program.	A	Management of Substance Use Disorders Work Group, 2021
Cognitive behavioral therapy has been shown to be especially effective for gambling disorder; however, there is a lack of research to associate a grade.	C	Menchon et al., 2018

A consistent, good-quality, patient-oriented evidence; B inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. CASE STUDY

Mrs. C. is a 69-year-old married woman who presents to your practice with a chief complaint of fatigue. She tells you that she is tired all the time, despite sleeping through the night. She is concerned she may be coming down with something. You ask her about other symptoms, and she confesses that she is under a lot of stress. Her husband has terminal cancer and is also depressed. He is still functional but has refused all interventions. Mrs. C. relates that she quit her job to take care of him, but it is "dragging her down" because he is so depressed. She has four children, three of whom are close by, but she feels she is bearing the burden herself, and the children do not realize what is happening. She tells you tearfully, "I want to have a life, too, before it is all over."

Review of her chart shows recent CBC and chemistry profiles that are normal, normal TSH, and normal EKG. There is a family history of alcohol abuse (her father) and suicide (a sibling).

1. What additional subjective data are you seeking?
2. What additional objective data will you be assessing for?
3. What national guidelines are appropriate to consider?
4. What tests will you order?
5. Are there any screening tools that you want to use?
6. What are the differential diagnoses that you are considering?
7. What is your plan of care?
8. Are there any *Healthy People 2020* objectives that you should consider?
9. What additional patient teaching may be needed?
10. Will you be looking for a consultation?

CHAPTER 21

Polypharmacy

Lori Martin Plank

Most experts agree that polypharmacy is an imprecise term that is utilized to describe the prescribing of many medications (five or more), as well as the prescribing of potentially inappropriate medications (PIMs), failing to prescribe necessary medications, and overprescribing (Chou et al, 2021; Khezrian et al., 2020; Pazan & Wehling, 2020). Older adults, particularly those with multiple chronic health conditions, most frequently experience polypharmacy. Polypharmacy is a global problem and occurs in a variety of health-care settings, including communities, hospitals, and long-term care settings (Chou et al., 2019; Gazarin et al., 2020; Jordan et al., 2021; Schneider et al., 2021; Sluggett et al., 2020).

Polypharmacy appears to be an unexpected consequence of advancing medical and pharmaceutical sciences, the development of clinical guidelines and evidence-based medicine, a rapid increase in the older adult population, and the desire to support those with chronic health conditions, especially older adults. Despite the recognition of the prevalence of prescribing PIMS to older adults over the past 40 years, many of the same problems remain because, especially near end of life (Ouslander, 2020). Currently, there is no shortage of research and publications on the dangers of polypharmacy, but change in the practice arena is slow. Research to date has not focused on demonstrating positive outcomes when polypharmacy is addressed (Baumgartner et al., 2020; Cross et al., 2020; Khezrian et al., 2020; Pazan & Wehling, 2020). A Cochrane review (Cross et al., 2020) found mixed results with using behavioral and educational measures to promote adherence in older adults with multiple medications.

Polypharmacy contributes to increased health-care costs and utilization (Clark et al., 2020). In addition to multimorbidity, obesity and metabolic syndrome and history of smoking are factors associated with polypharmacy (Khezrian et al., 2020). Clinical outcomes associated with polypharmacy include falls, frailty, functional and cognitive decline, hospitalization, and even mortality (Pazan & Wehling, 2020).

This chapter will examine polypharmacy trends and consequences in older adults, including underprescribing, overprescribing, and misprescribing; adverse drug reactions (ADRs) as an outcome of polypharmacy; iatrogenic illness related to drugs; specific areas of concern in prescribing for older adults; pharmacodynamics and pharmacokinetics that may affect safe prescribing in older adults; recommendations for safe prescribing in older adults; and recommendations for deprescribing, including tools.

PHARMACOKINETICS AND PHARMACODYNAMICS IN OLDER ADULTS

Certain changes occurring with the aging process alter the dynamic processes that drugs undergo to produce therapeutic effects. These changes involve the activities of pharmacokinetics (what the body does with the drug) and pharmacodynamics (what the drug does to the body). While all older adults will experience aging changes, the timing and extent will vary individually and are driven by biological mechanisms unique to the person, not chronological aging (Khan et al., 2019; Tam, 2016). Because of this individual response, close monitoring is required when prescribing pharmacotherapy for older adults.

Absorption

Absorption is the least affected pharmacokinetic change in older adults. Individual factors such as concurrent consumption of over-the-counter (OTC) drugs, including antacids, laxatives, and supplements, may alter the gastric pH, resulting in a less-favorable environment for the absorption of certain drugs. Calcium supplements or calcium-based antacids interfere with the absorption of iron products, whereas orange juice facilitates iron absorption—both by altering the acidity of the gastric pH. Some drugs are best absorbed when taken with food whereas others, such as levothyroxine, require an empty stomach for optimal absorption. Other factors in older adults that influence absorption include altered nutritional status and delayed gastric emptying, especially in those with diabetes (Andres et al., 2019; DiPiro et al., 2020; Katzung, 2021; Tam, 2016).

Distribution

Three physiological changes in older adults cause them to be more sensitive to the effects of drugs and more vulnerable to adverse reactions. Older adults generally have less lean body mass and more body fat; they have less total body water than younger adults. Serum albumin also tends to decline (Andres et al., 2019; DiPiro et al., 2020; Katzung, 2021). Body fat

© F.A. Davis Publishing

serves as a storage depot for lipophilic drugs, thus reducing the amount of circulating free drug available to act; this can also prolong the action of the drug as it is released over time. The decrease in lean body mass and total water volume cause hydrophilic drugs to be distributed in a smaller volume of water, so they are more concentrated than in younger adults. The decrease in serum albumin impedes the protein binding of drugs, so levels of free circulating drug are higher, intensifying the intended effect of the drug. Poor nutrition and dehydration also impact distribution.

Metabolism

The liver plays an important role in the biotransformation of many drugs. Whereas liver size is decreased in older adults, liver function tests are usually normal unless there is pathology such as hepatitis, liver cancer, nonalcoholic fatty liver disease (NAFLD), or cirrhosis—all of which affect drug metabolism (Katzung, 2021; Perumpail et al, 2017). Clinical studies suggest that certain drugs, including barbiturates, some benzodiazepines, and many psychotropics, are metabolized more slowly, prolonging their effect. Metabolism via the cytochrome P450 enzyme system is also less effective. Comorbid diseases affecting blood flow to the liver, such as heart failure, affect the ability of the hepatic system to metabolize drugs, as does severe malnutrition, which is common in older adults. Acetaminophen, an OTC analgesic, can cause severe liver injury and death when used in excess; this is important to note because many older adults use acetaminophen daily, and it is also contained in multiple cold and flu preparations, leading to unintentional overdose (Yan et al, 2018).

Elimination

The most profound pharmacokinetic change is reduced elimination of drugs. Most drugs are excreted in the urine via the renal system, although some are excreted in the feces via the biliary system and inhaled drugs via the lungs. Water-soluble drugs are excreted directly by the kidneys, and fat-soluble drugs are converted to water-soluble drugs by the liver first. Changes in kidney function begin in the fourth decade of life and continue to decline with each subsequent decade (Katzung, 2021). Therefore, by age 70 years an individual might reasonably have a 40% to 50% decrease in renal function, even in the absence of disease. These kidney function changes may prolong the half-lives of drugs. This is particularly important for drugs that are excreted unchanged in the urine and for drug categories known to be particularly nephrotoxic in older persons (e.g., radiocontrast materials, aminoglycosides, angiotensin-converting enzyme inhibitors, and NSAIDs). Drug accumulation resulting from decreased renal excretion is the most significant factor in adverse drug reactions in older adults (Triantafylidis et al., 2018). Serum creatinine is tied to lean muscle mass; because this muscle mass is significantly decreased in older adults, serum creatinine is not a valid indicator of renal function in older adults. Creatinine clearance should be used to evaluate kidney function in older adults when prescribing drugs (Andres et al., 2019; DiPiro, et al., 2020; Katzung, 2021).

Pharmacodynamics

Although some researchers believe that older adults are more "sensitive" to certain drugs, causing interactions between receptor and drug, evolving evidence shows that pharmacokinetic reactions and alterations in homeostatic mechanisms are responsible for these interactions. Drug responsiveness may vary depending on the patient's activity and stress levels and on the environment. For the most part, pharmacokinetic data from drug manufacturers demonstrates that older adults have higher plasma levels of a drug than younger adults, given the same dosage (Katzung, 2021), hence the directive to "start low, go slow" in prescribing for older adults. An exception to this is the blunted response of older adults to β-adrenoceptor agonists. Research continues in this area.

Adverse Drug Reactions

Studies have shown that adverse drug reactions (ADRs) are more common in older adults with polypharmacy (Scott et al., 2015). Multimorbidity, changes in pharmacokinetics, frailty, poor adherence to prescribed drug regime, and self-prescribing also contribute to ADRs (Zazzara et al., 2021). Some of the most frequent drugs implicated in ADRs include anticoagulants, antiplatelets, insulins, digoxin, oral hypoglycemics, NSAIDs, anti-epileptic agents, psychotropics, antipsychotics, diuretics, antibiotics, and drugs with anticholinergic activity (Pazan & Wehling, 2020). ADRs account for a significant number of emergency department visits by older adults worldwide, often requiring hospitalization. Failure to accurately diagnose an ADR can result in a prescribing cascade, where another drug is ordered to treat the side effect of one drug or the ADR, or the ADR is mistakenly diagnosed as another illness to be treated (Katzung, 2021). Providers treating older adults with polypharmacy need to have a high level of suspicion for ADRs when new symptoms present. Use of brown bag medication reviews, electronic medical record software alerts, and comprehensive and holistic geriatric assessment are helpful in preventing ADRs in community-based settings. Medication reconciliation upon discharge can detect any PIMs and correct them prior to hospital discharge; failure to do this can result in further ADRs after discharge (Weir et al., 2020).

COMPLEMENTARY AND ALTERNATIVE REMEDIES

Supplements including complementary and alternative remedies (CAM) are frequently implicated in ADRs in older adults. St. John's wort is one of the most used supplements, and studies have found some efficacy when it's taken for mild depression. However, it interacts with several other drugs, including warfarin, selective serotonin reuptake inhibitors (SSRIs [potential for serotonin syndrome]), benzodiazepines, statins, contraceptives, cyclosporine, and multiple drugs metabolized by the CYP450 enzyme system (Davies & O'Mahony, 2015; National Center for Complementary and Integrated Health [NCCIH], 2020).

Ginkgo is used for memory issues; it interacts with warfarin, heparin, and NSAIDs, leading to increased bleeding tendencies. Kava is used for anxiety. Kava interacts with dopamine agonists and antagonists as well as central nervous system (CNS) depressants. Valerian is used for insomnia; there are multiple drug-drug interactions, particularly with benzodiazepines, barbiturates, opioids, and other CNS drugs (Davies & O'Mahony, 2015; NCCIH, 2020). These are only a few complementary and alternative remedies, but clearly they are not benign substances, and their risk of drug-drug interaction is high. It is essential to elicit information on whether the older

© F.A. Davis Publishing

adult patient is taking any CAM or other OTC drugs during the initial encounter and all subsequent ones.

SEROTONIN SYNDROME

Serotonin syndrome is a serious, sometimes fatal ADR that occurs when two or more drugs with serotonergic activity are prescribed simultaneously or in such close succession that the initial drug has not been eliminated from the body (Scotton et al., 2019; Zazzara et al., 2021). A wide variety of drugs are potentially impacted including SSRIs, serotonin-norepinephrine reuptake inhibitors (SNRIs), monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants (TCAs), antihistamines, drugs of abuse, opioids, atypical antipsychotics, dietary and herbal supplements, and cold remedies (Scotton et al., 2019). Symptoms focus on three areas: altered mental status, ranging from insomnia, anxiety, and agitation to confusion; neuromuscular, including hyperreflexia, tremor, sustained clonus to rigidity with respiratory failure; and autonomic system from nausea, diarrhea, tachycardia, and hypertension to severe hyperthermia (Scotton et al., 2019). The combination of drugs along with altered pharmacokinetics in older adults are contributory factors; clinicians need to be alert to the possibility of serotonin syndrome when prescribing psychotropic drugs.

TARDIVE DYSKINESIA

Tardive dyskinesia (TD) is another ADR seen primarily with dopaminergic antagonist drugs, including first- and second-generation antipsychotic drugs and some gastrointestinal motility agents, usually after long-term use of these agents. Symptoms manifest as involuntary facial grimace and abnormal movements of the lips, tongue, face, and trunk. They are commonly seen in older adults, particularly females, with a history of schizophrenia, bipolar disorder, or schizoaffective disorder who have been prescribed dopamine antagonist agents. Symptoms are also seen less frequently in older patients with diabetes who are on metoclopramide for gastrointestinal dysmotility (Brasic et al., 2018). Best practices include patient education and consent prior to prescribing, prescribing the lowest possible dose that is effective, and considering alternative neuroleptics if symptoms of TD manifest. In many cases it is irreversible; however, changing to clozapine can decrease symptoms. Treatment of symptoms with valbenazine or botulinum toxin is successful in modulating symptoms in some cases (Caroff, 2020).

DRUG-INDUCED LUPUS ERYTHEMATOSUS AND DRUG-INDUCED SUBACUTE CUTANEOUS LUPUS ERYTHEMATOSUS

Drug-induced lupus erythematosus (DILE) and drug-induced subacute cutaneous lupus erythematosus (DSCLE) are iatrogenic illnesses occurring due to consumption of specific drugs over an extended timeline, usually years. DILE is an autoimmune disorder like systemic lupus erythematosus (SLE); however, it does not usually result in organ damage. Once the suspect drug is discontinued, DILE usually resolves within 6 months. Hydralazine, used in hypertension management, and procainamide, an antidysrhythmic are considered high risk drugs for DILE, with isoniazid as medium risk (He & Sawalha, 2018); the use of hydralazine and procainamide have declined as more efficacious drugs have been introduced. More recently, anti-tumor necrosis factor drugs (anti-TNF) used for rheumatoid arthritis, psoriatic arthritis, and inflammatory bowel disease have been implicated in DILE (He & Sawalha, 2018; Pan et al., 2021; Vaglio et al., 2018). DILE tends to produce higher autoimmune antibodies, particularly anti-nuclear antibodies (ANA), than known autoimmune diseases (Ferro et al., 2021; He & Sawalha, 2018; Pan et al., 2021; Vaglio et al., 2018; Yoshikawa et al., 2020). Symptoms of DILE include myalgia and arthralgia, sometimes with joint swelling, serositis, and fatigue. Proton pump inhibitors (PPIs), anti-TNF, chemotherapeutic agents, thiazide diuretics, anti-epileptics, terfenabine, calcium channel blockers (CCBs), and angiotensin-converting enzyme inhibitors (ACE-I) have resulted in DSCLE at lower levels than the DILE agents. Older adults are the primary patient population who are prescribed most of these drugs, so clinicians need to maintain a level of awareness about DILE and DSCLE (He & Sawalha, 2018; Pan et al., 2021; Vaglio et al., 2018; Yoshikawa et al., 2021).

ANTICHOLINERGIC BURDEN

The term *anticholinergic* refers to a wide variety of drugs that inhibit the action of the neurotransmitter acetylcholine, preventing it from binding to receptors on specific nerve cells, centrally and peripherally. As a result of this, involuntary muscle movement, mucus secretion, and digestion are reduced. Anticholinergic drugs are used therapeutically by older adults in the treatment of chronic obstructive pulmonary disease (COPD), asthma, overactive bladder, urinary incontinence, depression, psychosis, allergic rhinitis, Parkinson's disease, and gastrointestinal (GI) dysmotility and are given during surgery (Egberts et al., 2021; Green et al., 2019; Lisibach et al., 2021; O'Donnell et al., 2017; Stewart et al., 2021). Adverse effects of anticholinergic activity in drugs include dry mouth, dry eyes, constipation, blurred vision, urinary retention, heat intolerance, decreased sweating, cognitive impairment, delirium, confusion, increased heart rate, drowsiness, and dizziness (O'Donnell et al., 2017). A combination of factors, including altered pharmacokinetics in older adults, dosing and number of drugs with anticholinergic activity used by older adults, and extent of anticholinergic drug properties, results in an anticholinergic burden for many older adults. Several instruments have been developed by researchers to assess and quantify this anticholinergic burden (Egberts et al., 2021; Green et al., 2019; Lisibach et al., 2021; O'Donnell et al., 2017; Stewart et al., 2021); however, translation to clinical use is challenging. Drugs with strong anticholinergic qualities should be avoided or minimized in older adults due to safety (falls, cognitive changes), adverse effects, and quality of life issues. The Beers List and STOPP/START are two tools that recommend avoidance of anticholinergic drugs and list specific drugs with high anticholinergic activity. Two drugs frequently encountered with older adults include diphenhydramine (Benadryl®) and oxybutynin (Detrol®).

TOOLS TO ASSIST PROVIDERS TO AVOID PIMS AND POLYPHARMACY

As awareness of the dangers of polypharmacy evolve, the number of tools to prevent or alleviate it are proliferating. Several of the tools are focused on deprescribing. Two of the most widely used tools include the STOPP/START, Version 2 and the 2019

© F.A. Davis Publishing

BEERS list (American Geriatrics Society [AGS] Expert Panel, 2019; O'Mahony et al., 2015). STOPP/START (O'Mahony et al., 2015) is a tool designed to detect prescribing of PIMs. This screening tool of older persons' potentially inappropriate prescriptions (STOPP) consists of 80 clinically important criteria that relate to PIMs and can contribute to hospitalization for ADRs, including a brief explanation of each. This is used in conjunction with the screening tool to alert doctors to right treatment (START), which contains 34 criteria, supported by evidence, to remind prescribers to consider certain drugs that are appropriate for specific conditions but may be omitted. The expansion of the original STOPP/START added criteria on antiplatelet/anticoagulant drugs, drugs increasing anticholinergic burden, drugs impacting renal function, vaccines, analgesics, and urogenital drugs (Earl et al., 2020).

The Beers Criteria® (AGS Expert Panel, 2019) lists PIMs to be avoided in older adults; they are listed by drug category and by diagnosis. The 2019 update has several important revisions. Important additions among the nearly 70 modifications to the 2015 AGS Beers Criteria® were new medications, clarifications of criteria language and rationale, and the addition of selected drug-drug interactions. There is an additional article from the 2015 update (Hanlon et al., 2015) that details potential alternative drugs to those listed in the Beers Criteria®, which can be safely used in older adults. This is recommended to be used along with the 2019 update. The 2019 revisions include holistic information on nonpharmacological measures that are effective for specific conditions in older adults. The Beers Criteria® is not appropriate for patients on palliative care or hospice (AGS Expert Panel, 2019).

The STOPP/START and the Beers Criteria® are both valuable tools for prescribers, but they are not meant to be mandates for prescribing. Clinical judgment, knowledge of the patient who has the disease, clinician and patient shared goals, risk–benefit considerations, and quality of life all factor into decision making for individual patients. There may be times when drugs on these lists need to be prescribed; however, this should be done with full awareness of the aforementioned factors and the need for monitoring. Additional tools for deprescribing are listed in Table 21-1.

PREVENTING POLYPHARMACY/ ADDRESSING POLYPHARMACY

One of the first requirements for clinicians in preventing polypharmacy is awareness of the problem. The Centers for Medicare and Medicaid (CMS) is permitting longer visit times with patients; this extra time can help providers carefully review and discuss the patient's health conditions and medications. Goals of care should be jointly identified and agreed upon by the patient and the provider; doing so will drive the plan of care, which should be holistic and evidence-based and include lifestyle and other nonpharmaceutical interventions as well as pharmacotherapy (AGS Expert Panel, 2012). Once the goals are established, medications are reviewed and discussed, including how they "fit" with the goals, and then a plan to meet the goals is devised. Communication with any specialty providers is essential for clarity and consistency. Programs such as the patient-centered health-care home

(medical home) or the 4 Ms (mentation, medication, mobility, what matters) are helpful in providing structure (Fulmer, 2018). Staff and patients/families should be educated about the initiative, including the need to elicit/disclose all OTC, supplements, herbal preparations, and recreational drugs when interviewing for medication history. At every visit, medications should be reviewed and updated. The following script is helpful:

- "I'm going to review your medications as we have them on your chart. As I go through each one, please confirm or let me know if it has changed. If there are any additions—vitamins, supplements, herbal preparations, or anything that you use from the pharmacy without a prescription—please let me know."
- "Are there any medications that you have stopped taking?"
- "Are you taking your medications as ordered?"
- "Is there anything that you want to discuss about your medications?"

The Medicare Annual Wellness Visit (AWV) or annual physical examination is also an opportunity to revisit goals of care and medications.

Although some hospitals have medication reconciliation with a pharmacist prior to discharge, hospitalized patients should be seen within 48 hours of discharge to review discharge instructions and clarify medications to be taken. Encourage patients to bring in any drugs that they were taking prior to hospitalization to this appointment. A study by Weir et al. (2020) found that one out of two hospitalized older adults were discharged on at least one PIM, leading to increased risk of ADR and rehospitalization. It is not uncommon for older adults to misunderstand or misplace discharge instructions and resume taking "at home" medications, which might have been responsible for their hospitalization. Transition of care visits or calls by nursing can identify and intervene to prevent PIMs and decrease the risk of rehospitalization (Tomlinson et al., 2020).

Research in the areas of primary care delivery at home (Schneider et al., 2021) and in long-term care (Jordan et al., 2021) demonstrate that polypharmacy is rampant, resulting in poor quality of care, increased risk of ADRs, and hospitalization in some of the frailest older adults. The same strategies being used in primary care to address polypharmacy are available to providers and staff, but there is a strong need for education to increase awareness of the problem and potential solutions. In long-term care, consistency in provider and care staff contributes to person-centered care and promotes trust in patients and family members (Jordan et al., 2019; Jordan et al., 2021).

Deprescribing and Appropriate Prescribing

Deprescribing is one step in the continuum of good medication management. It is the systematic process of reducing or discontinuing a medication, initiated by a health-care professional in conjunction with the patient/family within the context of polypharmacy or PIM use. The goal of deprescribing is to optimize medication management and improve patient outcomes, considering patient preferences, safety, efficacy, and principles of multimorbidity. Presently there is global agreement about the need to deprescribe, but efforts have fallen short of demonstrating improved patient outcomes (Baumgartner et al., 2020). Deprescribing is a proactive, holistic endeavor that goes beyond the usual patient encounter and challenges clinical inertia. Health-care provider and the patient/family come together to discuss the patient's health trajectory and goals of care in the context of medication management. Scott et al. (2015) outline a 5-step process to deprescribing:

1. **Review all medications.** The initial step is review of all medications, including those prescribed by any prescriber, OTC drugs used on a frequent basis, herbal remedies, and dietary supplements. Recreational drugs and alcohol use should also be included because they impact the total picture. Medication reconciliation can be accomplished by the provider, pharmacist, nurse, or trained medical assistant. For outpatient visits, the "brown bag" review is frequently used. It is important to confirm what medications the patient is taking and, if there is nonadherence, to discuss the reason for nonadherence. Issues such as prohibitive costs of medications, side effects, pill burden, and misunderstanding about the rationale or purpose of a medication can be discussed at this point. Alcohol misuse or dependency on recreational drugs needs to be addressed.
2. **Assess ADR risks from individual medications.** Having all medications and related substances together facilitates the identification of drug-drug, drug-disease, or patient-related factors that can contribute to ADR risk. Using a deprescribing tool such as the Beers Criteria® or STOPP/START facilitates the identification of PIMs currently being used by the patient (Earl et. al., 2020). Is there a risk for falls related to a specific medication? What is the patient's functional and cognitive status? How complex is the medication regime? (Gazarin et al., 2020; Krishnaswami et al., 2019; Scott et al., 2015).
3. **Evaluate each drug's potential for elimination.** Begin by obtaining input from the patient/family because their commitment is critical to successful implementation. Is there a drug with no compelling indication? Using a drug/disease/indication table can be helpful in determining this—long-term use of PPIs is one example. Is there a drug prescribed for symptom control that is ineffective or no longer needed? Is there more than one drug ordered for the same indication? Is there a drug that is cost prohibitive or requires multiple daily doses? What is the anticholinergic drug burden for the patient, and can that be reduced (Scott et al., 2015)? Best practice is to discontinue one drug at a time.
4. **Prioritize which drug needs to be reduced or stopped.** Consultation with patient/family is essential to determine the drug and timeline for deprescribing. Patient/family education is important so that there is no misunderstanding about the rationale for deprescribing. If there is no compelling indication, start with a drug that is unlikely to cause adverse effects if deprescribed. In some cases, starting with dose reduction is prudent, then evaluating.
5. **Discontinue the drug and institute a monitoring plan.** Once the drug is stopped, instruct the patient/family to call with any concerns or changes, just as

© F.A. Davis Publishing

you would when making any change in medication regime for cause; for example, stopping an antihypertensive in a patient who is normotensive and experiencing dizziness. If possible, schedule a brief follow-up call in 7 to 10 days to reevaluate. For patients in long-term care settings, include health-care personnel in the plan and monitoring (Jordan et al., 2021).

Deprescribing at end of life is a special situation, sometimes referred to as deintensification (Curtin et al., 2020; Niznik et al., 2020; Ouslander, 2020; Thompson et al., 2019). The goal is to reduce or eliminate drugs that offer no therapeutic advantage at end of life while considering the individual person. Anticholinesterase inhibitors that have proven ineffective, statins, intensive treatment for diabetes that can lead to hypoglycemia, tight control of hypertension that can cause syncope, and anticoagulants that can lead to serious bleeding if the patient falls are frequently targeted in patients with a terminal illness. Close communication with family and staff is important to emphasize the rationale for deprescribing and to reassure that it will alleviate potential ADRs and improve patient quality of life at end of life (Ouslander, 2020).

Barriers to deprescribing include clinical inertia, provider time constraints, coordination of care with multiple prescribers, and resistance from patients or family members (AlRasheed et al., 2018; Jungo et al., 2021). However, a recent international study of family physicians in 31 countries demonstrated a willingness to deprescribe in the oldest-old and those with limited function or frailty (Jungo et al., 2021). Several studies of patients determined that they were receptive to having drugs deprescribed if they trusted their primary care provider (Achterhof et al., 2020; Holmes & Todd, 2017; Linsky et al., 2019). Interprofessional collaboration, including pharmacists and nurses, can support patients and prescribers in deprescribing.

Appropriate prescribing for older adults should be parsimonious in nature, person-centered and focused on patient goals for care, grounded in evidence, efficacious, cost-effective, safe, and easy to self-administer with minimal side effects. Tools such as the American Geriatrics Society's *Care for Patients with Multimorbidity* (AGS Expert Panel, 2012) provide guidance for busy clinicians about appropriate prescribing for older adults.

CHAPTER 22

Chronic Illness and the APRN

Evelyn Duffy

Evidence-based management of common chronic diseases is an essential skill for advanced practice registered nurses (APRNs) in order to provide quality care for patients. It is also essential to understand and manage complex challenges of older adults with chronic disease. This chapter reviews the effect of chronic illness on older patients, their families, providers, and the overall health-care system. Specific topics include the demographics of chronic disease, lifestyle risk factors, the significance of multiple chronic conditions (MCCs), new models of care that reorganize health care to improve outcomes for complex patients with chronic disease, reimbursement mechanisms that support chronic disease, and the role of the APRN in chronic illness.

DEFINITIONS OF CHRONIC DISEASE AND CHRONIC ILLNESS

The literature does not support a single uniform definition for chronic disease, but the concept of chronicity includes the knowledge that patients experience persistent and recurring health problems. Definitions of chronic disease also reflect the pathophysiology of disease and, more importantly, consider the meaning of chronic illness and the experience of the patient, family, and provider as they struggle to cope with the range of mildly complicated to extreme challenges. A condition is defined as chronic if it lasts 1 year or more, requires ongoing medical attention, limits independent living, social interactions, or basic activities of daily living (ADLs) (Gulley et al., 2018).

DEMOGRAPHICS OF CHRONIC ILLNESS

Increased life expectancy and health-care advances are the main reasons for the overwhelming increase in numbers of patients with chronic illness. In 2019 the population of individuals aged 65 years and older was 54.1 million, 30 million women and 24.1 million men, which represents 16% of the population. That number is projected to increase to 21.7% of the population in 2040 (Administration on Aging (AOA), 2021).

Most older Americans have at least one chronic condition, and many have multiple chronic conditions (AOA, 2021). In 2019 the most common chronic diseases in the population age 65 years and older include arthritis (48%), cardiac disease (14%), myocardial infarction (9%), angina (4%), chronic lung diseases (10%), stroke (9%), and diagnosed and undiagnosed diabetes (29%). From 2015 to 2018 82% of men and 86% of women aged 75 years and older had hypertension (AOA, 2021).

More than 2/3 of all deaths in the United States are caused by one or more of these five chronic conditions: heart disease, cancer, stroke, chronic obstructive pulmonary disease (COPD), and diabetes (Raghupathi & Raghupathi, 2018). Heart disease is the number one cause of death among both men and women.

Notable Changes in Incidence and Prevalence of Chronic Disease

From 2008 to 2018, coronary heart disease (CHD) annual deaths declined by 27.9%, but the burden of disease remains high (Virani et al., 2021). The prevalence of diabetes in the United States remains high, affecting 34.2 million or 10.5% of the population—diagnosed and undiagnosed (ADA, 2022). The prevalence of chronic kidney disease (CKD) in the United States has stabilized in recent years (Vart et al., 2020).

