As new scientific information becomes available through basic and clinical research, recommended treatments and drug therapies undergo changes. The author(s) and publisher have done everything possible to make this book accurate, up to date, and in accord with accepted standards at the time of publication. The author(s), editors, and publisher are not responsible for errors or omissions or for consequences from application of the book, and make no warranty, expressed or implied, in regard to the contents of the book. Any practice described in this book should be applied by the reader in accordance with professional standards of care used in regard to the unique circumstances that may apply in each situation. The reader is advised always to check product information (package inserts) for changes and new information regarding dose and contraindications before administering any drug. Caution is especially urged when using new or infrequently ordered drugs.

I dedicate this book to my husband Chris, my son Brendan, and Clover for their unwavering support during the writing of this book. To my parents, Nancy and Edward Kennedy, you continue to be models of successful aging that motivate me to continue to be passionate about advanced practice gerontological nursing. To graduates that I have worked with over the years, your continued dedication and expertise in working with older adults is appreciated and admired; thanks especially to those who also served as contributors to this edition.

—L.K.-M.

To my husband Mark who supported me as I worked on this book during the COVID-19 pandemic. To my children, Patrick, Colin, and Caitlin, you bless me every day. To my in-laws, Shirley and Art Duffy, who continue to live vital lives in their 90s. To my aunt, Karleen Groenke Sime who inspired me to become a nurse. Finally, to all my patients who challenge me to be the best provider I can be and my students who motivate me to constantly be better.

—E. G. D.

Preface

With the continued rapid growth of the older adult population, there remains an increased demand for health-care providers to deliver age-specific care and direct disease management. *Advanced Practice Nursing in the Care of Older Adults* will serve as a guide for advanced practice nurses who are privileged to provide care to older adults. Designed as a text for students, as well as a reliable source of evidence-based practice for advanced practice nurses, this book contains information on healthy aging, comprehensive geriatric assessment, and common symptoms and illnesses that present in older adults. Given the complexity of prescribing for older adults taking multiple medications, a chapter on polypharmacy is included. The book concludes with a chapter on care delivery for patients with chronic illnesses who face end-of-life care.

Throughout the book, case studies are included to provide further practice and review. An important feature of this book is the use of the Strength of Recommendation Taxonomy (SORT) (Ebell et al., 2004). which provides a direct reference to evidence-based practice recommendations for clinicians to consider in the care of older adults.

In Unit I, "The Healthy Older Adult," the first chapter, "Changes With Aging," addresses the normal changes of aging, expected laboratory values in older adults, presentation of illness, atypical disease presentation, bimodal conditions, and the impact of chronic illness on functional capacity. In the second chapter, "Health Promotion," updated information pertaining to health promotion and disease prevention strategies for older adults from *Healthy People 2030* and the U.S. Preventive Services Task Force (USPSTF) is provided, including information on immunizations and the Welcome to Medicare and Medicare Annual Wellness Visits. Also covered is an overview of physical activity, sexual behavior, dental health, and substance use, as well as a section pertaining to the older traveler. Recommendations for exercise, safe physical activity, and nutrition are provided in this unit. New to the book in this edition is Chapter 5, "Settings of Care," which addresses the special needs older adults require if the setting is acute or primary, in the community or in an institutional setting.

Unit II, "Assessment," opens with a detailed chapter on comprehensive geriatric assessment. Information on physical, functional, and psychological health is delineated, and information on social determinants of health is included. The chapter on assessment also includes an introduction to the Age-Friendly Healthcare Systems and the 4Ms Framework. Chapter 7, "Symptoms and Syndromes," provides the clinician with a concise description of more than 20 symptoms prevalent in older adults. New topics in this edition include muscle cramps and weakness, two very frequent chief concerns. A rapid reference detailing common contributing factors and associated symptoms and clinical signs that should be worked up for each presenting condition is included. Recommendations for diagnostic tests with accompanying results are used to form a differential diagnosis.

Unit III, "Treating Disorders," provides 13 chapters of concise, updated information pertaining to disease management of illnesses common in older adults, presented by body systems. New chapters in this edition include a comprehensive chapter on gynecological conditions, often underaddressed in geriatric texts. Each chapter opens with an assessment section that provides the reader with a focused review of systems and the physical examinations needed to obtain pertinent information for diagnosis and treatment of the older adult. Signal symptoms indicating atypical presentation of illness are highlighted at the beginning of each condition. The discussion of each problem and disorder follows a consistent monograph format:

- Signal symptoms
- Description
- Etiology
- Occurrence
- Age
- Ethnicity
- Contributing factors
- Signs and symptoms
- Diagnostic tests
- Differential diagnosis
- Treatment
- Follow-up
- Sequelae
- Prevention/prophylaxis
- Referral
- Education

Unit IV, "Complex Illness," addresses complex management of patients requiring chronic illness management, palliative care, and supportive care at end of life, and includes a chapter on polypharmacy. The text concludes with two appendices—"Physiological Influences of the Aging Process" and "Laboratory Values in the Older Adult"—both of which are ready references for the busy practitioner.

In addition to the content of the book, a Bonus Chapter, "Infectious Disease," is available on fadavis.com. This chapter includes COVID-19; HIV, a growing concern in older adults; Antibiotic Resistant Organisms; and MRSA. Also available online are selected references and additional case studies, which are provided to support critical thinking and are available for users to complete on their own or for educators to incorporate into their course requirements.

For the faculty, there are PowerPoint presentations and a well-developed test bank located on fadavis.com. The Active

© F.A. Davis Publishing

Classroom Instructors' Guide is an online faculty resource that maps the resources available with the text and includes lecture notes and suggested answers for case studies.

This book is written by and for advanced practice nurses involved in the care of older adults across multiple settings of care. While this book is intended as a guide for the management of care for older adults, clinicians are encouraged to deliver individualized, patient-centered care considering the latest clinical practice guidelines on prevention and management of conditions common in older adults.

Acknowledgments

The third edition of this book would not be a reality if not for the kind assistance and guidance of some wonderful people whom we would like to thank. To Susan R. Rhyner, our publisher, who believed in the timeliness of updating this edition given the impact that the APRN consensus model for advanced practice registered nurses has on nursing education and practice with the required inclusion of gerontology and geriatrics for all advanced practice nurses taking care of older adults. To Christine M. Abshire, our Senior Content Project Manager, who kept us on track and provided us order. To Liz Schaeffer for your outstanding editing and to Christine Becker and crew for carrying us over the finish line, without which we would not have completed the charge. To Brittany Scott, Zeinab Hassan, Reham Yasin, and Emily Monge who assisted in information retrieval, thanks for your timely research. We are most appreciative to our dedicated contributors who believe in the importance of creating a reference specific to the care of older adults written by advanced practice registered nurses. We also would like to acknowledge those who have contributed to our previous books. We especially want to acknowledge Kathleen Ryan Fletcher and Lori Martin-Plank for being a part of the journey over the past 20 years; your expertise and dedication to advanced practice gerontological nursing will not be forgotten.

CHAPTER 1

Changes With Aging

Laurie Kennedy-Malone

FUNDAMENTAL CONSIDERATIONS

The aged population continues to be incredibly diverse; it includes some individuals who are nearly twice as old as others and is reflective of growing cultural diversity as well. Knowing what is expected in aging, what diseases are prevalent in aging, and what constitutes successful aging is an immense challenge even for the most skillful advanced clinician. When assessing the aged individual, the advanced practice nurse should be familiar with the range of common and expected changes associated with aging so that older persons falling outside this range may be identified and interventions taken appropriately and expeditiously.

In the past, wellness was considered the mere absence of disease, but with more information from longitudinal studies of aging, we are learning a great deal about the characteristics of successful agers (Beard et al., 2016). What constitutes successful aging is beginning to emerge, and the illness–health continuum continues to expand to include adults living into old age. This chapter focuses on familiarizing the advanced practice nurse with fundamental underpinnings that serve to guide the approach to assessment and management of the older adult. In addition to appreciating the physiological changes that come with aging, the advanced practice nurse needs to understand how the changes that accompany aging influence reference laboratory values. Recognizing that presenting features of disease/illness may be different and having a greater awareness of the impact of chronic illness on functional capacity and quality of life provide the advanced practice nurse with a perspective in approaching the older adult that is different from that of younger adults.

PHYSIOLOGICAL CHANGES WITH AGING

The physiological changes associated with the usual aging process detailed by system and the impact of these changes are delineated in Appendix A. The clinician must be aware, however, that all the systems interact and, in doing so, can increase the older person's vulnerability to illness/disease. For example, the risk of respiratory infection in the older adult population is considerable, and the physiological influences may include limited chest wall expansion, cilia atrophy, and alterations in the immune system. During the clinical decision-making process, the clinician knowledgeable about physiological changes with aging will be less likely to undertreat a treatable condition. For example, the astute clinician will use the diagnostic process to differentiate the more benign seborrheic keratosis from the more serious melanoma in the aged individual. While educating the older patient, the informed professional will be less likely to attribute a finding to the aging process alone. Without knowledge of the physiological changes with aging, an age bias can lead to undertreatment, impacting the individuals' health and contributing to a growing cost of health care for older adults (Levy et al., 2020).

The major impact of these physiological changes can be highlighted with four primary points. First, there is a reduced physiological reserve of most body systems, particularly the cardiac, respiratory, and renal systems. Second, there are reduced homeostatic mechanisms that fail to adjust regulatory systems such as temperature control and fluid and electrolyte balance. Third, there are the changes in the sympathetic response, which contribute to orthostasis and falls, as well as lack of hypoglycemic response. Fourth, there is impaired immunological function: infection risk is greater and autoimmune diseases are more prevalent. The clinician is advised not to be complacent in that some processes previously considered normal, age-related changes are now being refuted. Historically, normal aging studies were conducted using a cross-sectional study method. Today, results are becoming increasingly available from longitudinal studies of aged populations, some of which began in the 1930s (Besdine, 2019).

This more-reliable methodology provides some challenges to previously held conclusions. The clinician is encouraged to stay informed regarding the research in expected and successful aging so that this information may be carefully considered, interpreted, and translated quickly into the clinical setting.

© F.A. Davis Publishing

LABORATORY VALUES IN OLDER ADULTS

Healthy individuals of all ages often have asymmetrical distribution of test results. Normality in a statistical sense may be extrapolated incorrectly to normality in terms of health. In addition, the standards with which to compare normal laboratory values that were previously available to the health-care worker have been based on randomly collected samples of younger healthy adults. Many factors can influence laboratory value interpretation in the older adult, including the physiological changes with aging, the prevalence of chronic disease, changes in nutritional and fluid intake, lifestyle (including activity), and the medications taken (Vásárhelyi & Debreczeni, 2017).

Clinicians may find reference ranges, therefore, to be preferable. Reference ranges or intervals, such as age or sex, can be defined demographically. For example, the reference range for older adults might be the intervals within which 95% of persons older than age 70 fall. These may be further defined physiologically (e.g., fasting or activity status) or pharmacologically (e.g., medication, tobacco, or alcohol use). Even this more precise method does not ensure a healthy sampled population as the standard and using the reference range method may not differentiate normal aging from disease. The reference values presented for older adults are presented in the Appendix B. Longitudinal chemical studies support the concept of biochemical individuality—that is, each individual's variation is often much smaller than that of the larger group. Biochemical individuality is of particular importance in detecting asymptomatic abnormalities in older adults. Significant homeostatic disturbances in the same individual may be detected through serial laboratory tests, even though all individual test results may lie within normal limits of the reference interval for the entire group.

The clinician must determine whether a value obtained reflects a common aging change, a disease, or the potential for disease. Although abnormal laboratory findings are often attributed to old age, rarely are they true aging changes. Misinterpretation of an abnormal laboratory value as an aging change can lead to underdiagnosis and undertreatment in some situations (e.g., anemia or urinary tract infection) and overdiagnosis and overtreatment in others (e.g., hyperglycemia or asymptomatic bacteriuria). At times, the result of a laboratory value may be within the appropriate reference range yet indicate pathology for the older adult (Vásárhelyi & Debreczeni, 2017).

The serum creatinine level may be within the normal range yet indicate renal impairment in a patient with inadequate protein stores, and different measures might need to be considered. One value of significance to the practitioner with prescriptive privileges is the calculation of creatinine clearance in the estimation of renal function—for instance, when dosing enoxaparin (Shaikh & Regal, 2017). Reduced renal function, particularly the glomerular filtration rate (GFR), affects the clearance of many drugs, and creatinine clearance provides an index of renal function for use in choosing doses of renally eliminated or nephrotoxic drugs (such as digoxin, H_2 blockers, lithium, and water-soluble antibiotics).

Finally, when considering which laboratory tests to order, it is worth remembering the doctrine *primum non nocere*, "first, do no harm." Excessive blood sampling may lower the hematocrit; repeated fasting tests may provoke nutritional compromise; and extensive use of tests often requires drugs that may cause adverse reactions. Any risks involved in laboratory testing must be considered with respect to the patient's clinical condition and weighed against the test's expected benefits. The clinician should plan in advance the use for each test result value obtained, especially for less specific or less sensitive tests such as sedimentation rate and serum alkaline phosphatase levels. "Ordering a test requires assessing the likelihood that a patient has specific conditions prior to the order, along with an understanding of the accuracy of test and as to how it will change management" (Dharmarajan & Pitchumoni, 2012, p. 267). Once laboratory tests are available for review, test results should be discussed with the patients, with abnormal test results interpreted for the aging individual and addressed with the patient and/or caregivers. In addition to understanding the fundamental changes that accompany aging and their influence on interpreting laboratory values and medication management, the advanced practice nurse needs to understand the presenting features of illness/disease in older adults (Jaul & Barron, 2017).

PRESENTING FEATURES OF ILLNESS/DISEASE IN THE OLDER ADULT

The manifestations of illness and disease in the older adult can be very different, even if the underlying pathological process is the same as in younger individuals. The advanced practice nurse should be aware of what can influence the presentation. It has long been understood that underreporting of symptoms by older adults may occur if they attribute the new sign or symptom to age itself (Fried et al., 1991; Levkoff et al., 1988). By erroneously associating aging with disease, disuse, and disability, older adults perceive this change as inevitable and either fail to present to the health-care provider or, if they do, fail to challenge the assumption that this represents normal aging. At times an acute symptom such as pain or dyspnea is superimposed on a chronic symptom, and the older adult may not recognize that it represents a new or exacerbated pathology (Bell et al., 2016). The advanced practice nurse is well advised to never attribute something to common aging without doing a careful and methodical search for a treatable condition.

Certain diseases are more common in the older adult and an understanding of the epidemiology is critical in the interpretation. Certain neoplasms and malignancies such as basal cell carcinoma, chronic lymphocytic leukemia, and prostate cancer have a high prevalence beginning in older adulthood. Neurological conditions such as Parkinson's disease, dementias, stroke, normal pressure hydrocephalus, and complex partial seizures are more common to have initial onset in older age. Polymyalgia rheumatica along with giant cell arteritis almost exclusively begins in patients older than age 50 (Narayan et al., 2017).

Complicating the care of older adults are those patients who develop geriatric syndromes that often involve multiple body systems and have more than one underlying cause (Fried et al., 1991). For patients presenting with one or more

© F.A. Davis Publishing

of the new geriatric giants—frailty, anorexia of aging, sarcopenia, and cognitive impairment—the risk escalates for falls, delirium, injuries, and depression, subsequently placing these patients at risk for iatrogenic events that could lead to hospitalization, institutionalization, and subsequently, death (Morley, 2017).

Altered Presentation of Illness

Advanced practice nurses managing the care of older adults are challenged to recognize altered, atypical, vague, or even nonspecific signs and symptoms of common conditions in older adults (Auerhahn & Kennedy-Malone, 2010). It is well documented that disease presentation may be different for the older adult, especially the frail older adult (Hofman et al., 2017). The failure to develop an elevated temperature or fever with an underlying infectious process differs greatly from presentation of illness in a younger patient. The patient with depression may not present with a dysphoric mood but rather agitation and psychotic features (Vonnes & El-Rady, 2021). The older adult may present with cardiac manifestations (atrial fibrillation, heart failure) of undiagnosed thyroid disease (Barbesino, 2019). Additional illustrative examples include jaundice, which is suggestive of viral hepatitis in younger individuals but may represent gallbladder disease or a malignancy in the older adult, and delusions or hallucinations, which are suggestive of bipolar disorder in younger individuals but may represent dementia or medication side effects in the older adult (Williams, 2009).

Because the symptoms or signs of illness or disease may be vague and nonspecific, possibly the opposite presentation than what is typically expected (Hofman et al., 2017), even a modest change in functional level or behavior should alert the clinician to carefully explore the potential for a treatable condition. Family members or caregivers may report that a patient may no longer be cooperating or participating in individual care. Unusual changes such as these become red flags to the beginning of an atypical presentation of illness. In many cases the progression of the condition is insidious, often presenting as a change in cognition or an alteration in functional status (Vonnes & El-Rady, 2021). Other significant changes in patients with altered presentation of illness often include new onset of falls, weakness, fatigue, anorexia, urinary incontinence, lack of pain, and unexplained tachypnea (Auerhahn & Kennedy-Malone, 2010; Hofman et al., 2017). Table 1-1 depicts common conditions that often have altered presentation of illness in older adults.

Bimodality of Age of Onset of Clinical Conditions

Understanding of the epidemiology of clinical conditions includes having the knowledge of etiology of the disease, prevalence and incidence rates, risk factors, age of onset, and distribution between the sexes. There are a number of conditions that are known or suggested to have a bimodal age of onset. In some conditions, the difference is not only the decade(s) in life that the disease more likely presents but the dominance of the sex in which the condition presents. Myasthenia gravis is one condition that tends to present initially in younger females, with a preponderance in older males (Dresser et al., 2021).

Often the presentation of the same illness is different for older adults as compared to their younger counterparts. The onset of the condition may be acute versus progressive, with different symptomatology and clinical signs. For instance, in patients with late onset rheumatoid arthritis, the joint involvement is more often in the larger joints such as the shoulder and they experience constitutional symptoms such as fever, malaise, weight loss, and depression (Kobak & Bes, 2018; Targońska-Stępniak et al., 2021). Knowledge of the bimodality of age onset of certain disease conditions will aid the advanced practice nurse in avoiding misdiagnosis or delay in diagnosis due to lack of recognition. Table 1-2 describes medical conditions that present differently in younger versus older adults.

TABLE 1-1 Atypical Presentation of Illness in Older Adults

ILLNESS	ATYPICAL PRESENTATIONS
Acute abdomen	Absence of symptoms or vague symptoms Acute confusion Alternation in function Change in appetite or anorexia Change in bowel habits Mild discomfort and constipation Some tachypnea and possibly vague respiratory symptoms Appendicitis pain may begin in right lower quadrant and become diffuse. Urinary urgency may also occur in appendicitis
Depression	Anorexia, vague abdominal complaints, new onset of constipation, insomnia, hyperactivity, lack of sadness, agitation, somatic complaints, change in bowel habits
Heart failure	Anorexia, change in function, confusion, nocturia, orthopnea, sacral edema in bedrest patients
Hyperthyroidism	Hyperthyroidism presenting as "apathetic thyrotoxicosis," i.e., lethargy, fatigue, and weakness; patients report palpitations, tachycardia, and new onset of atrial fibrillation; heart failure may occur with undiagnosed hyperthyroidism; resolution of chronic constipation; weight loss
Hypothyroidism	Hypothyroidism often presents with confusion and agitation; new onset of anorexia, ataxia, depression, and arthralgias may occur. In addition to elevated thyroid-stimulating hormone level in tandem with a low free or total T4 level, additional laboratory findings may be indicative of hyponatremia and hypercholesterolemia.