Multiple studies indicate that the risk of Alzheimer's disease and other dementias in the United States and other developed Western countries may have declined in the past 25 years. That change is hypothesized to be due to increasing levels of education and improved control of cardiovascular risk factors. The total number of people in the United States with Alzheimer's disease and other dementias is still, however, expected to continue to increase dramatically because of the population's aging population. By 2050 the number of people aged 65 years and older with Alzheimer's disease is estimated to reach 13.8 million compared to the 5.8 million in 2020 (2020 Alzheimer's Disease Facts and Figures, 2020). Whereas between 2000 and 2018 deaths from heart disease, stroke, and HIV declined, deaths from Alzheimer's disease increased 146.2%.

The requirements of care for specific chronic diseases, such as heart failure (HF) or HIV, have changed dramatically

© F.A. Davis Publishing

in the last two decades. HIV has evolved from an untreatable and usually fatal disease to a chronic illness with a life expectancy of several decades. The prevalence of HF continues to rise with an estimated 6 million Americans diagnosed. Prevalence is higher in men than in women. Prevalence is expected to increase by 46% from 2012 to 2030 (Virani et al., 2021). From age 45 through 95 the overall lifetime risk for HF ranges from 20% to 45%. Most patients with HF are very old, with increasing debility and very complex health-care regimens.

Health Risk Behaviors

According to the Centers for Disease Control and Prevention (CDC), four health risk behaviors are responsible for the majority of chronic disease and death, including tobacco use, poor nutrition, lack of physical activity, and excessive use of alcohol. The American Heart Association adds health factors such as cholesterol, blood pressure, and glucose control. The prevalence of cigarette smoking is down; in 2019, 14% of adults were still smoking cigarettes (about 34.1 million adults). In those aged 65 and older the prevalence is much lower, 8.4% (Virani et al., 2021). The Surgeon General reported that in 2020 more than 480,000 Americans died as a result of cigarette smoking and more than 41,000 died due to secondhand smoke exposure (Virani et al., 2021).

Binge or heavy drinking can lead to high-risk sexual behavior, unintentional injuries (e.g., motor vehicle crashes), falls, violence, and suicide. Excessive alcohol consumption can also lead to development of high blood pressure, heart disease, stroke, liver disease, several cancers, and dementia. (CDC, 2022a).

The U.S. prevalence of obesity in 2017 to 2018 was 41.9% (CDC, 2022b). This represented an increase from the prevalence in 1999 to 2000 of 30.5%. Individuals who are obese can suffer serious health problems, face discrimination, and have a reduced life expectancy. The greater the body mass index (BMI) (and waist circumference), the greater the risk of heart disease, stroke, type 2 diabetes, and certain cancers (CDC Adult Obesity Facts, 2021). They are also at risk for sleep apnea, osteoarthritis, gallbladder disease, respiratory problems, and depression. It is known that 85.2% of people with type 2 diabetes are overweight or obese (American Diabetes Association (ADA), 2022). There is strong evidence that modest weight loss (5% to 15%) can greatly reduce the risk of these conditions.

Prevention

The goals of national health promotion and disease prevention are to prevent or delay disease, decrease premature mortality, and improve health-related quality of life. Modification of behavioral risk factors and using preventive services such as screenings and immunizations can substantially reduce morbidity and mortality.

The 2010 passage of the Patient Protection and Affordable Care Act (PPACA), or the ACA, increased the opportunities for disease prevention. Ongoing efforts are aimed at redesigning the health system to support overall population health. One successful prevention initiative removed out-of-pocket costs and increased access to evidence-based clinical preventive services recommended by the U.S. Preventive Services Task Force (USPSTF). Results have demonstrated increased use of those preventive services, including tobacco counseling, cervical cancer screenings, and colorectal cancer screenings (Koh et al., 2016).

In the United States, diabetes affects 34.2 million or 10.5% of the population and prevalence is projected to increase approximately twofold for all U.S. adults (ages 18 to 79 years) by 2050, if current trends continue (CDC, 2020). Another successful intervention is the Centers for Medicare and Medicaid Services (CMS) Diabetes Prevention Program (DPP), an evidence-based intervention targeted to individuals with prediabetes, with the primary goal of weight loss and behavior change. The DPP is public–private partnership that uses lifestyle coaches to deliver evidence-based counseling interventions to Medicare beneficiaries with prediabetes. The results of the program demonstrated that participants lost at least a modest amount of weight through dietary changes and increased physical activity, which reduced their chances of developing diabetes. A list of all organizations recognized to deliver the evidence-based programs is available online at https://dprp.cdc.gov/Registry. There are more than 2,089 options.

MULTIPLE CHRONIC CONDITIONS

The U.S. health system was created to manage and pay for acute illness with a focus on one disease or health-related problem at a time. As the number of chronic conditions in an individual increases, there is a parallel risk for poor outcomes, often related to the unintended consequences of a single-disease approach. Those outcomes include poor functional status, unnecessary hospitalization, adverse drug events, conflicting medical advice from multiple providers, and even death. There is an increasing awareness that the health system and health-care providers require a new paradigm of care that recognizes patients with MCCs. To explore the public health problem of MCCs, the USDHHS created the Multiple Chronic Conditions Interagency Workgroup in 2008, and in 2010 they published the *Multiple Chronic Conditions: A Strategic Framework*. One of the main goals of the framework is to generate research to bridge knowledge gaps about individuals with MCCs (USDHHS, 2010). This work has not been updated.

Data from the 2018 National Health Interview Survey (NHIS) were used to generate estimates of MCCs for U.S. adults. Over half, 51.8% (129 million), of noninstitutionalized U.S. adults have at least 1 of the 10 most common chronic conditions, which include hypertension, CHD, stroke, diabetes, cancer, arthritis, hepatitis, CKD, asthma, or COPD. In addition, one in four adults (27.2% [68 million]) had more than two or more chronic conditions (Boersma et al., 2020). There was a marked disparity among those aged 65 and older who were on both Medicare and Medicaid and those on Medicare only. The "dual eligibles" on both Medicare and Medicaid had the highest prevalence—76.9% compared to 58.5% of those on Medicare alone (Boersma et al., 2020). The numbers from the NHIS do not include mental health issues or institutionalized older adults, which would substantially increase the estimates.

MCCs can contribute to frailty and disability, and older adults who are frail or disabled typically have MCCs. Functional limitations can often complicate access to health

© F.A. Davis Publishing

care, interfere with self-management, necessitate reliance on caregivers, and produce high levels of spending. Older adults with MCCs often require long-term services and supports (LTSS). LTSS include the broad range of paid and unpaid medical and personal care assistance that people may need when they cannot complete self-care tasks because of aging, chronic illness, or disability (Lewis et al., 2018). The 2017 report on LTSS expenditures found great variation from state to state (Eiken et al., 2017). They also note that the growth in expenditures was almost completely due to the increase in cost of home- and community-based services with institutional service expenditures unchanged. There is a growing trend to use managed care plans to provide LTSS (Lewis et al., 2018). Medicaid spending for managed LTSS has more than doubled from 2012 to 2015.

With the potential for continued growth of older adults requiring LTSS, it is especially important to increase knowledge about the high-risk factors related to MCCs that can increase costs or the risk of hospitalizations.

Other high-risk individuals with MCC include those with serious mental illness or behavioral health problems. Co-occurrence of mental and medical disorders is a disabling combination and occurs in approximately 30% of individuals with MCCs. Those with depression and a chronic medical condition are more likely to experience greater severity of both conditions. Substance use in older adults, while lower than in younger adults, is complicated by the changes with aging that make them more likely to experience adverse events (Lehmann & Fingerhood, 2018). They are more likely to have MCC and be on multiple medications that can interact with alcohol and other substances. Many of the common red flags such as difficulty at work or driving issues are not relevant in the older adult (Lehmann & Fingerhood, 2018).

Self-Care Management

Patients coping with MCCs are especially vulnerable to a sense of burden with their treatment regimen because they are required to engage in a complex array of self-care activities on a daily basis. Treatment burden is the impact on patient functioning and well-being that results from the time and energy required of the patient and their caregiver to accomplish the work required to implement treatment plans, health monitoring, and diet and exercise requirements (Sheehan et al., 2019). That work might include medication management, self-monitoring of blood pressure or blood sugars, visits to providers, laboratory and radiology testing, and lifestyle changes. Treatment burden may add to the difficulties already imposed by the disease or diseases themselves. It is unique to each patient but may add to the physical and psychosocial stressors resulting from the chronic condition or conditions themselves (Sheehan et al., 2019)

Many chronic conditions share common challenges in self-care management. Most require daily management of symptoms, complex medication regimens, nutrition, diet, and exercise. APRNs should discuss with patients the ways in which they are managing, or failing to manage, the chronic conditions in their everyday lives. The resulting person-centered care will allow plans to be put into place to minimize the burden by adjusting treatment to the unique constraints of the patient. As noted in Chapter 6, including the question of what matters most to the patient can help in creating of the person-centered care plan.

New models of care are essential to provide tools to improve self-management and quality support systems. The National Institute of Nursing Research (NINR) at the National Institutes of Health (NIH) has promoted self-management science as one of its core areas of research to improve and manage symptoms of acute and chronic illness (NINR, 2016). Two of the most successful and well-known self-management programs are the Arthritis Self-Management Program (ASMP), developed by Margaret Grey, and the Chronic Disease Self-Management Program (CDSMP), developed by Kate Lorig.

The two programs are supported by the evidence that they improve the quality of life of those who participate. They address topics including dealing with problems resulting from chronic disease; exercise; use of medications; communicating with family, friends, and health-care providers; nutrition; and how to evaluate new treatments (Stanford Medicine, 2016). Programs are held in the community, meet weekly for two-and-a-half hours for 6 weeks. Detailed information and a link to locate a program in your area are available at https://www.cdc.gov/arthritis/interventions/self_manage.htm.

Caregivers

As older adults become more functionally limited, caregivers become central members of the care team and play a major role in supporting the daily self-care management and maintaining the health and well-being of the care recipient. The Caregiving in the U.S. 2020 report identifies the continued increase in Americans providing unpaid care as our population ages. The estimated prevalence of caring for an adult aged 50 or older is 16.8% of the population, or 41.8 million people. The majority of caregivers are female (61%) and most care for a relative (89%) and 40% live with their care recipient. Caregivers report that those adults receiving care have more health and functional needs than what was reported in 2015 and there is increasing comorbidity with the average recipient having 1.7 chronic conditions. The typical care recipient is female (61%), with an average age of 50.1 years (National Alliance for Caregiving [NAC] & AARP, 2020).

Caregivers' tasks can include assistance with ADLs and instrumental ADLs (IADLs), medication and treatment management, monitoring signs and symptoms, or navigating health-care appointments and health-care systems. The demands of caregiving can create additional stress in the caregiver's life, commonly referred to as caregiver burden. Caregiver burden is associated with anxiety, depression, insomnia, poor self-care management, poor self-rated health, and greater mortality (NAC & AARP, 2020). Caregiver burden also directly affects decisions to place care recipients in long-term care facilities. About 40% of caregivers report high burden, 16% report moderate burden, and 43% report a relatively low burden (NAC & AARP, 2020).

Caregiving has traditionally been seen as a family obligation, but little attention has been paid to the type of formal support, guidance, and skills needed to perform caregiving. There are a few sporadic programs that provide educational support for caregivers. The Web site programsforelderly.com offers access to multiple resources to support the care of older adults that are available across the United States. Because prevalence of burden is not specific to stage of illness and is relatively stable over time, health-care teams should assess caregiver burden and refer burdened caregivers to supportive resources early in the course of chronic illness. Ongoing

© F.A. Davis Publishing

caregiver education should be provided by multiple members of the health-care team and should include caregiver involvement in decision making and guidance prior to any potential health-care crisis. The American Geriatrics Society in 2019 introduced their *Guiding Principles for Care of Older Adults with Multimorbidity* (Boyd et al., 2019). They emphasize the need to include the patient and caregiver in medical decision making; recognize the limitations of the evidence regarding the older adult population; frame management decisions in the context of harms, burdens, benefits, and prognosis; consider treatment complexity and feasibility; and use strategies for choosing therapies that optimize benefit, minimize harm, and enhance quality of life.

Health Literacy

The ability to use and correctly interpret health information is important for anyone with one or more chronic diseases. Health literacy involves using reading, writing, verbal, and numerical skills in order to obtain, process, and understand basic health information to make appropriate decisions (Samerski, 2019). Ninety million Americans are identified as having low health literacy, with more prevalence in those with lower socioeconomic status or less education, in older adults, in those with low English proficiency, and those on Medicaid (Hickey et al., 2018).

Research indicates that low health literacy contributes to a number of health-related problems, including a poor understanding about health conditions and services, the inability to provide self-care, difficulty understanding medication instructions, poor medication adherence, and low use of preventive services (Chen et al., 2018; Hickey et al, 2018). Individuals with limited health literacy also experience more negative outcomes. Due to the limited knowledge of their health problems, they make more medication errors, use more inpatient and emergency department care, and have worse overall health status and higher health-care costs (Chen et al., 2018).

Clinicians have trouble identifying patients with limited health literacy, so it is suggested that universal precautions are used regardless of the complexity of any information. Universal precautions defined in the AHRQ *Health Literacy Universal Precautions Toolkit,* 2nd edition include simplifying communication with and confirming comprehension for all patients, making the office environment and health-care system easier to navigate, and supporting any and all patient efforts to improve their health. Studies have shown that 40% to 80% of the medical information patients are told during office visits is forgotten immediately, and nearly half of the information retained is incorrect. The teach-back method is a way of checking understanding by asking patients to state in their own words what they need to know or do about their health. *Teach-back is a way to confirm that the provider has explained things in a manner that the patient understands* (Brega et al., 2015, p. 18).

ECONOMIC BURDEN OF CHRONIC DISEASE

Patients with MCC account for a disproportionate use and cost of care. They account for 64% of provider visits, 70% of inpatient stays, 83% of prescriptions, 71% of all health-care spending and 93% of Medicare spending (Bierman et al., 2021). Ninety percent of the $4.1 trillion in health-care spending in 2020 was for people with one or more chronic medical conditions (National Center for Chronic Disease Prevention and Health Promotion [NCCDPHP], 2021). Heart disease and stroke alone are costing $214 billion a year and $138 billion in lost job productivity. These statistics preceded the current COVID pandemic.

According to the CMS, Medicare spending for fee-for-service (FFS) beneficiaries in 2019 was 799.4 billion dollars. The one-third of beneficiaries with zero or one chronic condition accounted for only 6% of Medicare spending, whereas the 18% with six or more chronic conditions accounted for 54% of Medicare spending (Centers for Medicare and Medicaid Services (CMS), 2021). Per capita costs were highest for those with stroke, CKD, and chronic obstructive pulmonary disease.

Cost and complexity of care are greater for individuals with multiple chronic diseases, who account for 75% of overall health-care spending. Additional costs of chronic disease result from multiple acute care hospitalizations experienced by the seriously chronically ill population and readmission within 30 days. In 2010 the Hospital Readmission Reduction Program (HRRP) was established by the ACA. The program has been successful in reducing readmissions and lowering the cost of health care, including this vulnerable population (Gai & Pachamanova, 2019)

CHRONIC DISEASE IN UNDERREPRESENTED POPULATIONS

The older population in the United States continues to be more racially and ethnically diverse as the population of people of color grows. Underrepresented racial and ethnic populations have increased from 7.8 million in 2009 (20% of older adults) to 12.9 million in 2019 (24% of older adults) and are projected to increase to 27.7 million in 2040 (34% of older adults) (Administration for Community Living, 2021).

Chronic conditions can be more common or severe for some populations. Non-Hispanic Blacks are 50% more likely to have high blood pressure and with poorer control than are non-Hispanic Whites (CDC, 2017). Non-Hispanic Blacks are more likely to be aware of their hypertension and to have it treated, than are non-Hispanic Whites. Diagnosed diabetes is 77% higher among non-Hispanic Blacks, 66% higher among Hispanics, and 18% higher among Asians than among non-Hispanic Whites. Black women are twice as likely to be severely obese as almost every other group. Native Americans and Alaskan Natives are 60% more likely to be obese than non-Hispanic Whites (Reeves & Smith, 2020). As a result, life expectancy for non-Hispanic Blacks is 75.1 years, compared to 78.9 years for non-Hispanic Whites. However, the death rate for non-Hispanic blacks has declined 25% over the past 17 years. Hispanics, despite lower incomes and migrant patterns outlive non-Hispanic Whites by 3 years on average.

There are noticeable racial/ethnic differences in the prevalence of many chronic conditions and treatment for those illnesses. CKD is more common in non-Hispanic Black adults (16%) than non-Hispanic White adults (13%) (CDC, 2021c). The literature shows consistent disparities among Blacks and Hispanics compared to non-Hispanic Whites in the

© F.A. Davis Publishing

prevalence and incidence of Alzheimer's disease, mortality, participation in clinical trials, use of medications and other interventions, use of LTSS, and quality of care (Quiñones et al., 2020). Blacks have the highest death rate and shortest survival of any racial/ethnic group in the United States for most cancers, although the gap is closing, particularly for non-Hispanic Black men (Zavala et al., 2021).

FUNCTION AND FRAILTY

Aging is a highly variable process that leaves some older adults with strength and vitality, and others with increased vulnerability to illness, injury, and disease. That reduced physiological capacity contributes to the development of geriatric syndromes such as falls, delirium, and frailty (Leff et al., 2015). Consideration and documentation of geriatric syndromes and overall function is as important in the care of older adults with chronic disease as a medical diagnosis. ADLs and IADLs are used to measure functional status. ADLs are measures of functions that people perform daily and include feeding, bathing, dressing, grooming, toileting, ambulating, and transferring. IADLs are indicators of more complex functions required on a regular basis, including use of the telephone, shopping, housekeeping, laundry, transportation, management of medications, and handling of finances.

Older adults are often more concerned about the impact of their illness on daily function than they are about the specific diagnosis. Despite the importance of function to alert providers to changes in health or prognosis and to determine appropriate interventions, mobility and function are not routinely measured or monitored in clinical practice. It is important to systematically include mobility and functional assessment in clinical documentation.

Frailty is not synonymous with comorbidity or disability, but comorbidity is a risk factor for frailty, and disability is an outcome of frailty. Precise definition of frailty has been elusive (Junius-Walker et al., 2018). In their comprehensive literature review Junius-Walker and colleagues attempt to more clearly define the concept to allow for the development of policies and interventions. Frailty has evolved as a concept over the past decades and is now viewed from a more holistic perspective. Awareness of frailty will help to develop accurate assessments, help patients and families with anticipatory planning, and make appropriate decisions about interventions and treatment. From their systematic review they identified core concepts: vulnerability, genesis, characteristics, phenotype and adverse health-related outcomes. They (as cited in Junius-Walker et al., 2018) conclude that the WHO definition best reflects their core concepts: "*a progressive age-related decline in physiological systems that results in decreased reserves of intrinsic capacity, which confers extreme vulnerability to stressors and increases the risk of a range of adverse health outcomes*" (WHO, 2015, p. 63).

A screening tool for frailty, FRAIL, was developed by Dr. Fried in 2001. Aprahamian et al., (2017) conducted a study to compare the properties of the FRAIL with Fried's phenotype. They conclude that the FRAIL scale is time- and cost-effective in screening for frailty.

The FRAIL tool asks five screening questions about fatigue, walking, number of chronic diseases, and weight loss of more than 5% in 6 months to identify those at high risk of being frail. Those who answer yes to at least three of the screening questions are likely to be frail with a score of 1 or 2 considered a measure of prefrailty (Aprahamian et al., 2017). Identification of frailty in older adults is important because a likelihood of poor outcomes is very high. In frail older adults there is a higher frequency of primary care visits, home care and nursing home services, and a higher likelihood of rehospitalization and death (Junius-Walker et al., 2018).

EVIDENCE-BASED PRACTICE AND CHRONIC DISEASE

Available evidence to manage chronic disease is found within clinical practice guidelines (CPGs). Guidelines, however, are almost exclusively focused on one specific disease. It is essential to evaluate those guidelines to determine whether they are appropriate for frail, older adults with MCCs. There is wide diversity in the older adult population in life expectancy, functional status, and individual priorities and preferences related to health care. Those characteristics limit the use of specific disease-oriented models of care. Complex comorbid conditions and geriatric syndromes are common, and usual signs and symptoms, such as fatigue, may be due to one or several chronic diseases, problems, or syndromes, and require different or multiple interventions.

When CPGs have been evaluated for content that considers unique issues of complex older adults with multiple comorbidities, it has been determined that only a few CPGs address those issues. In 2019, Dent and associates published the *Physical Frailty: ICFSR International Clinical Practice Guidelines for Identification and Management*, and while focused on frailty, includes much of the content that has been identified as missing in less comprehensive CPG. Muth et al (2019) conducted a systematic review of eight guidelines that addressed managing multimorbidity and polypharmacy. The neglected content identified by both includes patient and caregiver concerns, setting clinical priorities based on life expectancy, managing expectations around prognosis, maintaining communication, and considering patient, provider, or system barriers to implementation (Dent et al., 2019; Muth et al., 2019).

Older adults with MCCs have poorer outcomes when treated according to disease-specific guidelines. Those negative outcomes may be due to decreased benefit from therapy directed at any one chronic disease, the presence of polypharmacy, or the increased likelihood that the high-risk older adult will have a poor response to any specific intervention. To improve decision making, clinicians require unique data about the frail older adults and alternative approaches that include patient and family values; communication and coordination with specialty providers, and other members of the team; and a restructured reimbursement system (Dent et al., 2019; Muth et al., 2019).

Experts continue to study the complex relationship between patients with MCCs and available evidence. To guide understanding about CPGs and MCCs, researchers developed a patient-centered and context-sensitive model of care called minimally disruptive medicine (MDM). MDM acknowledges the limitations of disease-centered treatment recommendations for patients with MCC. MDM suggests caveats to clinicians caring for complex patients. For example, following an evidence-based

© F.A. Davis Publishing

recommendation for a frail older adult with MCCs, especially when the recommendation is not strong, may do more harm than good (Trevena, 2018). Shared decision making and discussion regarding the burden of the treatment and the patient's ability to cope with the requirements address the need for a thoughtful approach to the application of the minimally disruptive medication approach.

LEGISLATION AND CHRONIC DISEASE

Accountable Care Organizations

The Patient Protection and Affordable Care Act included multiple payment and delivery system reforms with incentives for health systems to better manage the care of patients with chronic disease. Beginning in 2012, the law authorized Medicare to contract with accountable care organizations (ACOs) in a Medicare Shared Savings Program. ACOs provide financial incentives to improve the coordination and quality of care for Medicare beneficiaries while reducing costs. ACOs are groups of doctors, hospitals, and other health-care providers who come together voluntarily to give coordinated high-quality care to their Medicare patients. The primary goal of coordinated care is to ensure that patients with chronic disease receive quality care, while avoiding unnecessary duplication of services and preventing medical errors. When the ACO succeeds in delivering high-quality care and reduced spending, it will share in the savings it achieves (CMS, 2022a).

A key element of ACOs will relate to the effective discharge of patients from acute care settings and initiatives to reduce admissions. All members of the ACO are incentivized to coordinate care of patients across the continuum to achieve savings. In 2021 there are 512 Medicare ACOs serving over 12 million beneficiaries. They have demonstrated positive trends in savings, but with major variation in performance (Herrel et al., 2017). Organizations require time to create major transformation and determine new paths to affect positive changes in health-care delivery.

Hospital Readmission Reduction Program

A major provision of the ACA is the Hospital Readmissions Reduction Program (HRRP) that financially penalizes hospitals for excess readmissions within 30 days of discharge. The HRRP motivates hospitals to conduct interventions that reduce the likelihood of readmission and has drastically changed how hospitals manage complex patients at high risk for readmission (CMS, 2022a).

Before 2012, hospitals had little direct financial incentive to reduce readmission. The HRRP requires CMS to reduce payments to hospitals who experience excess readmissions. The HRRP initially targeted select diagnoses of HF, pneumonia, and acute myocardial infarction. In 2015, the additional diagnoses of COPD, total hip arthroplasty, and total knee arthroplasty were added (CMS, 2022a). As of 2015, penalties for excess hospitalizations increased to 3% of base payments by Medicare, and readmissions for these diagnoses are also treated as an indicator of the quality of a hospital's care and are publicly reported and available to consumers.

High rates of preventable hospitalizations and emergency department visits are still frequent poor outcomes. At least in part due to the financial incentives, the 30-day rehospitalization rates for Medicare beneficiaries decreased 7% from 2010 to 2016, from 18.3% to 17.1% (AHRQ, 2019). Many hospital readmissions are not preventable, but evidence and model programs are available to assist hospitals with system-wide changes that will decrease readmission rates. The HRRP has helped create collaborative relationships within hospitals, between medical institutions, and with surrounding communities that focus on improving the overall patient experience through hospitalization and post-discharge.

Patient-Centered Medical Home

The National Committee for Quality Assurance (NCQA) (2019) defined standards for the patient-centered medical home (PCMH), which reinforce the central components of primary care. Those core components include an ongoing relationship with a provider, person-centered care, enhanced access to care, coordinated care, quality and safety, and a payment structure. Additional requirements for PCMH designation include patient tracking and registry, a care management component, patient self-management support, advanced electronic communication (including electronic prescribing), and performance reporting and improvement. Outcome measures include patient and family satisfaction, decreased emergency department use, decreased hospitalization, improved health parameters (e.g., blood pressure, hemoglobin [Hb] A1c), provider satisfaction, decreased cost, improved preventive care, and patient language preference.

The 2019 Benefits of NCQA Patient-Centered Medical Home Recognition reported improved outcomes for PCMHs, including reduction in emergency department visits and hospitalizations, improved patient satisfaction, and increased use of measures such as recommended diabetes services, and decreased overall health-care costs (NCQA, 2019). APRNs are involved in PCMHs by providing primary care, care coordination, and health system navigation and serving as community team members.

TRANSITIONS OF CARE

Coordination of Care

Improving care coordination has been identified by payers and policymakers as a priority to improve quality and lower costs of health care. The National Quality Forum (2010) identified important performance measures of care coordination, including prevention of hospital admissions and readmissions, care transitions, the patient experience of care coordination, the importance of cultural and linguistically appropriate resources and services, and communication to support patient self-management. Others have identified continuity of care as an important measure of care coordination. The PCMH was developed in response to this identified need.

Transitional Care Models

Medicare's attention to preventing hospital readmissions places a high premium on care continuity and coordination, with a central focus on transitions across providers and sites of care. Transitional care is defined as a set of actions necessary to ensure the coordination and continuity of care as patients transfer between different sites of care or from one level of care to another within the same site. Health-care

© F.A. Davis Publishing

services for older adults exist on a complex continuum that includes primary care, acute care, post-acute care, long-term care, home health care, and community-based services. Each of the care settings along the continuum serves a specific purpose and meets the needs of specific patients, but also generates health-care transitions that occur as patients move across multiple providers, payers, and settings for different acute episodes or for the same episode of care. Efforts to improve care transitions are intended to improve patient safety and quality of care; decrease significant burden on patients, families, and caregivers; and decrease costs to patients, providers, and payers.

The transitional care model (TCM) defines transitional care as a "broad range of time-limited services designed to ensure health-care continuity, avoid preventable poor outcomes among at-risk populations, and promote the safe and timely transfer of patients from one level of care to another or from one type of setting to another." Transitional care functions in a complementary role to other health services, is time-limited, and has a specific focus on managing adverse outcomes of transitions (Naylor, et al., 2011, p. 747).

As a response to challenges facing the health-care system, APRNs were the first to develop and study transitional care, an empirically supported method to reduce readmissions post-hospitalization. The TCM has consistently shown reductions in readmissions, emergency department visits, and costs of care (Naylor et al., 2018).

Technology plays a significant role in communication and coordination of care to improve access to care and quality, especially with the implementation of electronic medical records (EMRs). Because hospital readmission is a common and costly problem and a target of recent health-care system reform, efforts to use technology to advance knowledge of high-risk patients and standardize evidence-based discharge information are priorities. The ability for timely follow-up in primary care after hospitalization motivated CMS to add financial incentive to provide for that follow-up. Reimbursement is now provided for the follow-up after hospital or post-acute care discharge.

Palliative Care

Chronic illnesses are marked by fluctuations over time, with the potential for worsening symptoms, decrease in function, and caregiver burden. Palliative care consists of specialized care for people living with serious illness. It focuses on providing relief from the symptoms and the stress of the serious illness, with the goal is to improve quality of life for both the patient and the family. Palliative care can serve as an intervention to manage chronic illness, not just at the end of life, but also in the early phases of illness to support patients and caregivers. Patients who receive early palliative care show significant improvements in quality of life and mood and may survive longer (Zhuang et al, 2018).

The Center to Advance Palliative Care emphasizes that palliative care is commonly used among people living with serious, complex, and chronic illnesses. The most common clinical conditions relevant to this discussion include cancer, congestive HF, COPD, and CKD and/or end-stage renal disease. Palliative care should be considered for close to half (45%) of all Medicare beneficiaries who have four or more chronic conditions for which palliative care services may be clinically indicated. Palliative care is used to alleviate symptoms, either in combination with or instead of curative treatment. For a thorough discussion of palliative care, review Chapter 23.