© F.A. Davis Publishing

TABLE 1-1 Atypical Presentation of Illness in Older Adults—cont'd

ILLNESS	ATYPICAL PRESENTATIONS
Malignancy	New or worsening back pain secondary to metastases from slow growing breast masses Silent masses of the bowel
Myocardial infarction (MI)	Absence of chest pain Vague symptoms of fatigue, nausea, and a decrease in functional and cognitive status. Anxiety, dyspnea, palpitations, discomfort, weakness, syncope, and vomiting are often experienced. A new onset of abdominal or upper extremity pain may be reported. Heart failure exacerbation or stroke Higher prevalence in females versus males Non-Q-wave MI
Infectious diseases process	Absence of fever or low-grade fever Malaise Sepsis without usual leukocytosis and fever Falls, anorexia, new onset of confusion and/or alteration in change in mental status, decrease in usual functional status
Peptic ulcer disease	Absence of abdominal pain, dyspepsia, early satiety Weight loss, anorexia, confusion, emesis, and melena New onset of confusion, unexplained tachycardia, and/or hypotension
Pneumonia	Absence of fever; mild coughing without copious sputum, especially in dehydrated patients; tachycardia and tachypnea; anorexia, decreased oral intake, myalgias, hemoptysis, lethargy, malaise, generalized weakness, and alteration in cognition Chest x-rays often unremarkable, especially in dehydrated patients, without the typical lobar consolidation
Pulmonary edema	Lack of paroxysmal nocturnal dyspnea or coughing; insidious onset with changes in function, food, or fluid intake, or confusion
Tuberculosis	Weakness, chronic fatigue, dyspnea, anorexia, impaired cognition, hepatosplenomegaly, abnormalities in liver function tests, and anemia.
Unstable angina	Fainting, weakness, dyspnea, pain in shoulder and neck, palpitation, nausea/vomiting, mid-back pain, numbness/tingling in the chest, loss of consciousness and nausea
Urinary tract infection	Absence of fever, worsening mental or functional status to include instrumental activities of daily living (ADLs), dizziness, anorexia, fatigue, weakness

TABLE 1-2 Select Bimodal Presentations of Illness in Younger Adults Versus Older Adults

TYPE OF CONDITION	YOUNGER ADULTS	OLDER ADULTS
Dermatological		
Psoriasis	• Late teens to 20s • Irregular course, which tends to generalize • Hereditary factors	• 50s—males • 60s—females • Sporadic onset
Gastrointestinal		
Inflammatory bowel disease Ulcerative colitis (UC) Crohn's disease (CD)	• 20–40 years old • Right lower UC • Insidious onset • Generally absence of perineal lesions	• >60–75 years old a second peak occurs • More often older women • Proctitis • Left-sided UC • Higher rates of anemia • May present as chronic diarrhea • Fistula development • Increased cases of associated malnutrition • Extraintestinal manifestations including arthritis spondylitis, uveitis, and erythema nodosum • More comorbid conditions • May be confused with other forms of colitis
Malignancies		
Hodgkin's lymphoma	• 20–30 years old • Possible infectious etiology	• >50 years old • Increased mortality

Continued

© F.A. Davis Publishing

TABLE 1-2 Select Bimodal Presentations of Illness in Younger Adults Versus Older Adults—cont'd

TYPE OF CONDITION	YOUNGER ADULTS	OLDER ADULTS
Musculoskeletal Conditions		
Rheumatoid arthritis	• Peak onset 30–50 years old • More common in females • Rheumatoid factor (RF) positive	• 65 years of age • Equal distribution among the sexes • Acute onset • More involvement of larger joints (shoulder) at the same time as smaller joints • Weight loss, myalgias • Polymyalgia rheumatica–like form • Comorbidities • Can present as RF negative • Lower platelet to lymphocyte ratio • Radiographic erosive changes
Neurological Conditions		
Myasthenia gravis (MG)	• 20–40 years old; predominately in females • Thymic hyperplasia frequently develops; thymoma uncommon thymoma	• 55–75 with late onset beginning ≥75, predominately in men • Dysphonia; dysphagia • More frequent ocular form MG • Increased rate of acetylcholine receptor antibody seropositivity • Increased secondary autoimmune comorbidities such as thyroiditis, systemic lupus erythematosus, rheumatoid arthritis, diabetes mellitus
Seizures	• Can begin at a very young age, different types of seizures can begin in young childhood. Contributing factors include high fever, head injury, infections such as malaria • Auras that include fear, epigastric distress and déjà-vu phenomena	• Thymoma more common presentation; thymic hyperplasia is less common • 60 years focal seizures with impaired awareness, with or without secondary evolution to tonic-clonic seizures, shorter in time duration. • Aura may present as dizziness; contributing factors include stroke, dementia, and brain tumors
Psychological Conditions		
Bipolar disorder	• 30 years old • Often presents with elation • Unlikely to present with cognitive impairment • Family history of bipolar disorder	• >50 years old • Irritability more common than elation • Common for cognitive impairment to be present • Rare that there is a family history

Sources: Dresser et al., 2021; Hernandez Fustes et al., 2020; Kobak & Bes, 2018; Lee, 2019; Mustafa et al., 2018; Singh et al., 2015; Smith et al., 1993; Smith, 2013; Targońska-Stępniak et al., 2021.

CHRONIC ILLNESS AND FUNCTIONAL CAPACITY

Approximately 80% of those 65 or older have one chronic disease, and 50% have two or more. The most common of these are related to heart disease, arthritis, respiratory problems, cancer, diabetes, and stroke (National Council on Aging, 2021). Treating patients with multimorbidities can be very complex and can result in polypharmacy. Patients with multimorbidities are known to have a treatment burden in terms of understanding and self-care management of their conditions. This burden entails patients not only managing the conditions but also attending multiple appointments and comprehending and affording complex drug regimens (van Merode et al., 2018).

These conditions often impair functional capacity and limit the person's ability to perform activities of daily living (ADLs) such as bathing and dressing, and instrumental activities of daily living (IADLs) such as managing medications and traveling. In 2018, it was found that 22% of the population aged 65 and older reported having a disability defined as having a lot of difficulty or having limited functional capacity with their vision, hearing, mobility, ability to communicate, impairment with cognition, or limitations with their self-care abilities (Federal Interagency Forum on Aging Related Statistic, 2020).

SUMMARY

Assessment and management of older adults is different from that of younger adults, and it is of critical importance that the advanced practice nurse working with the older adult have the knowledge, skill, and ability to recognize these differences and take them into consideration. This chapter highlighted how the approach of the clinician might be different based on an understanding of the physiological changes of aging and the impact

© F.A. Davis Publishing

of these changes on medication management and laboratory interpretation; how the presenting features of disease and illness may be different in the older adult; and how the older adult is disproportionately affected with chronic disease and functional impairments.

CHAPTER 2

Health Promotion

Lori Martin-Plank

Health promotion in older adults occurs on a global population level through the World Health Organization (WHO) and the United Nations, in conjunction with other international partners who have declared 2021–2030 as the Decade of Healthy Aging. Within this platform, they are dedicated to building infrastructures for health promotion and health equity for older adults, as well as advocating for the elimination of ageism worldwide. In the United States, government agencies such as the Centers for Disease Control and Prevention (CDC), Administration on Aging (AoA), and Centers for Medicare and Medicaid (CMS), among others, champion the charge of health promotion in older adults. As providers, we work with patients and families, but it is important to be aware of these resources and to utilize them when appropriate.

Health promotion for older adults consists of proactive commitment to health and wellness, taking control of one's health and initiating lifestyle changes, following preventive screening and counseling recommendations, and maintaining healthy social contacts. Health-care providers are in a unique position to influence their older adult patients to embrace health promotion and preventive health maintenance at every visit but particularly at the Welcome to Medicare and Annual Wellness Visits (AWVs). Strategies for health promotion in older adults include prevention and focus on maintaining and building functional capacity, expanding social networks, and preserving and enhancing self-care.

PRIMARY, SECONDARY, AND TERTIARY PREVENTION

Prevention is divided into primary, secondary, and tertiary areas.

- **Primary prevention:** Intervene before there is injury or a health problem. For example, Mr. P is a 62-year-old man presenting to your office for care. When reviewing his health history, you establish that he had chickenpox as a child. You know that the varicella virus lies dormant in the body but can reactivate in the form of varicella zoster or "shingles." You order Shingrix vaccine, a 2-dose series to prevent painful varicella zoster in nerve endings.
- **Secondary prevention:** Detection of a preclinical or an asymptomatic health condition. For example, Ms. J is a healthy 68-year-old woman seen in your office for a physical examination. You recommend a mammogram to screen for signs of breast cancer.
- **Tertiary prevention:** Intervention in known disease or health condition to slow progression and prevent condition from worsening. Mr. G is a 76-year-old man with type 2 diabetes mellitus. His current A1c is 6.5, but he is reporting two episodes of feeling sweaty, clammy, shaky, and dizzy after exercising in the morning. He checked his blood sugar, and it was 70 both times. He is currently on glipizide 5 mg once daily and metformin 500 mg, 2 tablets twice daily. You recognize that glipizide could be causing hypoglycemia and you tell him to stop the glipizide at this time, continue the current metformin regime, and recheck his blood glucose daily in the morning for 5 days. You instruct him to call your office immediately if he experiences symptoms again.

HEALTHY LIFESTYLE COUNSELING

Healthy lifestyle counseling is part of every clinician encounter with an older adult, although it is often superseded by the focus on chronic disease management or an acute, limited health problem. A quick question, "I know that you are not feeling well today, and we are addressing that now. I'm just wondering if you have been able to follow up on my suggestions about changing your diet since we last met. How is that going?" can change the focus to healthy lifestyle counseling and open the conversation for further dialogue (O'Connor et al., 2020; Troutman-Jordan, 2017). During a chronic disease management visit for hypertension and diabetes, "Your blood pressure is improved today, and I see that you have lost 2 pounds since your last visit. Are you following up on the diet and exercise recommendations we agreed on in [month]? How is that going for you?" shifts the conversation to healthy lifestyle counseling. Training a staff member at the office in motivational interviewing and lifestyle counseling can save

© F.A. Davis Publishing

clinician time and give the patient individual attention, or you can do the counseling yourself and use the added time feature for billing the visit. Placing handouts in the office with links to resources such as the CDC Healthy Aging, National Council on Aging (NCOA), National Institute on Aging (NIA), WebMD Healthy Aging, and links to phone apps for exercise or nutrition in older adults, can assist with health promotion. Most Medicare Advantage plans employ health coaches who will work one-on-one with older adults; have your office manager investigate these and share with patients or even contact the plan and request a health coach for an older patient that needs individual guidance. Office staff can also connect with the local hospital or community health center and post information in the office about upcoming events related to healthy aging, such as Senior Games or a mobile mammography unit. When seeing older adults who require a family caregiver, include them in part of the visit and lifestyle counseling. Contact the Area Agency on Aging or local health department for sources of assistance in the home and low literacy materials for older adults or handouts in other languages than English if this fits your patient population. In general, keep it simple, engage the patient/family—what are their priorities for healthy lifestyle—and individualize (Cheung et al., 2019; Evans et al., 2020; Whitehead, 2017).

Aging in Place

The concept of aging in place refers to the desire and ability of older adults to continue living in their home or in a supportive home-like community environment, regardless of physical or cognitive barriers (NIA, 2017). This was the primary model for aging in past decades when multigenerational families lived together, and women stayed at home and cared for family members. Societal changes, including industrialization, women in the workplace, globalization, relocation of families, decline in numbers of children in families, and extended life years for older adults, have resulted in challenges for older adults desiring to age in place. Simultaneously, health care acquired a corporate model, and the nursing home industry grew rapidly, providing an alternative living arrangement for older adults who were unable to remain at home due to disability, frailty, lack of support, or absence of family. The costs associated with long-term care are borne by the patient/family, with Medicaid assuming responsibility when patients have exhausted their financial resources. Many older adults are dissatisfied with the nursing home environment, desiring a more home-like place. Legislation (Credit for Caring, 2021; Supporting Our Direct Care Workers and Family Caregivers Act, 2021) has been introduced to pay family caregivers and to give tax credits to family caregivers. This may promote the return of care in the home.

One of the major factors facilitating aging in place comes from the technology sector, which has introduced "smart" home technology for safety and monitoring of older adults in their homes (Choi et al., 2021; Combs et al., 2021). From passive safety features such as motion sensors illuminating the path to the bathroom at night and use of video doorbells that display the faces of visitors to more sophisticated artificial intelligence that monitors the movement patterns of older adult inhabitants through wearables and sensors, smart technology has revolutionized aging in place (Agbadjé et al., 2020). Voice-activated smartphone or smart speaker assistants can keep a calendar with appointments and remind the older adult, set up alarms for medication management, and order groceries and other essentials to support aging in place. Social robots can keep older adults with dementia engaged and service robots help with bathing and activities of daily living (ADLs) (Jensen et al., 2019). Granny cams afford family caregivers access to the older adult remotely, and a phone app can turn lights, heat, and air conditioning on and off at a distance as well as lock doors for safety at night (Choi et al., 2019). Although all of this innovation comes with trade-offs, including loss of privacy and (in some cases) loss of freedom, studies show that older adults are willing to accept this for the ability to age in place (Carroll et al., 2021; Choi et al., 2021; Chung et al., 2016; *Dermody et al., 2021; Tural et al., 2021). Cost is a factor, although vendors work with the American Association of Retired People (AARP) and offer discounts. Medicaid is the first third-party payor to reimburse for passive remote monitoring in the home (Berridge, 2018); however, costs can be prohibitive and result in excluding older adults of lower socioeconomic status.

In addition to the traditional aging in place model, there are some aging in community models initiated by older adults for support and social interaction and by public entities for older adults with lower income; there are also university-based retirement communities for those with an interest in teaching and learning (Hou & Cao, 2021). Some of these are intergenerational whereas others are limited to older adults. Challenges of aging in community are sustainability, inclusion of lower socioeconomic groups, and balance of independent members who can assist those who need help (Hou & Cao, 2021).

Nutrition

The importance of good nutrition in older adults cannot be overemphasized, yet it is often overlooked by clinicians. The Welcome to Medicare visit, subsequent AWVs, or chronic health maintenance visits are all opportunities to address nutrition. Height and weight should be measured at each encounter and tracked to assess for evidence of involuntary weight loss or excessive weight gain, and clinicians should ask about appetite and food intake patterns. Visual inspection may provide clues through ill-fitting clothing, although this may not be accurate in low-income communities where donated clothing is the norm. Asking about food insecurity can uncover financial problems that require referral to the Area Agency on Aging or a local food bank. Questions about difficulty chewing or swallowing, feeling of fullness or lack of appetite, stomach pain associated with eating, nausea or vomiting, choking, constipation, or diarrhea are helpful in uncovering problems with eating. Assessing dentition during physical examination may reveal ill-fitting dentures or an edentulous patient (Clegg & Williams, 2018). Inquiring about changes in ADLs and physical activity is also relevant because a sedentary lifestyle can dampen the appetite, or conversely, lead to excessive snacking on salty or sugary finger foods. Inability to go grocery shopping will also limit food options. Meal patterns and types of food eaten should be obtained from the patient. Medications and over-the-counter (OTC) supplement usage is also important. Does the patient live alone? Is the patient able to prepare meals and do they

© F.A. Davis Publishing

have access to cooking facilities? These questions are helpful in assessing both anorexia of aging and obesity (Landi et al., 2017; Mangels, 2018; Reber et al., 2019; van der Meij et al., 2017). Use of a mnemonic such as DETERMINE

Diseases
Eating poorly
Tooth loss/mouth pain
Economic hardship
Reduced social contact
Multiple medications
Involuntary weight loss/gain
Needs assistance in self-care
Elder years/above age 80

is recommended for screening community-dwelling older adults by the *Proceedings of the Nutrition Society* (Corish & Bardon, 2019) in the European Union, whereas most authorities in the United States use the Mini-Nutrition Assessment-Short Form (MNA-SF), a six-question document that can be completed in advance (available at https://mna-elderly.com/forms/mini/mna_mini_english.pdf).

In long-term care settings, nutrition assessment is performed by a dietitian in conjunction with nursing and direct care staff; the screening tool used frequently is the MNA. Weight is typically monitored on a regular basis, and the dietary department is tasked with individualizing interventions. In residents who require assistance with feeding, it is important to monitor the efforts of direct care staff to ensure that the resident is not rushed or just set up and abandoned when unable to feed themselves.

Obesity presents another problem with nutrition. Although there is a decline in the prevalence of overweight and obesity after age 60 years, it remains a problem for many older adults. It is a major risk factor for decreased mobility and functional impairment as well as a cardiovascular risk. Overweight and obesity are associated with heart disease, certain types of cancer, type 2 diabetes, breathing difficulties, stroke, arthritis, and psychological problems.

Counseling on nutrition should be individualized to the need of each older adult. When appropriate, consider referring to a dietitian or recommend contacting the health coach at the insurance company. Home-delivered meals may also provide needed nutrition for those who are unable to cook their own meals. General guidelines for dietary counseling include the following:

- Limit fat and cholesterol.
- Maintain a balanced caloric intake.
- Emphasize the inclusion of grains, fruits, and vegetables daily.
- Ensure an adequate calcium intake, especially for women.
- Limit alcohol, if used, to one drink daily for women and two drinks daily for men: one drink = 12 oz beer, 5 oz wine, or 1.5 oz of 80-proof distilled spirits.
- Combine dietary interventions with regular physical activity for optimal results.

Oral Health

Oral health is closely aligned with nutrition and overall physical and mental health. Older adults have more problems with oral health, including xerostomia, dental caries, periodontal disease, tooth or mouth pain, mouth infections, or missing teeth (CDC, 2021b; Coll et al., 2020c). Recent estimates show that 26% of adults aged 75 and older have lost all their teeth; 68% have periodontal disease, and one in five older adults have dental caries (CDC, 2021). Periodontal disease is associated with type 2 diabetes mellitus, cardiovascular disease, and endocarditis. There is also concern in patients who have had joint replacements or heart valve replacement that transient bacteremia occurring with periodontal treatment or caries repair can infect prosthetics (Coll et al., 2020c). Although all older adults need to be screened for oral health issues, those with diabetes and dementia are considered high risk for complications, as are long-term care residents and lower socioeconomic groups. Dental care is excluded from Medicare coverage and is expensive for most retirees. Emphasizing prevention as cost-effective to older adults may help to motivate them for self-care.

Many clinicians lack education about oral health problems. The American Dental Association (2021) has information available and the European College of Gerodontology has partnered with the European Geriatric Medical Society to create guidelines for oral care in older adults, particularly those who are frail or lack access to dental care (Kossioni et al., 2018). Older adults should have an oral inspection by a clinician at least annually, at which time the need for oral care can be addressed and options for seeing a dental health professional discussed. Interventions for a dental abscess should serve as a red flag to the clinician to identify dental care as a priority. Older adults should be seen every 6 months by a dental hygienist and a supervising dentist for routine oral health maintenance (*American Dental Association, 2021; *Coll et al., 2020c). For those with limited means, some community college dental hygiene programs offer free screening and cleaning; dental school clinics and community health agencies may also have services available. Studies have been done with those with dementia and their care partners demonstrating that older adults with mild-moderate dementia can be trained to use an electric toothbrush for 2 minutes daily (Anderson et al., 2019). Another clinical trial compared two interventions to improve oral hygiene in low-income senior housing residents—one was face-to-face, individual meetings demonstrating brushing and flossing; the other was peer-managed group meetings with a health fair theme. Both groups successfully improved their oral hygiene; the face-to-face participants scored higher on measurements of gingival and plaque indices (Schensul et al., 2021; Schensul et al., 2018). Both studies show encouraging results in hard-to-reach older adult populations.

Xerostomia is a significant problem in older adults. Aging, certain medications, uncontrolled diabetes, toxicity from cancer chemotherapy or radiotherapy for head and neck cancer, and autoimmune conditions such as Sjögren's disease, contribute to dry mouth (American Dental Association, 2021). More than 100 medications are implicated in xerostomia; those that are anticholinergic have higher risk. Examples include antihistamines, decongestants, antidepressants, antipsychotics, diuretics, NSAIDs, benzodiazepines, muscle relaxants, antimuscarinics, analgesics, and Parkinson's drugs; inhaled steroids are implicated in another oral condition—candidiasis (Coll et al., 2021c). Clinicians should review medications periodically and substitute those that are efficacious

© F.A. Davis Publishing

but do not cause dry mouth when possible. Educate patients to brush with a fluoridated toothpaste and floss regularly, avoid high-sugar foods, and seek regular dental care.

Physical Activity

Although the level of physical activity in older adults has increased slightly, they remain the least active population group in the United States, with approximately 16% of older adults between 65 and 74 years of age meeting the standard for physical activity set by *Physical Activity Guidelines for Americans* (2nd ed.) in 2018 (2018 Physical Activity Guidelines). The recommendation for older adults age 65 and older is to perform a minimum of 150 minutes weekly of moderate-intensity aerobic activity or 75 minutes weekly of vigorous-intensity aerobic physical activity, or an equivalent combination of both. Further requirements include muscle-strengthening activities using all major muscle groups, with at least moderate-intensity, two or more days weekly. If older adults cannot achieve 150 minutes of moderate-intensity aerobic exercise due to chronic health issues, they should be as active as their health conditions and abilities permit (USDHHS, 2018). Additional focal areas for older adults are balance training and safety to prevent falls. In short, any physical activity is better than none.

Since the COVID-19 pandemic, many creative ideas have emerged, including exercise classes on Zoom or YouTube, virtual exercise support groups for seniors, e-health instructions, and intergenerational programs (Callahan et al., 2021; Howell et al., 2021; King et al., 2020; Stonerock & Blumenthal, 2017; Talley et al., 2019). The NIA (2021), NCOA (2021), and AARP (2020) have fitness program resources for older adults. Many Medicare Advantage programs subscribe to Silver Sneakers programs in conjunction with a local gym or YMCA. These and similar programs offer various physical activities, such as Zumba for seniors, yoga, resistance training, and cardio. The challenge for clinicians is to learn about these resources and share them with their patients. The Welcome to Medicare visit and AWV provide a dedicated space for meeting with older adults and discussing health promotion, including physical activity, and working on a plan. A written exercise prescription is recommended by the American College of Sports Medicine in their Exercise is Medicine program for older adults. The most recent research on optimizing physical activity in older adults endorses multicomponent programs that stimulate both brain and body simultaneously (Pothier et al., 2018).

Before embarking on an exercise program, all patients should have an evaluation of health history, including medications, present physical activity and functional level, potential barriers to exercise, and a physical examination. Older adults with known or suspected cardiac risk factors should have a stress test before engaging in vigorous exercise. All participants should be reminded of the need for adequate hydration and use of caution during extreme weather conditions.

The importance of continuous physical activity in maintaining function and preventing debility in long-term care residents is often overlooked. A recent follow-up study by Rodriguez-Larrad et al. (2021) highlighted the decline in both physical function and cognitive status in the 6-month period after completion of a randomized controlled trial implementing a progressive multicomponent physical fitness program in a select group of residents.

Safety

Quality of life and function are highly dependent on safety and injury prevention in older adults. Counseling involves reinforcement of extant recommendations, including wearing lap and shoulder seat belts in a motor vehicle, avoiding drinking and driving, having working smoke detectors in the residence, and keeping hot water set below 120°F. For older adults who drive a motor vehicle, periodic assessment of their ongoing ability to drive safely is vital to the older adult and the public at large. Most motor vehicle accidents involve young drivers and older drivers. Safe storage and removal of firearms is another important area to address. Possession of a firearm combined with depression, caregiver stress, irreversible illness, or decline in functional abilities can invite self-inflicted injury, suicide pacts, or other acts of violence. Counsel patients to avoid firearms in the home and to use alternative means for self-protection such as alarm systems and pepper mace spray.

According to the World Health Organization (2021), falls are the second cause of unintentional injury deaths worldwide; adults aged 60 years and older experience the most fatal falls. Many falls are preventable with education, training, and environmental modifications for safety. Because older adults are often embarrassed by a fall, most will not volunteer information to clinicians about falls, so clinicians need to be proactive and ask about any falls in the past 6 months, any changes in mobility, ADLs, or cognition. The AWV and chronic health maintenance visits are good opportunities to address safety and falls and to reinforce this information with a basic handout. There are also fall assessments and games on the Internet that can be used (Dispennette et al., 2019). The Timed Get Up and Go can also be used for an objective measure of a patient's mobility and balance. Emphasizing the need to be physically active to maintain strength and flexibility aligns with fall education. Patients who have recently fallen or had a change in mobility should be referred to physical therapy, which is a cost-effective preventive intervention. Occupational therapy will also make a home visit (with a clinician's order) for an environmental safety assessment (Georlee et al., 2020). If a patient is deemed at risk for falling, a team-based intervention may be the optimal approach, including a caseworker evaluation from the Area Agency on Aging; physical therapy to treat and evaluate the need for assistive devices and stable footwear; occupational therapy to evaluate vision, hearing, home environment, and modifications for optimizing function and ADL ability; and nursing to assess the patient and medications as part of a fall-risk evaluation (Miranda-Duro et al., 2021). Clinicians should review medications at every visit and consider their potential to impair cognition (psychotropics, narcotic analgesics, anticholinergics) or contribute to incontinence due to slow mobility (diuretics, laxatives), adjusting when necessary (Guirguis-Blake et al., 2018). The use of smart home technology should also be considered for environmental modification.

Research has identified patient perspective as a barrier or facilitator for fall education programs (Chen et al., 2016; Tzeng et al., 2020). One program implemented a brief home hazard reduction program through the Area Agency on Aging, with a control group and intervention group in those at high risk of falling (Stark et al., 2021). Although there was a reduction in the number of falls in the intervention

© F.A. Davis Publishing

group, it did not reach significance. Programs that are multifactorial in nature and consider patient perspectives, motivation, health literacy, and available resources are most likely to be beneficial in reducing future falls (Lach & Noimontree, 2018; *Tzeng et al., 2020).

Sexuality

The topic of sexuality and sexual behavior in older adults is rarely discussed. Many clinicians lack knowledge of how to approach the topic and consequently remain silent. They may have preconceived ageist biases and view older adults as asexual. Several research studies demonstrate that most older adults are still sexually active, although health issues may limit frequency or type of sexual expression (Gewirtz-Meydan et al., 2019; Srinivasan et al., 2019). Incorporating a sexual health history into an annual wellness visit or chronic health maintenance check adds a holistic element to care and personalizes the approach, leading to a healthy, trusting relationship (Johnson et al., 2019; Kuhle et al., 2021). The PLISSIT model offers a structured way for clinicians to introduce questions about sexual health—giving the patient **P**ermission to ask about sexual concerns, then proceeding to share **L**imited **I**nformation, targeting their concerns, sharing **S**pecific **S**uggestions for treatment of symptoms if known, and referring for **I**ntensive **T**reatment to the appropriate specialist (Palisano, 2017); for an older adult this could be a urologist, urogynecologist, psychologist, or sex therapist depending on the concern. This approach preserves the clinician/patient relationship and facilitates counseling and interventions to promote healthy sexual behavior. Studies have uncovered that a variety of stereotypes exist related to older adult sexuality and particularly the role of the older woman (Ricoy-Cano et al., 2020); many of these are fueled by religious or societal norms that no longer stand. With the help of the appropriate consultant, old myths can be dispelled.

Other areas of sexual health that need to be addressed are self-protection from sexually transmitted infections (STIs) and HIV when dating, and avoiding predators. In 2018, 17% of newly diagnosed HIV patients were aged 50 and older (CDC, 2018). Many older adults mistakenly believe that barrier protection is not needed because there is no risk of pregnancy. STIs, including genital herpes, human papilloma virus, gonorrhea, syphilis, and hepatitis are omnipresent threats, as is HIV. Patients need to be educated to ask partners about their sexual history, including past STIs and HIV, and to always use barrier protection. Education about preexposure prophylaxis and postexposure prophylaxis is also necessary for those in a sexual relationship with a person with HIV or at high risk of HIV (U.S. Food and Drug Administration [FDA], 2021).

LESBIAN, GAY, BISEXUAL, TRANSGENDER, QUEER AND OTHER SEXUAL AND GENDER DIVERSE PEOPLE (LGBTQ+)

At the present time, between 3% and 6% of older adults identify as LGBTQ+ on public health surveys—around 3 million people Fredriksen-Goldsen et al., 2017). The largest group is the oldest old—those 80 years and older. Approximately one-fifth of LGBTQ+ older adults do not share their sexual orientation and/or gender identity with health-care providers out of concern related to inadequate care (Caceres, 2019; Fredriksen-Goldsen et al., 2011). Common health problems in LGBTQ+ older adults include mental health issues, cardiovascular disease, obesity, HIV, and substance use (Fredriksen-Goldsen et al., 2019).

It is worth noting that some LGBTQ+ older adults (especially among the oldest old) may be more familiar with the terminology "homosexual." In addition, because "queer" has historically been used as a pejorative term they may find the term offensive (Travis, 2017). However, the term started being "reclaimed" in the 1960s by some members of the LGBTQ+ community as an act of resilience and defiance and may be a relevant term among people in the Baby Boomer generation and younger (Tamanna, 2018).

Although knowledge of the existence of LGBTQ+ persons is not new, recent initiatives in diversity, equity, and inclusion have heightened awareness, raising issues such as implicit bias and outright discrimination in caring for this population among health professionals. Most LGBTQ+ older adults desire respect, dignity, and professionalism from health clinicians (Caceres, 2019; Fredriksen-Goldsen et al., 2019). In the case of transgender older adults, whose gender identity may not be congruent with their sex assigned at birth, clinicians and allied health personnel need to use the correct name and pronoun and realize that driver's license and health insurance documents may not match. When one's legal documentation and identity do not 'match' and facilities or rooms are segregated by sex at birth, policies should be implemented to support rooming based on gender identity (e.g., man, woman) (Lambda Legal, 2016).

Fredriksen-Goldsen and colleagues (2017, 2019) have conducted a survey of LGBTQ+ older adults with high response rates, looking at specific time stamped and longitudinal data on LGBTQ+ older adults. One theme that emerges is resilience in the face of adversity; many LGBTQ+ older adults are highly educated, with graduate degrees, but their socioeconomic status is low due to employment discrimination; many are still working into their 80s. LGBTQ+ older adults of color experience the worst living situations and health disparities (Kim et al., 2017). Clinicians providing services to LGBTQ+ older adults need to learn about their specific healthcare needs and concerns, how to best communicate with them, and identify important people who should be included in their care (Redcay et al., 2019). The National Resource Center on LGBT Aging (https://www.lgbtagingcenter.org/) is a unique source of information and training for those working with LGBTQ+ older adults as well as older adults, their families and caregivers, and the public. Guidelines for the provision of primary and gender-affirming treatment to for transgender and nonbinary individuals are available through the University of California, San Francisco's The Department of Family and Community Medicine (https://transcare.ucsf.edu/guidelines). Professional continuing education providers also offer programs in cultural aspects of LGBTQ+ communities.

The LGBTQ+ older adult population is comprised of multiple heterogeneous groups (Caceres, 2019; Kim et al., 2017; Fredriksen-Goldsen et al., 2019) with a variety of sexual, social, and health-care needs. LGBTQ+ older adults may be more likely to live alone and have fewer options for informal

© F.A. Davis Publishing

caregiving from biological family members (Choi & Meyer, 2016). "Chosen" family members (e.g., an individual's partner or other LGBTQ+ adults) may be a source of care, but may lack any legal recognition provide care to their partner or others in the community who do not have a partner or children (Stewart & Kent, 2017). LGBTQ+ older adults who are caregivers may also have fewer social supports and be at higher risk for caregiver burnout (Stewart & Kent, 2017).

The oldest old tend to be more dependent, often requiring long-term care. LGBTQ+ older adults may feel the need to conceal their sexual orientation or gender identity from other residents and staff to avoid mistreatment. Transgender adults who need a high level of personal care may find it impossible to conceal their gender history, making them among the most vulnerable to inadequate or inequitable care, including elder abuse (Movement Advancement Project and Services and Advocacy for Gay, Lesbian, Bisexual, and Transgender Elders, 2010). Feeling the need to conceal one's identity may mean disconnecting from the larger LGBTQ+ community, increasing feelings of isolation. Experiences such as direct and indirect (e.g., implicit bias and microaggressions) discrimination and rejection by other residents, direct care workers, and other professionals in this setting increase LGBTQ+ older adults' vulnerability to depression, substance use, and other chronic health conditions. As such, clinicians in these settings need to be alert to subtle discriminatory practices from staff such as ignoring call lights and not toileting on schedule, leading to the need for incontinence care, which can entail rough handling of the patient. It is also important for clinicians to recognize individuals important to the LGBTQ+ older adult and facilitate completion of Advanced Directives and other legal documents to ensure the older adult's medical decision-making wishes are known (Stewart & Kent, 2017). Social workers can support LGBTQ+ older adults and/or their caregivers by arranging for a group for socialization.

Substance Use

Substance misuse remains a silent epidemic in older adults; its prevalence is growing, and the character of the substance use is changing from primarily alcohol to alcohol and other drugs (Chhatre et al., 2017; Tucker et al., 2021; Yarnell et al., 2020). With the influx of the Baby Boomer generation (those born between 1946 and 1964) into older adulthood, there is a trend of earlier exposure to alcohol and drugs such as cocaine, crack cocaine, heroin, marijuana, and prescribed or illicit opioids. Inpatient admissions for substance abuse by older adults have doubled between 2002-2012, although outpatient treatment remains the primary model (Suntai et al., 2020). Most older adults complete treatment for substance misuse; there is a markedly lower completion rate by Black patients compared to Hispanic and White patients. This may reflect socioeconomic disparities in which insurers do not cover the entire treatment, there is lack of availability of treatment facilities, or individuals are experiencing homelessness and have no treatment options (Suntai et al., 2020). Clinicians who refer older adults for treatment need to follow up to encourage completion. Opioid abuse or opioid use disorder has more severe effects on older adults, including death. Some opioid abuse is unintentional due to forgetting about a dose already used; some results from altered cognitive status or even delirium (Dufort & Samaan, 2021).

Clinicians can use the Welcome to Medicare visit and the AWVs to ask about substance misuse. Counseling regarding alcohol or other drug use can be preventive or interventional, depending on the initial assessment. Use the Michigan Alcohol Screening Test (MAST), the CAGE questionnaire, or the Alcohol Use Disorders Identification Test (AUDIT) to assess risk. For opioid misuse, the Opioid Risk Tool (https://www.drugabuse.gov/nidamed-medical-health-professionals/screening-tools-resources/opioid-risk-tool-oud-ort-oud) can be used (Ducharme & Moore, 2019). Using a person-centered, nonconfrontational approach and active listening during a health promotion visit will yield the most disclosure. Explaining how biological changes with aging can put the older patient at higher risk of complications is helpful (Kuerbis, 2020). Understanding of some factors that lead older adults to substance misuse is also important. Chronic pain, depression, social isolation, cognitive or mental health problems, and stress are major contributors to substance misuse (Dufort & Samaan, 2021; Kuerbis, 2020). Patients should be cautioned about the risk of falls, breathing problems, auto accidents, and heart problems related to substance misuse and encouraged to seek treatment. Naloxone (Narcan) should be prescribed for emergency use by family or friends of older adults who are on scheduled opioid medication.

If older adults are using benzodiazepines, explain the additive effect with opiates or alcohol, the risks to memory and cognition as well as risks for falling and serious injury (Maree, et al., 2016). Clinicians can work with the patient to initiate deprescribing for benzodiazepines and prescribe a selective serotonin reuptake inhibitor for depression or anxiety if indicated. Also recommend cognitive behavioral therapy or other counseling.

Very little hard data exist about cannabis use in older adults; a review of medical marijuana registries in 13 states revealed that 35% to 50% of users were aged 50 or older (Kuerbis, 2020). It is the most used illicit drug by older adults due to legalization, social acceptability, and decriminalization. Even when it is dispensed as medical marijuana, there are significant effects on the cardiovascular system in older adults, including increased blood pressure, heart rate, and respiratory rate, and loss of short-term memory (Kuerbis, 2020). There are also significant drug interactions between cannabis and multiple frequently prescribed drugs for older adults, including simvastatin, warfarin, amiodarone, alprazolam, and others (Medscape Drug App, 2021). Older adults using cannabis should be counseled about the risks versus benefits of ongoing usage.

Tobacco usage (smoking) in those age 65 and older is about 8.4% (Jamal et al., 2016), with many smokers reporting concurrent medical illness such as COPD or lung cancer. Using the 5 A's, assess willingness to quit and counsel on benefits of quitting at any age.

SCREENING AND PREVENTION

The table below shows the final recommendation summaries for older adults from the U.S. Preventative Services Take Force (USPSTF).

© F.A. Davis Publishing

Topic	Recommendation	Grade	Release Date
Abdominal aortic aneurysm: Screening: men aged 65 to 75 years who have ever smoked	The USPSTF recommends 1-time screening for abdominal aortic aneurysm (AAA) with ultrasonography in men aged 65 to 75 years who have ever smoked.	B	December 2019
Aspirin Use to Prevent Cardiovascular Disease	The USPSTF recommends for adults aged 40 to 59 years who have an estimated CVD risk of 10% or greater that shared decision making is used in determining initiation of low dose (81mg/day) of aspirin. Consider potential benefits and harms to the individual when discussing ASA use for prevention.	C	April 2022
	The USPSTF recommends against initiating ASA For adults 60 years or older aspirin for primary prevention of CVD.	D	
Breast Cancer: Screening: women aged 50 to 74 years	The USPSTF recommends biennial screening mammography for women aged 50 to 74 years.†	B	January 2016
Colorectal Cancer: Screening: adults aged 50 to 75 years	The USPSTF recommends screening for colorectal cancer in all adults aged 50 to 75 years.	A	May 2021
Depression in Adults: Screening: general adult population, including pregnant and postpartum women	The USPSTF recommends screening for depression in the general adult population, including pregnant and postpartum women. Screening should be implemented with adequate systems in place to ensure accurate diagnosis, effective treatment, and appropriate follow-up.	B	January 2016
Falls Prevention in Community-Dwelling Older Adults: Interventions: adults aged 65 years or older	The USPSTF recommends exercise interventions to prevent falls in community-dwelling adults aged 65 years or older who are at increased risk for falls.	B	April 2018
Healthy Diet and Physical Activity for Cardiovascular Disease Prevention in Adults With Cardiovascular Risk Factors: Behavioral Counseling Interventions: adults with cardiovascular disease risk factors	The USPSTF recommends offering or referring adults with cardiovascular disease risk factors to behavioral counseling interventions to promote a healthy diet and physical activity.	B	November 2020
Hepatitis C Virus Infection in Adolescents and Adults: Screening: adults aged 18 to 79 years	The USPSTF recommends screening for hepatitis C virus (HCV) infection in adults aged 18 to 79 years.	B	March 2020
Hypertension in Adults: Screening: adults aged 18 years or older without known hypertension	The USPSTF recommends screening for hypertension in adults aged 18 years or older with office blood pressure measurement (OBPM). The USPSTF recommends obtaining blood pressure measurements outside of the clinical setting for diagnostic confirmation before starting treatment.	A	April 2021
Intimate Partner Violence, Elder Abuse, and Abuse of Vulnerable Adults: Screening: women of reproductive age	The USPSTF recommends that clinicians screen for intimate partner violence (IPV) in women of reproductive age and provide or refer women who screen positive to ongoing support services. See the "Clinical Considerations" section for more information on effective ongoing support services for IPV and for information on IPV in men.	B	October 2018
Latent Tuberculosis Infection: Screening: asymptomatic adults at increased risk for infection	The USPSTF recommends screening for latent tuberculosis infection (LTBI) in populations at increased risk.	B	September 2016