Interprofessional Education and Interprofessional Teams

Prevention and management of complex older adults with chronic illness are best implemented by interdisciplinary teams in primary care and in most other sites of care. It is suggested that a larger interdisciplinary workforce is needed, and payment for primary care should reward practices that incorporate interdisciplinary teams. Interprofessional education (IPE) occurs when learners of two or more health and/or social care professions engage in learning with, from, and about each other to improve collaboration and the delivery of care (Institute of Medicine, 2015).

Researchers and educators continue to evaluate the impact of IPE on outcomes, including patient safety, patient and provider satisfaction, quality of care, health promotion, population health, and the cost of care. Core competencies for interprofessional practice were updated in 2016 by the Interprofessional Education Collaborative, which is now comprised of 16 health-care professional groups. Those competencies relate to values and ethics for interprofessional practice, roles, and responsibilities; interprofessional communication; and teams and teamwork (Interprofessional Education Collaborative, 2016).

Interprofessional practice continues to validate approaches to complex patient management. In one study, using a team consisting of a physician, nurse practitioner, clinical pharmacist, nurse, dietary specialist, and behaviorist, clinical outcomes were optimized in a low-income diabetic population. Interprofessional diabetic care improved outcomes related to the Hb A1c, triglycerides, and blood pressure values (Madsen et al., 2021). Improved interprofessional teamwork and team-based care play critical roles in many of the new primary care approaches, including the PCMH, chronic care coordination, and transitions of care.

PROVIDER REIMBURSEMENT FOR CHRONIC ILLNESS CARE

Chronic Care Management Services

There is widespread awareness that frail, older adult patients, and others with complex physical and functional problems often experience worsening disease, decreased function, unwanted transfers to skilled nursing facilities, and potentially costly emergency department visits or preventable hospital admissions or readmissions. Typically, those complex issues are not well addressed within the traditional outpatient office visit. As previously discussed, strategies and programs that include care coordination are known to lower the rates of adverse outcomes.

As of January 2015, Medicare started reimbursing physicians, nurse practitioners, and other non-physician providers for non–face-to-face care coordination for patients with two or more chronic conditions associated with significant risk of exacerbation, decompensation, functional decline, or death. Those services are known as chronic care management (CCM) services (CMS, 2022b).

© F.A. Davis Publishing

CMS stipulates that the clinician must provide at least 20 minutes of coordination for each 30-day billing period and lists seven components of CCM. Three components involve the patient and clinician, including continuous access to care management (including use of EMRs and 24/7 telephone coverage); continuous care with a designated health-care professional; and multiple ways for the patient or caregiver to communicate with that clinician (Agarwal et al., 2018). The next two requirements relate to the clinician's plan of care. Initially, there must be a comprehensive assessment and management of the patient's medical, cognitive, functional, and psychosocial needs, as well as the patient's environment, resources, and support. The second requirement requires creation of a comprehensive care plan. The third and fourth requirements include the management of transitions among clinicians and settings, and coordination with home- and community-based health-care professionals (Agarwal et al., 2018).

Incorporating all of the requirements for CCM can be challenging in many practices. It may be necessary to make additional investments in technology, staff training, and the care management protocols. Patient care benefits of CCM services include increased round-the-clock access to providers, enhanced care continuity across settings, stronger community support services, and the ability to develop a patient-centered care plan with providers.

Transitional Care Management Services

Reimbursement for intentional Transitional Care Management has been an incentive for a practice to make contact with the patient immediately after discharge from a hospital or post-acute setting (CMS, 2021). Within 2 business days of discharge, you or staff in your office must contact the patient by phone or document two or more unsuccessful attempts to contact the patient. You cannot bill for the service without the face-to-face visit. At least one face-to-face visit must occur within the time frame of the appropriate code. CPT Code 99495 requires communication in 2 business days, moderate complex decision making and face-to-face within 14 days of discharge. CPT Code 99496 requires the call within 2 business days, high complexity of decision making, and face-to-face within 7 days. CMS allows for concurrent billing of select additional codes—for example, codes for chronic care management.

The Annual Wellness Visit

The annual wellness visit (AWV) is a yearly preventive care visit offered at no cost to all Medicare Part B beneficiaries and separate from any physical examination. The purpose of the visit is to identify patient risk factors and plan for future preventive service needs. The visit is well reimbursed and can be conducted by a provider or another supervised professional. There are significant patient care benefits, including a yearly opportunity for a health-risk assessment, which includes psychosocial and behavioral risks, functional and cognitive assessments, as well as a general safety check. Older adults can also work with providers to update a preventive care plan and be connected to necessary community resources. You may bill for other medically necessary services on the same date as the AWV, but those services are subject to the deductible and coinsurance. Many patients come in for the AWV with the understanding that it is at no cost to them, so any additional service should be discussed.

Advance Care Planning Discussions

In 2016, Medicare began covering advance care planning discussions as a separate and billable service. Physicians, APRNs, and other health professionals are encouraged to have discussions with patients regarding end-of-life care preferences. Communication about serious illness care goals is now an intervention that is systematically integrated into our clinical care structures and processes. The CPT codes allow the clinician to explain and discuss advance directives and assist with the completion of approved forms. The codes are time-based and allow for a basic code, as well as an add-on code for each additional 30 minutes of time spent with patients (CMS, 2020).

End-of-life conversations are associated with better quality of life, reduced use of life-sustaining treatments near death, earlier hospice referrals, and care that is more consistent with patient preferences. Patients who engage in advance care planning are more likely to have their wishes known and followed. Best practice in communication about advance care planning should include discussions about individual goals of care, prognosis, decision-making preferences, and wishes for family involvement.

THE ROLE OF APRNS IN CHRONIC DISEASE

The effect of health-care reform as part of the ACA of 2010, the rise in complex chronic diseases, and the continuing growth of the aging population combine to create a huge demand for health-care services. Individuals with multiple chronic disease, including frail older adults, will interact frequently with the health-care system. APRNs will continue to play an essential role in individual patient quality of care, as well as health system reform.

National attention has been placed on the removal of all scope-of-practice restrictions on APRNs to drive down costs and increasing high-quality access to primary health care. Numerous studies have shown the importance of APRNs as key components of an overall health-care system strategy to address chronic disease (Buerhaus et al., 2018).

APRNs are ideally suited to incorporate elements of the CCM into practice because they excel in patient education and patient empowerment, with the goal of supporting the patient's self-management skills. APRNs are involved in technology and clinical information systems by using shared medical appointments, telehealth, electronic documentation and developing and maintaining data for quality improvement. APRNs embrace evidence-based care that is maximized with decision support tools and algorithms.

APRNs appreciate the diversity of the older population, including diversity of health trajectory, functional ability, cultural background, support systems, and individual values and preferences. The APRN's holistic approach to care includes prevention and support of healthy aging, education, care coordination, management and monitoring of complex medication and treatment regimens, counseling for family issues related to caregiving and finances, access to community resources, advance care planning, and the vigilant management of all comorbid conditions.

New health-care models and alternatives to traditional care address discontinuities in health care. APRNs are presently

© F.A. Davis Publishing

involved in unique strategies that target high-risk older adults across systems of care, partnerships with families and caregivers, identification of resources for individuals with chronic disease, and involvement in key policy decisions that affect those populations. APRNs are committed to providing affordable, accessible, and high-quality care through clinical practice, education, leadership, and research.

CASE STUDY

Mrs. A. is an 82-year-old woman. She lives with her 86-year-old husband, who has mild-to-moderate dementia. Mrs. A. has a primary care provider, endocrinologist, cardiologist, ophthalmologist, and podiatrist. She has a daughter nearby who assists with shopping and housekeeping. Mrs. A. is overweight and has hypertension, type 2 diabetes, CKD, macular degeneration, incontinence, and peripheral neuropathy with chronic pain. She has trouble sleeping, complains of chronic fatigue, and has fallen twice in the past 2 months. She is on nine prescription medications. Her self-care regimen includes monitoring her glucose, weighing herself daily, taking medications twice daily, and managing her nutrition and exercise. She is also responsible for managing her husband's meals and medications.

Additional comprehensive assessment is critical to developing a person-centered plan of care for Mrs. A. A multidisciplinary and continuity-of-care focus will prevent poor outcomes.

1. What multiple factors place Mrs. A. at high risk for poor outcomes?
2. What additional assessment data are essential to determine whether Mrs. A. can safely manage her complex health-care regimen at home?
3. How do Mrs. A.'s multiple chronic diseases contribute to the complexity of her care?
4. Are there caveats when using evidence for individual chronic diseases in light of her MCCs?
5. What communication is necessary to provide ongoing coordination of care?
6. What community resources may be available to support Mrs. A.?
7. What additional team members would be appropriate to contribute to a safe and person-centered plan of care?
8. What new models of care can potentially contribute to Mrs. A.'s quality of care while she is at home or in the event of a hospitalization?

CHAPTER 23

Palliative Care and End-of-Life Care

Joshua Borders, Freda Cowan

OVERVIEW OF PALLIATIVE CARE AND HOSPICE

Description: Palliative care is an interdisciplinary approach to care aimed at improving the quality of life of patients and their families facing a life-threatening illness. The goal of palliative care is the prevention and relief of suffering by means of early identification, assessment, and treatment of physical, psychosocial, and spiritual problems. Palliative care is provided in a variety of settings including hospitals, primary care and specialty clinics, patient homes, and nursing facilities. Palliative care:

- Provides relief from pain and other distressing symptoms
- Affirms life and regards dying as a normal process
- Intends to neither hasten nor postpone death
- Integrates the psychological and spiritual aspects of patient care
- Offers a support system to help patients live as actively as possible until death
- Offers a support system to help the family cope during the patient's illness and in their own bereavement
- Uses a team approach to address the needs of patients and their families, including bereavement counseling, if indicated
- Enhances quality of life, and may also positively influence the course of illness
- Is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and includes those investigations needed to better understand and manage distressing clinical complications (World Health Organization, 2018).

There are several well-described barriers to patients receiving palliative care, including provider reluctance to refer due to fear of upsetting patients or not understanding the benefits, confusion of terminology (hospice versus palliative care), and a lack of palliative care resources (Hawley, 2017). There are many potential benefits of palliative care, including improved end-of-life communication, reduction in distressing symptoms, and improved patient quality of life (Temel et al., 2017). Patients and families benefit from the availability of palliative care services early in the disease process, particularly when symptoms affect quality of life. Palliative care has also been shown to reduce health-care costs and lessen emergency department and hospital utilization (Cassel et al., 2018). In some cases, patients that receive palliative care services may actually live longer than those that do not receive palliative care (Temel et al., 2017).

As the disease advances and end of life nears, hospice care becomes an option. The National Hospice and Palliative Care Organization (NHPCO, 2020) defines hospice as "the model for quality, compassionate care for people facing a life-limiting illness, hospice provides expert medical care, pain management, and emotional and spiritual support expressly tailored to the patient's needs and wishes." Hospice uses the principles of palliative care, focusing on quality of life, but whereas palliative care is appropriate at the time of diagnosis with a life-limiting illness, patients are eligible for hospice when their prognosis is expected to be 6 months or less. Another important difference between hospice and palliative care are the goals of treatment. Palliative care is appropriate for patients receiving ongoing curative and aggressive medical treatments. However, most patients discontinue aggressive treatments when they opt to receive hospice. Hospice services are covered by Medicare, Medicaid, and most private insurance providers. Hospice is provided in a variety of settings including patient homes, nursing facilities, hospitals, and inpatient hospice facilities. Hospice provides the following services:

- An interdisciplinary team to facilitate the management of distressing symptoms at end of life
- Assists the patient and family with emotional, psychosocial, and spiritual care
- Provides grief and bereavement counseling to the family for at least a year following the death of the patient
- Provides short-term inpatient care when pain or symptoms become too difficult to manage at home or if the caregiver needs respite time

© F.A. Davis Publishing

- Delivers specialized services such as speech and physical therapy when needed
- Provides medications and medical equipment to facilitate the care of the patient (NHPCO, 2020)

Etiology: In the United States, the five leading causes of death in 2019 were heart disease, cancer, unintentional injuries, stroke, and chronic lower respiratory diseases. In 2020, because of the global coronavirus pandemic (COVID-19), COVID-19 deaths displaced unintentional injuries as the third leading cause of death in the United States (Ahmad & Anderson, 2021).

Numerous medical advances in the management of these illnesses have led to people living longer with chronic health conditions. Accurate prognostication of chronic illnesses is difficult, and the difficulty of prognostication can result in overuse of acute care interventions at the end of life and delays in referral to hospice care. In 2018, the median length of stay in a hospice program was 18 days, meaning one-half of patients died within 2.5 weeks of enrollment in a hospice program. The average length of stay in a hospice program was 89.6 days (NHPCO, 2020). Thus, most people are not benefiting fully from the Hospice Medicare Benefit, which is designed to provide care for patients in the last 6 months of life.

Occurrence: In 2017, for the first time, deaths of Americans at home (30.7%) surpassed those in the hospital (29.8%). The same year 20.8% of Americans died at nursing facilities and 8.3% of Americans died at a hospice facility (Cross & Warraich, 2019). It is important to provide access to hospice and palliative care services in all settings. The goal is to ensure a peaceful, dignified death with symptoms well-managed and support for the family and caregivers. Establishing the goals of care in treating older adults with life-limiting illnesses is essential.

Age: In 2018, average life expectancy was 78.7 years in the United States (Xu et al., 2020). The United States has an aging population with an expectation that by 2034, older adults (aged 65 and over) will outnumber children (Vespa et al., 2020). Palliative care is beneficial for frail older adults because there is limited data to suggest improved outcomes from aggressive medical interventions in this population (Lazris, 2019).

Caregiving needs increase with advanced age and are typically met by the family. Caregivers are at risk for physical and psychological distress, including depression, insomnia, fatigue, and anxiety, as well as physiological effects and financial burden (Sun et al., 2019). Palliative care can have a role in supporting families and improving caregiver outcomes (Hui et al., 2018).

Ethnicity: In the United States, Hispanic females have the longest life expectancy (84.3 years), followed by non-Hispanic females (81.1), Hispanic males (79.1), non-Hispanic black females (78), non-Hispanic White males (76.2), and non-Hispanic Black males (71.3) (Arias, 2020). Cultural influences affect how people define health and illness and shape their beliefs and practices in end-of-life care (Cain et al., 2018).

Contributing Factors: Contributing factors include advanced age and multiple comorbidities. The average overall life expectancy for females is 81.2 years; the average life expectancy for males is 76.2 years (Xu et al., 2020).

Signs and Symptoms: See Symptom Management.

Differential Diagnosis: Not applicable.

SYMPTOM MANAGEMENT

A few of the most prevalent symptoms in end-of-life care in the geriatric population are delirium, dyspnea, and pain. Additional symptoms such as nausea and vomiting, constipation, diarrhea, fatigue, depression, anxiety, and insomnia are common. These latter symptoms are described in detail elsewhere in this book. When addressing pharmacological symptom management in older adults, it is important to consider physiological changes, such as decreased renal and hepatic function and altered body fat distribution, that may alter drug metabolism, leading to higher serum drug levels. Older adults are more susceptible to adverse reactions, thus, begin with lower initial doses and titrate cautiously (American Association of Colleges of Nursing & City of Hope, 2019).

DELIRIUM

Description: Delirium is disturbance of attention and awareness accompanied by a change in baseline cognition, developing over a short period of time, fluctuating during the course of a day, and often worsening at night (Hshieh et al., 2020). Those with delirium have:

- A reduced awareness of their environment
- Disturbance of consciousness with impaired ability to focus, sustain, or shift attention
- Cognitive changes involving memory impairment, disorientation, and language disturbance
- Perceptual disturbances, including delusions and hallucinations

Delirium can be hyperactive with symptoms of hyperalertness, hypervigilance, and agitation, or delirium may be hypoactive and characterized by somnolence (Mattison, 2020).

Etiology: There are numerous potential causes of delirium in the dying patient related to the terminal disease itself, treatment of the disease, metabolic effects of organ failure, and electrolyte imbalance, including hypoglycemia, infection, hematological disorders, nutritional deficiencies, dehydration, hypoxia, uncontrolled pain, sensory deprivation, sleep disturbance, alcohol or drug withdrawal, diarrhea, constipation, and urinary retention. Many medications, particularly benzodiazepines and anticholinergic medications, can cause delirium. Opioids, particularly meperidine, may increase risk for delirium as well (Kates, 2020).

Occurrence: Delirium is common at end of life and can be very distressing to the family, as well as to the patient. Prevalence ranges from 13% to 93%. It is often unrecognized, particularly hypoactive delirium (Mattison, 2020). Terminal delirium is common as death approaches, affecting

© F.A. Davis Publishing

up to 90% (Hshieh et al., 2020; Mattison, 2020; Rieck et al., 2020).

Age: Advancing age is a risk factor for delirium (Li et al., 2020). Older patients presenting with delirium have up to 50% mortality at 1 year (Mattison, 2020).

Ethnicity: Delirium can affect all people. Utilize culturally sensitive screening tools.

Contributing Factors: The frail older adult with less physiological reserve, multiple comorbidities, polypharmacy, pre-existing dementia, previous history of delirium, and/or sensory impairment who is in an unfamiliar environment is more vulnerable to delirium. Patients admitted to the hospital, in particular to an intensive care unit, are at increased risk for delirium (Gravante et al., 2021; Li et al., 2020).

Signs and Symptoms: Acute onset and fluctuating course of inattention, altered level of consciousness, and disorganized thinking are signs of delirium. Disorientation, memory impairment, perceptual disturbances, psychomotor agitation or retardation, emotional instability, and impaired sleep–wake cycle are common findings (Hshieh et al., 2020; Mattison, 2020; Rieck et al., 2020).

Diagnostic Tests: Patient history and assessment, including a review of the patient's medications, are the first steps in diagnosing delirium. Disorientation, memory impairment, perceptual disturbances, psychomotor agitation or retardation, and impaired sleep–wake cycle are common findings. The Confusion Assessment Method (CAM) has been validated as an effective tool to diagnose delirium (Helfand et al., 2021). CAM assesses for the presence of acute onset and fluctuating course, as well as inattention and either disorganized thinking or altered levels of consciousness. These findings are diagnostic of delirium. Other tools include the Memorial Delirium Assessment Scale and the Delirium Rating Scale (Helfand et al., 2021). More invasive diagnostic tools may be indicated to determine the etiology if further evaluation is consistent with goals of care. In the terminally ill, the most common cause of delirium is medications, including opioids, anticholinergics, and benzodiazepines. The second most common cause of delirium is metabolic insufficiency due to organ failure (Klankluang et al., 2021).

Differential Diagnosis: Consider the possibility of dementia, depression, or the coexistence of either of these with delirium (Mattison, 2020).

Treatment: The first step in treating delirium is to identify the cause(s) if possible. Make appropriate changes to the plan of care based on the etiology. Perform regular medication reviews to eliminate unnecessary agents. Consider inadequate pain control as a cause of delirium; remember, however, that opiates can cause delirium and dose reduction may be necessary (Mattison, 2020). Deprescribing of psychoactive medications is also important (Hshieh et al., 2020). Evaluate fluid and electrolyte imbalances, infections, organ failure, hypoglycemia, drug toxicity, as well as withdrawal from alcohol and sedatives (Mattison, 2020). Attention should also be paid to providing a therapeutic environment, as well as a supportive and safe environment focusing on clear communication and a structured daily routine with consistent caregivers and a structured sleep–wake cycle, avoiding sensory overstimulation and providing for glasses and hearing aids if indicated, and providing physical activity and attention to oral intake and elimination (Hshieh et al., 2020). Frequent reassurance, touch, and verbal orientation may lessen behavior disturbances (Bush et al., 2017).

Nonpharmacological interventions are the mainstay of managing delirium. However, in the acutely agitated patient, a trial of pharmacological agents may be indicated. Neuroleptic agents are generally used, but there continues to be limited data to support their use (Rieck et al., 2020). Atypical antipsychotics, such as olanzapine, risperidone, quetiapine, and ziprasidone, can be considered for the agitated patient. However, these agents carry an increased risk of QT prolongation, with increased risk for cardiovascular events and death in the elderly with dementia (Bush et al., 2017; Hshieh et al., 2020). In the palliative care literature, haloperidol is considered the mainstay of delirium management, beginning with low doses, 0.5 mg intravenously or subcutaneously, or 1 mg orally (Hshieh et al., 2020). Titrate slowly in older adults. Chlorpromazine 25 to 50 mg is an alternative if more sedation is needed, but it may cause hypotension (Bush et al., 2017).

Benzodiazepines, such as lorazepam, may benefit patients with a seizure disorder or alcohol withdrawal and those who cannot tolerate antipsychotic medications. However, benzodiazepines may lead to paradoxical agitation, causing symptoms of delirium to worsen. Therefore, these agents should be used cautiously (Klankluang et al., 2021).

Anticholinergic medications should be avoided. Cholinesterase inhibitors have recently been found to aid delirium. In a double-blinded randomized study comparing rivastigmine patch 4.6 mg and melatonin 7 mg patch in 180 adults aged 60 to 85 years concluded that both were comparable in reducing severity of delirium (Hussien & Shoukry, 2020). Also, the melatonin agonist ramelteon is showing promise in the reduction and prevention of delirium (Khaing & Nair, 2021).

Follow-Up: Provide adequate treatment of underlying cause. Due to multimodal causes, an interdisciplinary approach is preferred.

Sequelae: Prompt evaluation and treatment can improve outcomes. Delirium is distressing to patients, their families, and health-care providers. Delirium contributes to increased morbidity and mortality. Older patients presenting with delirium have up to 50% mortality at 1 year (Mattison, 2020). Patients are at risk for falls and potential injury. In end-of-life care, the goal is supportive care to promote a peaceful, dignified death.

Prevention/Prophylaxis: Avoid polypharmacy. Discontinue unnecessary medications and use high-risk medications cautiously. Maintain adequate hydration and nutrition, as appropriate, with prompt attention to elimination needs. Minimize invasive devices such as catheters. Correct sensory deficits. Promote normal sleep patterns. Avoid physical restraints. Use music and massage. Provide a therapeutic milieu with appropriate environmental stimulation (Hshieh et al., 2020).

Referral: Refer the patient to a geriatric psychiatrist, geriatrician, geriatric nurse practitioner, and/or palliative medicine practitioner as needed.

Education: Teach the patient's family signs of delirium and ask that they report the signs promptly to the medical team. Teach nonpharmacological methods of providing a supportive environment. Avoid over-the-counter (OTC) medications (Mattison, 2020).

© F.A. Davis Publishing

DYSPNEA

Description: Dyspnea, also called breathlessness, shortness of breath, or air hunger, has been defined by the American Thoracic Society as a subjective experience of breathing sensations that vary in intensity (Hui et al., 2021; Parshall et al., 2012). The patient's experience of dyspnea is derived from the complex interplay of emotional, physical, social, and spiritual factors that may induce secondary physiological and behavioral responses. It is a distressing symptom at end of life and affects quality of life (Crombeen & Lilly, 2020).

Etiology: Dyspnea can have multiple causes, such as infection, cancer, heart failure, chronic obstructive pulmonary disease (COPD), obstructive sleep apnea (OSA), asthma, pulmonary fibrosis, interstitial lung disease, thrombotic events, pneumothorax, pleural effusion, anemia, amyotrophic lateral sclerosis, and anxiety. Dyspnea is physiologically complex, stemming from activation of receptors in the airway, lung parenchyma, chest wall, and peripheral or central chemoreceptors (Pisani et al., 2018).

Occurrence: Dyspnea is one of the most common symptoms experienced by patients as they approach the end of life. It is commonly reported in patients with advanced cardiovascular disease, pulmonary disease, and cancer (Stevens et al., 2018). Together, these diagnoses account for over 50% of all deaths in the United States (Ahmad & Anderson, 2021). An estimated 43% of patients with respiratory diagnoses and 25% of patients with cardiovascular diagnoses report dyspnea in the 24 hours prior to hospitalization (Stevens et al., 2018). In cancer patients, prevalence of dyspnea can be greater than 50%, with symptoms affecting treatment and frequently leading to hospitalization (Crombeen & Lilly, 2020).

Age: Certain causes, such as heart failure, cancer, and chronic lung disease, are more common in older adults.

Ethnicity: Not applicable.

Contributing Factors: Smoking and comorbidities can contribute to the development of dyspnea.

Signs and Symptoms: Shortness of breath at rest and/or exertion, tachypnea, use of accessory muscles, hypoxia, adventitious breath sounds, cyanosis, and pursed-lip breathing are all signs of dyspnea.

Diagnostic Tests: The first step in diagnosing dyspnea is the clinical patient interview and physical examination. The physical examination should include respiratory rate, oxygen saturation, and assessment of breath sounds, heart rate, heart sounds, presence or absence of jugular venous distension, pallor, cyanosis, or ascites (Budhwar & Syed, 2020). The clinical interview should at a minimum include lifestyle assessment (such as smoke or irritant exposure), modifying factors or self-interventions, and use of a dyspnea assessment tool (American Association of Colleges of Nursing & City of Hope, 2019). Multiple dyspnea assessment tools are validated; however, many are one-dimensional, disease-specific, or do not address the affective component in dyspnea in advanced disease. The American Thoracic Society and American College of Chest Physicians do not endorse one specific tool (Parshall et al., 2012). However, use of these tools in combination with the clinical interview, physical examination, and diagnostic testing, if warranted, while keeping in mind the patient's goals for care, can help determine the appropriate course of dyspnea treatment (Birkholz & Haney, 2018).

Examples of dyspnea assessment tools are the Modified Borg Scale, Visual Analog Scale, Numeric Rating Scale, Memorial Symptom Assessment Scale, Edmonton Symptom Assessment Scale, Dyspnea-12 (for congestive heart failure [CHF], COPD, interstitial lung disease [ILD]), Cancer Dyspnea Scale (cancer-specific and addresses the affective component of dyspnea as well), and Respiratory Distress Observation Scale for those patients who are unable to self-report (Aslakson et al., 2017).

Diagnostic tools should be used as appropriate, considering the patient's goals of care. Diagnostic tests include laboratory tests, such as complete blood count to determine anemia, basic metabolic panel to evaluate renal function, chest x-ray, and electrocardiogram (EKG). Computed tomography (CT) scan to evaluate for malignancy and/or pulmonary embolism may be indicated. Echocardiogram may also be performed to evaluate for poor cardiac ejection fraction or pericardial effusion (Budhwar & Syed, 2020).

Differential Diagnosis: Consider all etiologies as outlined previously. If cough is present, consider pneumonia; pleural effusion; side effects of medications, such as angiotensin-converting enzyme inhibitors; and gastroesophageal reflux disease (Budhwar & Syed, 2020; Crombeen & Lilly, 2020).

Treatment: Treatments should be aimed at the underlying etiology. Pharmacological interventions might include diuretics, bronchodilators, vasodilators, steroids, antibiotics, opioids, and/or sedatives (Budhwar & Syed, 2020; Crombeen & Lilly, 2020) (Table 23-1). Opioids remain the mainstay for treatment of dyspnea at end of life (Arya et al., 2020; Budhwar & Syed, 2020; Hui et al., 2018; Pisani et al., 2018; Slawnych, 2020). Similar to when used for the treatment of pain, opioids act on receptors in the central cortex and thereby affect the neurological perception of dyspnea. Opioids are likely underutilized for management of dyspnea due to fear that they will lead to respiratory depression. However, evidence suggests that when used judiciously ("start low and go slow"), opioids are safe for use in the management of dyspnea and do not hasten death (Pisani et al., 2018; Slawnych, 2020). There is no consensus on which opioid medication or dose is the most efficacious for the management of dyspnea. One author recommends that for hospitalized patients, clinicians start with morphine at low doses (1 to 2 mg IV) and titrate up every 15 minutes until patients are more comfortable (Pisani et al., 2018). Some authors suggest utilizing hydromorphone as the opioid of choice either in oral, IV, or subcutaneous formulations. For hospitalized patients at end of life, clinicians can use hydromorphone 0.5 mg IV or subcutaneously every 30 minutes as needed (Arya et al., 2020; Slawnych, 2020). In the case of severe dyspnea, particularly in patients that are at end of life, clinicians may opt to start a continuous opioid infusion.

© F.A. Davis Publishing

TABLE 23-1 Pharmacological Interventions for Dyspnea

Opioids	Morphine 0.5 to 10 mg orally every 3–4 hours prn SOB
Nebulized opioids	Further research is needed
Benzodiazepines	Studies reveal no significant benefit
Nebulized furosemide	Potential benefit, further research is needed
Bronchodilators, diuretics, steroids, antibiotics, vasodilators	As indicated based on etiology

For patients that are at end of life and for which IV access is limited, clinicians can use a butterfly needle inserted into the subcutaneous tissue as a method for opioid delivery (Slawnych, 2020).

Oral morphine can be used safely and effectively and may be a good choice for nonhospitalized patients. For patients who are opioid naïve, clinicians can start oral morphine 2.5 mg to 5 mg every 4 to 6 hours (Crombeen & Lilly, 2020). Oral morphine can then be titrated up to achieve comfort. Patients may require around-the-clock dosing or conversion to a long-acting formulation once symptoms are stable (Crombeen & Lilly, 2020). Morphine in an elixir formulation is often utilized by hospice for the management of pain/dyspnea even in patients that are no longer able to effectively swallow.