© F.A. Davis Publishing

Topic	Recommendation	Grade	Release Date
Lung Cancer: Screening: adults aged 50 to 80 years who have a 20 pack-year smoking history and currently smoke or have quit within the past 15 years	The USPSTF recommends annual screening for lung cancer with low-dose computed tomography (LDCT) in adults aged 50 to 80 years who have a 20 pack-year smoking history and currently smoke or have quit within the past 15 years. Screening should be discontinued once a person has not smoked for 15 years or develops a health problem that substantially limits life expectancy or the ability or willingness to have curative lung surgery.	B	March 2021
Osteoporosis to Prevent Fractures: Screening: women 65 years and older	The USPSTF recommends screening for osteoporosis with bone measurement testing to prevent osteoporotic fractures in women 65 years and older.	B	June 2018
Prediabetes and Type 2 Diabetes: Screening: asymptomatic adults aged 35 to 70 years who have overweight or obesity	The USPSTF recommends screening for prediabetes and type 2 diabetes in adults aged 35 to 70 years who have overweight or obesity. Clinicians should offer or refer patients with prediabetes to effective preventive interventions.	B	August 2021
Prevention of HIV Infection: Preexposure Prophylaxis: persons at high risk of HIV acquisition	The USPSTF recommends that clinicians offer preexposure prophylaxis (PrEP) with effective antiretroviral therapy to persons who are at high risk of HIV acquisition. See the "Clinical Considerations" section for information about identification of persons at high risk and selection of effective antiretroviral therapy.	A	June 2019
Sexually Transmitted Infections: Behavioral Counseling: sexually active adolescents and adults at increased risk	The USPSTF recommends behavioral counseling for all sexually active adolescents and for adults who are at increased risk for sexually transmitted infections (STIs). See the "Practice Considerations" section for more information on populations at increased risk for acquiring STIs.	B	August 2020
Statin Use for the Primary Prevention of Cardiovascular Disease in Adults: Preventive Medication: adults aged 40 to 75 years with no history of CVD, 1 or more CVD risk factors, and a calculated 10-year CVD event risk of 10% or greater	The USPSTF recommends that adults without a history of cardiovascular disease (CVD) (i.e., symptomatic coronary artery disease or ischemic stroke) use a low- to moderate-dose statin for the prevention of CVD events and mortality when all of the following criteria are met: (1) they are aged 40 to 75 years; (2) they have 1 or more CVD risk factors (i.e., dyslipidemia, diabetes, hypertension, or smoking); and 3) they have a calculated 10-year risk of a cardiovascular event of 10% or greater. Identification of dyslipidemia and calculation of 10-year CVD event risk requires universal lipids screening in adults aged 40 to 75 years. See the "Clinical Considerations" section for more information on lipids screening and the assessment of cardiovascular risk.	B	November 2016
Syphilis Infection in Nonpregnant Adults and Adolescents: Screening: asymptomatic, nonpregnant adults and adolescents who are at increased risk for syphilis infection	The USPSTF recommends screening for syphilis infection in persons who are at increased risk for infection.	A	June 2016
Tobacco Smoking Cessation in Adults, Including Pregnant Persons: Interventions: nonpregnant adults	The USPSTF recommends that clinicians ask all adults about tobacco use, advise them to stop using tobacco, and provide behavioral interventions and U.S. Food and Drug Administration (FDA)-approved pharmacotherapy for cessation to nonpregnant adults who use tobacco.	A	January 2021

Topic	Recommendation	Grade	Release Date
Unhealthy Alcohol Use in Adolescents and Adults: Screening and Behavioral Counseling Interventions: adults 18 years or older, including pregnant women	The USPSTF recommends screening for unhealthy alcohol use in primary care settings in adults 18 years or older, including pregnant women, and providing persons engaged in risky or hazardous drinking with brief behavioral counseling interventions to reduce unhealthy alcohol use.	B	November 2018
Unhealthy Drug Use: Screening: adults aged 18 years or older	The USPSTF recommends screening by asking questions about unhealthy drug use in adults aged 18 years or older. Screening should be implemented when services for accurate diagnosis, effective treatment, and appropriate care can be offered or referred. (Screening refers to asking questions about unhealthy drug use, not testing biological specimens.)	B	June 2020
Weight Loss to Prevent Obesity-Related Morbidity and Mortality in Adults: Behavioral Interventions: adults	The USPSTF recommends that clinicians offer or refer adults with a body mass index (BMI) of 30 or higher (calculated as weight in kilograms divided by height in meters squared) to intensive, multicomponent behavioral interventions.	B	September 2018

†The Department of Health and Human Services, under the standards set out in revised Section 2713(a)(5) of the Public Health Service Act and Section 9(h)(v)(229) of the 2015 Consolidated Appropriations Act, utilizes the 2002 recommendation on breast cancer screening of the U.S. Preventive Services Task Force. To see the USPSTF 2016 recommendation on breast cancer screening, go to http://www.uspreventiveservicestaskforce.org/uspstf/recommendation/breast-cancer-screening1.

Approach to Screening in Older Adults

Advances in medical science have yielded improved screening tools and preventive health interventions. For older adults with limited years to live, recent medical literature has focused on the risks, benefits, and harms of screening and treatments relative to the remaining years of life. Principles such as time to benefit (TTB) and life expectancy (LE) have been incorporated into the science of prognostication, or predicting mortality (Coll et al., 2020a, 2020b; Lee et al., 2018; Schoenborn, Jacobson, et al., 2020; Schonberg, Karamourtopoulos, et al., 2020), as part of individualizing prevention in older adults. Coll et al. (2020a, 2020b) present a comprehensive overview of cancer screening and treatment in older adults that outlines TTB, harms, and risks. If LE is deemed shorter than TTB, the test or intervention is not recommended. If TTB is shorter than LE, then the intervention or screening test should be considered. In cases where LE and TTB are closely aligned timewise, discussion between the patient and clinician is advised to arrive at a decision (Lee et al., 2018). Determination of LE can be done by using mortality indices that have been already developed. According to Lee et al. (2018), a systematic review found 16 distinctive indices; these have been compiled and translated into online calculators at a Web site ePrognosis.com (https://eprognosis.ucsf.edu/index.php). Data from trials of screening outcomes and procedure outcomes has been utilized in arriving at TTB.

Work on prognostication is ongoing, with various research groups seeking to refine the tools (Jaul et al., 2021; Schoenbornm, Massare, et al., 2020; Schonberg, Jacobson, et al., 2020) and add other variables, such as comorbidities and frailty, into the mix. Although prognostication is being advanced by researchers and population health advocates, translation to practice requires a commitment on the part of clinicians in practice. There has been some hesitancy on the part of clinicians initially, fueled in part by concerns of malpractice and interfering with the clinician-patient relationship, but this is gradually dissipating (Kotwal & Walter, 2020; Schonberg, Jacobson et al., 2020). Most recently, scripts have been created to guide the dialogue between patient and clinician for optimal communication (Kotwal & Walter, 2020; Schonberg, Karamourtopoulos, et al., 2020). Video examples of discussions are available on the ePrognosis Web site. Lee et al. (2020) acknowledge the uncertainty in using probabilistic predictions but point out that several evidence-based examples have arisen from this, including the CHADsVasc 2 for atrial fibrillation. Prognostication outcomes are indirectly related to overuse of medical testing and the Choosing Wisely initiative (discussed below).

Sensitivity and Specificity and Positive Predictive Value of Diagnostic Tests

Not every diagnostic test is useful to diagnose a disease. For older adults, selection of the right diagnostic tests should take into consideration the health status of the older adult patient and the individual's consensus for treatment. Health-care providers need to understand how effective select tests are in establishing a diagnosis in an older adult. It is important to know the strengths and weaknesses of the select tests.

Sensitivity and specificity are the usual statistical measures employed to evaluate how a test performs compared to the gold standard. Sensitivity, or true positive, is the ability of a diagnostic test to correctly identify a proportion of those patients who have the disease or condition out of all who have the disease or condition when measured against a gold standard (Monaghan et al., 2021). Specificity, or true negative, is the ability of a diagnostic test to correctly identify a

© F.A. Davis Publishing

proportion of those patients who do not have the disease or condition out of all who do not have the disease or condition (Monaghan et al., 2021). Sensitivity and specificity are inversely proportional—when sensitivity increases, specificity will decrease. How good is the test, compared to the gold standard, in identifying true positives?

$$\text{Sensitivity} = \frac{\text{Number of people correctly identified as having the disease}}{\text{Total number of people affected}}$$

OR

$$\text{Sensitivity} = \frac{\text{Number of true positives}}{\text{Number of true positives} + \text{Number of false negatives}}$$

How well does the test perform in identifying true negatives—those who do not have the disease, from true negatives and false positives?

$$\text{Specificity} = \frac{\text{Number of people correctly identified as not having the disease}}{\text{Total number of true negatives}}$$

OR

$$\text{Specificity} = \frac{\text{All not having the disease}}{\text{Number of true negatives} + \text{Number of false positives}}$$

Positive predictive value is another statistical term used when examining the value of a test to diagnose a condition. Unlike sensitivity and specificity, which are deemed stable components of a test, positive predictive value aims to predict if a person actually has the disease based upon the pre-test probability or likelihood prior to administering the diagnostic test (Loh et al., 2020). This requires knowledge of the risk factors for acquiring the disease and the prevalence of the disease in the population being tested (Aminsharifi et al., 2018; Monaghan et al., 2021). For example, a recent Cochrane Review (Dinnes et al., 2021) studied the performance of rapid antigen COVID-19 tests compared to the gold standard RT-PCR test. They sought to discover how it performed in those with symptoms and without symptoms. The positive predictive value of a test like this in a population where COVID-19 is rampant, such as the United States, would be much better than if it were used in New Zealand where COVID-19 cases are very scarce, due to a difference in risk factors and prevalence.

CHOOSING WISELY

Choosing Wisely is an initiative started by the American Board of Internal Medicine Foundation in 2012 to raise the awareness of overuse of medical tests and procedures. The American Geriatrics Society (AGS), 70 other specialty groups, and Consumer Reports are part of this national effort. The goal of Choosing Wisely is to support conversations and interactions between patients and their health-care providers about what care is necessary (Levinson et al., 2018; Wolfson et al., 2014). It began with the National Physicians Alliance and a medical ethicist calling on internal medicine, family practice, and pediatrics leaders to each identify five interventions that should not be implemented; building on this, specialty medical organizations were also asked to list five items that were evidence-based, frequently done in practice, billable, within the purview of their clinical specialty, but were unnecessary or overused. The respective medical societies utilized quality and safety committees to develop the lists, polled their membership, and sought approval from their governing board prior to publishing the list. Several organizations have written articles depicting the process underlying their recommendations, and the list has increased from five to 10 items (Levinson et al., 2018; Wolfson et al., 2014). The AGS Health in Aging patient Web site (https://www.healthinaging.org/choosing-wisely) lists 10 things that patients and health-care providers should question, along with rationale and resources (Box 2-1).

In addition to the AGS recommendations, older adults should discuss the harms and benefits of procedures and testing with their health-care provider. The Medicare AWV, chronic health maintenance visits, and the Welcome to Medicare visit offer opportunities for this dialogue.

Like prognostication, many of the Choosing Wisely recommendations incorporate age and 10-year life expectancy into their calculations, particularly screening and treatment

BOX 2-1

Choosing Wisely: 10 Things Clinicians and Patients Should Question

- Don't recommend percutaneous feeding tubes in patients with advanced dementia; instead offer oral-assisted feeding.
- Don't use antipsychotics as first choice to treat behavioral and psychological symptoms of dementia.
- Avoid using medications other than metformin to achieve hemoglobin A1c. (<7.5% in most older adults; moderate control is generally better.)
- Don't use benzodiazepines or other sedative-hypnotics in older adults as first choice for insomnia, agitation, or delirium.
- Don't use antimicrobials to treat bacteriuria in older adults unless specific urinary tract symptoms are present.
- Don't prescribe cholinesterase inhibitors for dementia without periodic assessment for perceived cognitive benefits and adverse gastrointestinal effects.
- Don't recommend screening for breast, colorectal, prostate, or lung cancer without considering life expectancy and the risks of testing, overdiagnosis, and overtreatment.
- Avoid using prescription appetite stimulants or high-calorie supplements for treatment of anorexia or cachexia in older adults; instead, optimize social supports, discontinue medications that may interfere with eating, provide appealing food and feeding assistance, and clarify patient goals and expectations.
- Don't prescribe a medication without conducting a drug regimen review.
- Don't use physical restraints to manage behavioral symptoms of hospitalized older adults with delirium.

© F.A. Davis Publishing

of cancer (Coll et al., 2020a, 2020b; Saletti et al., 2018), although the primary intent is to eliminate tests and procedures that will not benefit older adults and can cause unnecessary harm or reduced quality of life. Not all clinicians agree with using age cutoffs or life expectancy criteria for cancer screening and treatment recommendations. Schoenborn et al. (2020) found that while there was general agreement about the need to stop overscreening, clinicians questioned the use of age as the determining factor. Some felt that population health and individual patient management were misaligned and were concerned about bias and limiting access to care. Rowe et al. (2021) sought family physician rationales for not following the AGS Choosing Wisely recommendations; reasons included clinical inertia, patient preference, and underestimating harms or overestimating benefits of a test or procedure.

In addition to the AGS recommendations, other important Choosing Wisely endorsements include elimination of routine electrocardiograms and stress testing on those with no cardiovascular problems (Rehman et al., 2018), excluding lipid labs on those on statins, avoiding percutaneous coronary stents in those with stable angina, and omitting a full perioperative work-up for cataract surgery (Mafi et al., 2019). Several researchers continue to monitor health care for overuse. Morgan et al. (2019) has published an annual update on medical overuse for 5 years, noting that there is still much work to be done to eliminate the problem. Chalmers et al. (2021), using Medicare fee for service claims for 2015–2017, identified serious overuse issues in for-profit, non-teaching hospitals, primarily in the Southern United States. Zikmund-Fisher et al. (2017) identified several barriers to implementing Choosing Wisely, including malpractice, patient desire for testing or newer drugs, medication costs, insurance issues, lack of time for shared decision making, health-care providers ordering unnecessary tests, and rewards for ordering tests (payer, performance).

Welcome to Medicare Visit

Beginning in 2003 with the passage of the Medicare Modernization Act (MMA), the focus on older adults shifted to prevention and health promotion (Ng et al., 2017). In 2005, as part of the MMA, CMS introduced the Welcome to Medicare visit, also known as the Initial Preventive Physical Exam (IPPE); this includes a medical and social health history review as well as education about preventive services and their benefit. The Welcome to Medicare visit is a one-time covered service during the first 12 months of Medicare B enrollment for fee-for-service Medicare enrollees. For a variety of reasons, it has taken some time for this concept of preventive services in older adults to be adopted (Chung et al., 2018). Ng et al. (2017) reported that there was little to no change in use of preventive services by older adults since the initiation of the Welcome to Medicare visit. Chappell (2017) found that physicians were uncomfortable with the idea and did not know how to conduct this visit or the Medicare AWV. This resulted in additional tests being ordered, and the patient would then be billed for the visit, which is supposed to be a free benefit. This created some ill will between patients and clinicians over billing. There were also misunderstandings about the difference between the IPPE and a routine annual physical examination, which is not covered by Medicare. CMS has created a short video for clinicians to explain the difference (https://www.youtube.com/watch?v=r7yOUaMJyJU). The Welcome to Medicare visit and subsequent AWVs are best conducted by a clinician who is known and trusted by the older adult patient. In preparation for the visit, it is helpful to have information on local resources for health promotion, such as exercise programs, senior centers, home safety, Area Agency on Aging services, advanced directives, and substance abuse treatment sources, readily available. The goal of the visit is to develop a wellness plan using shared decision making with the patient. This can be reviewed and updated at subsequent AWVs. Components of the Welcome to Medicare visit and the AWV can be found on the CMS Medicare Learning Network Web site (https://www.cms.gov/Outreach-and-Education/Medicare-Learning-Network-MLN/MLNProducts/preventive-services/medicare-wellness-visits.html). Section 410.16 addresses the Welcome to Medicare Visit, which includes:

- Medical and social history with special attention to risk factors; family history, social history, medications, allergies, OTC use (including supplements)
- Functional, ADLs, home safety, hearing, and fall risk assessments
- Depression screening
- Vital signs, body mass index
- Opioid use, screening for abuse, alcohol, tobacco use
- Socialization, diet, and physical activity

Nurse practitioners, with their holistic health approach and emphasis on prevention, are the ideal clinicians to perform Medicare Welcome and AWVs.

Annual Wellness Visits

Annual wellness visits were introduced in 2011 as part of the Affordable Care Act, offering wellness and preventive health opportunities with no copay to older adults on Medicare (Fox & Shaw, 2015; Ng et al., 2017). The visit is covered once every 12 months and includes an initial health risk assessment and personalized prevention plan, jointly developed by clinician and older adult patient. After the initial visit, the health risk assessment and prevention plan are updated at subsequent visits (Coburn et al., 2018). If other elements are added (e.g., the patient comes in with an upper respiratory tract infection and asks for treatment), the patient will be billed for the visit because it is no longer an AWV (42 CFR 410.15).

Like the Welcome to Medicare visit introduced earlier, AWVs have had a slow uptake trajectory to date. Ganguli et al. (2018) reported that between 2011 and 2015 the percentage of eligible Medicare beneficiaries receiving AWVs only increased from 7.5% to 18.8%, and most of them are concentrated in higher socioeconomic areas, in practices associated with Accountable Care Organizations or with the Medicare Electronic Health Record Incentive Program (Albright et al., 2016). Using Medicare data up to 2015, Ganguli et al. (2018) found that 51.2% of practices offered no AWVs; only 23.1% offered visits to one-quarter of their eligible beneficiaries. Some practices serving lower socioeconomic groups did not offer AWVs, or those with complex care needs did not receive the visits. Tipirneni et al. (2019) proposed that AWVs be expanded to include other health-care

© F.A. Davis Publishing

team members such as social workers and community health workers and include an assessment of social determinants of health with referral to community resource agencies. This will decrease health disparities and allow those with limited access to care and complex health and social needs to benefit from preventive health planning. The Association of Community Health Centers and CMS have both developed tools to include social determinants of health in the AWVs; policy advocacy is needed to obtain funding and implement them (Tipirneni et al., 2019).

Simpson et al. (2018) and Simpson and Kovich (2019) surveyed advance practice nurses in Indiana who worked with Medicare patients related to underuse of AWVs. The survey found a deficit in their knowledge related to the content and extent of health risk appraisals and the need to develop a Personalized Prevention Plan (PPP). The main author of the survey advocates for advance practice nurses, with their focus on prevention and holistic health, to be the clinicians of choice for AWVs (Simpson, 2019). Most recently Simpson et al. (2021) reported on a research project where nurses performed monthly follow-up phone calls after AWVs to support older adults' PPP. They identified seven areas that impacted implementation of the PPP, including mental health, social support, stress, community/environment, motivation, health promotion behaviors, and healthcare access, discussing how the personalization and contact helped older adults to overcome barriers to their plan and how follow-up is needed to ensure success of the PPP. They advocate for a team-based approach to the AWV to alleviate the burden on clinicians' time and to offer patients a more holistic, comprehensive, and personalized approach to prevention, with follow-up as needed. Bluestein et al. (2017) surveyed eligible patients and providers in their practice. They found that if the provider recommended the AWV that patients would be more likely to do it; providers were also supportive but confused by the complexity of the regulations. They emphasize that staff support is essential to delivering AWVs; their model utilized a nurse care manager along with office staff for increasing awareness among eligible patients, scheduling the visit, and doing the risk assessment and personalizing the PPP under the supervision of the physician. An added benefit to the practice was that the nurse care manager learned more about the patients and was able to follow up on their specific needs while being a trusted contact with the provider.

The Welcome to Medicare visit and AWVs are important opportunities for health promotion and establishing a personalized prevention plan for older adults; clinicians are urged to devise a plan to incorporate them into their management of older adults.

Immunizations

The adult immunization schedule is updated annually and can be found on the CDC's Web site at https://www.cdc.gov/vaccines/schedules/hcp/imz/adult.html.

The information is also available on a free downloadable phone app (https://www.cdc.gov/vaccines/schedules/hcp/schedule-app.html#download)

The CDC and the Advisory Committee on Immunization Practices (ACIP) collaborate on immunization recommendations (Freedman et al., 2021).

INFLUENZA VACCINE

Everyone 6 months of age and older is recommended to get an annual influenza vaccine, including healthy adults. Vaccination is especially important for those older than 65 years because they are at higher risk of serious influenza complications and for people who live with or care for people at higher risk for serious influenza complications. Flu vaccine protects against the flu viruses that research indicates will be most common during the upcoming season. Every year vaccines are updated to better match circulating viruses. Full immunity from vaccination occurs after about 2 weeks. Influenza vaccines for older adults contain no live viruses (Schmader et al., 2021).

DIPHTHERIA, TETANUS, AND PERTUSSIS VACCINES

Adults who have never received the tetanus, diphtheria, and acellular pertussis (Tdap) vaccine should receive a single dose, even if they recently received the tetanus and diphtheria (Td) vaccine. After this dose, a booster of Tdap or Td should be administered every 10 years. Boostrix® should be used for adults 65 years or older; if this is unavailable, use either vaccine product (CDC, 2018).

RECOMBINANT ZOSTER VACCINE (SHINGRIX)

The recombinant zoster vaccine (RZV) Shingrix is currently the only zoster vaccine on the market. For those age 50 years or older, a two-dose series 2 to 6 months apart (minimum interval: 4 weeks; repeat dose if administered too soon) is recommended regardless of previous herpes zoster or history of prior zoster vaccine live (ZVL, Zostavax) vaccination (Gagliardi et al., 2019; Weinberger, 2021).

PNEUMOCOCCAL VACCINES

There are two different pneumococcal vaccines. The pneumococcal polysaccharide vaccine (PPSV23) and the pneumococcal conjugate vaccine (PCV13). Annually over 25,000 people older than age 50 die from pneumococcal disease (*Weinberger, 2021). With a weakened immune system, older adults are at greater risk for this condition, especially those with multimorbidities. Dosing recommendations are as follows (CDC, 2019):

- Routine vaccination: Age 65 years or older (immunocompetent): 1 dose PPSV23. If PPSV23 was administered prior to age 65 years, administer 1 dose PPSV23 at least 5 years after previous dose.
- Shared clinical decision making: Age 65 years or older (immunocompetent): 1 dose PCV13 based on shared clinical decision making if previously not administered. PCV13 and PPSV23 should not be administered during the same visit. If both PCV13 and PPSV23 are to be administered, PCV13 should be administered first. PCV13 and PPSV23 should be administered at least 1 year apart.

COVID-19 VACCINES

All older adults should be vaccinated against COVID-19 with one of the available vaccines licensed for emergency use in the United States. There is also an immunization global entity that collaborates with the United States and other countries on COVID-19 vaccine initiatives (Becerra, 2021; Privor-Dumm et al., 2021; Al-Tawfiq & Memish, 2019).

© F.A. Davis Publishing

As of October 22, 2021, when requested for an individual among the groups recommended for a booster consistent with the FDA emergency use authorization (EUA) and the CDC's recommendation, all CDC COVID-19 vaccination program enrolled providers must make available and administer upon request: (1) for those who received the Moderna primary series, a single Moderna COVID-19 vaccine booster dose (which is half of the dose that is administered for a primary series Moderna dose) at least 6 months after completion of the Moderna primary series, in risk groups CDC has previously recommended receive Pfizer-BioNTech booster dose, under the FDA's EUA; or (2) for those who received a primary Janssen dose, a single Janssen COVID-19 vaccine booster for all persons aged 18 years or older at least 2 months after receipt of the primary Janssen dose, under the FDA's EUA.

Among the groups recommended by CDC to receive booster vaccination after a Pfizer-BioNTech, Moderna, or Janssen COVID-19 vaccine primary series, a single booster dose of any of the currently authorized or approved COVID-19 vaccines may be provided as a heterologous booster dose, under the FDA EUAs.

With the onset of the COVID-19 pandemic, issues with vaccine hesitancy and mistrust of the health-care system by underrepresented communities came to the forefront. Bhanu et al. (2021) reported on a systematic review identifying barriers to vaccine use and suggestions to address them. Some factors included misinformation, the perception that being healthy meant that the vaccine was unnecessary, believing that the vaccine was ineffective or caused harm, mistrust of the health system, and having access to the vaccine. Reasons that facilitated acceptance of the vaccine were fear of acquiring the disease, understanding how the vaccine works, recommendation by a health-care provider trusted by the patient, vaccine setting and accessibility, realization of age as a risk factor, support from the community, and vaccine reminders (Bhanu et al., 2021). Researchers concluded that increased education efforts with the underrepresented communities combined with culturally competent discussions with trusted health-care professionals and expanded access can produce maximal vaccine action (Bhanu et al., 2021; Loskutova et al., 2020).

TRAVEL AND LEISURE

Older adults represent a significant proportion of international travelers. Reasons for travel include tourism, business, visiting friends and relatives, medical tourism, missionary work, volunteer opportunities, pilgrimage, and study abroad. Travel can be greatly rewarding but is physically demanding and poses risk to the traveler.

Travel Medicine

Travel Medicine is a worldwide interdisciplinary medical specialty and evolved from many published studies of disease risks in international travelers in the mid-70s. The first international conference on travel medicine was held in Zurich in 1988, and the International Society of Travel Medicine (ISTM) was formed during the second conference in Atlanta, 1991 (Dupont & Steffen, 2020). The ISTM has its own body of knowledge, practice guidelines, offers a Certificate in Travel Health (CTH) and continuing professional development, holds biannual conferences, and has a directory of travel clinics. Travel medicine has become increasingly complex due to constantly changing global infectious disease epidemiology, changing patterns of drug resistance, and travelers with challenging circumstances (see Box 2-2). Some of the main reasons primary care providers (PCPs) refer patients to travel medicine specialists (TMSs) include the need for yellow fever or other travel vaccines, complex itineraries, medical comorbidities, the need for malaria chemoprophylaxis, and older travelers (Gerstenlauer, 2019a). Unfortunately, many travelers do not seek pretravel health, or may obtain pretravel advice from practitioners who are not equipped to provide current and accurate information. This can result in mistakes with disastrous consequences for the traveler. To provide pretravel consultations, practitioners need to be able to impart all necessary information regarding the health risks of the destination countries and health prevention measures as well as order the appropriate vaccines and medications. Providers can access country-specific epidemiologic information from the WHO or the CDC. Travel health software programs such as Tropimed and Shoreland Travax can be used while seeing patients, but these programs do not replace travel medicine training. The *CDC Health Information for International Travel*, known as "The Yellow Book," is published biannually and is a great resource for health professionals providing care to international travelers.

The Older Traveler

More older adults (ages 60 and older) are traveling due to increased quality of life, medical technology advances, and a longer time spent in retirement. Most older travelers enjoy traveling and return home in good health. Perceived mental and physical benefits of international travel include a temporary escape from medical appointments, group camaraderie, broadening language and cultural horizons, increased physical activity, and better weather (Liew & Flaherty, 2020).

However, older travelers face higher health risks and exacerbation of their chronic disease than younger travelers because of normal age-related physiologic changes, immunosenescence, atherosclerosis, comorbid conditions, functional impairments, polypharmacy, and being in a foreign environment. Cardiovascular disease (CVD) disease is one of

BOX 2-2
International Travel During COVID-19 Pandemic

The COVID-19 pandemic declared by the World Health Organization on March 11, 2020, greatly impacted international travel. Overseas travel for U.S. citizens in 2020 decreased by 78.2% (National Travel and Tourism Office, 2021). At the time of this text's publication, The Centers for Disease Control and Prevention (2021) does not recommend traveling internationally unless a person is fully vaccinated by one of the FDA-approved COVID-19 vaccines. If an individual is not fully vaccinated and must travel, see cdc.gov/coronavirus. All travelers need to follow all airline and destination requirements related to travel, mask wearing, testing, or quarantine, before traveling.

© F.A. Davis Publishing

the most common preexisting medical conditions among international travelers, and is the leading cause of death, accounting for 70% (Liew & Flaherty, 2020). The lower atmospheric pressure during air travel may trigger decompensation of preexisting CVD and expose passengers to potentially life-threatening inflight cardiac emergencies. Malignancies and trauma are the next most common causes of death abroad, while infectious diseases account for less than 10% (Darrat & Flaherty, 2019). Older travelers are less able to adapt physiologically and less able to adjust to climatic extremes. Comorbid conditions such as hypertension, dyslipidemia, diabetes, and COPD are often coexisting, and each requires a combination of medications, leading to polypharmacy. Medication adherence during travel can be difficult because of time zone changes and travel disruption. Some travelers may withhold certain medications due to undesired effects (e.g., not taking a diuretic on a long plane ride). Selecting appropriate medication can be more difficult as older adults undergo physiologic changes that alter the pharmacokinetic and pharmacodynamic nature of medications potentially causing increased drug interactions, adverse events, and altered drug action (Lewis et al., 2019). In a large CDC study, 61% of drug-drug interactions occurred in adults 50 and older and 41% had at least three comorbid conditions (Sbaih et al., 2018). Older adults represent ~8% of ill-returned travelers but have more severe disease compared to younger travelers. Navigating airports, poorly constructed roads, walking uphill, and stair climbing can be physically demanding with risk of injury. Sensory impairments and language barriers create communication difficulties.

The Pretravel Consultation

The pretravel consultation offers a dedicated time to prepare travelers for the health risks that might arise during their trip. The objectives are to perform an individual risk assessment, communicate anticipated health and safety risks, and provide risk reduction management measures, such as immunizations, malaria chemoprophylaxis, medications as needed, and education for specific risk behaviors. During the consultation, provide copies of the individualized trip information and educational materials for later reference and recall to avoid information overload. Educational materials are available on the CDC Travelers Health Web page (www.cdc.gov/travel).

Barring any communication technology issues, telemedicine can serve as a convenient alternate to an in-person pretravel visit, reducing cost and time and improving access to care. For telemedicine pretravel consultations, providers need to follow the same professional standards as with in-person consultations (CDC, 2020). Medications and vaccinations can be prescribed during a telemedicine encounter. Travelers can then seek vaccinations in the PCP's office or local health clinics and obtain prescriptions from their pharmacy. A valuable resource on telemedicine, including requirements by state, is available at https://prognocis.com/wp-content/uploads/2017/01/Telemedicine-Whitepaper.pdf.

Air travel is contraindicated for patients with certain conditions, such as those who are less than 3 weeks post uncomplicated myocardial infarction and those who are less than 10 days post thoracic or abdominal surgery (CDC, 2020). Providers should determine whether recent outbreaks or other safety notices have been posted for the traveler's destination; information is available on the CDC and U.S. Department of State Web sites. Disease exposures related to special activities merit discussion (e.g., river rafting and schistosomiasis or leptospirosis, spelunking and histoplasmosis). Flying from lowlands to high-altitude areas and trekking or climbing in mountainous regions introduces the risk of altitude illness. Compared to tourists, individuals who are visiting friends and relatives have higher travel risks, seek pretravel health less often, and may only get required vaccines as opposed to routine and recommended vaccines (*Ferrara et al., 2019). Host factors and trip details to assess with degree of risk are listed in Table 2-1.

IMMUNIZATION STATUS

The provider needs to inform the traveler of the necessity to receive routine, required, and recommended vaccines based on their medical history, immunization status, and their travel destination. Country-specific required and recommended vaccines can be found in the travel software programs or at the CDC vaccinations page. Written confirmation of the doses taken should be noted on the WHO approved International Certificate of Vaccination or Prophylaxis (ICVP), referred to as the "yellow card." The yellow card must be kept with the traveler's passport because it serves as proof of vaccination. Preferably, all vaccinations should be taken at least 4 to 6 weeks before the planned departure to give full protection against a disease. If a traveler has an incomplete vaccine series, continue the series, regardless of how much time has passed. Providers should report all adverse events that might be caused by vaccination to the CDC/FDA Vaccine Adverse Events Reporting System (VAERS).

ROUTINE VACCINES

All travelers should be current with routine vaccines before international travel, regardless of destination. A visit for travel health is an opportunity to bring an incompletely vaccinated person current on routine vaccines. Routine vaccines for older adults include influenza, pneumococcal, Td/Tdap, zoster, COVID-19, and hepatitis B for those at risk. The CDC sets U.S. adult vaccination schedules annually, based on the recommendations of Advisory Committee on Immunization Practices (ACIP). Some travelers may be immune to the disease for which immunization is being considered. Testing for antibody titers can determine whether vaccination is needed. If a person does not have adequate written documentation of vaccinations, these persons should be considered susceptible and started on the age-appropriate vaccination schedule. Exceptions are that self-reported doses of influenza and pneumococcal 23 are acceptable (General Best Practices for Immunizations, 2021).

REQUIRED VACCINES

Country-specific required vaccines need to be prioritized because the traveler may be denied entry to the country without proof of vaccination. For example, travelers to Mecca and Medina annually for the week-long Hajj pilgrimage require COVID-19 vaccination and the quadrivalent meningococcal conjugate vaccine, which must have been received in the past 3 years and at least 10 or more days in advance of arrival because this pilgrimage is one of the largest mass gatherings and may result in the occurrence and spread of infectious diseases (Al-Tawfiq & Memish, 2019).

© F.A. Davis Publishing

TABLE 2-1 Risk Assessment During Pretravel Consultation

HOST FACTORS	LOWER RISK TRAVEL	HIGHER RISK TRAVEL
Age, gender, nationality, occupation	Younger age	Older age
Immune status, allergies	Immunocompetent	Immunocompromised
Underlying conditions	Controlled chronic disease(s)	Unstable chronic disease(s)
Mental status	Cognitively intact	Cognitive impairment
Physical status	Physically fit	Poor physical health
Functional status	High functional ability	Functional Impairments
Medications	Minimal medications	Polypharmacy (>5–6)
Special conditions, dietary restrictions, specialist care, prosthetics, medical equipment and supplies	No special conditions, routine health maintenance specialty care	Disability or handicap, psychiatric condition, seizure disorder, dietary restrictions, recent surgery, cardiopulmonary or cerebral vascular event, severe allergies, chronic diseases
Immunization status	Current with routine, prior travel vaccines	Not current with routine vaccines, refuse recommended vaccines, inadequate timing
Trip Details	**Lower Risk Travel**	**Higher Risk Travel**
Itinerary, country destination(s) including regions, order of travel	Industrialized, nontropical, one country	Developing, tropical countries, multiple countries
Duration of trip, departure and return dates	Shorter (<3 weeks)	Longer (>3 weeks)
Reason for travel	Tourism, business	Mission, medical tourism, volunteerism, visiting friends or relatives
Trip organization	Organized prepackaged	Independent
Traveling style	Group	Traveling alone
Accommodations	Tourist, luxury	Hostel, budget hotel, camp, local host family
Location of activities	Urban, large cities	Rural, smaller cities, villages, jungle, rain forests, desert, remote
Type of activities	Usual tourist	Adventure (i.e., backpacking, scuba diving, climbing, trekking, hiking, cycling, spelunking), refugee camps, disaster relief, medical missions, wading or swimming in fresh water, cruise ships
Budget	**High**	**Low**
General hygiene standards, food and water restrictions	Well-known tourist areas, adherence	Local restaurants, street vendors, tap water
Modes of travel	Commercial	Local, motor bikes, under own power
Prior international travel history	Previous travel, experience with malaria chemoprophylaxis, altitude	Novice or only traveled to Western Europe
Challenges related to prior travel	Uneventful	Eventful (illnesses, injuries, hospitalizations, evacuations)
Anticipated interaction with animals	None expected	Monkeys, bats, elephants
Risky sexual encounters	None anticipated	Anticipated
Supplemental travel insurance	Purchased	No plans to get

Yellow fever (YF) is a mosquito-borne vaccine-preventable disease that is transmitted to humans by the bites of infected mosquitoes. YF vaccination (YF-VAX) is mandatory for all travelers to certain endemic countries in tropical and subtropical regions of Africa and South America. This can include travelers who may be staying in an endemic country only briefly, such as during an airport layover, before being allowed to enter other countries on their itinerary (Tropimed, 2018). The CDC gives country-specific information on YF vaccine requirements and recommendations. Travelers need to have received their dose at least 10 or more days in advance of arrival. The ACIP published a new recommendation in 2015 that one dose of YF-VAX provides long-lasting protection and is adequate for most travelers (CDC, 2020). However,

© F.A. Davis Publishing

some countries may still require a booster after 10 years, and boosters may be recommended for certain travelers. YF-VAX is available only in certified yellow fever vaccination clinics.

RECOMMENDED VACCINATIONS FOR TRAVEL

- **Cholera** is caused by bacteria that are spread from person-to-person by drinking contaminated water or eating contaminated food. It is rare and can be prevented with practicing food and water precautions and hand washing in areas with outbreaks. A single-dose oral cholera vaccine was approved by the ACIP in 2016, but only for adults ages 18 to 64.
- **Hepatitis A** is a contagious virus found in contaminated food and water that causes liver disease. The vaccine is recommended for all international travelers regardless of travel destination (CDC, 2020).
- **Hepatitis B** is a contagious virus found in the blood and body fluids of infected people that causes liver disease. The vaccine mitigates the risk of nosocomial transmission if accessing rudimentary health services abroad, so is recommended for all international travelers (CDC, 2020).
- **Japanese encephalitis** is transmitted by mosquitoes. It occurs rarely but is a risk for travelers with rural exposure for more than 4 weeks or prolonged residence in endemic areas.
- **Meningitis** is caused by bacteria spread through close personal contact. The vaccine is recommended for Hajj pilgrims and for travelers to the meningitis belt of sub-Saharan Africa during the dry season (December through June). Only meningococcal ACWY is used for travel health.
- **Polio** is a disease caused by a virus. It is mainly spread by person-to-person contact, by eating undercooked food, or drinking fluids contaminated with the feces of an infected person. Travel to Afghanistan, Nigeria, and Pakistan may be a risk for this disease. A booster dose is recommended for previously vaccinated travelers to affected countries.
- **Rabies** kills about 60,000 people a year, 40% of whom are children (Global Alliance for Rabies Control [GARC], 2019). In the United States, rabies is mostly found in wild animals such as bats, raccoons, skunks, and foxes (CDC, 2020); however, in many other countries, especially rural areas of economically disadvantaged countries in Africa and Asia, up to 99% of human cases are acquired from infected dog bites, which are responsible for most of the rabies deaths in people (GARC, 2019). Rabies can be prevented by vaccinating pets, avoiding wildlife, and seeking medical care after exposure before symptoms start (CDC, 2020). The pre-exposure rabies vaccine will reduce the number and type of postexposure vaccines needed. When considering the rabies vaccine, consider the risk of animal exposure, access to local health care, and availability of rabies immune globulin and rabies vaccine at the traveler's destination. Providers should consult with local or state health officials for recommendations on postexposure prophylaxis recommendations (CDC, 2020).
- **Typhoid fever** is transmitted by contaminated food and water in endemic areas. Two vaccines are available: a weakened live oral with a series of 4 doses and an inactivated injectable.

Foodborne and Waterborne Illnesses

Travelers' diarrhea (TD) is the sudden onset of abnormally loose, frequent stools and affects 30% to 70% of travelers (CDC, 2020). Intestinal pathogens like bacteria cause 80% to 90% of TD, viruses 5% to 15%, and protozoa 10%. Careful selection of food and beverages and hand washing are important for prevention, but never eliminate the risk, typically due to poor local restaurant hygiene (CDC, 2020). Hepatitis A, cholera, and typhoid vaccines as appropriate, can help prevent food- or waterborne infections. Early antibiotic therapy can shorten the duration of illness, alleviate the disability associated with TD, and prevent the risk of long-term complications (CDC, 2020). Combining the antibiotic with an antimotility agent such as loperamide can shorten the course further. Using antimotility agents alone are recommended for mild TD, and antibiotics can be reserved for moderate to severe TD (CDC, 2020). To minimize the risk of antibiotic-associated side effects, colonization, and resistance, use single-dose regimens, and select an antibiotic agent that minimizes microbiome disruption and risk of colonization. The traveler will need to self-treat, so clear written guidance about TD prevention and instructions on treatment are crucial. Prophylactic antibiotics are not recommended for most travelers but may be considered for short-term travelers who are high-risk hosts (e.g., immunosuppressed, significant medical comorbidities) and where the benefits outweigh the risks (CDC, 2020; van Aalst et al., 2018). Fluoroquinolones have been the most effective antibiotics for the prophylaxis and treatment of bacterial TD, but increasing resistance to *Campylobacter* and *Shigella* species, the association with tendinitis, and increased risk of *Clostridioides difficile* infection limit their use. Alternatives include azithromycin, rifaximin, and rifamycin SV (CDC, 2020).

Mitigating Travel Risks

The pretravel consultation provides an opportunity to educate the traveler about their destination risks, as well as management of these safety risks and chronic diseases while traveling. Topics to be explored are numerous and could be organized into a checklist, placing priority on the most serious and frequently encountered issues (see Table 2-2). Provide the traveler a clinician letter on letterhead outlining allergies, existing medical conditions, prescribed medications (including generic names), and any medical equipment required. Give the traveler a list of travel clinics or sources of medical care in case they need to seek medical care; preferably with English-speaking, American-trained providers. Encourage the use of mobile applications to tract certain chronic illnesses while traveling. Medications requiring prescriptions in the United States may be available over the counter abroad; however, discourage travelers from buying these medications, especially from non-pharmacy sources, because of the risk of obtaining substandard or counterfeit medications (CDC, 2020). Advice on self-treatable conditions may minimize the need for travelers to seek medical care while abroad and possibly lead to faster return to good health.

Malaria Chemoprophylaxis

Malaria is a preventable illness but unfortunately is one of the most severe public health problems in the world. It is a leading cause of morbidity and mortality in many developing

© F.A. Davis Publishing

TABLE 2-2 Management of Safety Risks and Chronic Diseases While Traveling

CONDITION OR SITUATION	RECOMMENDATIONS
Acclimatization	• Drink at least 3 or 4 liters of bottled water or isotonic drinks daily. • Avoid intense physical activity in the first few days after arrival.
Allergies, life-threatening	• Carry EpiPen, diphenhydramine, steroid dose pack. • Avoid triggers.