Some guidelines suggest trial of a benzodiazepines for dyspnea refractory to opioids or in the case of concurrent anxiety (Hui et al., 2018; Slawnych, 2020). Inhaled/nebulized opioids and anesthetics have not proved to effectively treat dyspnea (Crombeen & Lilly, 2020). It is also recommended to reduce excessive secretions with anticholinergics such as scopolamine, hyoscyamine, atropine, or glycopyrrolate. There is usually little benefit from suction, particularly in patients that are at end of life (Slawnych, 2020).

Diuretics may help improve dyspnea in patients who are volume overloaded due to heart failure or in the case of lymphangitic carcinomatosis. Nebulized furosemide has been used as a novel intervention to help with dyspnea, although its mechanism of action is unknown (Pisani et al., 2018). Corticosteroids are often used to reduce airway inflammation in a variety of terminal diseases (Hui et al., 2018; Pisani et al., 2018).

Nonpharmacological interventions include the use of a fan directed at the cheek or face, oxygen if hypoxic, elevation of the head of the patient's bed, relaxation and breathing exercises, cooler room temperatures, acupuncture, and stress reduction techniques (Hui et al., 2018; Pisani et al., 2018). Temporary ventilator support can be explored if clinically indicated for severe reversible conditions. The routine application of oxygen to patients who are near death is not supported. Oxygen therapy for those who are hypoxic has shown to be beneficial for managing dyspnea (Pisani et al., 2018). Implement oxygen therapy if there is a subjective report of relief. Interventional therapies to be considered for dyspnea management related to refractory pleural effusions include thoracentesis, pleurodesis, and tunneled catheter to drainage. Other interventional options for refractory dyspnea related to obstruction can be bronchoscopy or stenting (Budhwar & Syed, 2020; Hui et al., 2018).

Follow-Up: Follow-up is dependent on etiology. Ongoing assessment, reevaluation, and adjustment of plan of care should be used as needed. Monitor for therapeutic effect, as well as adverse effects from interventions.

Sequelae: Dependent on etiology and goals of care, dyspnea should improve when the cause is treated. However, dyspnea is also common in the dying person, and the goal is comfort measures when death is an anticipated outcome.

Prevention/Prophylaxis: Preventive measures are dependent on the cause. Smoking cessation is beneficial, as is the avoidance of smoke exposure. Use energy conservation and durable medical equipment for the severely dyspneic patient with advanced illness. If the patient is an aspiration risk, modifying food textures and a speech therapy consult may be beneficial.

Referral: Referral may be indicated based on etiology and goals of care. Appropriate referrals may include visits to a palliative care specialist, cardiologist, pulmonologist, and/or oncologist.

Education: Smoking cessation; the proper use of medications, including inhalers and nebulizers; the use of fans; energy conservation; and potential adverse effects of medications.

PAIN

Description: "Pain is an aversive sensory and emotional experience typically caused by, or resembling that caused by, actual or potential tissue injury" (Sukel, 2019). The prevalence of cancer pain is high with less optimal treatment reported by patients (Fee Voon Ho, et al., 2020). The patient's own report is the best indicator of pain (Schwan et al., 2019). Most older adults, including those with dementia, can effectively communicate pain, but a more detailed assessment of pain can be challenging. Several pain assessment tools are available, including the Visual Analogue Scale (VAS), Numerical Analogue Scale (NAS), Wong-Baker FACES Pain Rating Scale, Pain Assessment in Advanced Dementia (PAIN-AD) Scale, NOPPAIN, and Checklist of Non-Verbal Pain Indicators (Lukas, 2019: Resnick et al., 2019; Sirsch et al., 2020).

Etiology: Pain is categorized as somatic, visceral, neuropathic, or mixed (American Association of Colleges of Nursing & City of Hope [AACN & COH], 2020). Somatic pain originates from cutaneous, bone, and musculoskeletal tissues. Examples include muscle pain, such as fibromyalgia or myofascial pain; inflammatory pain, such as an acute injury or chronic

© F.A. Davis Publishing

inflammatory pain, including arthritis; and mechanical pain related to fractures or dislocations or compression of tissue by bony structures. Somatic pain is typically well localized and described as aching. Visceral pain originates in the thoracic, abdominal, and pelvic viscera. It is diffuse pain and often radiates. Neuropathic pain is nerve pain due to dysfunction of the nervous system. Examples include diabetic neuropathy, neuropathy due to herpes zoster, and peripheral vascular disease (Schwan et al., 2019). Psychological pain should be considered as well, related to depression, anxiety, personality disorders, somatization disorders, and post-traumatic stress disorder. Common causes of pain in older adults are low back pain, cancer pain, and neurogenic pain syndromes (Schwan et al., 2019). Patients also experience nonmalignant pain from cardiac, renal, pulmonary, hepatic, neurological, or immune disorders (AACN & COH, 2020).

Occurrence: Pain is a common end-of-life symptom in older adults. Fifty percent of older adults report chronic pain, and it is not alarming that up to 70% report pain in more than one site of the body (Schwan et al., 2019). About 53% of patients with cancer experience pain (Sirsch et al., 2020), and about 45% to 80% of nursing home residents experience pain (Sirsch et al., 2020). Women and men are at equal risk for undertreatment of pain (American Association of Colleges and Nursing & City of Hope, 2020).

Age: The comorbidities experienced with aging make pain more likely. Older adults, particularly those with dementia, are at risk for undertreatment of pain (American Association of Colleges and Nursing & City of Hope, 2020). Many of the interventions to treat these challenging symptoms are pharmacological interventions. It is important to consider geriatric pharmacology when formulating treatment plans. Several physiological factors affect drug distribution, including cardiac output, regional blood flow, body mass and composition (which affect hydrophilic and lipophilic drug distribution), and plasma protein concentration. These changes make an older adult person more susceptible to adverse drug effects. Drug metabolism and clearance in an older adult is often slowed due to declining renal and liver function. Drug interactions, particularly with drugs metabolized through the P450 enzyme system, also put an older adult at risk. The health-care provider needs to be mindful of these effects when prescribing. Begin with low doses and titrate carefully, with frequent reassessment, to optimize pain relief and minimize adverse effects (Yang et al., 2020).

Ethnicity: Nondominant cultures are at risk for undertreatment of pain; biases exist in pain assessment and management. Culture impacts access to medical care, including access to medications (American Association of Colleges and Nursing & City of Hope, 2020).

Contributing Factors: Multiple comorbidities, as stated earlier in the text.

Signs and Symptoms: Complete a thorough pain assessment, including history, location, intensity (using an appropriate pain assessment tool), quality, pattern, aggravating/relieving factors, temporal pattern medication history, and cultural influences (Portenoy, 2020). Clinicians conducting the comprehensive pain assessment should utilize one of the validated pain tools and also assess the holistic impact of pain, including physical, psychological, social, and spiritual factors, as well as capturing medical diagnoses, comorbid conditions, psychiatric history (including substance abuse history), and prior treatments for pain (Sirsch et al., 2020).

Diagnostic Tests: Patient history and physical examination should direct appropriate diagnostic testing to assess the underlying cause.

Differential Diagnosis: Determine somatic, visceral, and/or neuropathic pain, or treatment-related pain.

Treatment: Treatment of pain should include a multidimensional approach consisting of both pharmacological (see Table 23-2) and nonpharmacological interventions. The World Health Organization (WHO) analgesic ladder has been revised to include integrative therapies at each stage of opioid medication escalation. The previous analgesic ladder has been found not to be effective for noncancer chronic pain syndromes (Yang et al., 2020). The addition of integrative therapies is an attempt to reduce the overuse of opioids while utilizing the holistic approach of evidence-based alternative and complementary modalities (Yang et. al., 2020). The first step of the WHO ladder recommendation is the use of NSAIDs and acetaminophen for mild pain. Acetaminophen is still considered an effective agent for pain associated with osteoarthritis and low back pain. Many experts recommend limiting intake of acetaminophen to 3,000 mg per 24 hours to prevent overdose and decrease liver risks associated with its use (Portenoy, 2020). In those with hepatic insufficiency or alcohol abuse, acetaminophen dose should be reduced by 50% to 75%. Liver failure is an absolute contraindication.

Recent guidelines from the American Geriatrics Society advise against the routine use of NSAIDs in older adults for several reasons (Yang et al., 2020). These include gastrointestinal (GI) toxicity, renal toxicity, and platelet dysfunction, as well as adverse effects on blood pressure control and heart failure management. The risk of myocardial infarction or stroke is increased with the use of NSAIDs (Portenoy, 2020). The risk increases with concurrent use of corticosteroids. Concurrent use of daily acetylsalicylic acid (ASA) and/or selective serotonin reuptake inhibitors (SSRIs) also may pose additional risk for GI bleeding. Administering NSAIDs with food, proton pump inhibitors, or histamine-2 blockers can help prevent

TABLE 23-2 Pharmacological Interventions for Pain Management

Acetaminophen	Limit to 3,000 mg or less in older adults
NSAIDs	Avoid routine use in older adults
Opioids: morphine, oxycodone, hydromorphone, fentanyl	Severe pain, start low go slow
Tramadol	Weak opioid antagonist and selective norepinephrine reuptake inhibitor (SNRI)
Methadone	Opioid agonist and NMDA antagonist
Buprenorphine	Opioid agonist-antagonist

© F.A. Davis Publishing

GI challenges (Portenoy, 2020). The COX-2 inhibitors may place a person at greater risk for cardiovascular events, including myocardial infarction (Portenoy, 2020). When using NSAIDs, the maximum daily doses (MDDs) for specific NSAIDs are ASA, 4,000 mg/day; ibuprofen, 2,400 mg/day; Naprosyn, 1,375 mg/day; and Toradol, 120 mg/day in 24 hours (Portenoy, 2020).

Patients with moderate-to-severe pain with functional impairment and/or decreased quality of life due to pain can be considered for opioid therapy (Davis et al., 2020). The WHO ladder adds opioids, typically in combination with acetaminophen, which should limit the number of total opioids. Examples include codeine, hydrocodone with acetaminophen, and oxycodone with acetaminophen. These are used for moderate pain (Davis et al, 2020).

For severe pain, the WHO ladder includes opioid pain medications. Opioid administration in the older adult population should consist of a "start low and go slow" approach. Consider long-term opioids in those patients who do not respond to more conservative management and who continue to experience pain-related distress or functional impairment and demonstrate benefit from the opioid medication. Clinicians may prescribe a trial of opioids in cancer survivors with chronic pain (Davis et al., 2020). The only absolute contraindication to the use of opioids is if there is a history of rash, wheezing, or edema (Schwan et al., 2019). Common opioids include morphine, oxycodone, and hydromorphone. Tramadol is a weak opioid agonist and a serotonin-norepinephrine reuptake inhibitor. It has a ceiling dose and can lower the seizure threshold, as well as contribute to hypoglycemia, and can lead to serotonin syndrome (Davis et al., 2020). Monitor the patient on short-acting pain medication. If the patient requires regular dosing every 4 to 6 hours, consider a long-acting formulation, but monitor closely for adverse effects (including altered mental status). Patients with continuous pain may be treated with around-the-clock dosing to achieve steady state (Davis et al., 2020).

Controlled-release opiates are appropriate for chronic pain (Prommer et al., 2021). Examples of long-acting opioids for pain control include morphine sulfate sustained release, oxycodone sustained release, hydromorphone sustained release, fentanyl patch, and the Butrans patch (Davis et al., 2020). Methadone is a unique opioid in that it appears to also act as an *N*-methyl-D-aspartate (NMDA) antagonist in addition to opioid receptor bonding. This unique element helps in the treatment of neuropathic pain management (Davis et al., 2020; Portenoy et. al., 2020). Methadone is also a long-acting pain medication, but it requires careful dosing and monitoring due to its variable half-life, potential prolongation of QT interval, and numerous drug interactions (Davis et al., 2020).

Be cautious with opioid rotation and use an appropriate equianalgesic dosing chart (Davis et al., 2020). Pay attention to renal and hepatic impairment. Choose an opioid with less active metabolites (fentanyl, hydromorphone, methadone) if renal function is declining (Portenoy, 2020). Monitor for signs of drug accumulation, which can include delirium, sedation, and myoclonus. Also monitor polypharmacy due to potential for drug interactions. If opioids are no longer necessary, they should not be stopped abruptly. They should be tapered because abrupt withdrawal could potentiate withdrawal symptoms (Davis et al., 2020).

Anticipate, assess for, and identify potential adverse effects (Resnick et al., 2019). Common adverse effects include constipation, nausea, sedation, urinary retention, and pruritis (Resnick et al., 2019). Long-term adverse effects include constipation, mental clouding, fatigue, osteoporosis, osteopenia, reduced libido, risk of myoclonus, mood changes, risk of opioid-induced hyperalgesia, and increased risk of sleep-disordered breathing (Resnick et al., 2019).

Unless a patient is in the dying process, if a patient becomes unarousable or experiences opioid-induced respiratory depression, the opioid can be reversed by using an opioid antagonist such as naloxone (Resnick et al., 2019). Sedation precedes respiratory depression, so monitor closely, particularly in the opioid-naïve patient. Begin with short-acting medications before adding a long-acting formulation (Portenoy, 2020). Sedation can occur during the inception of opioid treatment, yet tolerance generally develops to the effect. If sedation persists, consider rotating to another opioid. Methylphenidate can also be used to counteract sedation (Portenoy, 2020).

Most people develop a tolerance to all of the adverse effects, except for constipation, which typically requires an aggressive bowel regimen with regular dosing of a laxative and stool softener and/or osmotic agent. Most often this regimen is started while the opioid is prescribed (Portenoy, 2020). Methylnaltrexone is approved for severe opioid-induced constipation, and naloxone given orally has also demonstrated effectiveness (Portenoy, 2020). In addition, lubiprostone is approved for treating opioid-induced constipation (Resnick et al., 2019). Monitor bowel function closely to avoid obstipation, but if fecal impaction occurs, administer a lubricant, such as a glycerin suppository or mineral oil enema, and disimpact manually. Suppositories and enemas should be avoided in patients with neutropenia and thrombocytopenia. Because disimpaction can be a painful procedure, the patient may require premedication with an appropriate analgesic (Resnick et al, 2019).

Clinicians should educate patients and families about potential risks and benefits when initiating treatment, including adopting a universal precautions approach to minimize abuse, addiction, diversion, as well as clarify myths and misconceptions about opioid therapy. Clinicians should educate patients and families regarding safe storage, use, and disposal of controlled substances, as well as caution with using alcohol or sedating over-the-counter (OTC) medications (Portenoy, 2020).

Adjuvant medications may improve pain control and can be added at any step of the WHO step ladder (Forbes, 2011) (see Table 23-3). Tricyclic antidepressants may improve neuropathic pain. Adverse effects due to anticholinergic activity need to be considered. Nortriptyline and desipramine may be better tolerated in the older adult (Portenoy, 2020). Duloxetine, an inhibitor of norepinephrine and serotonin reuptake, is another option, indicated for diabetic neuropathy and chronic musculoskeletal pain, as well as for fibromyalgia (Portenoy, 2020). Anticonvulsants can be beneficial for lancinating neuropathic pain, which is often described as burning, shooting, and electrical. Gabapentin and pregabalin are commonly used (Schwan et al., 2019). Topical analgesics, such as lidocaine 5% patch, can be beneficial for postherpetic neuropathy. Capsaicin cream has shown benefit in neuropathic and non-neuropathic pain syndromes; however, about 30% of

© F.A. Davis Publishing

people do not tolerate the adverse burning sensation when treatment is initiated (Schwan et al, 2019). The use of topical agents, such as anti-inflammatories, anesthetics, compounded creams or gels with baclofen, tricarboxylic acids (TCAs), ketamine, or other combinations, show evidence that benefits outweigh harms; evidence quality is intermediate, and strength of recommendation is moderate (Portenoy, 2020). The effectiveness of ketamine is insufficient to make a recommendation for routine clinical use although it has proven to be acceptable with close monitoring (Portenoy, 2020).

Corticosteroids improve the pain of nerve or spinal cord compression. They also reduce edema and inflammation, resulting in improved pain control (Hardy et al., 2021). Corticosteroids also may improve pain management related to bowel obstruction and headaches caused by increased intracranial pressure (Hardy et al., 2021). Caution is advised due to the adverse effects of corticosteroids and therefore the use of long-term corticosteroids for chronic pain is usually reserved for end-of-life use (Portenoy, 2020). Clinicians can follow state-specific regulations to allow access to medical cannabis or cannabinoids for patients with chronic pain after consideration of the potential benefits and risks of available formulations (evidence-based benefits outweigh harms; evidence quality intermediate, strength of recommendation moderate) (Yang et al., 2020). A study by Yang and associates (2020) revealed that the majority of participants used cannabis for medical purposes, with the most common symptoms being pain/arthritis, followed by insomnia, anxiety, and depression. Calcitonin may be beneficial for bone pain due to vertebral compression fracture, pelvic fractures, and pain due to bony metastatic disease (Hardy et al., 2021). Baclofen, a muscle relaxant, can be used for spasticity due to central nervous system injury and neuromuscular disorders. Start with a low dose and increase slowly to minimize dizziness, sedation, and GI disorders. Baclofen should be tapered slowly to avoid potential delirium and seizure (Hardy et al., 2021).

Nonpharmacological approaches include behavioral therapies such as relaxation, mindfulness, distraction, imagery, prayer, and cognitive reframing (Sandvik et al., 2020). Physical measures include heat and/or cold application, repositioning, massage, and other complementary therapies such as acupuncture (Sandvik et al., 2020).

Radiation therapy is effective in the relief of pain related to tumor or masses. Radionucleotides also can be used for bone pain related to bone cancer. Chemotherapy, biological response modifiers, hormone therapy, and bisphosphonates all can reduce pain in patients with malignancies (Henson et al., 2020). Interventional procedures such as neuroablation, nerve blocks, celiac-plexus block, implantable drug delivery systems, vertebroplasty, and kyphoplasty can also help in the treatment of chronic pain (Henson et al., 2020).

TABLE 23-3 Adjuvant Pain Medications

Tricyclic antidepressants: desipramine, nortriptyline, amitriptyline	Neuropathic pain
SNRI: duloxetine	Diabetic peripheral neuropathy, fibromyalgia, and musculoskeletal pain
Anticonvulsants: gabapentin, pregabalin	Neuropathic pain
Capsaicin topical	Neuropathic and non-neuropathic pain
Lidocaine topical	Postherpetic neuralgia
Corticosteroids	Pain due to nerve compression; anti-inflammatory
Cannabinoids	State-specific regulations

Follow-Up: Perform ongoing assessment, reevaluation, and adjustment of plan of care as needed. Monitor for therapeutic effect, as well as adverse effects. Older adults are more susceptible to the adverse effects of opioids and other nonopioid analgesics and adjuvant medications and, thus, require close follow-up (Portenoy, 2020).

Sequelae: Unrelieved pain is associated with functional impairment, falls, mood disorders (including depression and anxiety), sleep and appetite disturbances, and decreased socialization (Hardy et. al., 2020). Improved pain control improves function and quality of life. Potential negative outcomes of opioids can include sedation, respiratory depression, coma, and death. These adverse events can typically be avoided by choosing the appropriate medication for the patient, starting at a low dose, and titrating slowly to effect while monitoring for adverse effects. Addiction can occur and should be monitored (Sirsch et al., 2020).

Prevention/Prophylaxis: Prevention/prophylaxis is dependent on etiology. Pain escalation may indicate advancing disease, particularly in the cancer patient; a new clinical finding; or tolerance to current opioid drug dose. Monitor with ongoing assessment. Anticipate painful procedures, such as wound care, and treat appropriately. Clinicians should incorporate a universal precautions approach to minimize abuse, addiction, and adverse consequences of opioid use, and should be cautious in coprescribing other centrally acting drugs (Resnick et al., 2019).

Referral: Refer the patient to a palliative care or pain management specialist for complicated pain syndromes or intolerance to common analgesics.

Education: Explain causes of pain syndromes, treatment strategies, and importance of regular follow-up for reassessment of pain and possible adverse effects. Educate patient and family about the risks of opioids and appropriate interventions for common adverse effects such as nausea and constipation. Advise the patient, family, and staff that sedation precedes respiratory depression and to report excessive sedation promptly. Educate the patient and family on the risk also of drug diversion and stress safe keeping of opioids. Educate patients and families on risks and benefits of nonopioid analgesics and the need to report to the clinician any changes regarding their pain management needs. Also instruct the patient and family on safe disposal of opioid medications after they are discontinued.

© F.A. Davis Publishing

THE DYING PATIENT

Description: Death and dying are mostly considered medical events today, but there is growing acceptance of hospice and palliative care as creating a more natural dying experience. According to the *NHPCO Facts and Figures* (National Hospice and Palliative Care Organization [NHPCO], 2020), in 2018, the percentage of Medicare patients to die under hospice care varied significantly by state with a low of 22.8% (Alaska) to a high of 60.5% (Utah). Of the patients enrolled in hospice care, 51.5% died at home, 17.4% in a nursing facility, 12.8% died in a hospice inpatient facility, 12.3% died in an assisted living facility, and 6% died in "other" locations including the hospital (NHPCO, 2020).

Etiology: Physiological changes of aging and multiple comorbidities influence the dying process.

Occurrence: Mortality rate is 100%. All people will die.

Age: Risk of death increases with advancing age.

Ethnicity: The meaning and experience of death are often influenced by one's culture and ethnicity. Honor the patient's cultural beliefs, traditions, rights, and rituals (Cain et al., 2018; National Consensus Project for Quality Palliative Care & National Coalition for Hospice and Palliative Care, 2018).

Contributing Factors: Advancing age, terminal illness, and comorbidities.

Signs and Symptoms: End-of-life symptoms commonly include pain, delirium, dyspnea, nausea and vomiting, constipation, noisy secretions, and fever (Albert, 2017). Other symptoms observed in the actively dying are disorientation, agitation, restlessness, generalized weakness, drowsiness, sleeping more, decreased oral intake, dysphagia, fever, bowel changes, and incontinence (Table 23-4). Although most people sleep more as death approaches with only brief periods of interactions, some experience a surge of energy. A dying person may also

TABLE 23-4 Quick Reference Guide for Symptom Management

SYMPTOM	TREATMENT
Fatigue	• The most prevalent of symptoms reported in advanced disease • Rule out possible causative factors and evaluate which might be treatable given goals of care: anemia, iron deficiency, electrolyte imbalances, hypothyroidism, hypoxia, nutrition deficiencies, medications, anxiety/depression, sleep abnormalities • Exercise, physical therapy, occupational therapy • Assistive devices, caregiving support (hygiene, cleaning, meals) • Stimulants such as methylphenidate (Ritalin®) 2.5–5 mg PO QD or bid to start, then titrate prn • Dexamethasone (Decadron®) 2–8 mg PO QD, do not give in the evening • Mirtazapine (Remeron®) 15 mg PO QHS to enhance sleep, also improves appetite and mood
Insomnia/Sleep Disorders	• Evaluate sleep patterns current and prior to diagnosis • Suggest sleep hygiene measures: reduce caffeine in afternoon/evening, do not watch TV/computer/cellphone/tablets in bed, limit alcohol intake, cool room, warm bath before bed • Relaxation therapy such as mindfulness exercises, meditation, guided imagery • For some, pharmacological therapies ineffective if used daily • Zolpidem (Ambien®) 5–10 mg PO QHS; lower doses for women; safety concerns–sleep walking/eating • Mirtazapine (Remeron®) 15 mg PO QHS to enhance sleep, also improves appetite and mood • Buspirone (Buspar®) 5–20 mg PO tid • Trazodone (Desyrel®) 25–50 mg PO QHS • Avoid antihistamines (diphenhydramine) for sleeping aid, especially in elderly or frail

Constipation [Acute]	• Assess frequency, volume, consistency, and normal patterns of bowel movements
	• Diarrhea may be due to impaction; rectal examination indicated
	• Goal ≈3/week without straining, pain, tenesmus
	• Identify potential causative factors that can be addressed: opioids, anticholinergics, antihistamines, phenothiazines, tricyclic antidepressants, diuretics, iron, chemotherapy, ondansetron, antacids, dehydration, inactivity, hypercalcemia, hypokalemia, partial bowel obstruction, spinal cord compression, autonomic neuropathy, depression, anorexia, hypothyroidism
	• Encourage varied diet
	• First evacuate bowel: magnesium hydroxide (Milk of Magnesia) 30 mL PO QD, magnesium citrate 150–300 mL per day, bisacodyl 2–3 tabs PO QD or 10 mg suppository or Fleet's Enema® (nothing per rectum if patient thrombocytopenic [<50,000 platelets] or neutropenic [ANC <500–1,000]); limit Fleet's and other sodium phosphate agents in renal dysfunction; if these are ineffective, give:
	  • Methylnaltrexone (Relistor®) SQ (for opioid-induced constipation only); dosing is weight based; contraindicated in obstruction
	  • Naloxegol (Movantik®) 12.5 or 25 mg PO Q AM [for opioid-induced constipation only]
	  • Naldemedine (Symproic®) 0.2 mg PO QD [for opioid-induced constipation for patients with chronic noncancer pain]

Continued

© F.A. Davis Publishing

TABLE 23-4 Quick Reference Guide for Symptom Management—cont'd

SYMPTOM	TREATMENT
Constipation [Ongoing Prevention]	• All patients on opioids should have an order for a bowel regimen • Add stimulant and softener combination (e.g., senna/docusate) and titrate to effect (max 8 tabs/day) • Increase with upward titration of opioid dose • If persistent, consider adding bisacodyl 2–3 tabs PO QD or 1 rectal suppository QD; lactulose 30–60 mL PO QD; metoclopramide (Reglan®) 10–20 mg PO QID; magnesium hydroxide (Milk of Magnesia) 30 mL PO QD • When constipation is related to opioids or in debilitated patient, changing the diet or adding fiber supplements is rarely helpful • Educate patients/families; there is much stigma about discussing bowel function *Even when not eating, patients should have bowel movements every 1–2 days. Untreated constipation can lead to discomfort and increased pain, as well as agitation in the cognitively impaired patient.*
Diarrhea	• Evaluate for potential causes of diarrhea common in palliative care and correct/treat when feasible: medications (overuse of laxatives, antibiotics, magnesium, chemotherapy, immunotherapy), infection, diet, herbal products (e.g., milk thistle, cayenne, ginger), fecal impaction, malabsorption syndromes from surgery or tumor, radiotherapy that includes abdomen in treatment field, inflammatory bowel disease, and other comorbid disorders • Loperamide (Imodium®) 2 mg PO; start with 4 mg, followed by 2 mg after each bowel movement, not to exceed 8 capsules/24 hours • Diphenoxylate/atropine (Lomotil®) 1–2 tabs PO QID, maximum 8 per 24 hours • Tincture of opium: 0.6 mL PO q 4–6 hours prn • Methylcellulose (e.g., Metamucil®) or pectin can help provide bulk to liquid stools • Octreotide (Sandostatin®) 50 mcg SQ/IV q 8 hours, maximum 1,500 mcg/day • Cholestyramine: 2–4 g PO/day before meals (especially for *Clostridioides difficile* diarrhea) • Pancrelipase (Creon®, Pancreaze®) 500–2,500 lipase units/kg PO with meals
Dyspnea [Shortness of Breath; Air Hunger]	• Identify and treat reversible causes: airway obstruction (e.g., bronchodilators and/or corticosteroids), infection (e.g., antibiotics), CHF or fluid overload (e.g., diuretics), anxiety (e.g., anxiolytics) • Opioids are first-line therapy; start with morphine 2.5–5 mg PO every hour (any opioid can be used); titrate upward aggressively 25%–50% if unrelieved • Liquids may be easier to swallow or can be placed sublingually [although absorbed enterally]: morphine liquid; oxycodone liquid • Parenteral (IV or SQ) opioids can be used if patient unable to swallow • Add anxiolytics (benzodiazepines) if anxiety is present [e.g., lorazepam every 4 hours as needed] or opioids fail to provide relief • Elevate head of bed [can use a fan for comfort]; pursed lip breathing • Consider oxygen only if patient is hypoxemic • Distraction, relaxation, mindfulness, create calm environment
Anorexia	• Educate and counsel patient/family regarding anorexia as a natural response to disease; interventions below only when loss of appetite bothersome to patient • Environmental alterations: small, frequent meals; moist foods or those with sauce/gravy take less energy to eat; assistance with meal preparation to improve energy for eating • Dexamethasone (Decadron®) 4 mg PO QD or prednisone 20 mg PO QD, especially when prognosis <6 weeks • Dronabinol (Marinol®) 2–10 mg PO every 4 hours, use with caution in the older adult • Mirtazapine (Remeron®) 15 mg PO QHS to enhance sleep, also improves appetite
Nausea and Vomiting *Not intended to prevent or treat chemotherapy-induced nausea and vomiting*	• Rule out potentially reversible causes: constipation, central nervous system disease, pain, altered electrolytes, ↑ICP, obstruction, antibiotics, chemotherapy, radiation therapy, opioids, digoxin *If nausea and vomiting due to activation of chemoreceptor trigger zone (CTZ) (e.g., medication-induced):* • Prochlorperazine (Compazine®) 10 mg PO q 6 hours or 25 mg PR q 8 hours • Haloperidol (Haldol®) 0.5–4 mg PO or IV/SQ q 6 hours • Ondansetron (Zofran®) 4–8 mg PO or IV q 8 hours (best when used for chemotherapy or radiation-induced nausea/vomiting; less effective when treating opioid-induced nausea and vomiting) • Olanzapine (Zyprexa®) 2.5–10 mg PO QD–bid • Promethazine (Phenergan®) 12.5–25 mg IV q 6 hours or 25 mg PO or PR q 6 hours *If nausea and vomiting due to gastric stasis causing early satiety, GI tract spasm:* • Metoclopramide (Reglan®) 10–20 mg PO or IV tid AC & HS [not with bowel obstruction] • Hyoscyamine (Levsin®) 0.125–0.25 mg PO/SL q 4 hours prn *If nausea and vomiting due to vestibular effects (nausea exacerbated by movement):* • Scopolamine transdermal patch 1.5 mg q 3 days (especially if underlying mechanism is vestibular; increased nausea or dizziness with ambulation) • Cyclizine (Meclizine®) 25–50 mg PO every 8 hours; best for motion sickness or increased intracranial pressure *If mechanism of nausea and vomiting is unclear, or unresponsive to other therapies:* • Dexamethasone (Decadron®) 4–8 mg PO/IV daily • Dronabinol (Marinol®) 2–10 mg PO every 4 hours *Administer antiemetics around the clock (scheduled). If nausea is controlled, then try reducing after 2–3 days.*

© F.A. Davis Publishing

TABLE 23-4 Quick Reference Guide for Symptom Management—cont'd

SYMPTOM	TREATMENT
Pain in the Final Hours of Life	• Observe for escalating pain and increase medications accordingly • May need to change route if swallowing is diminished; alternatives include transdermal, concentrated liquids taken orally in small volumes, parenteral • Abruptly discontinuing opioids or benzodiazepines may precipitate withdrawal syndrome; reduce dose 25% daily if no sign of pain in comatose patient; return to previous dose if any sign of return of pain • Myoclonus may occur; treat with clonazepam (Klonopin®) 0.5 mg PO tid, MAX 20 mg/day or lorazepam (Ativan®) 0.5–2.0 mg PO/IV q 4 hours if patient unable to swallow; may require midazolam (Versed®); IV/SQ; rotate opioids
Delirium and Agitation	• Identify and treat reversible causes: full bladder, fecal impaction, pain, dyspnea (hypoxemia, secretions, pulmonary edema), severe anxiety, nausea, pruritus, medications (e.g., corticosteroids, neuroleptics, anticholinergics), dehydration, infection • Reduce noise, orient gently, reduce nighttime interruptions to promote sleep/wake cycle • Haloperidol (Haldol®) 0.5–2 mg PO every 2–4 hours prn or IV/SQ 50% of oral dose (may repeat q 1 hour prn in severe delirium) • Olanzapine (Zyprexa®) 2.5–5 mg PO QHS; to start, increase to 10 mg after one week • Risperidone (Risperdal®) 1–2 mg PO q PM, increase by 0.5–1 mg q 2–7 days • Quetiapine (Seroquel®) 12.5–25 mg PO q 12–24 hours; to start, increase up to 50 mg bid • Chlorpromazine (Thorazine®) 12.5–25 mg PO/SQ q 4–12 hours, or 25 mg per rectum q 4–12 hours (IV can cause hypotension; avoid unless other agents ineffective and oral/rectal route unavailable) • Buspirone 5–20 mg PO tid
Excessive Secretions ["Death Rattle"]	• Atropine 0.4 mg SQ q 15 minutes prn • Scopolamine transdermal patch 1.5 mg topical, start with 1 mg (about 4-hour onset), increase to 2 mg after 24 hours. If insufficient, begin scopolamine 50 mcg/hour IV or SQ; double every hour to maximum of 200 mcg/hour • Glycopyrrolate (Robinul®) 1–2 mg PO or 0.1 mg–0.2 mg IV/SQ q 4 hours prn or 0.4–1.2 mg/day continuous IV/SQ infusion (this agent does not cross the blood brain barrier; less likely to cause confusion) • Hyoscyamine (Levsin®) 0.125–0.25 mg PO q 4 hours (liquid can be placed sublingually) • Change patient's position • D/C IV and/or enteral fluids as they may increase discomfort (e.g., cough, pulmonary congestion, sensations of choking/drowning, vomiting, edema, pleural effusions, ascites) • If fluids not discontinued, IV or SQ rate ought not exceed 500 mL/24 hours • Furosemide (Lasix®) prn to control overhydration. • Control thirst by moistening lips and mouth with substitute saliva (Oral Balance Moisture Gel® or Salivart®, at bedside; apply as frequently as needed) *Patients may be too weak to expectorate. This is not painful but distressing to family. Suctioning is traumatic, can cause bleeding and is painful. Do not suction beyond the oral cavity.*

References (and for more details): Dahlin et al., 2016; Ferrell et al., 2019.

Authors: Patrick Coyne, MSN, ACNS-BC, ACHPN, FAAN, FPCN; Constance Dahlin, MSN, ANP-BC, ACHPN, FPCN, FAAN; Judith Paice, PhD, RN, ACHPN, FAAN Published 2021 by: City of Hope Division of Nursing Research & Education (NRE) 1500 E Duarte Road, Duarte, CA 91010 Phone: 626.218.2346 Email: NRE@coh.org; www.cityofhope.org/NRE: Permission granted

experience near-death awareness (American Association of Colleges of Nursing & City of Hope, 2019).

Diagnostic Tests: Usually not appropriate in the dying patient.

Differential Diagnosis: Not applicable.

Treatment: Assess the dying person frequently for objective signs of distress, such as grimacing and moaning, and treat distressing symptoms as follows: morphine liquid concentrate for pain and/or shortness of breath/air hunger; oxygen may be beneficial if the person is hypoxic; lorazepam liquid concentrate for restlessness and anxiety; haloperidol liquid concentrate for agitation/delirium or nausea; glycopyrrolate, or hyoscyamine for upper airway secretions; acetaminophen suppository for fever; and haloperidol liquid concentrate or prochlorperazine suppository for nausea and vomiting. For seizures, lorazepam can be given subcutaneously or IV, and diazepam or phenobarbital rectally. In the dying patient, glucocorticoids such as dexamethasone are often effective adjunctive medications for pain, anorexia, nausea, and asthenia (Albert, 2017; American Association of Colleges of Nursing & City of Hope, 2019). Focus on comfort measures such as oral care, skin care, continence care, and repositioning as appropriate; provide a calm environment (American Association of Colleges of Nursing & City of Hope, 2019).

Include the interdisciplinary team when addressing the spiritual, psychosocial, and emotional needs of the patient and the family. For most people, being "fully present" with the dying person is important. When death is inevitable, the dying person's attention shifts to the spiritual process of withdrawing from life. This process can create fear of abandonment, fear of the unknown, and fear of the dying process itself. Thus, it is essential for active involvement of the interdisciplinary team to support the patient and family through this process (American Association of Colleges of Nursing & City of Hope, 2019; National Consensus Project for Quality Palliative Care & National Coalition for Hospice and Palliative Care, 2018).

© F.A. Davis Publishing

Follow-Up: Ensure 24-hour access to care for the dying patient and their family. Provide bereavement care for the family (National Consensus Project for Quality Palliative Care & National Coalition for Hospice and Palliative Care, 2018).

Sequelae: Death of the patient; bereavement follow-up for the family. Ensure adequate symptom management and family support during the terminal phase (National Consensus Project for Quality Palliative Care & National Coalition for Hospice and Palliative Care, 2018).

Prevention/Prophylaxis: Effective communication of the patient's end-of-life wishes and advance care planning are essential. Too often these discussions are held when death is imminent. Rather, these discussions should occur at a time in the person's life when they can clearly express their essential wishes (Rietjens et al., 2017).

The delivery of bad news can have a profound and lasting impact (De Leo et al., 2020). An established model for the delivery of bad news is the A-B-C-D-E method, which encourages use of advanced preparation, building of a therapeutic environment, communication, dealing with patient/family reactions, and encouraging/validating emotions (Rabow & McPhee, 1999). Another useful tool is the S-P-I-K-E-S protocol, with its focus on Setting, Perception, Invitation, Knowledge, Empathy, and Strategy/Summary (Baile et al., 2000). Ensure that the setting of the meeting is private and free from interruptions. Ask about the patient's perception of their illness. This can be done by using open-ended questions to assess understanding. It is then helpful to obtain the patient's invitation/permission to provide the bad news. Understand that the amount of information desired from the patient can vary based on situation and culture. Use of a warning prior to the actual delivery of bad news can lessen the emotional impact. Avoid use of medical jargon. Use silence and empathetically validate any emotions that arise. It is helpful to have tissues available in advance. Summarize the news and facilitate questions. Establish a plan and "next steps." Ensure that the patient and family can contact you later if any further questions arise (Berkey et al., 2018).

Education: Teach the patient's family the signs of impending death and ask them to notify the medical team of distressing symptoms. Educate on comfort measures such as oral care, repositioning, and incontinence care. Prepare the family for the patient's possible near-death experience. Educate the patient's family on the signs of death and care at the time of death. Educate on bereavement resources (American Association of Colleges of Nursing & City of Hope, 2019).

GRIEF AND BEREAVEMENT

Description: Experiencing the loss of a loved one is a universal human experience. Bereavement is the condition of having experienced the death of a loved one and adjusting to a world without the deceased. Grief is the emotional response experienced by those who are bereaved. Grief is a normal response to loss and mourning which has both biological and psychological adaptive processes (Rabins, 2019; Riordan et al., 2020). Grief and bereavement are affected by the circumstances at the time of death. There are three primary types of grief: anticipatory, normal, and prolonged grief (Riordan et al., 2020). Originally, anticipatory grief was used to describe an increased detachment by family prior to the death of a loved one. This detachment was felt to be protective and aided in the emotional recovery of the bereaved. Use of the term anticipatory grief evolved to include all forms of pre-death grief and can be experienced by everyone involved, including the patient. Normal grief encompasses the typical emotional, physical, cognitive, and spiritual reactions to a loss (Riordan et al., 2020).

Prolonged grief (formerly referred to as complicated grief) is prolonged, intense, and disabling, with troubling thoughts, dysfunctional behaviors, dysregulated emotions, and/or serious psychosocial problems impeding adaptation to the loss (Boelen & Smid, 2017; Lundorff et al., 2017). Prolonged grief disorder (PGD) is a proposed ICD-11 diagnostic category to classify those individuals who experience prolonged disfunction (6 months or greater) related to loss (Boelen & Smid, 2017). In prolonged grief, individuals experience pervasive yearning, preoccupation with the deceased, and severe emotional pain (Lundorff et al., 2017). Delayed grief occurs when the normal grief reaction is suppressed or postponed, with the survivor avoiding the pain of loss either consciously or unconsciously. Exaggerated grief consists of intense reactions such as nightmares, delinquent behavior, phobias, and suicidal thoughts. Masked grief occurs when the survivor is unaware that behaviors interfering with normal functioning are the result of loss.

Etiology: Death of a loved one as experienced by family and caregivers.

Occurrence: Grief is very subjective, but some component of normal grief is experienced by most (90%) bereaved individuals. Anticipatory grief is estimated to occur in up to 15% of caregivers (Riordan et al., 2020). Prolonged grief is estimated to occur in 10% of survivors (Lundorff et al., 2017).

Age: Affects people of all ages. Consider multiple cumulative losses in older adults. Consider developmental stages of children in bereavement care. Bereaved older adults are more likely to suffer complications (see Sequelae).

Ethnicity: Grief is influenced by one's culture, ethnicity, and religion (Rabins, 2019; Sadak & Weiser, 2017).

Contributing Factors: Contributing factors that increase risk of prolonged grief include older age, violent or unnatural death, psychiatric comorbidities, social isolation, and previous losses (Riordan et al., 2020).

Signs and Symptoms: Normal grieving includes physical, emotional, cognitive, and behavioral responses. Common grief reactions include somatic symptoms; sleep and appetite

© F.A. Davis Publishing

disturbances; memory loss and impaired concentration; social withdrawal and disinterest in prior activities; a sense of the presence of the deceased person, and auditory or visual hallucinations; questioning of spiritual and religious beliefs; and emotional reactions, which may include relief, numbness, helplessness, self-reproach, sadness, guilt, and despair (Riordan et al., 2020).

Prolonged grief typically includes intense shock, anger and denial, feelings of numbness or hopelessness, a blunted emotional expression and anxiety, panic, and chronic depression, as well as a risk for self-harm, such as suicide or substance abuse. Those with complicated grief often have ruminating thoughts, excessive avoidance of reminders of the loss, and difficulty regulating emotion. Symptoms often persist for at least 6 months and interfere with functioning (Riordan et al., 2020).

Diagnostic Tests: Screening for depression with patient health questionnaire (PHQ-9) may be indicated. The Prolonged Grief Disorder-13 (PG-13) Questionnaire can be used as a diagnostic screening tool to measure prolonged grief.

Differential Diagnosis: Depression, including risk of suicide.

Treatment: Most people that experience grief will have no need for treatment or clinical intervention. However, active listening, validation of feelings, discussion of support systems, anticipatory guidance of what to expect through loss, and psychoeducation are techniques that can be used universally in management of bereaved individuals (Fields et al., 2018; Riordan et al., 2020). In the case of prolonged grief, psychotherapy has been shown to improve symptoms (Fields et al., 2018). Antidepressants may have limited efficacy in managing prolonged grief but can be used as a second-line treatment (Fields et al., 2018; Riordan et al., 2020). Complicated grief therapy is a specialized type of psychotherapy that uses motivational interviewing and cognitive behavioral therapy to help improve adaptation (Riordan et al., 2020). Hospice enrollment of the deceased has also been shown to significantly reduce depression and grief of those left behind (Riordan et al., 2020). It should also be noted that many hospice organizations offer bereavement counseling that may be available even if the deceased was not enrolled in hospice care.

Interventions to support grief work include (American Association of Colleges of Nursing & City of Hope, 2019):

- Support grieving as a normal experience. Being present and actively listening are essential. Allow the person to tell their story.
- Assist with identifying support systems such as extended family, friends, and support groups, such as local hospice bereavement support groups.
- Provide emotional and spiritual support. Consider referral for bereavement support groups and pastoral counseling. Provide written materials about grief. Encourage expression of feelings and encourage reminiscence and life review. Journal writing, letter writing, and drawing pictures can be beneficial.
- For complicated grief, refer to a bereavement specialist, health-care provider, and/or psychologist/psychiatrist.
- Caregivers can support the bereaved by sending a note, attending the funeral or memorial service, or making a supportive phone call.
- Staff bereavement may include encouraging staff to express their grief, reviewing deaths and their effects on staff, enabling staff to attend memorial services, creating staff mourning rituals, and encouraging self-care.

Follow-Up: Bereavement is associated with increased morbidity and mortality (see Sequelae). Ensure regular health-care appointments with the primary care provider for appropriate assessment, screening, and interventions.

Sequelae: Bereaved older adults aged 60 to 89 are more than twice as likely to suffer cardiovascular events or stroke within 30 days of the death of a partner. Widowed men have a 77% higher risk of death within 3 years following loss compared with married men (Riordan et al., 2020). Of those bereaved with prolonged grief, a majority (88%) meet criteria for other psychiatric diagnoses including major depression, posttraumatic stress disorder, or anxiety (Kristensen et al., 2017; Riordan et al., 2020). Screen and treat appropriately.

Prevention: Grief assessment begins at the time of a patient's admission to a hospital, long-term care facility, or hospice, as well as at the time of diagnosis of an acute, chronic, or terminal illness. Assess grief frequently during the bereavement period. Allow expression of grief through appropriate support (Fields et al., 2018; Riordan et al., 2020).

Referral: Refer surviving family and friends to bereavement support groups, grief counseling, and psychiatric care, if indicated. Follow-up with the health-care provider is essential as well.

Education: Instruct on normal grief reactions, bereavement resources in the community, and awareness of signs of complicated grief and depression.

CASE STUDY

Mrs. M. is an 85-year-old woman with breast cancer with metastasis to the lungs and bone. She is receiving palliative chemotherapy. Her husband died 5 years ago, and she is currently living with her daughter, who works outside the home. A private caregiver has been hired through a community agency. Mrs. M. enjoys visits from her family and fellow church members. Mrs. M. is seen by the nurse practitioner when she comes to her follow-up appointment in the oncology clinic. She is experiencing moderate-to-severe right chest wall pain. She also is experiencing dyspnea on exertion, nausea, constipation, and fatigue. A recent CT scan revealed disease progression on third-line chemotherapy.

Her past medical history includes metastatic breast cancer, hypertension, and hypothyroidism. Current medications: hydrochlorothiazide 12.5 mg PO daily and

CASE STUDY—cont'd

levothyroxine 50 mcg PO daily; and senna PO bid for constipation/APAP. She has no known allergies.

Exploring her symptoms: She rates her right chest wall pain at 7/10. It is a dull, aching pain and worsens with activity. The pain has been present for 2 weeks. Hydrocodone/APAP had initially helped but is no longer effective. Because of the pain and dyspnea, she spends most of her time sitting in a reclining chair or lying in bed. Her appetite has decreased. She has not moved her bowels in 2 days. She complains of anorexia, fatigue, and insomnia.

Focused physical examination: temperature 98.2°F, heart rate (HR) 75 beats per minute, respiratory rate (RR) 22 breaths per minute, blood pressure (BP) 120/80 mm Hg, oxygen saturation 94%, weight 105 pounds, height 5 feet 4 inches, body mass index (BMI) 18 kg/m^2.

Mrs. M. is in moderate distress. She appears thin and frail. Her color is sallow, and her heart sounds reveal regular rate and rhythm, no murmur, rub, or gallop. Her lungs have bibasilar crackles, greater on the right, no wheezing. Her abdomen is soft with active bowel sounds, nontender to palpation.

1. What would you recommend for her symptom management?

appendix A

Physiological Influences of the Aging Process

AGE-RELATED CHANGE	APPEARANCE OR FUNCTIONAL CHANGE	IMPLICATION
	Integumentary System	
Loss of dermal and epidermal thickness	Fragility of skin	Prone to skin tears
	Impaired nutrient transfer	Slower wound healing
Flattening of dermal papillae	Shearing and friction force more readily peels off the epidermis	Prone to skin breakdown and injury
	Diminished cell-mediated immunity in the skin	Increased risk of dermatological infections
Atrophy of the sebaceous glands	Decreased production of oil and cerumen	Frequent pruritus and xerosis
		Increased risk of cerumen impaction
Atrophy of the eccrine glands	Decreased sweating ability	Impaired thermoregulation
Decreased vascularity	Slower recruitment of sweat glands by thermal stimulation	Alteration in thermoregularity response; diminished ability to adapt to temperature changes
		Fluid requirements may change seasonally
	Decreased body odor	Loss of skin water
	Decreased heat loss	Increased risk of heat stroke
	Dryness	Increased prevalence of pruritus
Collagen cross-linking	Collagen production reduced	Increased wrinkling of skin
Elastin regression	Laxity of skin	Increase risk for pressure injury
Loss of subcutaneous fat	Intraosseous atrophy, especially to the back of hands and to the face	Loss of fat tissue on soles of feet—trauma of walking increases foot problems
Decreased elasticity	Skin is slack and hangs loosely	Difficulty assessing skin turgor
Loss of subcutaneous tissue	Purpuric patches after minor surgery	Evaluate why injury is occurring; be alert for potential abuse or falls
Decreased number of melanocytes	Loss of pigment	Teach the importance of using sun block creams; refer to a dermatologist as needed
	Pigment plaque appears	Presence of lentigo or "liver spots"
Decreased turnover rate of keratinocytes	Increased exposure of the epidermal cells to the environment to include UV radiation	Increased risk of neoplastic skin cancers and malignant melanoma
Decline in fibroblast proliferation	Decreased epidermal growth rate	Decreased tissue repair response
	Slower re-epithelialization	
	Decreased vitamin D production and synthesis	Increased risk for developing osteoporosis and other conditions associated with vitamin D deficiency

Continued

© F.A. Davis Publishing

AGE-RELATED CHANGE	APPEARANCE OR FUNCTIONAL CHANGE	IMPLICATION
Decreased hair follicle density	Loss of body hair	Reduces the body's ability to sweat and regulate body temperature
Decreased growth phase of individual fibers	Thin, short villus hairs predominate	Senescent alopecia
	Slower hair growth	
Loss of melanocytes from the hair bulb	Graying of the hair	Potential effect on self-esteem
Alternating hyperplasia and hypoplasia of nail matrix	Longitudinal ridges	Nails prone to splitting
	Thinner nails of the fingers	Advise patient to wear gloves, keep nails short, and avoid nail polish remover (causes dryness)
	Thickened, curled toenails or claw-like nails known as onychogryphosis	Painful ambulation. Impaired or restricted activities; refer patient to podiatrist
	Respiratory System	
Decreased lung tissue elasticity	Decreased vital capacity	Reduced overall efficiency of ventilatory exchange
	Increased residual volume	Diminished ventilatory response to hypoxia and hypercapnia
	Decreased maximum breath capacity	Decreased sensation of dyspnea
Thoracic wall calcification	Increased anteroposterior diameter of chest	Obscuration of heart and lung sounds
Cilia atrophy	Change in mucociliary transport; mucous-producing cells increase	Increased susceptibility to infection
Decreased respiratory muscle strength	Reduced ability to handle secretions and reduced effectiveness against noxious foreign particles	Prone to atelectasis
	Partial inflation of lungs at rest	
Less sensitivity to hypoxia; impaired ability to recognize bronchoconstriction	Increased respiratory distress	Increased risk of mortality from acute respiratory conditions
	Cardiovascular System	
Heart valves fibrose and thicken	Reduced stroke volume: cardiac output may be altered	Decreased responsiveness to stress; heart rate and blood pressure take longer to return to normal resting rate following exertion
	Slight left ventricular hypertrophy	Increased incidence of murmurs, particularly aortic stenosis, and mitral regurgitation
Mucoid degeneration of mitral valve	S_4 sound commonly heard	Increased risk for mitral valve prolapse
	Valve less dense; mitral leaflet stretches with intrathoracic pressure	Potential for rupture of the chordae tendineae, which leads to acute mitral regurgitation or the enhancement of pre-existing insufficiency
Fibroelastic thickening of the sinoatrial node; decreased number of pacemaker cells	Slower heart rate	Potential for oxygen deprivation; risk of syncope, potential need for pacemaker
	Irregular heart rate	Increased prevalence of atrial fibrillation and extra heartbeats become more common (S_4)
Collagen accumulation around heart muscle	Cardiac fibrosis	Heart chamber dilatation, or even infarct rupture.
Elongation of tortuosity and calcification of arteries	Increased rigidity of arterial wall	Aneurysms may form
Elastin and collagen cause progressive thickening and loss of arterial wall resiliency	Increased peripheral vascular resistance	Decreased blood flow to body organs
Loss of elasticity of the aorta dilation	Increase pulse pressure	Increased systolic blood pressure, contributing to coronary artery disease; aortic aneurysm
Increased lipid content in artery wall	Lipid deposits form	Increased incidence of atherosclerotic events such as angina pectoris and stroke

© F.A. Davis Publishing

AGE-RELATED CHANGE	APPEARANCE OR FUNCTIONAL CHANGE	IMPLICATION
Decreased baroreceptor sensitivity (stretch receptors)	Decreased sensitivity to change in blood pressure	Prone to loss of balance with the potential for falls
	Decreased baroreceptor mediation to straining	Valsalva maneuver may cause sudden drop in blood pressure, orthostatic hypotension, and dizziness when the patient changes from a lying or sitting position to standing
	Gastrointestinal System	
Atrophy of muscles and bones of the jaw	Difficulty with mastication	Ability to thoroughly chew food is impaired and can contribute to dysphagia with solid foods
Dental enamel thins	Staining of tooth surface occurs	Tooth and gum decay; tooth loss
Gums recede	Teeth deprived of nutrients	Gingivitis
Fibrosis and atrophy of salivary glands	Prone to dry mucous membranes	Shift to mouth breathing is common; frequent complaints of dry mouth are expressed
	Decreased salivary ptyalin	Membrane more susceptible to injury and infection
		May interfere with breakdown of starches
Atrophy and decrease in number of taste buds	Decreased taste sensation	Altered ability to taste sweet, sour, and bitter
		Change in nutritional intake
		Excessive seasoning of foods
Presbyesophagus (aging esophagus)	Decline in esophageal peristalsis	Occasional discomfort as food stays in esophagus longer
	Delay in esophageal emptying	
	Subtle decrease in lower esophageal and upper esophageal pressures	
	Stiffening of the esophageal wall	Increase in dysphagia and aspiration
Decreased hydrochloric acid secretion	Reduction in amount of iron, vitamin B_{12} and calcium that can be absorbed	Possible delay in vitamin and drug absorption, especially calcium and iron
Decreased gastric blood flow	Compromised repair mechanism in the stomach	Increase susceptibility to gastric ulcer, atrophic gastritis, peptic ulcer disease and gastrointestinal medication side effects
Decreased abdominal muscle tone	Altered motility	Prone to constipation, functional bowel syndrome, esophageal spasm, diverticular disease
	Decreased colonic peristalsis	Prone to constipation and obstipation, fecal impaction
Partial loss of gastric glands in the mucosa of the stomach	Hypochlorhydria	Chronic atrophic gastritis
	Achlorhydria	
Decreased proportion of dietary calcium absorbed	Altered bone formation, muscle contractility, hormone activity, enzyme activation, clotting time, immune response	Symptoms more marked in women than in men
Decrease in hepatic mass and hepatic blood flow	Decreased storage capacity	Decreased efficiency in metabolizing drugs that pass through the liver
	Decrease in the activity of Cytochrome P450 enzyme system	
Less efficient cholesterol stabilization absorption	Increased evidence of gallstones	Atypical presentation of acute cholecystitis
	Genitourinary and Reproductive Systems	
Reduced renal mass	Decreased sodium-conserving ability	Administration and dosage of drugs may need to be modified
Loss of glomeruli	Decreased glomerular filtration rate	Susceptibility to develop acute kidney injury
	Decreased creatinine clearance	Progression of chronic kidney disease
	Increased blood urea nitrogen concentration	Increase risk for developing kidney injury

Continued

© F.A. Davis Publishing

AGE-RELATED CHANGE	APPEARANCE OR FUNCTIONAL CHANGE	IMPLICATION
Histological changes in small vessel walls	Decreased renal blood flow	Changes in drug levels with ↑ risk of adverse drug effects
Decline in number of functioning nephrons	Decreased ability to dilute urine concentrate	Altered response to reduced fluid load or increased fluid volume
		Susceptibility of nocturia especially if fluids consumed before bedtime
Reduced bladder muscular tone	Decreased bladder capacity or increased residual urine	Sensation of urge to urinate may not occur until bladder is full
	Decreased detrusor contraction strength	Increased risk of urinary tract infections
	Age-related post void residual	Episodes of urinary incontinence may develop
Atrophy and fibrosis of cervical and uterine walls	Loss of rugosity in the vaginal rugal folds	Potential for vaginal prolapse
Reduced number and viability of oocytes in the aging ovary	Menopause	Decline in fertility
Structural change in the vulva	Reduction in pubic hair	Increased risk of developing genitourinary syndrome of menopause
	Decreased fat in the labia majora,	
	Decrease size of labia minora and vestibular bulbs	Increased risk for itching and burning of the vulva
Decreased vaginal wall elasticity	Vaginal lining thin, pale, friable	Post-coital bleeding
	Altered mucosal immune response	Increased risk for genital infections
		Atrophic vaginitis
	Narrowing of vaginal canal	Dyspareunia
	Loss of vaginal rugae	
Decreased levels of circulating hormones	Reduced lubrication during arousal state	Increased frequency of sexual dysfunction
		Decreased arousal and orgasm
Degeneration of seminiferous tubules with a selective loss of germ cells	Decreased seminal fluid volume	Decreased sperm concentration; decrease fertility
	Decreased force of ejaculation	Decreased percentage of sperm progressive motility
	Reduced elevation of testes	Alteration in sexual arousal
Decreased sperm production	Decreased concentration	Increased sperm DNA fragmentation and mutation
	Decrease total sperm count	
		Impairment in fertility
Proliferation of prostatic stromal and glandular tissue	Prostatic hypertrophy	Potentially compromised genitourinary function; urinary frequency and increased risk of malignancy
Narrowing of urethral lumen in males	Alteration in urinary flow and pressure	Increased risk for lower urinary tract dysfunction
Testicular volume decreases	Decrease in the number of Leydig cells	Decreased testicular function
	Increased secretion of gonadotropins	Biofunctional sperm parameters worsen, decreasing (seminal fluid volume, sperm concentration, percentage of progressive motility, and percentage of spermatozoa with normal form)
Involution of mammary gland tissue	Connective tissue replaced by adipose tissue	Easier to assess breast lesions
	Neuromuscular System	
Decreased muscle mass	Decreased muscle strength	Increased muscle cramping
		Increased risk for developing sarcopenia
	Tendons shrink and sclerose	Slight decreased tendon reflexes especially the Achilles' tendon