Altitude	• The risk of altitude illness is dependent on the elevation at destination, rate of ascent, and exertion.
	• Inadequate acclimatization may lead to altitude sickness in any traveler going to 8,000 feet/2500 m (CDC, 2020).
	• Prior experience with altitude is a good indication of risk.
	• CDC guidelines are:
	  • Ascend gradually, if possible, not going directly from a low elevation to more than 9,000 ft/2,750 m sleeping elevation in 1 day.
	  • Once above 9,000 ft/2,750 m, move sleeping elevation no higher than 1,600 ft/500 m per day, and plan an extra day for acclimatization every 3,300 ft/1,000 m.
	  • Consider using acetazolamide to speed acclimatization if abrupt ascent is unavoidable.
	  • Avoid alcohol for the first 48 hours; continue caffeine if a regular user.
	  • Participate in only mild exercise for the first 48 hours.

Basic health practices	• Reinforce frequent hand washing, hand sanitizers, masks as required, carrying extra tissues or toilet paper, wearing safety belts, safe sexual practices, protection of passport, valuables. • Carry contact information for the primary care provider, specialists, and significant others.
Bloodborne pathogens	• Inform the patient on what to do in case of needlesticks or bloodborne pathogen exposure. • Discuss use of postexposure prophylaxis for HIV. • Avoid tattooing, body piercing, and injections with nonsterile needles.
Cardiovascular disease	• See a cardiologist pretravel. • Carry a copy of most recent electrocardiogram. • Bring identification cards for cardiac devices. • If on warfarin for atrial fibrillation, consider the use of nonvitamin K antagonist oral anticoagulants for a more favorable risk-benefit profile, easier adherence, and negation of the need for International Normalized Ratio monitoring abroad. • Carry nitrate spray.
Casual sex	• Use condoms. • Discuss use of postexposure prophylaxis for HIV. • Stress that avoidance is better.
Cognitive impairment	• If possible, have a traveling companion. • Consider treatment with acetylcholinesterase inhibitors and/or memantine. • Use pre-organized group travel. • Encourage patient to carry a hotel's business card and to photograph hotels, buses, cruise ships or tour company's names to help recall.
Diabetes	• Consider use of continuous glucose monitoring devices. • Check blood glucose every 4 to 6 hours during air travel. • Use mobile apps to tract blood glucose, activity, diet. • Accept somewhat higher blood glucose levels during travel days to avoid hypoglycemia. • Try to simplify treatment regimen to avoid multidosing. • Carry snacks to avoid hypoglycemia.
Dietary restrictions	• The patient may need to self-select from available food choices because specialty diets may not be available. • Check ahead of time to see if specialty diet can be ordered during travel. • The patient may need to bring their own food and snacks. Obtain a doctor's note allowing you to carry liquid "medical foods" through security at the airport so nothing is confiscated by Transportation Security Administration.
Environmental hazards	• Avoid contact with wild animals to reduce the potential for bites and scratches that can transmit rabies. • Avoid walking barefoot where animals can defecate to avoid certain parasitic infections. Avoid wading or swimming in freshwater where there is risk for schistosomiasis or leptospirosis. • Apply sunscreen to skin exposed to the sun. Adhere to water/food and feeding hygiene.
Fitness for travel	• Evaluation is not usually a part of pretravel consultation. • Recommend seeing the primary care provider at a separate appointment or a specialist as appropriate. • Encourage regular exercise or training in preparation.

© F.A. Davis Publishing

TABLE 2-2 Management of Safety Risks and Chronic Diseases While Traveling—cont'd

CONDITION OR SITUATION	RECOMMENDATIONS
Immunocompromised	• If a traveler cannot tolerate recommended immunizations or prophylaxis, consider counseling the traveler to change the itinerary, alter planned activities, or deferring the trip. • The traveler's specialty care provider may need to be contacted to discuss any concerns.
Jet lag	• This is a risk when traveling across more than three time zones. • It can affect mood, concentration, and coordination. • Per CDC (2020), if the destination is more than 3 hours different than your normal time zone, follow the sleep and waking routines of your destination when you arrive. • Consider scheduling travel to arrive at your destination at least 2 days before any important events.
Long-distance flights	• Use antithrombosis compression socks. • Ensure sufficient nonalcohol, non-caffeine hydration and exercise. • Take diuretics as prescribed.
Medications	• Keep medications in original bottles in carry-on luggage. • Keep a copy of medication list. • Ensure patient has enough for the entire trip plus a few days extra in case of delays. • If crossing time zones, take medication based on elapsed time and not time of day. • Check with the U.S. embassy or consulate to clarify medication restrictions in the destination country. Some countries do not allow narcotics or psychotropic medications. • Educate the patients about any drugs ordered and review for drug interactions. • Try to simplify schedules to avoid polypharmacy and help adherence. • If refrigeration is needed, consider travel ice packs, refrigerators in hotel rooms, or use of ice buckets.
Medical supplies	• Keep these in their original containers in carry-on luggage. • Check all batteries and bring extras. • Adapters may be needed. • Those on continuous positive airway pressure may need an alternative if destination has inadequate electricity.
Medical alert bracelet, necklace, or card	• Make sure those with drug allergies and certain medical conditions have one.
Motion sickness	• Try to avoid situations that tend to trigger symptoms. • Try to optimize position to reduce motion perception (e.g., drive instead of riding in a vehicle, or sit in the front seat, sit over the wing of an aircraft, choose a window seat on flights and trains) (CDC, 2020). • Maintain hydration and eat small frequent meals, limiting alcohol, caffeine. • Avoid smoking. • Use distractions such as controlled breathing, listening to music, aromatherapy, flavored lozenges.
Personal safety	• Avoid driving or riding at night in developing countries. • Avoid motor scooters, overcrowded buses and vans, walking alone, alcohol excess, which can increase the risk of personal assault, robbery, drowning. • Look for security bulletins related to the destination and consider areas to avoid (e.g., areas of civil unrest). • Have contact information for the U.S. embassy.
Foodborne or waterborne infections	• Perform regular hand washing. • Drink bottled or boiled water, carbonated drinks, beer, wine. • Avoid drinks with ice cubes, street food, unpasteurized dairy products. • Eat only fruits washed and peeled by yourself and recently cooked and hot-served food. • Avoid buffets.
Pulmonary conditions	• Notify the airline in advance if oxygen or other equipment is needed on the plane. • Prepare for chronic obstructive pulmonary disease or asthma exacerbations by having lung function tested before travel. • Have standby medications readily available.
Supplemental insurance	• Medicare and most medical insurance policies do not cover health care in other countries; consider supplemental insurance coverage for emergency medical and dental treatment, reimbursement for cost. • Consider trip cancellation insurance in the event of illness. • Provide information on medical evacuation/repatriation insurance and emergency medical assistance services.
Vectorborne diseases	• Use insect repellents with N, N-diethyl-meta-toluamide (DEET), 20%–40%. Apply over sunscreen. • Use mosquito nets. • Wear long pants, long sleeves, hats. • Avoid staying outdoors from dusk to dawn when insects are the most active. • Use air conditioning or tight window screens. • Treat clothing, gear, and bedding with permethrin up to 2 weeks before travel.

© F.A. Davis Publishing

countries (Gerstenlauer, 2019b). It occurs mostly in economically disadvantaged tropical and subtropical areas in Africa, South America, and South Asia. The most vulnerable are persons with little or no immunity against the disease, like travelers or migrants coming from areas with little or no malaria transmission. Visitors of friends and relatives have a disproportionately high prevalence of travel-related morbidity, particularly infectious diseases, including malaria (Volkman et al., 2020). They are also less successful at implementing key approaches to malaria prevention. Malaria is transmitted by the bite of an *Anopheles* mosquito that is infected by a protozoan parasite of the *Plasmodium* genus. For travelers going to malaria-endemic countries, it is important to discuss bite avoidance, insect repellents, malaria chemoprophylaxis, and symptom awareness. Malaria should always be a consideration when fever or other flu-like symptoms are present in a traveler who had risk, even after a year post travel (Gerstenlauer, 2019). Long-term travelers may face barriers in obtaining sufficient antimalarial medication to cover their entire stay because Medicaid and some private insurance plans in the United States limit antimalarial dispensing to a 34-day supply and may not permit vacation overrides (Volkman et al., 2020). Malaria chemoprophylaxis is not always covered by insurance.

Choosing a medication for chemoprophylaxis must be individualized and must consider the traveler's medical history, current medications, potential side effects, past history, cost of the medication, time till departure, as well as malaria drug resistance in the area(s) of travel. No antimalarial drug is 100% protective and must be combined with the use of personal protective measures. The drugs are generally well tolerated. Side effects may develop but do not usually require stopping the medication. All recommended chemoprophylaxis regimens involve taking a medication before, during, and after travel. Recommendations for drugs can be found in malaria information by country https://www.cdc.gov/malaria/travelers/country_table/c.html.

SUMMARY

Improved quality of life and ease of travel has increased the number of older adult international travelers. Older travelers have special considerations and unique challenges that are important to address in preventing travel-related complications. Older travelers should be specifically counseled to reduce their risks by obtaining pretravel health. PCPs are increasing called upon to provide travel health. The PCP needs to be ready to give tailored and accurate advice to a wide variety of travelers. APRNs are very suited to this role and are encouraged to seek additional professional training to become an effective travel health specialist.

CASE STUDY

J.B. is a 73-year-old widow, living alone in an urban area. It has been almost 3 years since her husband died, and J.B. has worked through her grief, settled his affairs, and is ready to move forward with her life. She has no children. Her sister lives in another state. J.B. has some close friends in the area. She currently attends Zumba classes twice weekly at the local senior center and she has joined a women's walking group. She also sings in the local community chorus group. J.B. is in good health; she takes lisinopril 10 mg PO daily for hypertension and a multivitamin. Family history includes:

- Father—deceased from a stroke
- Mother—deceased from colon cancer
- Younger sister—living with breast cancer.

Due to taking care of her late husband, J.B. has neglected some preventive health screenings. She recently began dating and is attracted to a 66-year-old divorcee, L.D., in the community chorus. He is very social; they have gone out for coffee and meals, and he is hinting that he wants to get to know her better. He has a vacation home in Florida and has invited her to come for a week.

1. You are seeing J.B. for her AWV. What are some important areas to address with her in terms of screening?
2. During the visit J.B. confides in you that she has not been sexually active in many years due to her husband's protracted illness and death. She is very attracted to L.D. but is also anxious and verbalized that L.D. seems to have had a few relationships since his divorce. How would you counsel J.B. about safe sex and dating?
3. What is the purpose of the AWV and what areas need to be addressed?
4. J.B. has a cough and a sore throat during the AWV and asks if you can examine her and prescribe something. How would you address this with her?

CHAPTER 3

Exercise in Older Adults

Lori Martin-Plank

According to the 2020 Profile of Older Americans (Administration on Aging [AoA], 2021), people older than age 65 years represented 16% of the total U.S. population in 2019. The U.S. Census projection (2017) predicts that older adults will reach 23.4% of the population in 2034 and will outnumber children younger than 18 at that time. Most of these older adults will live in the community, either with a partner or alone, and will desire to age in place. This projection presupposes that these individuals must be physically able to function and perform most activities of daily living (ADLs) with minimal assistance or have caregiver assistance.

Data related to physical activity or exercise in older adults comes primarily from self-reported surveys, including the National Health Interview Survey (Federal Interagency Forum on Aging-Related Statistics, 2020). According to *Older Americans 2020*, in 2018 approximately 16% of older adults between 65 and 74 years of age met the standard for physical activity set by *Physical Activity Guidelines for Americans* (2nd ed.); this percentage decreased to 7% for those 85 years of age and older (Federal Interagency Forum on Aging-Related Statistics, 2020).

The Senior Report 2021 (United Health Foundation, 2021) reports that exercise in older adults in the United States (those aged 65 years and older), increased from 17.6% to 23.1% from 2017 to 2019. Although any increase in physical activity is encouraging, these figures clearly show that we are making very slow progress in this area. Recommendations from the *Physical Activity Guidelines for Americans* (2nd ed.) state that older adults aged 65 and older perform a minimum of 150 minutes weekly of moderate-intensity aerobic activity or 75 minutes weekly of vigorous-intensity aerobic physical activity, or an equivalent combination of both. Additional requirements call for muscle strengthening activities involving all major muscle groups, using at least moderate-intensity, two or more days weekly. If older adults cannot achieve 150 minutes of moderate-intensity aerobic exercise due to chronic health issues, they should be as active as their health conditions and abilities permit (U.S. Department of Health and Human Services, 2018). In addition to the above requirements, older adults should engage in balance training activities weekly and be mindful of safety in exercising related to their health conditions and abilities.

AVAILABLE RESOURCES

Guidelines and position statements for increasing physical activity in adults and older adults have been issued by several authorities, including the American College of Sports Medicine (ACSM), American Heart Association (AHA), U.S. Preventive Services Task Force (USPSTF), U.S. Department of Health and Human Services (USDHHS), and the National Strength and Conditioning Association (NSCA). Additionally, the *Healthy People 2030* initiative has several sections dedicated to health promotion in older adults. Numerous agencies, such as the Centers for Disease Control and Prevention (CDC), American Osteopathic Association (AOA), National Institute on Aging (NIA), National Council on Aging (NCOA), and Centers for Medicare and Medicaid (CMS), have programs to promote wellness and quality of life in older adults, including physical activity projects. The ACSM's Web site, Exercise Is Medicine, has extensive resources for providers and the public (http://exerciseismedicine.org), and the Preventive Cardiovascular Nurses Association (PCNA) has a Heart Healthy Toolbox (http://pcna.net/clinical-tools/tools-for-healthcare-providers/heart-healthy-toolbox) with a variety of free tools for use by clinicians. Health insurance companies, including Medicare Advantage plans, offer programs such as *SilverSneakers* at selected gyms or YMCAs, and most of these locations have individualized health coaching services available to their members. The challenge for clinicians working with older adults is learning about these free resources and discovering how to assimilate them in a meaningful way into their clinical encounters, and to engage patients in regular physical activity.

Research on Physical Activity in Older Adults

There is no shortage of research related to physical activity and older adults, including randomized clinical trials; however, the timelines in most studies are concentrated on short-term outcomes, and some studies have very specific foci, which may not easily translate into everyday life. Callow et al. (2020, 2021) and Jiménez-Pavón et al. (2020) both speak to the mental health benefits of physical exercise by older adults in the COVID-19 era, while Langhammer et al. (2018) address the overall importance of physical activity in older adults.

© F.A. Davis Publishing

Several studies focus on improving gait speed and dual-task processing to stimulate body and brain health (Merchant et al., 2021; Pothier et al., 2018; Trombini-Souza et al., 2020). Blumenthal et al. (2019) found that an aerobic exercise program in sedentary older adults with mild cognitive impairment improved their executive function abilities. Beauchamp et al. (2019) highlighted the impact of psychological mediators in promoting adherence to a group exercise program for older adults, while Cho and Kim (2020) reported on the beneficial psychological effect of exercise in older adults overall. A study by Buttelli and colleagues (2021) discovered that a Pilates program for older women with dyslipidemia successfully improved both aerobic capacity and blood glucose but had no effect on lipoprotein profile. Multiple studies addressed the positive impact of resistance training on strength and mobility (Fragala et al., 2019; Krčmárová et al., 2018; Kumbhare et al., 2019; Marcos-Pardo et al., 2019); Stojanović et al. (2021) devised a chair-based program with resistance bands that improved fitness and metabolic markers in older women. Sipilä et al. (2018) compared a program with physical and cognitive training versus physical training alone on mobility and fall prevention in older adults; Hopewell and colleagues (2020) performed a systematic review and meta-analysis of multifactorial interventions to prevent falls in community-dwelling older adults. Phu et al. (2019) found that balance training using virtual reality was effective in improving performance in older adults at high risk for falling. Muellmann et al. (2018) conducted a systematic review of the effectiveness of e-health interventions such as text messaging, phone apps, pedometers, and wearable fitness trackers in promoting physical activity in older adults; findings demonstrated that e-health interventions were effective in the short term. Results comparing the efficacy of e-health versus in-person program outcomes were inconclusive. A study by Rincé and colleagues (2021) showed the positive impact of an individualized rehabilitation program on mobility for the oldest-old.

Of the many areas of research related to older adults and physical activity, almost all demonstrate the value of interventions to promote physical activity and there has been great diversity in research approaches to this topic. Studies that focused on older adults and exercise found that short-term interventions, both individual and group and face-to-face and electronically, were effective in increasing physical activity when delivered as part of a multifaceted program of educational and cognitive-behavioral participation. Health education alone was ineffective in this population. Healthcare personnel–recommended physical activity and an exercise prescription were effective in the short term. None of the studies reviewed had a long enough duration to measure persistence of effort.

BARRIERS AND FACILITATORS TO EXERCISE FOR OLDER ADULTS

Patient Barriers

- Lack of time
- Perceived need for equipment
- Perceived barrier to beginning exercise/physical activity
- Disability or functional limitation
- Unsafe neighborhood or weather conditions
- No parks or walking trails
- Depression
- High body mass index (BMI)
- Lack of motivation
- Interpersonal loss or significant life event
- Ignorance of what to do

Patient Facilitators

- Social support
- Positive self-efficacy
- Motivation to engage in physical activity
- Good health, no functional limitations
- Frequent contact with prescriber
- Regular schedule, planned program
- Satisfaction with program
- Insurance incentive
- Improvement in mobility or health condition
- Staff (of exercise or physical therapy facility) support

Clinician Barriers

- Time to assimilate information on physical activity specific to older adults
- Time to counsel patients on the importance of physical activity and lifestyle changes
- Lack of knowledge about how to write an exercise prescription
- Lack of awareness of resources in the community to support physical activity in older adults
- Focus on medical interventions for chronic disease management in lieu of lifestyle changes
- Failure to follow up to insure implementation of recommendations for physical activity

Examples of Medical Contraindications for Exercise Therapy

- Unstable angina
- Uncompensated heart failure
- Severe anemia
- Uncontrolled blood glucose
- Unstable aortic aneurysm
- Uncontrolled hypertension or tachycardia
- Severe dehydration or heat stroke
- Low oxygen saturation

PLAN FOR INCORPORATING EXERCISE INTO PATIENT ENCOUNTERS

One of the easiest ways to address exercise or physical activity with older adults is utilizing the Welcome to Medicare visit or the Annual Wellness Visit (AWV). Both visits are focused on individual patient issues, including lifestyle, items identified during the health risk assessment (such as sedentary lifestyle), and patient goals, and both have more encounter time built into the visit.

There are several helpful professional resources that focus on the components of an exercise prescription and how to

© F.A. Davis Publishing

write one, including Medscape, the American College of Sports Medicine (ACSM), *UpToDate*, and the American Academy of Family Physicians (see Resources). Clinicians' knowledge about their older adult patients and their functional levels and interests can help in designing the exercise prescription or plan. For example, some older adults enjoy dancing; some like to play golf, bike, or swim; while others may prefer tai chi or yoga in addition to walking. The ideal exercise prescription is one that the patient will follow; any increase in physical activity is better than none. For many older adults who are sedentary, walking is an aerobic activity. The four recommended components for maximal benefit from an exercise program are aerobic activities, resistance training for muscle strengthening, flexibility exercises (stretching), and balance training to lessen the chance of falls (DiPietro et al., 2019; Fragala et al., 2019; King et al., 2019; Tricco et al., 2017). Recent studies have demonstrated that there are comparable benefits from high-intensity interval training (HIIT) and moderate-intensity continuous training (Campbell et al., 2019). Erickson et al. (2019) found that physical activity benefited those with cognitive deficits in later life. Another systematic review by Jakicic et al. (2019) reported that, contrary to prior evidence, physical activity of any bout duration was correlated with improved health outcomes, including all-cause mortality; this is encouraging for those with limited endurance or attention span.

The ACSM recommends that clinicians discuss the benefits of exercise and physical activity at every visit (2021); their *ASCM's Guidelines for Exercise Testing and Prescription* (11th ed., 2021) is a comprehensive resource and includes exercise prescriptions that are specific to several health conditions. This can serve as a quick resource for busy clinicians in addition to their Exercise is Medicine Web site.