© F.A. Davis Publishing

AGE-RELATED CHANGE	APPEARANCE OR FUNCTIONAL CHANGE	IMPLICATION
Decreased myosin adenosine triphosphatase activity	Prolonged contraction time, latency period, relaxation period	Decreased motor function and overall strength
Deterioration of joint cartilage	Joint space narrowing	Potential for pain, crepitation, and limitation of movement; osteoarthritis
Loss of water from the cartilage	Narrowing of joint spaces	Loss of height
Decreased bone mass	Decreased bone formation and increased bone resorption, leading to osteoporosis	More rapid and earlier changes in women
Decreased osteoblastic activity and increased osteoclast activity	Decreased bone mineral density	Greater risk of fractures
Osteoclasts resorb bone	Hormonal changes	Gait and posture accommodate to changes
Increased proportion of body fat	Centripetal distribution of fat and invasion of fat in large muscle groups	Anthropometric measurements required
Regional changes in fat distribution		Increased relative adiposity
Thickened leptomeninges in spinal cord	Loss of anterior horn cells in the lumbosacral area	Leg weakness may be correlated
Accumulation of lipofuscin	Altered RNA function and resultant cell death	Increased risk for developing macular degeneration
	Cellular degeneration	
Loss of neurons and nerve fibers	Decreased processing speed and vibratory sensation	Increased time to perform and learn
	Altered pain response	
	Decreased deep tendon reflexes, especially Achilles' tendon	Safety hazard
Decreased conduction of nerve fibers	Decreased psychomotor performance	Alteration in pain response
Neurofibrillary tangles in hippocampal neurons	Disrupts the synaptic communication between neurons	Heavy tangle formation and neuritic plaques in cortex of patients with Alzheimer's disease
Changes in sleep-wake cycle	Decreased stage 4, stage 3, and rapid eye movement phases	Increased or decreased time spent sleeping
	Deterioration of circadian organization	Increased nighttime awakenings
	Decrease in melatonin production	Changed hormonal activity
Slower stimulus identification and registration	Delayed reaction time	Prone to falls
Decline in proprioception function	Impaired balance	Higher propensity for falls
Decreased brain weight and volume	Cerebral atrophy	May be present in absence of cognitive impairments
		Also increases risk of subdural hematoma
Sensory System		
Morphological changes in choroid, epithelium, retina	Decreased visual acuity	Corrective lenses required
		Decreased mobility
		Slower walking speed
		Increased depression due to change in quality of life because of limited vision
		Impairment in instrumental activities of daily living
	Visual field narrows	Increased possibility of disorientation and social isolation
Decreased rod and cone function	Slower light and dark adaption	Increased risk for falls and injury
Pigment accumulation	Pigment dispersion syndrome	Blurred vision or halos may alter vision
Decreased speed of eye movements	Difficulty in gazing upward and maintaining convergence	Limitation in locating/reading objects that are above the level of the eye (i.e., road signage, items on shelves)

Continued

© F.A. Davis Publishing

AGE-RELATED CHANGE	APPEARANCE OR FUNCTIONAL CHANGE	IMPLICATION
Sclerosis of pupil sphincter	Difficulty in adapting to lighting changes	Glare may pose an environmental hazard
	Increased threshold for light perception	Dark rooms may be hazardous without availability of accessible lighting
Increased intraocular pressure	Increased incidence of glaucoma	Decreased vision due to decline in peripheral vision and increased glare.
Decreased contrast sensitivity	Distorted depth perception	Incorrect assessment of height of curbs and steps; potential for falls
Ciliary muscle atrophy	Altered refractive powers	Corrective lenses often required
Nuclear sclerosis (lens)	Presbyopia	Near work and reading may become difficult
		There is a continuous loss of the ability of the eye to change its focus on objects at close distances.
		Glare, especially at nighttime driving, because of light scattering.
Deposit of calcium and cholesterol salts	Arcus senilis	Does not affect vision.
Senile miosis due to dilator muscles atrophy	Decrease in the size of the pupils	Pupils are less responsive to changes in ambient lighting.
Lens yellows	Color vision may be impaired	Less able to differentiate low color tones: blues, greens, violets
Reduction in number of cones at the fovea		Difficulty in distinguishing amongst pills and tablets in these low color tones
Diminished tear secretion	Dullness and dryness of the eyes	Irritation and discomfort may result
	Intactness of corneal surface jeopardized	Increased risk of corneal abrasion
Loss of auditory neurons	Decreased tone discrimination and voice localization	Suspiciousness may be increased because of paranoid dimensions secondary to hearing loss
	High-frequency sounds lost first	Social isolation
Angiosclerosis calcification of inner ear membrane	Progressive hearing loss, especially at high frequency	Difficulty hearing, particularly under certain conditions such as background noise, rapid speech, poor acoustics
	Presbycusis	Can result in loneliness, isolation, dependence
Decreased number of olfactory nerve fibers	Decreased sensitivity to odors	May not detect harmful odors such as rancid foods or noxious gases
	Affects flavor of food which is a combination of taste and smell	Potential safety hazard
		Loss of appetite
Number of taste buds diminished	Alteration in taste sensation	Possible changes in food preferences and eating patterns
Reduced tactile sensation	Decreased ability to sense pressure, pain, temperature	Misperceptions of environment and safety risk
	Endocrine System	
Decline in secretion of testosterone, growth hormone, insulin, adrenal androgens, aldosterone, thyroid hormone	Decreased hormone clearance rates	Increased mortality associated with certain stresses (burns, surgery); increased prevalence of hormonal disease
Defects in thermoregulation	Shivering less intense	Susceptibility to temperature extremes (hypothermia/ hyperthermia)
Reduction of febrile responses	Poor perceptions of changes in ambient temperature	Unrecognized infectious process operative
	Reduced sweating; increased threshold for the onset of sweating	Delayed healing of the skin
		Hyperthermia
	Fever not always present with infectious process	Delay in diagnosis of infectious, inflammatory, or neoplastic disease

© F.A. Davis Publishing

AGE-RELATED CHANGE	APPEARANCE OR FUNCTIONAL CHANGE	IMPLICATION
Alteration in tissue sensitivity to hormones	Increased insulin resistance and glucose intolerance	Increased incidence of type 2 diabetes
Dysregulation of mineralocorticoid receptor	Vasoconstriction	Increase in blood pressure
Nodularity and fibrosis of thyroid	Increase in the development of thyroid nodules	Increased frequency of thyroid disease
Decreased basal metabolic rate	Alteration in carbohydrate tolerance	Increased incidence of obesity
Hematological System		
Decreased percentage of marrow space occupied by hematopoietic tissue	Ineffective erythropoiesis	Stem cell proliferation and maturation however is preserved.
	Decrease in trabecular bone in the marrow.	
Immune System		
Thymic involution and decreased serum thymic hormone activity	Decreased number of T cells	Less vigorous and/or delayed hypersensitivity reactions
	Production of anti–self-reactive T cells	
Decreased T-cell function	Impairment in cell-mediated immune responses	Increased risk of mortality
Decreased B-cell function		
Appearance of autoantibodies	Decreased cyclic adenosine monophosphate and glucose monophosphate	Increased incidence of infection
	Decreased ability to reject foreign tissue	Reactivation of latent infectious diseases. Increase risk for developing herpes zoster
	Increased laboratory autoimmune parameters	Increased prevalence of autoimmune disorders
Redistribution of lymphocytes	Impaired immune reactivity	Increased risk for developing sepsis
	Slowed inflammatory process	
Changes in serum immunoglobulin	Increased immunoglobulin A levels	Increased prevalence of infection
	Decreased immunoglobulin G levels	Slowed wound healing

appendix B

Laboratory Values in the Older Adult

LABORATORY TEST	NORMAL VALUES	CHANGES WITH AGE	COMMENTS
		Urinalysis	
Protein	0–5 mg/100 mL	Rises slightly	May be due to kidney changes with age, urinary tract infection, or renal pathology.
Protein-to-creatinine ratio	≤0.2 mg/mg	May increase	Ratio value >3.5 mg/mg confirms nephrotic proteinuria.
Glucose	0–15 mg/100 mL	Declines slightly	Glycosuria appears after high plasma level; unreliable.
Specific gravity	1.005–1.020	Lower maximum in elderly, 1.016–1.022	Decline in nephrons impairs ability to concentrate urine.
		Hematology	
Erythrocyte sedimentation rate	Male: 0–20 mm/hour Female: 0–30 mm/hour	Slight increase in normal aging. Elevated in inflammatory conditions. May be decreased during heart failure. Upper limit of reference range in males 40 mm/hour and 45 mm/hour in females	Neither sensitive nor specific in the aged. ESR should not be used alone to diagnose an inflammatory process in older adults. Levels above 50 are considered significant for disease and mortality risk.
Iron	50–160 mcg/dL	Slight decrease due to impaired production of gastric acid	Decrease is due to impaired production of gastric acid
Iron binding	230–410 mcg/dL	Decrease	
Hemoglobin	Male: 13 gdL	Male: 11.5 gm/dL	Anemia common in the elderly but not a normal change with aging. In males a decline in testosterone production results in a decline in hemoglobin, but not below that of a normal female.
	Female: 11.0 g/dL	Female: 11.0 gm/dL	
Hematocrit	Male: 40%–54% Female: 36%–46%	Slight decrease speculated	Decrease in anemias, multiple myeloma, protein malnutrition, CKD, rheumatoid arthritis. Increased in dehydration, severe diarrhea.
Leukocytes	4,300–10,800/mm^3	Drop to 3,100–9,000/mm^3	Decrease may be due to drugs or sepsis and should not be attributed immediately to age.
Lymphocytes	500–2,400 T cells/mm^3 50–200 B cells/mm^3	T-cell and B-cell levels fall	Risk of infection is higher; immunization is encouraged.
Platelets	150,000–350,000/mm^3	No change in number	
		Blood Chemistry	
Albumin	3.5–5.0 g/dL	Decline	Related to decrease in liver size and enzymes; protein-energy malnutrition common. Regardless of reason for decline if less than normal need to correct serum calcium as calcium is bound to albumin.

Continued

© F.A. Davis Publishing

LABORATORY TEST	NORMAL VALUES	CHANGES WITH AGE	COMMENTS
Globulin	2.3–3.5 g/100 mL	Slight increase	
Total serum protein	6.0–8.4 g/100 mL	No change	Decreases may indicate malnutrition, infection, liver disease.
Blood urea nitrogen	Men: 10–25 mg/100 mL Women: 8–20 mg/100 mL	8–28 mg or slightly higher	Increases with dehydration, GI bleeding, pre-renal failure. Decreases due to low protein diet, malnutrition, overhydration. Decline in glomerular filtration rate; decreased cardiac output. All electrolytes need to be evaluated when a concern for renal disease exists.
Creatinine	0.6–1.5 mg/100 mL	Increases to 0.6–1.2 mg/100 mL seen	Related to decreases in lean body mass. Unreliable indicator of abnormalities in renal function, especially in the frail older adult and/or those with sarcopenia.
Creatinine clearance	104–124 mL/min	Decreases 10%/decade after 40 years of age	Decreased renal impairment, hyperthyroidism, thiazides, increased hypothyroidism.
Glucose tolerance	62–100 mg/dL after fasting; <120 mg/dL after 2 hours postprandial	Slight increase of 10 mg/dL/decade after 30 years of age	Diabetes increasingly prevalent; drugs may cause glucose intolerance.
Triglycerides	40–150 mg/100 mL	20–200 mg/100 mL	Risk of coronary artery disease Elevated in non-fasting collection, hypothyroidism, alcoholism.
Cholesterol	120–200 mg/dL	Increases by 30–40 mg/dL by age 60	Risk of cardiovascular disease Goal for LDL cholesterol to be less than 100 mg/dL.
Thyroxine (T4)	4.5–13.5 mcg/dL	3.3–8.6 mcg/dL	Changes suggest thyroid disease; may be seen in euthyroid patients with acute or chronic illness or caloric deficiencies.
Triiodothyronine (T3)	90–220 ng/dL	Decrease 25%	May impact metabolism, body temperature, or heart rate.
Thyroid-stimulating hormone (TSH)	0.5–5.0 mcg/mL	Slight increase	Sensitive indicator for diagnosing thyroid disease.
Alkaline phosphatase	20–130 IU/L	Increase by 8–10 IU/L	Increases by 20% between the third and eighth decade. Elevations may be found with bone abnormalities, drugs (e.g., narcotics), and consumption of a fatty meal. For best results, this test should be ordered during fasting.
Serum alkaline aminotransferase (ALT)	M: 10–55 units/L F: 7–30 units/L	Overall increases can measure to 17–30 U/l	Increases can be due to cancer (liver, bone) leukemia, RA, multiple myeloma.
Serum aspartate aminotransferase (AST)	M: 10–40 units/L Female: 9–25 units/L	Overall increases can measure to 18–30 U/l	Increases can be due to MI, hepatitis, pancreatitis, liver cancer.

Bonus Chapter

COVID-19

Signal Symptoms: Coronavirus disease 2019 (COVID-19) affects different people in different ways. The symptoms are characterized mainly by cough, fever, fatigue, and dyspnea. Other common symptoms include a headache, sore throat, joint and muscle pain, and loss of the sense of smell and taste.

A Cochrane review found that at least one half of patients had a cough, sore throat, fever, myalgia/arthralgia, fatigue, and/or headache (Struyf et al., 2021). Anosmia and ageusia were also common features and may be useful as red flags for diagnosis. The presence of fever, myalgia/arthralgia, fatigue, and headache substantially increased the possibility of COVID-19 when present. Presentation may change based on the COVID variant. For example, for those affected by some of the more recent variants, symptoms have been similar to that of a sinus infection, but without many of its other classic signs.

Description: COVID-19 is caused by the severe acute respiratory syndrome (SARS) coronavirus (CoV) 2, which was first noted in Wuhan, China, in December 2019. After multiple cases were identified worldwide, it was officially designated as a pandemic by the World Health Organization (WHO) on March 11, 2020.

Etiology: Coronaviruses are a class of viruses that cause a variety of diseases from the common cold to more severe infections. *Corona*, meaning "crown," describes the spikes that cover the outer lipid layer of the virus. In each spike, there is a single strand of ribonucleic acid (RNA)-containing protein (Chorba, 2020). The main spike protein causing infection is the S protein. These spikes have been the target for the development of vaccines to combat viruses from influenza A to Ebola. Viruses are not living organisms; they depend on the host's DNA to replicate and cause disease. The SARS-CoV-2 virus enters the human cell by attaching to the angiotensin-converting enzyme 2 (ACE2) receptor. These receptors are primarily located in the upper and lower respiratory tracts, the gastrointestinal (GI) tract, and the kidneys.

Seven coronaviruses are known to infect humans. They primarily infect the upper respiratory and GI tracts. The coronavirus that causes the common cold was first identified in 1966. Several newly emerged viruses are zoonotic, meaning the infectious source originated in animals and mutated to novel viruses transmittable in humans. The SARS-CoV-1 emerged in China in 2003 and spread to four other countries before the infection was contained. In 2012, another novel coronavirus emerged, Middle East respiratory syndrome (MERS) CoV. Although very deadly, resulting in a 35% mortality rate, it was not very transmissible. When SARS-CoV-2 was first identified in 2019, it was not clear if it would result in a disease like SARS-CoV-1 (more transmissible but less deadly) or if it would be like MERS.

The median time of incubation after infection with SARS-CoV-2 is 5 days, but it can be up to 2 weeks during which the patient is contagious. How contagious a disease is can be described by the R0 (pronounced "R naught"), or reproduction number. The R0 describes how many people will contract a contagious disease from a person with the disease. The at-risk population are those who have not been vaccinated or have not previously contracted the disease. For COVID-19, the original estimates of the R0 underestimated the infectivity. In February 2020, the WHO estimated the R0 to be 2.0 to 2.5, whereas average R0 has been 5.7 to 5.9—more than double the original estimate. As more people are vaccinated or have had the disease, the R0 may drop, but the evolving variants and their susceptibility to the vaccines will make a difference. As a comparison, measles has an R0 of 12 to 18 among unvaccinated people.

Occurrence: The first cases of COVID-19 were identified in Wuhan city, Hubei province, Peoples Republic of China, in December 2019. The genome was published for the virus in January 2020. The WHO declared a Public Health Emergency of International Concern on January 30, 2020. The first confirmed case in the United States was identified in February 2020. On March 11, 2020, the WHO declared COVID-19 a pandemic. The numbers of infections and deaths from COVID-19 continue to rise. As of June 13, 2022, there were 545,226,550 cases reported worldwide with 6,334,728 deaths; more than 1,000,000 of these deaths

© F.A. Davis Publishing

occurred in the United States alone. More men than women are diagnosed with COVID-19 and men are more likely to die of the disease.

Occurrence: Individuals of any age are susceptible to COVID-19, but it commonly affects those who are middle-aged and older adults. The risk of developing dangerous symptoms increases with age. Those who are aged 85 and older are at the highest risk of serious symptoms. In the United States, nearly 81% of deaths from the disease have been in people aged 65 and older (Centers for Disease Control and Prevention [CDC], 2022a). Risks are even higher for older people when they have other existing comorbid conditions.

Ethnicity: The relationship between ethnicity and COVID-19 is unclear.

Contributing Factors: COVID-19 can affect anyone and can cause symptoms ranging from mild to very severe. Those with risk factors may be more likely to need hospitalization or intensive care, or they may be more likely to die of the infection. More men than women are diagnosed with COVID-19 and are more likely to die of the disease. Other contributing factors include:

- Residence in a long-term care facility
- Obesity
- Cardiovascular disease
- Diabetes
- Chronic respiratory disease
- Chronic kidney disease
- Chronic liver disease
- Smoking
- Malignancy
- Cerebrovascular disease
- Solid organ or blood stem cell transplant
- Hypertension
- Dementia
- Immunosuppression
- HIV infection
- Substance use disorders.

Signs and Symptoms: A Cochrane review found that at least one-half of patients had a cough, sore throat, fever, myalgia/arthralgia, fatigue, or headache (Struyf et al., 2021). Anosmia and ageusia was also common feature in some COVID variants. The presence of fever, myalgia/arthralgia, fatigue, and headache substantially increased the possibility of COVID-19 when present. Cough and sore throat were common in those without COVID-19, so these symptoms alone were less useful for diagnosis (Struyf et al., 2021).

In contrast to SARS-CoV-1, patients with COVID-19 were noted to have more thrombo-embolic pathologies and an increased risk of developing coagulopathy similar to disseminated intravascular coagulation and venous and arterial thrombosis and resulting pulmonary embolism.

Mild to moderate hepatic injury has also been observed as signs of acute phase inflammation or direct viral infection causing hepatitis. Acute kidney injury (AKI) has been associated with higher disease severity and is an adverse prognostic sign for survival. SARS-COV-2 may directly target the kidney parenchyma.

The neurologic system is also affected by COVID-19, causing headache, confusion, anosmia, dysgeusia, nausea, and vomiting. This neuroinvasion may be the cause of alterations in respiratory and cardiovascular regulation.

Diagnostic Tests: There are three types of diagnostic tests used in identifying SARS-CoV-2 infection.

Nucleic Acid Amplification Testing (NAAT): NAAT testing is a reverse transcriptase polymerase chain reaction (RT-PCR) diagnostic test that is considered the gold standard for detecting SARS-CoV-2 infection for people who are symptomatic and asymptomatic. The RT-PCR test amplifies and detects the presence of SARS-CoV-2 genetic material. RT-PCR tests look for the genetic material of the SARS-CoV-2 virus in the nose, throat, or other areas in the respiratory tract. A nasopharyngeal, oropharyngeal, or nasal swab; saliva; or a lower respiratory tract specimen is obtained and sent to the laboratory for testing. A positive result occurs when the SARS-CoV-2 primers match the DNA in the sample and the sequence is amplified, creating millions of copies from an infected individual (Bustin & Nolan, 2020). The primers only amplify genetic material from the virus, so it is unlikely a sample will be positive if viral RNA is not present. If it does, it is called a false positive. A negative result happens when the SARS-CoV-2 primers do not match the genetic material in the sample and there is no amplification or virus (Kucirka et al., 2020). A false-negative result happens when a person is infected, but there is not enough viral genetic material in the sample for the RT-PCR test to detect it. This can happen early after a person is exposed. Overall, false-negative results are more likely than false-positive results.

Conventional RT-PCR tests must be processed in a laboratory, which result in waiting a day or more before getting a result. Errors in test preparation or sample collection may result in false negatives in both asymptomatic and symptomatic people. The RT-PCR test has been found to be 87% sensitive and 97% specific (Blessen et al., 2020).

In patients who have had a recent SARS-CoV-2 infection, NAATs can detect SARS-CoV-2 RNA in specimens obtained weeks to months after the onset of COVID-19 symptoms (Rhee et al., 2020; Xiao et al., 2020). Currently molecular diagnostic assays are unable to differentiate between the presence of remnant viral RNA (noninfectious) and replication-competent (infectious) virus (Rhee et al., 2020). The probability of recovering infectious virus more than 10 days from the onset of symptoms in those with mild disease and more than 20 days in those with severe disease is very low (Arons et al., 2020; Bullard et al., 2020). The CDC (2021) recommends that NAATs should not be repeated in asymptomatic persons within 90 days of a previous SARS-CoV-2 infection unless the individual experiences new symptoms consistent with COVID-19. If reinfection is suspected, then the individual should follow isolation protocol pending test results. Results should be interpreted in consultation with an infectious disease specialist. Review of history, test results, and RT-PCR Ct value and presence of signs and symptoms of COVID-19 (CDC, 2021).

Antigen-Detection Rapid Diagnostic Tests (Ag-RDTs): An Ag-RDT detects viral antigens using a lateral flow immunoassay intended for the qualitative detection of nucleocapsid protein antigen from SARS-CoV-2. WHO (2021) recommends that Ag-RDTs meet the minimum performance requirements of ≥80% sensitivity and ≥97% specificity, which is comparable to the NAAT. Ag-RDTs are designed to directly identify SARS-CoV-2 proteins produced by replicating virus in respiratory secretions. Results are available within 15 minutes. Antigen is usually detectable using an anterior nasal swab during the

© F.A. Davis Publishing

acute phase of infection. A positive result, indicating the presence of viral antigen, along with patient history and the presence of clinical signs and symptoms are consistent with a diagnosis of COVID-19. The test is most reliable in patients who are symptomatic and who test within the first 5 to 7 days of symptom onset when the viral load is higher (WHO, 2021). The reliability of the result is dependent on the sensitivity and specificity of the test, as well as the incidence of infection in the population tested. The results of antigen testing are most reliable in areas with a high pre-test probability of infection (those communities with transmission and a test positivity rate 5% or more) (WHO, 2021). When there is a high pre-test probability of infection, an Ag-RDT may be considered diagnostic without a confirmatory NAAT. Confirmation may be best when considering prescribing therapeutics. When there is no transmission or low transmission there is a lower pre-test probability of infection, and there will be more false positives. In such situations RT-PCR testing is preferred. For a patient who has a positive Ag-RDT in the setting of low pre-test probability, a confirmatory NAAT should be considered. Negative Ag-RDT results in a symptomatic patient should be treated as a probable case, and confirmation with NAAT should be considered.

Serology Tests: Serology tests look for antibodies against SARS-CoV-2 in the blood. Antibodies determine whether someone has been previously infected or vaccinated against a virus that causes a disease, but they cannot determine a current infection. When ordering antibody tests, it is important to know the type of information various tests provide and how to interpret test results. Antibody testing is not currently recommended to assess immunity to COVID-19 following vaccination.

Immunoglobulin M (IgM) is the first antibody that is formed against infection and is usually detectable within 1 to 2 weeks. The body then forms immunoglobulin G (IgG), which is usually detectable 2 weeks after the illness starts. IgM usually disappears from the blood within a few months, but IgG can last for years. Some antibody tests look for both IgM and IgG, and some only test for IgG. A positive antibody test means that the person being tested was likely infected with COVID-19 in the past. A negative antibody test means that the person may not have had COVID-19 in the past. However, the person could have a current infection, and the sample may have been collected too soon to give a positive result. In fact, there may be a lag of up to 21 days before antibodies are detectable, meaning the diagnosis of an active case of COVID-19 may be missed (CDC, 2021). Antibody levels decrease over time, so those who had COVID in the past may not have detectable levels of antibodies. It is not known if a positive antibody test means you are protected against getting infected in the future (CDC, 2021).

Other Diagnostic Tests:

- Pulse oximetry
- Arterial blood gas
- Complete blood count
  - Leukopenia
  - Lymphopenia (A low absolute lymphocyte count can be a marker of severe COVID-19.)
  - Thrombocytopenia
- Comprehensive metabolic panel
  - Electrolytes
  - Glucose
  - Blood urea nitrogen (BUN)
  - Creatinine
  - Estimated glomerular filtration rate (eGFR)
  - Elevated aminotransferase levels
  - Lactate dehydrogenase
  - Total bilirubin
- Clotting factors
  - Partial thromboplastin time
  - Prothrombin time/International Normalization Ratio
  - D-dimer
- Inflammatory markers
  - C-reactive protein
  - Ferritin
  - Albumin
  - Sedimentation rate
- Cardiovascular markers
  - Troponin
  - Brain natriuretic peptide
- Imaging
  - Chest x-ray
  - Chest computed tomography

Differential Diagnosis:

- Acute pulmonary edema
- Acute respiratory distress syndrome
- Chronic obstructive pulmonary disease exacerbation
- Community-acquired pneumonia (bacterial or viral)
- Influenza
- Interstitial lung disease
- Nonspecific viral upper respiratory tract infection
- Opportunistic pulmonary infection
- Pulmonary embolism
- Streptococcal pharyngitis

Treatment: Approximately 80% of patients with COVID-19 have mild illness that does not warrant medical intervention or hospitalization (Stokes et al., 2020). Health-care providers must identify patients who may be at high risk for progression to severe COVID-19 because these patients may be candidates for antivirals or anti-SARS-CoV-2 monoclonal antibody treatment.

Options available for the treatment of nonhospitalized adults with mild to moderate COVID-19 who are at high risk of disease progression have increased. Factors that play a role in selection of the best treatment option for an individual patient include:

- Clinical effectiveness and availability of the specific treatment option
- Likelihood of administering parenteral medications
- Potential for significant drug–drug interactions
- The local prevalence of variants of concern (National Institutes of Health [NIH], 2022).

The COVID-19 Treatment Guidelines Panel made recommendations for using the following therapeutic interventions for patients outside the hospital setting. These are listed in order of the panels preferred therapies.

Nirmatrelvir/ritonavir (Paxlovid) 100 mg PO is a SARS-CoV-2 protease inhibitor antiviral combination medication given U.S. Food and Drug Administration (FDA) Emergency Use Authorization (EUA) in December 2021 for adults and children (age 12 years and older weighing at least 40 kg) with mild to moderate COVID-19 symptoms and at high risk

© F.A. Davis Publishing

for progression to severe COVID-19. It is not approved for pre-exposure or post-exposure prophylaxis. In the EPIC-HR trial, ritonavir-boosted nirmatrelvir reduced the risk of hospitalization or death by 88% compared to placebo in nonhospitalized adults with laboratory-confirmed SARS-CoV-2 infection (Hammond et al., 2022; Mahase, 2021).

Nirmatrelvir blocks the activity of an enzyme that SARS-CoV-2 needs to replicate. Ritonavir acts as a booster to increase nirmatrelvir drug levels, slowing the metabolism of nirmatrelvir to maintain plasma levels (NIH, 2022). The approved dose is 300 mg nirmatrelvir (two 150 mg tablets) with 100 mg of ritonavir (one 100 mg tablet), with all three tablets taken together twice daily for 5 days. Doses should not be chewed, broken, or crushed and must be initiated within 5 days of symptom onset. Dose adjustment is needed in patients with eGFR of 30 to less than 60 mL/min. Avoid using this medication if eGFR is below 30 mL/min.

Ritonavir has many drug–drug and drug–herbal interactions of clinical significance that may limit its use. The COVID-19 Treatment Guidelines Panel recommended careful review of each patient's concurrent medications, including over-the-counter medications and herbal supplements, to evaluate for potential drug–drug interactions. Each clinician should determine whether there are any potential strategies to minimize risk of drug–drug interactions. For example, consider adjusting the dose of concomitant medication, using an alternative, temporarily holding the medication, or increased monitoring for adverse reactions. Ritonavir is contraindicated in patients taking certain CYP-3A4 inducers or substrates (e.g., amiodarone, diltiazem, fluconazole) (Lemaitre et al., 2022). Serious adverse events may include hepatotoxicity and HIV-1 resistance in HIV-positive patients. Common medication side effects include dysgeusia, diarrhea, hypertension, and myalgia. Ritonavir-boosted nirmatrelvir has demonstrated antiviral activity against all coronaviruses that are known to infect humans (Owen et al., 2021).

Remdesivir (RDV) is an antiviral IV medication that was developed more than a decade ago to treat hepatitis C and respiratory syncytial virus (RSV). Unfortunately, RDV was not found to be effective in those diseases. Later, RDV was tested in clinical trials during an Ebola outbreak, but it was not found to be effective. Other studies suggested that RDV was effective against viruses in the coronavirus family, such as MERS and SARS.

RDV became the first drug to receive emergency use authorization from the FDA to treat people hospitalized with COVID-19 and in nonhospitalized patients with mild to moderate COVID-19 who are at high risk of disease progression. It is an antiviral medication that works by interrupting production of the virus. Coronaviruses have genomes made up RNA. RDV interferes with one of the enzymes the virus needs to replicate RNA. RDV has been studied in nonhospitalized patients with mild to moderate COVID-19 who were at high risk of progressing to severe disease. One trial showed that 3 consecutive days of IV RDV resulted in an 87% relative reduction in the risk of hospitalization or death compared to placebo (Gottlieb, 2022).

RDV should be initiated as soon as possible and within 7 days of symptom onset. In the nonhospitalized patient, RDV is a 3-day consecutive daily infusion. Patients should receive RDV in a setting where patients can be monitored and managed for potential allergic reactions. Patients should be monitored during the infusion and for at least 1 hour after infusion.

The COVID-19 Treatment Guidelines Panel recommends bebtelovimab and molnupiravir as alternative therapy options. These should only be used when neither of the preferred treatment options is clinically appropriate.

Molnupiravir is an oral antiviral medication that increases the frequency of mutations in the viral RNA that impairs SARS-CoV-2 replication in humans (Jayk Bernal et al., 2022). In the MOVe-OUT trial, molnupiravir reduced the rate of hospitalization or death by 30% compared to placebo in nonhospitalized patients with COVID-19 (Jayk Bernal et al., 2022). EUA was issued in December 2021 for its use in those older than 18 years. Patients must be COVID positive with mild to moderate symptoms. Molnupiravir is not authorized to initiate in hospitalized patients with severe or critical COVID-19 and is not authorized for use as pre-exposure or postexposure prophylaxis. Those who receive a prescription for molnupiravir take it for 5 days, and it must be initiated within 5 days of onset of symptoms. No renal or hepatic adjustments are necessary. Molnupiravir should not be crushed and may be taken with or without food. There are no known drug-to-drug interactions. The most common reported adverse reactions have been diarrhea, nausea, dizziness, and headache

Bebtelovimab is a monoclonal antibody given by infusion that targets against the spike protein of SARS-CoV-2. In February 2022, the FDA authorized emergency use to treat mild to moderate COVID-19 in adults and children with positive SARS CoV-2 test results who are at high risk for progressing to severe COVID-19. It is not recommended for use in those who are likely to be infected with a SARS-CoV-2 variant that is not able to be treated by bebtelovimab, those who are hospitalized with COVID-19, or those who require oxygen therapy and/or respiratory support due to COVID-19. Treatment should be initiated as soon as possible after a positive viral test for SARS-CoV-2 and within 7 days of symptom onset. Possible side effects include itching, rash, infusion-related reactions, nausea, and vomiting.

Symptom Management: Management of symptoms such as fever, cough and myalgias may be treated using over-the-counter antipyretics, analgesics, or antitussives. Patients should be advised to drink fluids frequently to avoid dehydration. Adequate rest is required during the acute phase of illness, and activity should be increased according to the patient's tolerance. Those who experience dyspnea may benefit from resting in the prone position rather than the supine position.

Other COVID-19 Treatment Guidelines Panel Recommendations: The panel recommends avoiding use of certain therapies. These therapies and rationales for avoiding them are discussed in Table BC-1. Use this information to educate patients who may ask about the effectiveness of these therapies.

Follow-Up: Follow-up is dictated by the severity of the disease and the organs affected. Patients with a history of AKI need follow-up renal function tests and may need to be comanaged with a nephrologist. Pulmonary damage may be severe and irreversible. Follow-up with pulmonary function tests, pulmonary rehabilitation, and comanagement with a

TABLE BC-1 COVID-19 Treatments to Avoid

AGENT	RATIONALE
Chloroquine or hydroxychloroquine (HCQ) with or without azithromycin	• Several randomized trials have failed to show a clinical benefit for HCQ in nonhospitalized patients with early, asymptomatic, or mild COVID-19 (Mitja et al., 2020; Skipper et al., 2020). • In a large randomized controlled trial of hospitalized patients in the United Kingdom, HCQ did not decrease 28-day mortality when compared to the usual standard of care (RECOVERY Collaborative Group et al., 2020). • Chloroquine and HCQ have similar toxicity profiles. Cardiac adverse events have been reported in people who received hydroxychloroquine include QTc prolongation, Torsades de Pointes, ventricular arrythmia, and cardiac deaths (Nguyen et al., 2020). • Adding azithromycin and using it in combination with HCQ has been associated with a higher incidence of QTc prolongation and cardiac adverse events in patients with COVID-19 (Chorin et al., 2020; Mercuro et al., 2020).
Ivermectin	• This antiparasitic drug has not been approved by the U.S. Food and Drug Administration for treatment of any viral infection, including COVID-19. • Use should be avoided except in clinical trials. • Although ivermectin has been shown to inhibit replication of SARS-CoV-2 in some studies, other studies suggest that to achieve plasma concentrations necessary for efficacy against COVID it would require doses up to 100-fold higher than those approved for use in humans (Chaccour et al., 2020). • Studies had incomplete information and significant methodological limitations, which made excluding common causes of bias difficult. • Many of studies have not been peer reviewed, and some have now been retracted (COVID-19 Treatment Guidelines Panel, 2022).
Anticoagulants and antiplatelet therapy	• Avoid initiating therapy in the emergency department for the prevention of venous thromboembolism or arterial thrombosis unless the patient is being admitted to the hospital or has other indications for the therapy (Connors et al., 2021).
Dexamethasone or other systemic corticosteroids	• It is not recommended to treat outpatients with mild to moderate COVID-19 who do not require hospitalization and on supplemental oxygen (Clemency et al., 2022; Ezer et al., 2020). • Patients who take corticosteroids for other reasons should continue to do so unless directed by their provider.

pulmonologist may be needed. The return of taste and smell may take months to years and may not return at all.

Sequelae: The aftermath of COVID-19 is highly variable. New focus has been on the long-term effects that many patients experience after the acute phase of COVID-19 has resolved. These symptoms have been referred to by many names, including post-COVID conditions, long COVID, and post-acute COVID-19. Ongoing studies to evaluate the morbidity related to these long-term conditions are needed. Identifying changes in patients that persist after an acute infection with COVID-19 is an important role of the provider.

Cardiovascular complications were documented in a study by Xie et al. (2022). They found long-term effects in patients across the disease severity spectrum, with those with more severe disease experiencing more severe long-term effects. Similar findings were also noted by Satterfield et al. (2022). Dyspnea was one of the most prevalent symptoms and may be multifactorial due to pulmonary and cardiac complications.

In a systematic review and meta-analysis, Lopez-Leon and colleagues (2021) identified more than 50 long-term effects of COVID-19. In the older adult, the persistent fatigue, dyspnea, cognitive residual, effects on smell and taste, and joint pain all have the potential of directly and indirectly affecting functional ability and independence in activities of daily living and instrumental activities of daily living.

Prevention/Prophylaxis: The best prevention of COVID-19 disease is vaccination. The worldwide effort to develop a vaccine to prevent COVID-19 resulted in the fastest introduction of an effective vaccine ever realized to date. The effort was facilitated by advances in virology and the information from work done on other viral diseases such as hepatitis C and HIV. Initially, vaccines that demonstrated efficacy were granted EUA, and many applications continue to carry only that authorization, including boosters and vaccine forms used in children. Currently in the United States there are two vaccines approved by the FDA for use in adults. The first vaccine, from Pfizer-BioNTech, was approved on August 23, 2021, and will now be marketed as Comirnaty. The approval of the Moderna COVID-19 vaccine was granted in January 2022, and it will now be marketed as Spikevax. The Johnson & Johnson vaccine, brand name Janssen, was approved for emergency use in February 2021. The advantages of this vaccine are that it is a single injection and it is easier to store because it does not require the freezing temperatures necessary for the mRNA vaccines, so it was initially a popular choice. Since its EUA, however, it has faced a number

© F.A. Davis Publishing

of setbacks due to reported serious side effects, including blood clots and Guillain-Barré syndrome. To date, it has not received final FDA approval.

Types of COVID 19 Vaccines: Historically, vaccine development was a lengthy process involving much trial and error using a weakened or killed version of the targeted pathogen. The idea that a vaccine could be created that was affective against SARS-CoV-2 in less than a year was a daunting expectation. That historical perspective contributed to the vaccine skepticism that was and continues to be so rampant in the United States. Three types of vaccines are approved for use in the United States:

- *mRNA vaccines.* A new type of technology, mRNA technology, addresses the spike protein like the one on the coronavirus (Katella, 2022). This technology had been successfully used to develop a vaccine against the MERS virus, which is genetically like the SARS-CoV-2 virus (Glassman et al., 2022). The spike protein created by mRNA vaccines is recognized as foreign and activates the immune system to make antibodies that will recognize the SARS-CoV-2 spike protein and attack it if exposed. Both the Pfizer-BioNTech and Moderna are mRNA vaccines.
- *Carrier or virus vector vaccine.* This type of vaccine does not contain the antigen but uses a modified version of the virus to deliver the genetic code for the antigen (Katella, 2022). The resulting cellular immune response triggers the T cells and the production of antibodies by the B cells. The Johnson and Johnson vaccine used this type of technology. The Oxford-AstraZeneca vaccine also uses this type of technology. Although it is approved in the United Kingdom and used worldwide, it is not approved for use in the United States.
- *Protein adjuvant vaccines*. This type contains the spike protein of the coronavirus formulated as a non-disease-causing nanoparticle (Katella, 2022). When injected it also stimulates a cellular immune response. Produced by Novavax, this type of vaccine is not yet approved for use in the United States.

Healthy Habits: SARS-CoV-2 is primarily spread by respiratory droplets aerosolized by coughing, sneezing, talking, singing, or even just breathing. Wearing masks helps to prevent the spread especially when indoors. Although contact with droplets on surfaces is less likely to cause disease, surface decontamination, good hand hygiene, and avoiding touching the nose, mouth, or eyes if the hands are potentially contaminated are other commonsense measures to prevent illness.

Referral: Due to the unpredictable effects of COVID-19, which range from minor symptoms similar to the common cold to severe cardiopulmonary collapse, all patients must be evaluated thoroughly and referred for additional consultation if they are high risk or presenting with worrisome symptoms. There are many case examples of patients being evaluated in the emergency department and sent home to recover, only to return later needing intubation and intensive care. More recent variants have been less likely to result in hospitalization. Patients who are fully vaccinated and boosted are still susceptible to some of the more recent variants, but they are generally not becoming seriously ill.

Education: Patients need to understand the safety of the vaccines, and providers should utilize the technique of motivational interviewing to understand any hesitancy. Use shared decision making to come to a decision regarding protection against COVID 19. Encourage good hand hygiene and following the CDC recommendations for masking. Help patients understand their personal risk and the fact they may require a higher level of protection. Encourage testing for COVID when symptomatic or after exposure. For patients with long-term symptoms of COVID, provide support and up-to-date information as it becomes available.

Clinical Recommendation	Evidence Rating	References
The presence of fever, myalgia/arthralgia, fatigue, and headache substantially increased the possibility of COVID-19 when present.	A	Struyf et al., 2021
80% of patients who had COVID continue to complain of at least one long-term effect, with fatigue and headaches being the most frequently cited.	A	Lopez-Leon et al., 2021
Nirmatrelvir/ritonavir (Paxlovid), an oral SARS-CoV-2 protease inhibitor antiviral combination, reduced the risk of hospitalization or death by 88% compared to placebo in nonhospitalized adults with laboratory-confirmed SARS-CoV-2 infection.	A	Hammond et al., 2022
The mRNA vaccines, Spikevax (Moderna) and Comirnaty (Pfizer-BioNTech), have received full U.S. Food and Drug Administration (FDA) authorization for the primary series in individuals 18 years and older (Spikevax) and 16 years of age and older (Pfizer-BioNTech). Use in individuals below these ages and additional booster shots remain under FDA Emergency Use Authorization.	A	CDC, 2022d

HUMAN IMMUNODEFICIENCY VIRUS (HIV) AND ACQUIRED IMMUNE DEFICIENCY SYNDROME (AIDS)

Signal Symptoms: Acute infection presents with nonspecific symptoms often described as "flu-like symptoms" 2 to 4 weeks after infection. These symptoms include fever, chills, rash, night sweats, muscle aches, sore throat, fatigue, swollen lymph nodes, and/or mouth ulcers. Symptoms can last a few days or up to several weeks. Older adults usually present after they have been infected with HIV for several years. At this point, the virus is in the late stages and the presenting signs are those of an opportunistic infection, which indicates that the virus is more likely to have progressed to AIDS. This population presents with advanced infection, the signs and symptoms that include thrush, unintentional weight loss, unexplained anemia, unexplained thrombocytopenia, *Pneumocystis jirovecii* pneumonia, or other opportunistic infections (Centers for Disease Control and Prevention [CDC], 2021a; Chou et al., 2019; U.S. Department of Health and Human Services [USDHHS], 2021).

Description: HIV is classified as a retrovirus. This means the viral genetics consist of RNA rather than DNA. After entering the cytoplasm of a human lymphocyte, the viral RNA is transcribed by means of an enzyme called reverse transcriptase into DNA, which in turn integrates itself into human DNA in the cell's nucleus. This proviral genetic combination takes over the mechanism of the cell, producing new HIV virions, which in turn infect and destroy other T-lymphocytes. Understanding this cycle provided the pharmacological basis for antiretroviral medication used to treat HIV.

Untreated or poorly managed HIV results in progressive degradation of immune function. Profound immune compromise is designated as AIDS. AIDS is clinically defined as <200 CD4 cells/mm^3, subjecting the person to severe debilitating, sometimes fatal, concomitant or opportunistic infections. Although to date there is no cure, early detection and proper antiretroviral treatment can result in a normal life span.

Etiology: In the 1980s, medical anthropologists traced the origins of HIV to a zoonotic virus subsequently named Simian immunodeficiency virus (SIV). Direct exposure to the blood of an infected animal during hunting or eating seems the most plausible explanation for the crossover to human infection. The origin of HIV itself is believed to have occurred between 1884 and 1924 with the first documented case occurring in approximately 1931 in West Africa. There are two strains of HIV: HIV-1 and HIV-2. HIV-1, being the most virulent and most easily transmittable strain, accounts for the vast majority of worldwide cases.

HIV-1 was first introduced into the Americas via Haiti around 1966 and was sexually spread into the United States around 1972. The pandemic spread is overwhelmingly via heterosexual transmission. Dispersion has been facilitated by worldwide air travel, contamination of blood supplies before adequate testing, and contaminated needles and syringes used for injectable drugs. In the United States, localization of the disease in the gay, Haitian, and injectable drug–using communities accounts for the stigma that continues to negatively affect prevention, diagnosis, and care (Bailes et al., 2003).

Occurrence: The CDC published an updated national profile report of the diagnosis of HIV infection in the United States and dependent areas in 2019, which provides the most recent statistics available. At the end of 2019, an estimated 1,189,700 people age 13 and older had HIV in the United States, including an estimated 158,500 people who were undiagnosed (CDC, 2021b). In 2016, about 80% of new HIV infections in the United States were transmitted from the nearly 40% of infected people who have an unknown HIV-positive status or are not receiving HIV care (Li et al., 2019).

Age: In the United States in 2018, 51% of people diagnosed with HIV were age 50 and older. In the same year, the incidence of HIV among the same population was one in six new diagnoses (CDC, 2020a).

In the transgender community age greater than 55 years, during the period from 2015 to 2019, the CDC reported a 71% increase in the rate of new diagnoses (CDC, 2019, 2020a).

Gender

Please see Table BC-2 below for details.

Ethnicity: While anyone who is exposed bears the same risk of infection, some racial/ethnic communities have a higher percentage of HIV and thus there is increased risk of new infections with each sexual encounter or IV drug use.

At year-end 2019 in the United States, HIV prevalence was 1,044,977 people living with diagnosed HIV infection. The highest rate (1,027.5) and the largest percentage (40%) were for Black/African Americans, followed by rates of 673.1 for multiracial, 411.3 for Hispanic/Latino, 153.9 for White, 153.0 for Native Hawaiian/other Pacific Islander, 132.0 for American Indian/Alaska Native, and 82.3 for Asian persons. See Table BC-3 below.

Contributing Factors: Although the virus is found in multiple body fluids of HIV-positive persons with detectable serum viral loads, the concentrations necessary for human transmission are typically in blood, semen, vaginal fluid, and breast milk. The efficacy of transmission is predicated on the amount of virus present and the availability of target receptor sites (i.e., sites that are most plentiful) in the blood.

TABLE BC-2 Incidence and Prevalence of HIV by Gender

GENDER	% OF NEW HIV DIAGNOSES IN 2018	NUMBER OF HIV-INFECTED PERSONS WITHIN THE ESTIMATED 1.2 MILLION POPULATION OF THE UNITED STATES (2019)
Men	81%	912,100
Women	19%	261,800
Transgender	2%	—

TABLE BC-3 Incidence of HIV by Race/Ethnicity (no prevalence here)

RACE/ ETHNICITY INCIDENCE	NUMBER OF NEW HIV DIAGNOSES IN 2019	INCIDENT RATES PER 100,000 IN 2019
Black/African American	15,334	37.3
Hispanic/Latino	10,120	16.7
White	9,013	4.6
Asians	737	3.9
American Indian/ Alaska Native	210	8.6
Native Hawaiians and other Pacific Islanders	66	11.1
Multiracial	918	12.6

Centers for Disease Control and Prevention. (2021c). HIV Surveillance Report, 32. *http://www.cdc.gov/hiv/library/reports/hiv-surveillance.html.*

Sex: HIV/AIDS is primarily transmitted by penile–vaginal or penile–anal sex, age of the participants notwithstanding. Anything compromising the integrity of mucous membranes, including preexisting inflammation, the presence of other sexually transmitted infections (STIs), or traumatic sexual practices, increases the risk of transmission. Because HIV is present in blood, semen, and preseminal fluid, anal sex that is unprotected by barriers such as latex condoms ranks as the highest transmission risk. The receptive partner is at most risk, although the insertive partner can also be infected by an HIV-positive receptive partner. These principles of risk also hold true for penile-vaginal sex. Circumcision has been demonstrated to significantly reduce the risk of HIV acquisition but not transmission.

Intravenous Drug Use: The use of HIV-contaminated needles and syringes is a significant mode of transmission. Eliminating the use of shared equipment, including cleaning practices and supplies, can mitigate risk. The use of a cleaning solution of 1:10 bleach to sterile water used to flush the needle and syringe can significantly reduce risk.

Pregnancy: Vertical transmission from mother to child can occur during pregnancy, delivery, or breastfeeding. Maternal testing should occur at first obstetrician (OB) visit, at third trimester, and at the onset of labor. Prompt and adequate antiretroviral treatment (that results in nondetectable viral loads), safe delivery practices, and access to infant feeding formula are likely to result in a seronegative child (Branson et al., 2006).

Occupational Transmission: The risk of occupational transmission is relatively small but has occurred in a variety of settings. There is no risk of HIV transmission with exposure of HIV-infected fluids to intact skin. Needle-stick injuries are the most common mode of occupational transmission in developed countries. The risk of this mode of transmission is estimated at 0.3% in an unprotected recipient but is mitigated by using latex gloves and minimizing the depth of the puncture (deeper punctures pose more risk). The risk can be further reduced to infinitesimal levels with prompt administration of a proper antiretroviral regimen to the person receiving the injury. An immediate referral should be made to an infectious disease specialist for comprehensive advice. In occupational exposures, bodily fluids in addition to blood, sexual fluids, and breast milk are also potentially infectious. These fluids include cerebrospinal fluid, synovial fluid, amniotic fluid, pleural fluid, peritoneal fluid, and pericardial fluid. Because semen and cervicovaginal secretions have been demonstrated to contain both virus and virus-infected cells, such secretions should be considered infectious. Urine, feces, and saliva are not considered infectious.

Stigma: Stigma has a profound effect on the ability to seek testing and to adhere to treatment. For the sake of community health and individual patients, primary care providers are ethically obligated to thoughtfully examine and carefully acknowledge their own biases to facilitate gaining trust from the patient for testing and for ensuring support needed to adhere to treatment.

Signs and Symptoms: The signs and symptoms of HIV/AIDS infection can be divided into acute presentation and chronic infection as follows:

Acute presentation is defined by the intact immune response to a pathogen: general malaise, myalgia, chills, low-grade fever, and fatigue. Occasionally a nonpruritic macular rash with a generalized distribution is present. This presentation can range from 3 days to 3 weeks and is consistent with a response to other viral illnesses. There are no HIV-specific presenting symptoms. Diagnosis is provided by HIV screening and testing.

Chronic disease in an untreated patient is marked by unexplained wasting, extreme fatigue, unexplained anemia or thrombocytopenia, and/or the presence of opportunistic infections such as thrush, disseminated lymphadenopathy, the presence of Kaposi's sarcoma, or *Pneumocystis jirovecii* pneumonia (formerly known as *Pneumocystis carinae* pneumonia or PCP). Because this is not an exhaustive list, HIV infection should be considered whenever an odd or difficult to treat infection is encountered.

The American Academy of HIV Medicine and the American Geriatrics Society agree that at age 50 years, an HIV-seropositive adult should be considered a geriatric patient. In providing primary care to these patients, it is important to recognize that the combination of the illnesses of aging and of HIV are considered "multimorbidity" or "polypathology." Unlike simple "comorbidity," in multimorbidity age plus debilitating conditions synergize to make morbidity and mortality worse than might otherwise be the case. The sum is greater than the parts (AAHIVM Provider Education Center, n.d.).

Diagnostic Tests: There are two groups of testing in HIV care: diagnostic tests and treatment tests. Primary care providers will use diagnostic tests and should be familiar with the testing used to guide HIV care.

Diagnostic testing can detect HIV infections but cannot tell how long a person has had HIV or if the person has AIDS. The CDC recommends that everyone ages 13 to 64 years be tested for HIV at least once in their lifetime. Diagnostic testing is also recommended for people with HIV risk factors such as vaginal or anal sex with an HIV-positive person or unknown HIV status person, before having sex with a new partner,

© F.A. Davis Publishing

having sex with many people, or sharing drug equipment with others.

Three types of screening and diagnostic tests are available: nucleic acid tests (NAT), antigen/antibody tests, and antibody tests. NAT identify HIV virus in the blood and can determine whether a person has HIV and how much of the HIV virus is present (viral load). NAT are accurate 10 to 33 days after an exposure. Antigen/antibody tests determine the presence of HIV antibodies and antigens in the blood and are available as a rapid test with a finger prick. Antigen/antibody tests are accurate 18 to 90 days after an exposure. HIV antibody tests are the most common rapid test and are currently the only approved self-test. Antibody tests are accurate 23 to 90 days after exposure. The HIV antibody test detects antibodies to HIV in blood or oral fluid. The error rate is higher for oral testing compared to blood testing (CDC, 2020b).

Differential Diagnoses: HIV infection should be considered in any person with unusual or recurrent infections. In the spectrum of HIV illness, AIDS is defined as a CD4 count <200 cells/mm^3 in an HIV-seropositive patient; the presence of opportunistic illness also meets the criteria. Opportunistic illness indicates severe immune decline. Such illnesses include:

- Pulmonary or disseminated tuberculosis (TB)
- Invasive cervical cancer
- Esophageal candidiasis
- Cryptococcosis
- Cryptosporidiosis
- Cytomegalovirus (CMV) retinitis, or infection outside of liver, spleen, or lymph nodes
- Herpes simplex virus (HSV)—chronic ulcers, bronchitis, pneumonitis, or esophagitis
- Kaposi's sarcoma
- Pruritic papular eruption of HIV
- Lymphoma—Burkitt's or primary brain
- Mycobacterium avium complex, disseminated or extrapulmonary
- PCP pneumonia
- Progressive multifocal leukoencephalopathy
- Brain toxoplasmosis
- HSV encephalitis
- HIV wasting syndrome
- Disseminated histoplasmosis
- Isosporiasis
- Recurrent salmonella septicemia
- Recurrent bacterial pneumonia
- (Waymack & Sundareshan, 2021)

Treatment: There is no effective cure for HIV. The goal of antiretroviral therapy (ART) is to reduce replication of the HIV virus so that the volume of virus is below the level of accurate detection, currently measured at less than 50 to 20 copies of virus/mL. In an untreated person, viral loads can be greater than 1 million copies/mL.

Advances in ART have made it possible for people with HIV to live a near-expected functional life span without progressing to AIDS and importantly, without transmitting HIV to sexual partners or fetuses (Thompson et al., 2021). Comprehensive evidence-based HIV primary care guidance is more important than ever as there is increasing emphasis on maintaining health throughout the life span. To achieve desired outcomes, people with HIV must be consistently engaged in care and be able to access uninterrupted treatment, including ART.

Immediate ART, also known as rapid ART and same-day ART, refers to starting HIV treatment medications as soon as possible, preferably the same day as the HIV diagnosis (Coffey & Bacon, 2021). Rapid ART initiation has been shown to reduce time to linkage to care and viral load suppression. Rapid ART is appropriate for nearly all people newly diagnosed with HIV, people with suspected acute HIV, and people with a positive rapid HIV antibody test before confirmatory tests results are available if the concern for HIV infection is high. While rare in the outpatient clinic setting, rapid ART is not appropriate for people with certain untreated opportunistic infections such as cryptococcal meningitis and central nervous system tuberculosis. To reduce the risk of immune reconstitution inflammatory syndrome (IRIS), there needs to be a short period of treatment for the opportunistic infection prior to starting ART. Another scenario that would not be appropriate for rapid ART involves those people with a preliminary positive rapid HIV test result but who have a low probability of HIV infection. In these cases, the preliminary result is more likely to be a false positive, and the confirmatory result should be obtained before starting ART. When an HIV test results are positive, a rapid referral to an HIV specialist should be made. If a specialist is not immediately available, guides to contacts are provided in the Referral Section of this chapter. Prior to giving a prescription to a patient, consider local accessibility of medications; this includes the patient's ability to meet the steep co-pay.

For a person who has chronic HIV and is looking to start or restart ART, a consultation with an HIV expert is needed. ART regimens should be selected based on resistance history as well as the person's comorbidities, tolerance of previous antiretrovirals, adherence challenges, and insurance status with respect to medication co-pays. Assistance may be provided through Ryan White funding. HIV specialists will be able to assist in accessing funding.

ART is heavily reliant on the cytochrome p450 pathway for metabolism; therefore, other medications commonly used in primary care such as statins, psychoactive medications, contraceptives, some antibiotics, antiepileptics, steroid injections, and vitamins carry the potential for serious drug–drug reactions. Primary care providers are urged to consult with an HIV specialist or HIV pharmacist before starting or stopping any medications.

When the CD4 count is measured at less than 200 cells/ mm^3 (AIDS), the patient is started on prophylactic medication for certain common opportunistic infections. The appropriate dosages for prophylaxis are suboptimal for treatment. Medication changes, and possibly resistance testing, are indicated in the instance of breakthrough infection. Consultation with the HIV specialist is recommended. If an HIV specialist is not immediately accessible, refer to the DHHS link https://clinicalinfo.hiv.gov/en/guidelines. This resource gives updated recommendations for ART. Up-to-date listings for HIV specialists are found at https://aidsetc.org/consultation.

Use of alternative therapies by the HIV seropositive population is very common. Despite this, reporting of these therapies is uncommon. Some herbal remedies have demonstrated potential for significant drug–drug interactions that either increase adverse ART effects or block intended effectiveness.

© F.A. Davis Publishing

Most herbal remedies and dietary supplements have not been adequately researched. Use of these agents should be continuously monitored and promptly reported to the HIV specialists by the primary care provider.

The rules of ART are rigid. Safe and effective therapy requires that agents be used in combination. Not all antiretrovirals work cooperatively. Regimens are carefully choreographed among the classes of antiretroviral agents and are coordinated with medications prescribed for comorbidities, alternative therapies, and occasionally diet. Failure to understand these principles can result in organ damage, resistance to ART, and failure to control HIV (Briggs & Narsavage, 2004; Coffey & Bacon 2021; Thompson et al., 2021).

Follow-Up: The HIV care continuum is a public health model that outlines the five steps that people with HIV go through from diagnosis to achieving and maintaining an undetectable viral load:

1. Diagnosis of HIV infection
2. Linkage to HIV medical care
3. Receipt of HIV medical care
4. Retention in medical care
5. Achievement and maintenance of viral suppression

The HIV care continuum is a tool to help identify gaps in services and develop strategies that better support a person with HIV to thereby achieve an undetectable viral load. Primary care is integral to this process by assuring that the patient is linked to and retained in HIV care and by establishing an ongoing relationship with the HIV team.

Testing: As was previously mentioned, there are two categories of testing: diagnostic testing, in which primary care providers have a significant role and testing is used to guide HIV treatment, which is primarily the purview of an HIV specialists, and treatment testing. This section defines use of treatment tests that facilitate the primary care team's understanding.

Basically, treatment tests are viral load tests that are used to measure the efficacy of ART, CD4 counts that roughly measure immune function, and viral genotypes and phenotypes that are used to individualize the selection of ART. People who have no documentation of HIV status should have an HIV antigen/antibody test at initiation into care. A CD4 cell count with percentage and a quantitative HIV RNA (viral load) level should be obtained on initiation of care.

In collaboration with HIV specialists, after ART is initiated, HIV RNA (viral load) should be rechecked in 2 to 4 weeks but no later than eight weeks, and then every 4 to 8 weeks until a viral load <50 copies/mL is achieved. If therapy is effective, this load reduction should occur within three months after which viral loads can be obtained in 3- to 4-month intervals. If nondetectable viral loads are not achieved within a 3-month interval, the patient should return to the HIV specialist for genetic testing of the virus. Viral load testing can be extended to every 6 months for adherent patients with stable CD4 counts who maintain an undetectable viral load for 2 years.

CD4 cell count should be checked every 3 to 6 months for the first 2 years after starting ART, or if viremia develops, or if CD4 cell count is $<300/mm^3$. After 2 years, CD4 cell count laboratory values can be extended to every 12 months if CD4 cell count is 300 to $500/ mm^3$ and HIV RNA is suppressed, or if CD4 cell count is $>500/mm^3$ with HIV RNA suppression, then CD4 cell counts are optional (Thompson et al., 2021).