Clinicians can now schedule visits billed with extra time to initiate or follow up on a prescribed exercise program. Busy practices can train a staff member to meet with patients to monitor progress of existing exercise programs, contract with an exercise physiologist or coach, or incorporate physical therapy training into the initial program. Older patients can also be referred to health coaching services or gym programs included in their medical insurance. Clinicians can set an example of healthy exercise by scheduling times to walk with patients in a nearby park or somewhere close to the office or sponsoring a patient walking group. Telehealth visits utilizing motivational interviewing can be used for exercise counseling and follow-up. The clinician office can display materials promoting exercise and other healthy lifestyle behaviors or have a dedicated closed-circuit TV with messages. Handouts depicting online programs dedicated to older adult fitness can be made available to patients.

Clinician judgment should be used when assessing the patient and prescribing an exercise routine. Major authorities agree that all adults who do not have symptoms and have no diagnosed chronic health condition, such as osteoarthritis, heart disease, or diabetes mellitus, do not need to consult with a health-care professional about increasing physical activity (Centers for Disease Control and Prevention [CDC], 2021). Patients with chronic conditions should consult a health-care provider for physical activity goals that are realistic and safe (U.S. Department of Health and Human Services, 2018). Healthy adult men older than 45 years and healthy women older than 55 years who are considering a *vigorous* exercise program need health-care provider screening and routine stress testing. Sedentary older adults and all adults with cardiac disease or strong risk factors should undergo screening and stress test if they are undertaking a *vigorous* exercise program (Lee et al., 2017).

In 2018, 1.2 million U.S. adults aged 65 and older resided in a long-term care (LTC) facility (AARP, 2019), many of them representing frail older adults. Izquierdo et al. (2016) raised the question of whether it is ethical not to provide physical activity for frail older adults. At the same time, a group of preeminent geriatricians, physical therapists, and gerontologists formed a taskforce under the auspices of the International Association of Geriatrics and Gerontology Global Aging Research Network (IAGG-GARN) and the European division of IAGG to make recommendations for physical activity and exercise standards in long-term care settings (de Souto Barreto et al., 2016). Acknowledging the heterogeneity of the population, the group devised two sets of recommendations—one advocating for a decrease in sedentary behavior for all residents of LTC settings, and the other utilizing evidence from metanalyses and other research to develop a guideline for a select subset of LTC residents capable of participating in a structured exercise program to maintain functional and ADL abilities for as long as possible. For the first group, utilizing short breaks in sitting two to five times daily, such as walking to the dining room instead of using a wheelchair, is recommended. For those capable of structured exercise, a multicomponent program of moderate intensity done twice weekly for 35 to 45 minutes each time is recommended (de Souto Barreto et al., 2016). The importance of promoting physical activity in older adults living in LTC facilities cannot be underestimated because this age-group increases in numbers; benefits are not only individual, but also economic in terms of preventing costly hospitalizations and delaying functional decline.

KEY GUIDELINES FOR SAFE PHYSICAL ACTIVITY

The key guidelines for adults also apply to older adults (Physical Activity Guidelines Committee, 2018). In addition, the following key guidelines are for older adults only:

- As part of their weekly physical activity, older adults should do multicomponent physical activity that includes balance training as well as aerobic and muscle strengthening activities.
- Older adults should determine their level of effort for physical activity relative to their level of fitness.
- Older adults with chronic conditions should understand whether and how their conditions affect their ability to do regular physical activity safely.
- When older adults cannot do 150 minutes of moderate-intensity aerobic activity a week because of chronic conditions, they should be as physically active as their abilities and conditions allow (Table 3-1).

© F.A. Davis Publishing

TABLE 3-1 Examples of Common Health Conditions in Older Adults with Exercise Recommendations

HEALTH CONDITION: CONSIDER COMORBIDITIES FOR ALL	RECOMMENDED ACTIVITIES: START LOW INTENSITY, GO SLOW	COMMENTS: CONSIDER COMORBIDITIES FOR ALL
Osteoarthritis	Walking, aquatic activities, tai chi, resistance exercises, cycling	Vary type and intensity to avoid overstressing joints; heated pool
Coronary artery disease	Walking, treadmill walking, cycle ergometry	Supervised program with blood pressure and heart rate monitoring
Heart failure	Walking, treadmill walking, cycle ergometry	Individualize to patient; supervised program
Type 2 diabetes mellitus	Resistive, aerobic, aquatic, recreational activities	Proper shoe fit; may need insulin reduction if insulin dependent
Anxiety disorders	Walking, biking, weightlifting	If able to do high-intensity exercise, this benefits anxiety
Depression	Walking, cycling, recreational activities	Group participation helpful to keep patient engaged
Fibromyalgia	Aerobic, aquatic therapy, strengthening, tai chi, Pilates	Heated pool, gentle stretches, counsel about possible increased pain initially
Chronic obstructive pulmonary disease	Cycle ergometer, treadmill walking; individualize	Supervised program—consider pulmonary rehabilitation program
Chronic venous insufficiency	Walking, standing exercises	Supervised program
Osteoporosis	Weight-bearing exercises, weight training	Assess balance and risk for falls before beginning
Parkinson's disease	Walking, treadmill walking, stationary bike, dancing, tai chi, Pilates, boxing	Assess balance and risk for falls before beginning; American Parkinson Disease Association resources
Peripheral arterial disease	Lower extremity exercises, treadmill walking, walking	Very short intervals initially, progress as tolerated
Age-related sleep disorders	Tai chi, walking, aquatherapy, biking	Assess balance and risk for falls before beginning
Dementia	Walking, recreational activities	Provide safe environment, assess fall risk and ability to participate

© F.A. Davis Publishing

SUMMARY

There is strong evidence from a variety of sources that increasing physical activity in older adults will improve health and quality of life in both healthy adults and those with chronic health conditions, in the community and in long-term care settings (Buttelli et al., 2021; Campbell et al., 2019; de Souto Barreto, 2016; DiPietro et al., 2019; Hopewell et al., 2020; Kumbhare et al., 2019; Langhammer et al., 2018; Lee et al., 2017). Primary care providers can play an important role in promoting physical activity for all older adult patients at every visit, using an individualized approach. Resources are available to assist with this effort.

CASE STUDY

A. G., a 72-year-old man, comes in for follow-up of laboratory test results. He has coronary artery disease (CAD), hypertension (controlled), impaired fasting glucose (IFG), benign prostatic hyperplasia, and mild degenerative joint disease (DJD). Since being diagnosed with IFG he has cut back on soda consumption and is also seeing a dietitian for counseling. He is a former smoker (last use 12 years ago) and admits to being a "couch potato." Current medications: Lisinopril 20 mg orally (PO) daily, hydrochlorothiazide 12.5 mg PO daily, simvastatin 20 mg PO daily in the evening, and tamsulosin 0.4 mg PO daily. He has a prescription for nitroglycerin 0.4 mg sublingually as needed for chest pain but has never needed to use it. He occasionally takes Tylenol Arthritis Pain or Aleve if the DJD bothers him. Vital signs are blood pressure (BP) 134/72, heart rate (HR) 70 (reg), respiratory rate 18 breaths per minute (bpm) (afebrile), and BMI 34.2. Pulse oximetry is 99% on room air. Laboratory test results are unremarkable except for high-density lipoprotein (HDL) 32 and fasting blood sugar (FBS) 125. Mr. G expresses frustration at the lack of change in his fasting glucose despite cutting back on soda. He asks you, "What else can I do? I don't want to get diabetes." You encourage him to increase his physical activity level gradually, beginning with walking.

1. What strategies will you use to promote increased physical activity in this patient?
2. What additional objective data will you be assessing for?
3. What national guidelines are appropriate to consider?
4. Will you need to order any tests before he begins this program? If so, what tests?
5. Are there any screening tools that you want to use?
6. What is your plan of care?
7. Are there any *Healthy People 2030* objectives that you should consider?
8. What additional patient teaching may be needed?
9. How will you follow up on the planned increase in physical activity?

CHAPTER 4

Nutritional Support in the Older Adult

Evelyn Duffy

AGING EFFECTS ON NUTRITIONAL HEALTH

Nutritional issues in older adults are common. Both extrinsic and intrinsic factors contribute to the risk for developing undernutrition and overnutrition/obesity (Kalan et al., 2020). Malnutrition can be present in both conditions (Scrinis, 2020). Identifying factors that can contribute to a decline in nutritional health can allow for safeguards to be put into place before the patient experiences malnutrition (Haines et al., 2020). Extrinsic factors include access to transportation, which can limit access to both food and health service, safety of the environment in which the patient lives that can compromise the ability to get outside and exercise, and the cohort of the older adult. If more traditional male and female roles were adopted, with the loss of a spouse, a male may have no experience in food preparation and undernutrition becomes a very real possibility. Food insecurity in older adults was evaluated in a study by Fernandes et al. (2018). They note that 23% of older adults live in a food insecure household. Those 70 to 74 years old, females, those with less education, and those with low income or reporting it, was difficult to live within their current income. The group living in a food insecure household were also more likely to have a chronic disease or obesity. When the choice is between medical care, medications, or food, the latter is the priority. It is not surprising that the group reporting food insecurity also reported a lower quality of life (Fernandes et al., 2018, Steiner et al., 2018).

PHYSIOLOGICAL CHANGES WITH AGING THAT AFFECT NUTRITIONAL HEALTH

The process of aging itself affects the ability of older adults to achieve adequate nutrition. Changes in physiology from the loss of olfactory sense, decrease in the sense of taste, compromised dentition, decreased saliva, decreased gastric acidity, lactose intolerance, decreased intestinal mobility, and constipation all affect the nutritional status of older adults. The result of these challenges can be involuntary weight loss (Chapter 7, Symptoms and Syndromes) and malnutrition. Patients may not be aware of the loss of weight, or they present with that concern.

Age affects the gastrointestinal (GI) system from the mouth to the rectum. In the mouth the tooth enamel thins, increasing the risk of decay, which is increased further by the wearing down of the surface of the tooth, often exposing the pulp. There is bone loss in oral structures so that teeth may become loose. Improved dental hygiene and regular dental care have resulted in fewer older adults becoming edentulous, but dentures are not yet a thing of the past and tooth loss is still quite common. Root canals and implants are costly and not covered by Medicare, leaving many older adults unable to afford these options. Medicare managed care plans often include dental coverage and have resulted in the increase in the older adult population choosing these commercial insurance plans (Meyerhoefer et al., 2019).

In older adulthood, the oral mucosa thins and there is less saliva production. This is compounded by many medications commonly used by older adults, especially those with anticholinergic properties. The lack of saliva makes the creation of a food bolus difficult and increases the risk of dysphagia. The number of taste buds on the tongue declines with age, decreasing or changing the sense of taste. The sense of smell may decrease or be absent, and the combination of decreased taste and smell results in a decrease in the perception of the flavor of food. Flavor is what is often referred to as the "taste" of food, but flavor is a result of smell and taste, as well as the qualities of food that stimulate the pain fibers on the tongue, namely spiciness, temperature, and texture. When older adults cannot appreciate the flavor of food, they often lose their appetite and loss of appetite is a leading cause of malnutrition (Fluitman et al., 2021).

With aging there is an increase in body fat and decrease in lean muscle mass. Fat doesn't metabolize nutrients, so the result is a decrease in the metabolic rate and calories burned. This decreases the caloric need but not the nutrients required, which remain the same or increase. The diet of older adults

© F.A. Davis Publishing

needs to include foods that are nutrient dense (Baugreet et al., 2017). Both medication and disease common in older adults contribute to a decrease in hydrochloric acid production and a subsequent decline in the absorption of micronutrients. Although the liver decreases in size with aging, it maintains function, and decreased serum albumin should not be considered a normal change with aging. However, serum albumin is not a reliable marker for malnutrition because it is a negative acute phase protein and decreases in response to inflammation, which occurs with many chronic diseases that are common in older adults. There is a decline in intestinal motility which, when combined with decreased fluid intake and a decrease in body fluid, increases the possibility of constipation (An et al., 2018).

A loss of functional ability can also compromise the ability to meet nutritional requirements. When instrumental activities of daily living (IADLs) are affected, it may impair ability to get to the store and purchase food, as well as coordinate and prepare food in the kitchen. A decline in activities of daily living (ADLs) can make the process of eating challenging. Diseases such as depression, cognitive impairment, or stroke can all affect the ability to use utensils or the desire to feed oneself. To help those with physical limitations, the use of positioning or adaptive equipment, the introduction of finger foods, or feeding the patient can improve nutrition. Nurse practitioners should consider referral to occupational therapy for any patient experiencing feeding, eating, or swallowing difficulty. Occupational therapists are essential to helping patients address these needs and improve functional independence (American Occupational Therapy Association, 2017).

CALORIC NEED

A calorie is a measure of energy, and caloric needs are based on energy expenditure. As adults age and muscle mass declines, so does the metabolic rate, energy expenditure, and caloric need. The recommended daily caloric intake is dependent on activity level and sex. Recommendations for women older than 65 years include: sedentary 1,600 kcal; moderately active 1,800 kcal; or active 2,000 kcal. For men, the requirement is greater: sedentary 2,000 kcal; moderately active 2,200 kcal; active 2,600 kcal to age 75 years, and then it declines to 2,400 kcal. To calculate caloric needs for an individual, an excellent online resource is available at http://www.bmi-calculator.net. At this site, using the Harris Benedict Equation, you can calculate caloric needs as well as body mass index (BMI), body fat percentage, and basal metabolic rate (BMR). Using the calculator, you can also determine calories needed for weight loss or weight gain over a specified amount of time.

NUTRIENTS

Although the need for calories decreases as adults age, the need for nutrients does not, and in some cases may increase, as it does for calcium (Clegg & Williams, 2018). This increases the challenge of meeting nutritional needs. The current edition of *Dietary Guidelines for Americans 2015–2020* (8th ed.) was published in 2020 and is available for download at https://health.gov/sites/default/files/2019-09/2015-2020_Dietary_Guidelines.pdf. Appendix 7, *Nutritional Goals for Age-Sex Groups Based on Dietary Reference Intakes & Dietary Guidelines Recommendations*, is a comprehensive list of all nutrients for adults over the age of 50 years (see Table 4-1).

TABLE 4-1 Daily Nutritional Goals for Age–Sex Groups Based on Dietary Reference Intakes and *Dietary Guidelines* Recommendations

	FEMALE 51+	MALE 51+
Calorie level(s) Assessed	**1,600**	**2,000**
Macronutrients		
Protein, g	46	56
Protein, % kcal	10–35	10–35
Carbohydrate, g	130	130
Carbohydrate, % kcal	45–65	45–65
Dietary fiber, g	22.4	28

Calcium and Vitamin D

Aging affects the levels of both calcium and vitamin D. The role of both calcium and vitamin D in maintaining healthy bones and teeth is well understood. Calcium is also important in maintaining cell structure and has a role in almost every system in the body. It is responsible for vascular contraction and vasodilation, muscle function, nerve transmission, intracellular signaling, hormonal secretion, and in the clotting cascade. An expanded role of vitamin D in the health of the cardiovascular, respiratory, endocrine, nervous, and immune system has been noted, as well as its effect on the expression of genes that can cause cancer.

Serum calcium levels are maintained with very narrow limits of 8.5 to 10 mg/dL. Serum calcium reflects both calcium bound to protein and ionized calcium. When albumin is low for any reason, the serum calcium may be artificially low, and a corrected calcium needs to be calculated. The formula, *Corrected calcium (mg/dL) = measured total Ca (mg/dL) + 0.8 (4.0 - serum albumin [g/dL]), where 4.0 represents the average albumin level in g/dL*, is complex, but apps and online calculators are readily available. To complete the calculation, you must know both the serum calcium and albumin, so it is important that the laboratory test includes both measures. Many basic metabolic panels do not include albumin. Although ionized calcium will provide a more accurate measure, it is not used routinely due to the cost. It is appropriate to order if the patient has either hypocalcemia or hypercalcemia as calculated from serum calcium. Aging affects the absorption of calcium from the intestines and the ability of the kidney to synthesize $1,25(OH)_2D_3$, which helps to regulate calcium absorption. The increase in lactose intolerance with aging can contribute to low intake of calcium due to the avoidance of dairy products. The current daily nutritional goal for calcium for adults older than 50 years is 1,200 mg a day for women and 1,000 mg a day for men. Acquiring calcium from food sources rather than taking supplements is preferred because that approach also results in the consumption of other nutrients.

Screening for vitamin D deficiency has become routine in many practices, and a serum 25(OH)D is the correct test to order. Levels less than 30 nmol/L (less than 12 ng/ml) are associated with poor bone health. Levels between 30 and 50 nmol/L (12 to 20 ng/mL) may represent inadequate levels, but a level greater than or equal to 50 nmol/L (greater than or equal to 20 ng/mL) is considered adequate. Very high levels greater than 125 nmol/L (greater than 50 ng/mL) can result in adverse effects. Synthesis of vitamin D occurs in the skin and depends on exposure to sunlight. With aging, the skin's ability to convert vitamin D declines. Dark-skinned individuals require more sunlight to stimulate the production of vitamin D. Vitamin D is not present in many foods, but it is often fortified in dietary sources. The current daily recommendation for vitamin D is 600 IU for those adults older than 50 years and 800 IU for those older than 70 years. High doses of vitamin D supplementation are contraindicated in hyperparathyroidism, so a parathyroid level may be indicated prior to initiating therapy if there are symptoms or signs of that disorder. The current use of vitamin D supplementation is being questioned as several intervention studies have not been able to show a benefit (Amrein et al., 2020).

Vitamin B_{12} and Folate

Vitamin B_{12} is necessary for DNA synthesis and red blood cell production. It is a nutrient present in animal-based foods or from supplements. Vegetarians and those who abuse alcohol are at risk for B_{12} deficiency. Several common medications can interfere with the absorption of B_{12}, including metformin, proton pump inhibitors, and H_2 blockers (Mohn et al., 2018). A deficiency of vitamin B_{12} can result in a megaloblastic, macrocytic anemia and neurological symptoms. Peripheral neuropathies, cognitive impairment, and functional disability can all result from the deficiency.

Folate, folic acid, is also a B vitamin, B_9. Large amounts of folic acid have the potential to mask a vitamin B_{12} deficiency. Like B_{12}, it is necessary for DNA metabolism and red blood cell development. Folate is present in dark leafy green vegetables, liver, and lentils. Analysis of older adults' food and energy intake found that there was a decline in the consumption of micronutrients, including B vitamins. Their diets were high in fats and added sugars, and they were possibly consuming too much folate (vitamin B_9), which since 1996 has been mandated by the U.S. Food and Drug Administration (FDA) to be included in grain products to prevent neural tube defects in babies. If older adults don't get enough vitamin B_{12} in their diet the folic acid may exacerbate some of the symptoms of B_{12} deficiency.

Fiber

The recommended daily reference intake for fiber in adults older than 50 years is 22.4 g for women and 28 g for men. To put this into perspective, a cup of oatmeal contains 9 g of fiber whereas an apple is just over 2 g. The intake of dietary fiber is often low in older adults and if increased too quickly can result in bloating and gas. Barkoukis (2016) recommends increasing intake of fiber at 3 to 5 g increments twice weekly. The role of fiber in improving glycemic control, reducing cholesterol, increasing stool bulk, and decreasing transit time, which is increased in older adults and contributes to constipation, is critical to adequate nutritional health.

In addition to these benefits, fiber-rich foods such as fruits, vegetables, and whole grains increase the total intake of vitamins, minerals, and antioxidants. Foods low in fiber are also often those foods with a lower nutrient composition and decrease the nutrient density of the older adult's diet and increase the risk of malnutrition and obesity. When older adults are very frail, careful assessment is needed to balance their nutritional need with the possibility that a diet high in fiber may cause early satiety. A diet high in fiber requires adequate fluid intake to avoid the development of constipation or, even in the most severe case, bowel obstruction.

DEHYDRATION

Dehydration is a form of malnutrition. The risk for dehydration increases with age. The physiological changes with aging increase the risk of inadequate fluid. A decrease in fluid consumption can be a direct result of the decline in thirst sensation or result from a fear of incontinence. More fluid means more trips to the bathroom, which can be challenging to older adults with functional limitations from arthritis or other chronic disease, cognitive decline, or frailty. Concentration of urine by the kidneys is decreased, resulting in less fluid being

© F.A. Davis Publishing

reabsorbed and smaller fluid reserves (Vilmundardottir & Skuladottir, 2021). These changes may be complicated by medications, particularly anticholinergics and diuretics.