Vaccines: Vaccines are recommended to prevent HIV-positive people from contracting infections that are vaccine preventable. To prevent herpes zoster, a two-dose series recombinant zoster vaccine should be given to people age greater than 50 years who are on ART and have CD4 cell counts greater than 200 cells/mm^3. For vaccination recommendations, consult current vaccination schedules. Live virus vaccines are contraindicated for HIV-positive people.

Cancer Screens: Cancers associated with smoking and infection are of particular risk in this population. Cancers associated with smoking that are common to these patients include lung, kidney, stomach, laryngeal, and oral. Cancers associated with infection include anal, vaginal, penile, nasopharyngeal, and Hodgkin's lymphoma associated with Epstein Barr virus. Hepatitis B and C viruses carry additional risk of cancer in the HIV-seropositive patient.

Dental examinations are of special importance, so an oral health examination should be performed semiannually due to increased risk of oral cancers. Smoking cessation should be emphasized, as well as cervical and anal Papanicolaou (PAP) testing. Screening for the following cancers should begin earlier than for the HIV-seronegative population and should be more frequent:

- Lung: Age 55 and 80 years who have 30 pack years of smoking and are current smokers or who have quit in the last 15 years should have an annual low-dose computed tomography (CT) scan of their chest until smoking has been discontinued for 15 years.
- Prostate: Follow U.S. Preventive Services Task Force or American Cancer Society guidelines and consider patient wishes.
- Colon: Age 50 to 75 years. Screen prior to age 50 if there is a family history of colon cancer. Colonoscopy every 10 years if normal, or more frequently if polyps are identified.
- Cervical: Begin within 1 year of sexual activity. Repeat at diagnosis of HIV and annually three times; if normal, reduce interval to every 3 years. Perform human papillomavirus (HPV) testing if PAP abnormalities are found. Continue screening past 65 years of age.
- Breast: Age 50 to 75 years. Perform mammography every 2 years.
- Anal: No current national recommendations. Some experts recommend anal cytology for males and females with HIV who have receptive anal sex, but only if high-resolution anoscopy is available.

Sexual History: Sexual history should be taken as a part of routine health care, as well as when signs or symptoms of an STI are present. A sexual history should include the "Five Ps": Partners, Practices, Protection from STIs, Past History of STIs, and Pregnancy Intention (Barrow et al., 2020, Thompson et al., 2021).

Sequelae: Special considerations for the >50-year-old HIV-infected population include:

- After initiation of ART, only plasma glucose criteria should be used to diagnose diabetes. Patients with diabetes mellitus should have an HbA1c level monitored every 6 months with an HbA1c goal of <7%, in accordance with the American Diabetes Association Guidelines. In the older and particularly frail person, studies indicate that overzealous glycemic control among type 2 diabetes

© F.A. Davis Publishing

is harmful and suggest a targeted glycosylated hemoglobin of 8%.
- Increased renal and hepatic monitoring should be implemented in older people with HIV that have multimorbidity and polypharmacy.

HIV infection accelerates age-related decline in pulmonary health—particularly with respect to chronic obstructive pulmonary disease (COPD)—independent of smoking histories, drug abuse, and opportunistic infections. This decline prompts increased attention to pneumonia, influenza, and COVID vaccinations as well as emphasis on smoking cessation.

Osteoporosis and bone fractures occur more commonly in the HIV infected, and these injuries increase with age. HIV-infected patients are at increased risk for vitamin D deficiency, thus requiring screening and replacement. The use of proton pump inhibitors may also contribute to osteoporosis. Post-menopausal HIV seropositive women require routine screening. Additional factors such as nutritional deficiency, smoking, physical inactivity, and androgen deficiency should also be addressed.

Treatment for hypertension remains the same in the HIV-infected population as in the HIV seronegative; however, the increased risk of renal and cardiovascular disease suggests that agents affecting the renin-angiotensin system may be especially helpful.

Despite effective antiretroviral treatment, neurocognitive disorders—particularly those affecting subcortical domains—remain a risk that increases with age. Because it does not test subcortical domains, the Mini-Mental State Examination is not an effective screening test. Valcour et al. (2011) recommend the Montreal Cognitive Assessment (free at http://www.mocatest.org) in addition to a routine neurological exam, screening for depression, and executive function testing (*Aging Report – AAHIVM*, n.d.).

Prevention/Prophylaxis: HIV is primarily sexually transmitted, with high serum viral loads being reflected in higher viral volume in genital secretions and tissue. In addition to adherence to ART, barrier protection (latex condoms) is an effective means of transmission prevention when used correctly. It has been said that it is easier to have sex than to talk about it; nevertheless, primary care providers should familiarize themselves with the variety and correct use of condoms and other barriers, as well as sex toys and sexual practices, in order to productively engage in open, frank, and useful risk-reduction discussions.

Pre-Exposure Prophylaxis (PrEP): PrEP is a medication for HIV at-risk people that prevents acquiring HIV from sex or IV drug use. PrEP is recommended for men or women with an HIV-positive partner or injecting partner, a recent bacterial STI, multiple sex partners, inconsistent condom use, or transactional sex. Before starting PrEP, a negative HIV test must be completed within 7 days of the start of PrEP medications. A PrEP prescribing provider can be located using https://preplocator.org/ (CDC, 2021d Update).

Nonoccupational Postexposure Prophylaxis (nPEP): Nonoccupational postexposure prophylaxis (nPEP) should be started within 72 hours of a sexual or injection-related substantial HIV risk exposure. If the exposure is not an isolated event such as sexual assault or infrequent condom failure, then the person is a candidate for ongoing HIV risk and should be evaluated for PrEP after completing nPEP. Nonoccupational postexposure prophylaxis is not recommended when the reported exposure is not a substantial risk of HIV transmission and/or when prevention is sought more than 72 hours after a potential exposure. All people who report behaviors or situations of recurring HIV exposures or who receive nPEP more than once per year should be provided risk-reduction counseling and PrEP (CDC, 2018, 2021d).

MULTIDRUG-RESISTANT ORGANISMS (MDRO)

Signal Symptoms: Symptoms of infection with multidrug-resistant organisms (MDRO) vary depending on the part of the body that is infected. Infection can occur in any part of the body, including the skin, lungs, urinary tract, or bloodstream. The severity of these infections depends on the type of bacteria that causes the infection and the site of the body where the infection occurs.

Description: MDRO are defined as microorganisms, predominantly bacteria, that are resistant to one or more classes of antimicrobial agents.

Etiology: Microorganisms, such as bacteria, viruses, fungi, and parasites, are living organisms that evolve over time. Their primary function is to reproduce, thrive, and spread quickly and efficiently. Microorganisms adapt to their environments and change in ways that ensure their survival. If something stops their ability to grow, such as an antimicrobial, genetic changes can occur that enable the microbe to survive. There are several ways this occurs. The four major resistance mechanisms of microbes are to alter cell permeability to decreased drug uptake, modify the drug targets so antibiotics cannot act on them, efflux pumps to pump out the antibiotics, and modifying enzymes of the antibiotic to inactivate them (Sharma et al., 2019).

- Intrinsic or natural resistance is a result of the structural characteristics of the bacteria and not associated with previous use of antibiotics. *Pseudomonas aeruginosa* and *Klebsiella pneumoniae* are inherently resistant to ampicillin due to the permeability barrier provided by its gram-negative outer membrane (Reygaert, 2018).
- Acquired resistance occurs when bacteria generally susceptible to an antimicrobial change in a way that protects them from the antibiotics. These resistance mechanisms can be present together or in different combinations within the bacterial cell, allowing high level resistance to multiple antibiotics at the same time (Kapoor et al., 2017; Reygaert, 2018). The major resistant mechanisms of microbes are decreased drug uptake, efflux pumps, and enzymes that inactivate an antimicrobial chemical and target alterations by mutation.
- Modification of target sites often result from spontaneous mutation of a bacterial gene on the chromosome in the presence of the antibiotic (Kapoor et al., 2017; Reygaert, 2018). In the case of penicillin, the binding protein in the bacteria is altered, so penicillin can no longer bind to that protein, making penicillin ineffective (Kapoor et al., 2017). For example, methicillin-resistant *Staphylococcus aureus* (MRSA) developed resistance to methicillin and all other β-lactams.
- Enzymatic inactivation is the ability to destroy or inactivate the antibiotic resulting in antibacterial resistance (Kapoor et al., 2017; Reygaert, 2018). Beta-lactamases inactivate the β-lactam ring of penicillin, cephalosporins, and related drugs. The antibiotic is unable to bind to the penicillin-binding protein (PBP), which interferes with cell wall synthesis (Kapoor et al., 2017). *Neisseria* gonorrhea is now largely resistant to penicillin because of penicillinase activity.
- Decreased accumulation by decreased permeability or increased efflux occurs because the antibiotic is unable to access the site of action in enough concentrations to kill the organisms (Kapoor et al., 2017; Reygaert, 2018). Resistant organisms make their membrane less penetrable preventing the entry of antibiotics. Gram-negative organisms can limit the penetration of antibiotics because of an alteration in the number of outer membrane proteins (OMP) (Kapoor et al., 2017). The OMP change in number or character so that β-lactam uptake is substantially diminished contributes considerably to β-lactam resistance in gram-negative bacteria, e.g., *Pseudomonas aeruginosa* resistance to imipenem (Kapoor et al., 2017).
- Drug efflux occurs in some bacteria. The efflux pump is developed when antibiotic enters the cell, which throws out the antibiotics outside the cell limiting adequate drug levels (Reygaert, 2018). This type of resistance is seen in *Streptococcus pneumoniae* to macrolides.

Occurrence: The Centers for Disease Control and Prevention (CDC) (2019) reported more than 2.8 million antibiotic-resistant infections occur in the United States each year, and more than 35,000 people die. In a retrospective study by Nelson et al. (2021), the estimated national cost to treat these infections caused by six multidrug-resistant bacteria identified in the report was more than $4.6 billion annually. Conscientious infection prevention and control efforts in the United States reduced deaths from MDRO by 18% overall and by nearly 30% in hospitals (CDC, 2019a).

Age: Infection with an MDRO occurs most often in young children, older adults, or in people who have an existing severe illness or chronic health conditions. However, these organisms can infect anyone at any age. In 2017, older adults accounted for over one-third of the cost of care and deaths resulting from these antibiotic-resistant infections.

Gender: N/A

Ethnicity: The current literature describing racial and ethnic disparities in antibiotic-resistant infections in the United States is limited and inconsistent at best. Racial and ethnic data are not routinely collected or checked for accuracy (See et al., 2017). In one of the existing studies, it suggests that Black, Hispanic, and lower-income people are at higher risk of infection with community-acquired antibiotic-resistant pathogens such as methicillin-resistant *S. aureus* and drug-resistant *S. pneumoniae* (See et al., 2017).

In the review by See and colleagues (2017) using the CDC's Emerging Infections Program surveillance data for invasive community-associated (CA) MRSA cases from 2009 to 2011 in 33 counties of 9 states, they noted an incidence of 4.59 per 100,000 among Whites and 7.60 per 100,000 among Blacks (See et al., 2017). The racial disparity in CA-MRSA rates was primarily attributed to socioeconomic factors. This population has a higher rate of comorbidities and racial and ethnic minorities are hospitalized more often

© F.A. Davis Publishing

for preventable conditions, which puts them at increased risk for drug-resistant healthcare-acquired infections (See et al., 2017).

The newly established National Action Plan for Combating Antibiotic-Resistant Bacteria has not prioritized racial or ethnic disparities in antibiotic resistance-related outcomes for further research (CDC, 2021a). The COVID-19 pandemic has exposed the impacts of systemic health inequalities on racial and ethnic minorities in the United States. Black and Hispanic/Latino populations have been disproportionately impacted by COVID-19, accounting for nearly half of the cases and 37% of the deaths (CDC, 2020a). This disparity has highlighted the need to explore the role of racial and ethnic disparities in influencing health outcomes.

Contributing Factors:
Factors that increase risk for infection with MDRO

- Recent antibiotic therapy
- Immunosuppressed, chronic diseases, and inflammatory conditions
- Older age and frailty
- Surgery, invasive procedures, and/or dialysis
- Presence of an indwelling device
- Hospitalization or living in a long-term care facility

Diagnostic Tests: MDRO is identified by bacterial culture, antibiotic sensitivity testing, other specific laboratory tests, along with clinical signs and symptoms. The site for culture will depend on the signs and symptoms that the patient is exhibiting.

Individuals with MDRO may be colonized with the microorganism and not exhibit symptoms of infection but can still spread the MDRO into the environment. The colonized host may not be ill, though they have shed microorganisms to other people, and depending on the portal of entry and/or the immune system of the susceptible host, they may put the individual at risk for illness.

Differential Diagnosis: N/A

Treatment: The decision regarding treatment of MDROs is based on whether the patient has an active infection or if the patient is colonized with the organism. (See individual MDRO.)

Candida auris (C. auris)

- **Incidence:** The CDC (2020b) reported 746 cases of *Candida auris* across the United States. Worldwide, 46 countries reported cases of *C. auris*.
- **Threat:** Serious
- **Pathogen:** *C. auris* is a budding yeast, which almost never forms short pseudohyphae and does not form germ tubes (Ahmad & Alfouzan, 2021; CDC, 2020c; Černáková et al., 2021).
- **Types:** *C. auris* is a yeast species belonging to the genus *Candida*.
- **Common sites of infection:** It can cause invasive candidiasis and fungemia; the central nervous system, kidneys, liver, bones, muscles, joints, spleen, or eyes are invaded.
- **Populations affected:** Candidiasis is most often acquired in hospitals by patients with immunosuppressive states, presence of invasive catheters, chronic medical conditions, dialysis, recent exposure to antibiotics or antifungal agents, parenteral nutrition, and intensive care unit (ICU) admission.
- **Resistance patterns:** *C. auris* is often multidrug resistant, with some strains resistant to all three available classes of antifungals.
- **Transmission:** *C. auris* is efficiently transmitted person to person. *C. auris* can spread through contact with contaminated surfaces and fomites when shed from infected or colonized patients (CDC, 2021b; Lee et al., 2018). Shared multiuse patient equipment such as temperature probes and pulse oximeters may act as reservoirs of *C. auris*. *C. auris* can colonize skin and persist in the health-care environment, allowing for transmission between patients.
- **Treatment:** The choice of an agent should be based on local antimicrobial sensitivities, site of infection, cost, and comorbid conditions. CDC does not recommend treatment of *C. auris* identified from noninvasive sites (such as respiratory tract, urine, and skin colonization) when there is no evidence of infection (CDC, 2021b). Treatment is complicated because *C. auris* is easily mistaken as various other *Candida* species. Echinocandins are currently recommended as first-line therapy for the treatment of *C. auris* (Ostrowsky et al., 2020; Pappas et al., 2015). Agents approved by the U.S. Food and Drug Administration (FDA) in this class include anidulafungin, caspofungin, and micafungin (Ostrowsky et al., 2020; Pappas et al., 2015). Agents in this class are available for IV administration only. In patients who are unresponsive to echinocandin therapy or who have persistent fungemia for more than 5 days, the CDC recommends switching to liposomal amphotericin B (CDC, 2021b; Pappas et al., 2016)

Carbapenem-Resistant Enterobacterales (CRE)

- **Incidence:** Carbapenem-resistant Enterobacterales (CRE) accounts for more than 13,000 nosocomial infections and contribute to more than 1,000 deaths annually in the United States (CDC, 2019).
- **Threat:** Urgent
- **Pathogen:** Gram-negative bacilli
- **Types:** *Escherichia coli*, Enterobacter, *Klebsiella oxytoca*, and *K. pneumoniae*
  - **Common sites of infection:** These bacteria can cause pneumonia, urinary tract infections (UTIs), septicemia, endocarditis, meningitis, and severe intra-abdominal infections.
  - **Populations affected:** Prior and recent antibiotic use, residency in long-term acute care facilities, admission to an ICU, presence of indwelling medical devices, poor functional status, increased age, solid organ, or stem cell transplantation. Patients who need ventilators, urinary catheters, or IV catheters, and those who are immunocompromised are at risk for CRE infections.
  - **Resistance patterns:** Any isolate resistant to at least one of these: imipenem meropenem, doripenem, ertapenem, meropenem/vaborbactam, or imipenem/relebactam (Tamma et al., 2021; Tilahun et al., 2021).
  - **Transmission:** CRE transmits from person to person, often via the hands of health-care personnel or through contaminated medical equipment.

© F.A. Davis Publishing

- **Treatment:** The choice of an agent should be based on local antimicrobial sensitivities, site of infection, cost, and comorbid conditions.
  - Ciprofloxacin, levofloxacin, trimethoprim-sulfamethoxazole, nitrofurantoin, or a single dose of an aminoglycoside are preferred treatment options for uncomplicated cystitis caused by CRE (Tamma et al., 2021; Tilahun et al., 2021).
  - Ceftazidime-avibactam, meropenem-vaborbactam, imipenem-cilastatin-relebactam, and cefiderocol are preferred treatment options for pyelonephritis and complicated UTIs caused by CRE resistant to both ertapenem and meropenem. Extended infusion (lasting 3–4 hours) meropenem is a preferred treatment option for pyelonephritis and complicated UTIs caused by CRE resistant to ertapenem but susceptible to meropenem, when carbapenemase testing results are either not available or negative (Tamma et al., 2021; Tilahun et al., 2021).
  - Extended infusion (lasting 3–4 hours) meropenem is the preferred treatment for infections outside of the urinary tract caused by CRE resistant to ertapenem but susceptible to meropenem, when carbapenemase testing results are either not available or negative (Tamma et al., 2021; Tilahun et al., 2021).
  - Ceftazidime-avibactam is an alternative treatment for ertapenem-resistant, meropenem-susceptible CRE infections outside of the urinary tract (Tamma et al., 2021; Tilahun et al., 2021).

Pseudomonas aeruginosa with Difficult-to-Treat Resistance (DTR-P. aeruginosa)

- **Incidence:** The CDC (2019) reports that 32,600 cases of multidrug-resistant *P. aeruginosa* infection occurred in patients hospitalized in the United States in 2017, resulting in 2,700 deaths.
- **Threat:** Serious
- **Pathogen:** Gram-negative, strict aerobic, rod-shaped bacterium
- **Types:** *P. aeruginosa*
- **Common sites of infection:** Healthcare-associated infections including bloodstream infections, ventilator-associated pneumonia, catheter-associated UTIs, and surgical site infections.
- **Populations affected:** Common in individuals with an immunocompromised state such as cystic fibrosis, bronchiectasis, neutropenia, burns, cancer, AIDS, organ transplantation, uncontrolled diabetes mellitus, and ICU admissions. Individuals with invasive devices due to the ability to form biofilms.
- **Resistance patterns:** DTR-*P. aeruginosa* is defined as nonsusceptibility to at least one antibiotic in at least three classes for which *P. aeruginosa* susceptibility is generally expected: penicillin, cephalosporins, fluoroquinolones, aminoglycosides, and carbapenems (Tamma et al., 2021).
- **Transmission:** DTR-*P. aeruginosa* can spread in healthcare settings from one person to another through contaminated hands, equipment, or surfaces.
- **Treatment:** The choice of an agent should be based on local antimicrobial sensitivities, site of infection, cost, and comorbid conditions.
  - Ceftolozane-tazobactam, ceftazidime-avibactam, imipenem-cilastatin-relebactam, cefiderocol, or a single dose of an aminoglycoside is the preferred treatment for uncomplicated cystitis and pyelonephritis and complicated UTI.
  - Ceftolozane-tazobactam, ceftazidime-avibactam, and imipenem-cilastatin-relebactam, as monotherapy, are the preferred treatment options for the treatment of infections outside of the urinary tract (Tamma et al., 2021).

Extended-Spectrum β-Lactamase Producing Enterobacterales (ESBL-E)

- **Incidence:** ESBL-E infections in the United States have increased by 53% from 2012 through 2017, due to increased community-acquired infections (Jernigan et al., 2020).
- **Threat:** Serious
- **Pathogen:** Produced by both gram-positive and gram-negative bacteria.
- **Types:** *E. coli*, *K. pneumoniae*, *K. oxytoca*, *P. aeruginosa*, *Proteus mirabilis*
- **Common sites of infection:** ESBL-E can cause a variety of illnesses, including UTIs, pneumonia, blood infections, wound infections.
- **Populations affected:** ESBL-E infections occur more often in people who are older, immunocompromised, and those with chronic disease, previous antibiotic treatment, hospitalizations, and open wounds or drains.
- **Resistance patterns:** ESBL-E have a broad-spectrum β-lactamase enzyme that enables them to inactivate most penicillins, cephalosporins, and aztreonam (Tamma et al., 2021).
- **Transmission:** Direct contact with an infected person's bodily fluids and contact with equipment or surfaces that have been contaminated.
- **Treatment:** The choice of an agent should be based on local antimicrobial sensitivities, site of infection, cost, and comorbid conditions.
  - Nitrofurantoin and trimethoprim-sulfamethoxazole are preferred treatment options for uncomplicated cystitis caused by ESBL-E. Fluoroquinolones and carbapenems are also effective treatment options against ESBL-E cystitis, though discouraged when there are other safe and effective alternatives. Fluoroquinolones carry multiple black box warnings; the older adult is at higher risk for these adverse events when taking fluroquinolones.
  - Ertapenem, meropenem, imipenem-cilastatin, ciprofloxacin, levofloxacin, or trimethoprim sulfamethoxazole are preferred treatment options for pyelonephritis and complicated UTIs caused by ESBL-E.
  - Carbapenem antimicrobial is preferred for the treatment of infections outside of the urinary tract caused by ESBL-E (Tamma et al., 2021).

Methicillin-Resistant Staphylococcus Aureus (MRSA)

- **Incidence:** In 2017, 120,000 *S. aureus* bloodstream infections and 20,000 associated deaths occurred in the United States (Kourtis et al., 2019). After years of progress, the rate of decline of MRSA bloodstream infections has slowed, whereas bloodstream infections caused

© F.A. Davis Publishing

by methicillin-susceptible *S. aureus* are increasing slightly in the community (3.9% annually, 2012–2017) (Kourtis et al., 2019).

- **Threat:** Serious
- **Pathogen:** Gram-positive cocci in clusters, aerobic
- **Types:** There are two distinct types of MRSA. HA-MRSA (hospital acquired or healthcare acquired) and CA-MRSA (community acquired). Resistance in CA-MRSA may differ from HA-MRSA and is generally susceptible to more antibiotics than HA-MRSA. The definition of CA-MRSA has not been standardized. Attempts at definitions have focused on timing, infection that occurred within 48 to 72 hours of hospitalization, risk factors, those with no history of the following: hospitalization or surgery, permanent indwelling catheters or percutaneous medical devices, resident in long-term care facility, receiving dialysis.
- **Common sites of infection:** Skin and soft tissue infections most common in CA-MRSA. With HA-MRSA, infections often cause more severe illness: pneumonia, osteomyelitis, endocarditis, toxic shock, bacteremia and sepsis, and surgical and medical device site infections.
- **Populations affected:** HA-MRSA usually affects those with multiple comorbidities. CA-MRSA usually affect younger persons, that is, young adults, and athletes.
- **Resistance patterns:** HA-MRSA is multidrug resistant to broad-spectrum antibiotics such as methicillin, oxacillin, and cephalosporins. CA-MRSA is susceptible to many antibiotics except for β-lactam antibiotics.
- **Transmission:** Transmitted by direct and indirect contact.
- **Treatment:** The choice of an agent should be based on local antimicrobial sensitivities, site of infection, cost, and comorbid conditions. Uncomplicated MRSA infections may be treated with orally administered trimethoprim/sulfamethoxazole, tetracyclines, such as doxycycline or minocycline, and clindamycin (Kourtis et al., 2019). Newer agents, such as linezolid and tedizolid, and delafloxacin can be used though they can be cost prohibitive (Kourtis et al., 2019; See et al., 2017).
  - Complicated MRSA infections may be treated intravenously with vancomycin and daptomycin. Telavancin, ceftaroline, and quinupristin-dalfopritin may be used in certain circumstances, though they can be cost prohibitive (Kourtis et al., 2019; See et al., 2017). Decolonization for HA-MRSA should be based on the patient's medical condition and expected outcome (Liu et al., 2011). Decolonization therapy for CA-MRSA is not a recommended control measure for either individuals or outbreaks (Liu et al., 2011).

Vancomycin-Resistant Enterococci (VRE)

- **Incidence:** Enterococci ranked as the third most frequently reported pathogen across all types of adult healthcare–associated infections in 2015 to 2017 in the United States (Weiner-Lastinger et al., 2020) In 2017, there were an estimated 54,500 patients hospitalized for VRE infections and an estimated 5,400 VRE-associated deaths (CDC, 2019b).
- **Threat:** Serious
- **Pathogen:** Enterococci are facultative anaerobic gram-positive cocci in pairs. Enterococci is naturally present in the gastrointestinal tract.
- **Types:** *Escherichia faecalis* and *Escherichia faecium*
- **Common sites of infection:** VRE can cause bacteremia, urinary infection, intra-abdominal and pelvic infections, wound infections, pneumonia, endocarditis, or meningitis.
- **Populations affected:** Infection is more likely in people with chronic diseases, those who are immune compromised, those who have recently received antibiotics, or patients in long-term acute care hospitals or ICU settings. It is also more common in patients with indwelling devices such as IV lines or urinary catheters.
- **Resistance patterns:** Enterococci (*E. faecalis*, *E. faecium*) can become resistant to vancomycin by acquisition of genetic information from another organism**.** VRE has a minimum inhibitory concentration to vancomycin of greater than or equal to 32 mg/mL based on the Clinical and Laboratory Standard Institute 2020 *Performance Standards for Antimicrobial Susceptibility Testing*.
- **Transmission:** VRE spread indirectly from person to person on the hands of caregivers or contact with contaminated items or surfaces (CDC, 2019b). VRE can spread directly from person to person by contact with contaminated body fluids. VRE can remain alive for weeks unless the environment is cleaned and disinfected (CDC, 2019b).
- **Treatment:** The choice of an agent should be based on local antimicrobial sensitivities, site of infection, cost, and comorbid conditions. Antibiotics used include linezolid and quinupristin/dalfopristin, while the role of daptomycin and tigecycline requires further definition (Narayanan et al., 2019). Treatment for those colonized with VRE is not necessary (CDC, 2019b).

Follow-Up: N/A

Sequelae: MDRO infections place a substantial health and economic burden on the U.S. health-care system and population. In general, patients and those who reside in nursing homes with MDRO infections may experience prolonged illness and hospital stay, require more care, bear increased financial burden due to medical care, and are associated with significant morbidity and mortality.

Prevention/Prophylaxis: The risk of becoming colonized or infected with an MDRO infection is multifactorial, and advanced age, comorbid illnesses, invasive medical devices, frequent antibiotic exposure, and dependence on health-care workers all serve as contributing factors. There is no one-size-fits-all approach in optimizing antibiotic use for all settings.

The CDC (2019a) defines antibiotic stewardship as the effort to measure antibiotic prescribing; to improve antibiotic prescribing by clinicians and use by patients so that antibiotics are only prescribed and used when needed; to minimize misdiagnoses or delayed diagnoses leading to underuse of antibiotics; and to ensure that the 4Ds (see below) are utilized when an antibiotic is needed.

The goal of antimicrobial stewardship is to treat infection with minimal toxicity to the patient and minimal contribution to development of resistance. The 4Ds of antimicrobial

A	Tamma et al., 2021
Extended-spectrum β-lactamase producing Enterobacterales have a broad-spectrum β-lactamase enzyme that enables them to inactivate most penicillin, cephalosporins, and aztreonam.	A	Tamma et al., 2021
Decolonization therapy for community acquired- methicillin-resistant *Staphylococcus aureus* is not a recommended control measure for either individuals or outbreaks.	A	Liu et al., 2011
Treatment for those colonized with vancomycin-resistant enterococci is not necessary,	A	Centers for Disease Control and Prevention (CDC), 2019b

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. For information about the SORT evidence rating system, go to www.aafp.org/afpsort.xml.

stewardship, initially described by Joseph and Rodvold (2008), are the following: (1) Choose the right drug that covers clinically suspected microorganisms, considering local resistance patterns. (2) Order the right dose by making sure each antimicrobial is dosed for source of infection and patient factors such as weight and renal function. (3) De-escalation to pathogen-directed therapy is achieved by following cultures closely and narrow coverage to microorganism isolated in culture. (4) Right duration of therapy antimicrobials must have a stop date consistent with current guidelines (Doron & Davidson, 2011) (i.e., community-acquired pneumonia: 5-day course of antibiotic treatment, Metlay et al., 2019).

Educate patients and their families about antibiotic use. Only prescribe antibiotics when they are needed. Antibiotics are not indicated for viral illness; they are treated through symptom management such as cough medication, acetaminophen, and so forth. Encourage them to seek care if they are not better or if their symptoms worsen. Educate them about possible harms from antibiotics such as allergic reaction, *Clostridioides difficile*, and antibiotic-resistant infections

Consider a consultation with an infectious disease specialist for advice about proper antibiotic therapy. Referencing local antibiograms is recommended to guide the clinician in selecting the best empiric antimicrobial treatment pending microbiology culture and susceptibility results. By carefully assessing every patient and making decisions using these principles, clinicians can promote safe and effective use of antimicrobials and ensure medicine stays on the winning side of the battle against antimicrobial resistance.