Dehydration can result in constipation, fecal impaction, cognitive impairment, further functional decline, and even death. The role of dehydration in the development of delirium, while often multifactorial, is drawing increased attention (Mudge et al., 2021). Conversely, delirium can result in dehydration. Risk factors for dehydration include frailty and cognitive and sensory impairment, all of these are also risk factors for delirium.

FEEDING

Current practice encourages the use of oral food intake to meet the nutritional needs of older adults in all settings in patients with the ability to consume food orally. If a patient is having difficulty with oral intake, a complete physical examination is warranted to determine whether there is a treatable cause. A multidisciplinary team evaluation can help determine whether there are means, such as therapy or utensil modification, that could ameliorate the problem without the use of nutritional supplementation. Discussing the patient's food preferences, modifying the environment, or providing assistance with feeding are all strategies that may be effective. Speech therapists can be particularly helpful in finding a way for patients to meet their nutritional needs by prescribing thickened liquids, special straws that control the amount of liquid delivered, or diets to address swallowing challenges. If the issue is a lack of appetite, adding an appetite stimulant to the patient's regimen temporarily may be appropriate. Several options are available, although none have clear evidence for use in older adults. Megestrol (Megace) improves appetite and increases weight in patients with cancer and cachexia, but there is limited evidence of effectiveness in older adults. It should not be used in patients who are sedentary, due to an increased risk of thromboembolism. Mirtazapine (Remeron) is an antidepressant that has a noted side effect of weight gain. Use as an appetite stimulant would be off label but could be a choice in those patients who also have a depressed mood. Risk factors include dizziness, orthostatic hypotension, and falls. Dronabinol (Marinol) is a manmade form of cannabis used as an appetite enhancer. It acts on the central nervous system (CNS) and could have significant CNS side effects. If the patient is unable to meet his or her caloric or nutritional needs despite these measures, nurse practitioners must identify the least invasive intervention to increase the patient's intake to meet his or her needs.

ORAL NUTRITIONAL SUPPLEMENTS

Oral nutritional supplements can be recommended for those patients whose diet alone is not adequate to meet their caloric or nutritional requirements. Coverage by Medicare or Medicaid in ambulatory patients is inconsistent, but if available, it requires documentation of weight loss, albuminemia, or other symptoms of malnutrition. The Centers for Medicare and Medicaid Services (CMS) defines involuntary weight loss that must be clinically investigated as 5% in 1 month, 7.5% in 3 months, or 10% in 6 months.

Most oral supplements contain from 240 to 360 calories. Depending on the patient's needs, one to three cans daily can be recommended. The best practice is to take the supplements between meals, not instead of a meal. See Table 4-2 for a comparison of commonly used nutritional supplements. There are subtle differences among products, and most are available in sugar-free versions for use in older adults with diabetes. Formulas to help with diabetic nutrition while protecting blood glucose control are sold as Boost Glucose Control (Boost, 2018) and Ensure Glucerna (Abbott Nutrition, 2018). Nutritional beverages, such as Ensure and Boost, contain a base of calories from carbohydrates, fats, and proteins, with added vitamins and minerals. Each supplement brand also offers versions with higher levels of nutrients, such as protein, to meet a patient's individual needs (see Table 4-2). For patients who cannot tolerate the shake consistency, Abbott makes a clear liquid product.

In 2018, Sauer et al. analyzed original studies on the impact of nutritional interventions in community-dwelling older adults who had or were at risk for malnutrition. Twenty articles

were included in the analysis. In addition to oral nutritional supplements other interventions were implemented in the studies, including advice from a dietitian, counseling, and home visits. These benefits included improved nutritional and functional status, increased weight, improved muscle (handgrip) strength. There was inadequate evidence in the 20 studies included to conclude that nutritional interventions had an impact on complications, readmissions to hospital, morbidity, or mortality.

NUTRITIONAL SUPPLEMENTS AND THE HOSPITALIZED PATIENT

Hospitalized patients have a high incidence of malnutrition. Malnourished patients are more likely to experience poor outcomes, be hospitalized longer, and incur higher health-care costs (Ruiz et al., 2019). For the surgical patient this can be complicated further by the surgical stress response that results in metabolic activation requiring an increase in nutrients, particularly protein, to support healing and recovery (Gillis & Wischmeyer, 2019). Gillis and Wischmeyer recommend that nutritional interventions need to be implemented before the surgical procedure and continued postoperatively to address increased nutritional need. The use of the Duke University Preoperative Malnutrition Score is one method for assessing the need for intervention. For critically ill hospitalized patients this often means the use of enteral nutrition (EN) or parenteral nutrition (PN). Currently there is much debate regarding the best time to initiate either EN or PN, the proper nutrients for best outcome, the tradition of measuring gastric residual, and the method of continuous feeding (Arabi et al., 2017). These are all areas that present the challenge of future exploration to determine the best practice based on evidence. Enteral feedings in the hospitalized patient can contribute to GI motility disorders. The most commonly seen problems are constipation and diarrhea.

NUTRITION AND DISEASE

Wound Healing

Nutritional intervention can help to both prevent and heal pressure injuries (Wong et al., 2019). The financial benefit is greatest for prevention of pressure ulcers. Inadequate nutrition alters several important components of wound healing, including immune function, collagen synthesis, and wound tensile strength and yet the contribution of nutrition in wound healing may be overlooked. Patients with involuntary weight loss and protein calorie malnutrition are at increased risk for delayed and impaired healing. Chronic wounds are associated with a long-term inflammatory state that can cause catabolic metabolism, protein calorie malnutrition, and dehydration. Patients given adequate nutritional supplements, orally or with the use of enteral or parenteral feedings develop fewer pressure ulcers, and their existing pressure ulcers heal faster. Providing nutritional supplements corrects deficiencies of macronutrients and micronutrients and provides nutrients for safeguarding and strengthening tissue and supporting tissue repair. The 2019 Prevention and Treatment of Pressure Ulcers/Injuries: Quick Reference Guide includes nutrition as one of its five key recommendations. In addressing nutrition, they include 15 specific evidence-based actions.

Oral nutritional supplements available over the counter can be recommended for enhancement of healing in those with calorie and protein malnutrition. When extra calories are not desirable for the enhancement of healing in the normal-weight or overweight adult, consider the use of whey protein supplements, which are low in calories in the powder form, widely available, and inexpensive. The 2019 Guidelines recommend the specific addition of arginine, zinc, and antioxidant nutrition along with protein for malnourished patients with stage 2 or greater wounds. See Table 4-3 for a comparison of oral nutritional supplements designed to optimize wound healing.

USE OF ENTERAL NUTRITION

A guideline for the Care and Management of Enteral Feeding in Adults was published by the Royal Devon and Exeter National Health Foundation Trust (2015). They emphasize that oral food intake is always preferred, and that enteral feeding should only be considered when nutritional needs cannot be met orally. The overall consideration for enteral feeding is that the patient is malnourished or at risk and has an inadequate or unsafe intake and an intact gastrointestinal (GI) tract. For EN to be effective and safe, the patient must have a GI tract with sufficient length and absorptive capacity to obtain nutritional benefit. Their recommendations include the use of multidisciplinary teams, the use of nasogastric route for a short term of less than 4 weeks with the use of a percutaneous endoscopic gastrostomy (PEG) tube when nutrition is required for more than 4 weeks. Common reasons to consider PEG tube insertion include dysphagia due to neurological disease or stroke, head and neck malignancy with accompanying dysphagia, GI dysfunction or malabsorption, upper GI obstructions, cystic fibrosis, or psychiatric disease. The American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.) clinical practice guideline recommends that patients on admission to the intensive care unit (ICU) are assessed for nutritional risk and that enteral nutrition (EN) be initiated within 24 to 48 hours in patients who are unable to maintain nutrition themselves (Taylor, et al., 2016). Early initiation of EN in those patients unable to eat maintains the integrity of the GI system, which in turn decreases physiological stress and improves the immune response with the result of decreasing disease severity and rate of infection as well as a reduction in mortality (Taylor et al., 2016). An exception to the recommendation for early initiation of EN is when prolongation of life is not in the patient's best interest.

ENTERAL FEEDING IN PALLIATIVE CARE

Malnutrition and cachexia adversely affect cancer patients' quality of life at many points during the course of their care. During noncurative phases of cancer treatment, improved nutrition via enteral feeding can improve the patient's quality of life by decreasing nausea, vomiting, and pain related to eating. It can also postpone loss of autonomy. Oral feeding problems and weight loss in patients with dementia are expected in the late course of the disease, at a point where it

is not possible to determine the patient's desires. In addition, oral feeding may increase the risk of developing pneumonia due to aspiration. In view of conflicting results from recent research about whether enteral feeding improves nutrition and length of life, particular care should be taken in deciding whether patients with dementia should have a gastrostomy. A review of current evidence regarding the advantage of artificial nutrition in end-stage dementia warned that initiating tube feeding resulted in negative outcomes, including aspiration pneumonia, malnutrition, and expedited death (Newman et al., 2020)—the very outcomes initiating tube feeding was intended to prevent. Decisions regarding enteral nutrition (EN) during end-of-life care or where patients are not lucid enough to make an informed judgment are particularly challenging and must be made on a case-by-case basis, considering the patient's wishes, if known.

A multidisciplinary approach is appropriate to determine whether all the patient's needs have been assessed. Request a consultation from a speech and language therapist to evaluate for dysphagia, which is common in late dementia, as well as other neurological disorders, including Parkinson's disease and head and neck malignancies. Educate the family about the possible complications and the possibility that the patient may need to be restrained, should a feeding tube be inserted, to prevent unintentional removal. Offer the alternative of comfort feeding, in which the patient is offered safe and preferred foods in a supported and assisted environment as desired.

MALNUTRITION

Signal Symptoms: Deficit in muscle mass, depleted visceral protein.

Description: Malnutrition is a condition resulting from inadequate intake of calories and/or protein, or an inability to absorb and/or digest adequate calories and/or protein (Corish & Bardon, 2019). Malnutrition can result in decreased quality of life, is a predictor of mortality, and results in higher health-care costs, especially during hospitalization (Mangels, 2018). The World Health Organization "Malnutrition Fact Sheet" (2021) further expands the definition to include "undernutrition (wasting, stunting, underweight), inadequate vitamins or minerals, overweight, obesity, and resulting diet-related noncommunicable diseases." Obesity and the related nutritional challenges are discussed later in this chapter. Although undernutrition and malnutrition are often used interchangeably and represent the same nutritional deficit, there are varying types of malnutrition depending on the initial insult. Malnutrition is the result of many interconnected factors both related to diet and non-dietary factors, and each of these can affect the health outcomes (Scrinis, 2020). The role of inflammation has been identified as a key component of malnutrition. Starvation-related malnutrition is a result of chronic starvation but lacks an inflammatory component (e.g., anorexia nervosa); chronic disease-related malnutrition is a result of the presence of mild to moderate chronic inflammation (e.g., organ failure or rheumatoid arthritis); and acute disease/injury-related malnutrition is attributed to acute and severe inflammation (e.g., burns, trauma, or acute systemic infection) (Scrinis, 2020). Protein-calorie malnutrition is diagnosed by a combination of clinical factors. Generally, an unexplained involuntary weight loss and a drop in the serum albumin level to less than 3.5 g/dL may be indicative of a nutritional deficit. However, because a decrease in serum albumin and prealbumin levels is also understood to reflect the inflammatory response it is important to focus on the history and physical examination of the patient rather than depending on laboratory values alone (Keller, 2019; Soeters et al., 2019). Undernutrition in older adults is multifactorial: age-related organ changes; psychosocial factors such as depression, social isolation, and poverty; and functional decline pose risks for developing this often underrecognized medical condition (Mangels, 2018; O'Keeffe et al., 2019). Despite the increased prevalence of malnutrition in older adults, it often remains underdiagnosed.

Etiology: To identify modifiable determinants of malnutrition, O'Keeffe et al. (2019) embarked on a systematic review of the literature. They included 23 studies and 30 potential factors in the final analysis. The quality of the studies and what they identified as a high risk of bias resulted in their concluding that strong evidence is lacking in identifying modifiable factors. They did note that moderate evidence supported hospitalization, eating dependency, poor self-perceived health, poor physical function, and poor appetite as determinants of malnutrition (O'Keeffe et al., 2019). Although several factors can lead to malnutrition in older adults, certain age-associated factors are precursors to malnutrition, including reduced food and micronutrient intake, decreased absorption of ingested food, and the increased bodily demands for protein, calories, or micronutrients because of physiological stressors (O'Keeffe et al., 2019). Inflammation is increasingly recognized as a risk factor for malnutrition due to the metabolic stressors on the body during an inflammatory state. Inflammation influences both nutritional requirements and intake, causing anorexia while increasing resting energy expenditure (Keller, 2019).

Occurrence: The State of Senior Hunger in America 2019 (https://www.feedingamerica.org/research/senior-hunger-research/senior) notes that nearly 5.2 million seniors, or 1 in 14, were food insecure in 2019.

Age: Malnutrition can occur at any age. Frail older adults and people more than 80 years old are at the highest risk for malnutrition. Prevalence is higher in women because of the higher number of women than men in this age bracket. In 2016, the Administration for Community Living (ACL) estimated that 50% of older Americans are malnourished (ACL, 2020).

Ethnicity: Because the reason for malnutrition varies, no specific ethnic prevalence is known.

Contributing Factors: Any of several factors may contribute to malnutrition in older adults. Some physical factors include decreased olfactory sensitivity; loss of taste buds; being edentulous; gastroesophageal reflux disease; dysphagia; poor dietary habits; certain chronic diseases with or without an inflammatory component such as intestinal ischemia, hyperthyroidism, chronic pain, chronic obstructive pulmonary disease, stroke, constipation, chronic impaction, malabsorption syndromes, obesity, and cholelithiasis (O'Keeffe et al., 2019; Scrinis, 2020). Limitations in the ability to not only prepare

© F.A. Davis Publishing

food but also to eat due to tremors and arthritic upper extremity conditions can lead to malnutrition. Using the Mini-Nutritional Assessment, an association between frailty and malnutrition was found to be bidirectional, meaning that those who are frail are more likely to be malnourished and malnourishment is a risk factor for frailty (Lorenzo-López et al., 2017). Medications have the potential to affect nutritional status in multiple ways and deserve a careful review. As the number of medications increase, the likelihood of interference increases. Medications may alter taste and smell (antibiotics, antihistamines, antifungals, chemotherapeutic agents), decrease salivary gland production contributing to dry mouth (anticholinergic agents), and cause malabsorption of nutrients (acetylcholinesterase inhibitors, proton pump inhibitors, statins, antiplatelet medications, and metformin) (Little, 2018). Psychosocial factors including dementia, depression, social isolation, low income, and lack of transportation all can contribute to the risk for malnutrition (Mangels, 2018). Hospitalization and living in a residential care setting with a restricted diet, drug-nutrient interactions related to polypharmacy, social isolation, and ultimately poverty, also may contribute to malnutrition (Mathewson et al., 2021).

Signs and Symptoms: Identification of older adults at risk for malnutrition is a complex process; however, unexplained weight loss is identified as the best factor for predicting increased risk of malnutrition. Assessment of malnutrition is complex because it involves investigation of physiological, pathological, psychological, social, functional, environmental, and financial parameters to determine the possible causes of the malnutrition. Comprehensive assessment of the following diagnostic characteristics is essential in identifying at-risk and presently malnourished patients: history and clinical diagnoses, physical examination/clinical signs, anthropometric data, laboratory data, food/nutrient intake, and functional assessment (Keller, 2019). In patients with suspected malnutrition, all risk factors for poor nutritional status should be assessed using objective measures as indicated including screens for depression, mental status examinations, functional status assessments. Several nutritional screening tools have been developed and are available for use. The Mini-Nutritional Assessment-Short Form (MNA-SF) was designed for older adults and includes six questions regarding weight loss, appetite, mobility, psychological stress, neuropsychological problems, and body mass index (BMI) (Haines et al., 2020). It may be used as an initial screening tool and followed by using the full 18-question MNA, including the measurement of albumin, prealbumin, cholesterol, and lymphocyte count. These forms are the most commonly used and have been validated as a nutritional screening device for older adults (Soysal et al., 2019). Another frequently used screening tool is the Malnutrition Universal Screening Tool (MUST), which adds the BMI and the presence of acute disease. Unlike the MNA, the MUST does not include the use of biomarkers.

A thorough review of prescribed and over-the-counter medications is indicated to determine whether the patient is taking any substance that can cause anorexia, such as acetylcholinesterase inhibitors, thiazide diuretics, angiotensin receptor blockers, angiotensin-converting enzyme inhibitors, and potassium-sparing diuretics (Little, 2018). Other medications of concern are those that inhibit the absorption of micronutrients such as proton pump inhibitors, statins, high-dose aspirin, or metformin. The patient on multiple medications, especially when they are medications that appear on the *Beers List of Potentially Inappropriate Medications*, are at increased risk.

An important purpose of the physical examination is to determine whether malnutrition is related to abnormalities in the cardiac, respiratory, intestinal, endocrine, hepatic, neurological, or renal systems. Inspect for signs of nutritional deficiencies such as nail abnormalities, brittle hair, bruising, the presence or jaundice or pallor, cheilosis, glossitis, loss of subcutaneous body fat, muscle wasting, or edema. If a patient is found to be 15% or more below ideal body weight or had a recent loss of 10% under baseline weight, consider protein-calorie malnutrition. Weight loss alone is not diagnostic; using a tool such as the MNA will provide a more reliable assessment (Mathewson et al., 2021)

Body mass index (BMI) is calculated using the formula weight in kilograms divided by height in meters squared. BMI is an effective measurement for obesity, but it is generally not as sensitive in indicating malnutrition. In the normal healthy older adult, the BMI should range from 18.5 to 24.9 kg/m^2; BMI less than 18.5 kg/m^2 generally indicates a weight deficit and is an indication that nutritional intervention is required. A higher mortality rate has been noted in older adults with a BMI less than 23 kg/m^2. Due to changes with aging, the BMI should be used with caution as an indicator of malnutrition in older adults (Padilla et al., 2021).

In older adults, skinfolds may be used as an estimate of body fat. The skinfolds that best represent adiposity include the triceps and subscapular (Padilla et al., 2021). The disadvantage of the use of skinfolds is that the ratio of fat and total body fat is not constant and decreases with age. Handgrip strength should also be assessed over time; a decrease in strength can indicate nutritional deficits related to the loss of muscle function. Low handgrip strength with malnutrition have been found to increase mortality risk (Wang et al., 2019).

Diagnostic Tests: There is no gold standard test for diagnosis of malnutrition. If physical examination raises the concern that a disease is the cause of malnutrition, appropriate studies should be completed to further assess those concerns. Diagnostic studies may also be useful to identify the severity and type of malnutrition. In screening for malnutrition, laboratory values should be considered only as an indirect measurement or as a tool to evaluate treatment. A complete blood count should be ordered to determine anemia and rule out infection and immunocompromised status. Inflammatory markers such as leukocytosis, elevated blood glucose, or C-reactive protein level may be indicators of a nutritional deficit; however, they are not yet considered diagnostically specific for malnutrition (Haines et al., 2020; Keller, 2019). Total lymphocyte counts less than 1,500 $cells/mm^3$ can be noted in malnutrition (Keller, 2019). Protein, iron, folate, and/or vitamin B_{12} deficiencies should be assessed to further identify nutritional deficiencies.

A serum albumin level less than 35 g/L—especially less than 30 g/L—predicts protein depletion and had been the most common biochemical parameter indicated when considering malnutrition (Keller, 2019). However, serum albumin levels can be skewed in patients who are acutely ill or

© F.A. Davis Publishing

have systemic inflammation. These conditions reduce albumin synthesis and can increase its degradation. A low serum albumin can be a predictor of poor surgical outcomes. Because the half-life of albumin is 21 days, serum albumin levels rise slowly following nutritional supplementation. Prealbumin has an average life span of 2 to 3 days; this shorter life span increases its usefulness as an indication of acute change in nutritional state (Keller, 2019). A level below 10 mg/dL is associated with short-term malnutrition. It can be a useful indicator of repletion, especially when refeeding an older adult (Keller, 2019).

Serum transferrin is an acute phase reactant and a transport protein for iron. Its half-life is 10 days. Iron levels, liver disease, and inflammation will impact levels of serum transferrin. In patients with coexisting iron-deficiency anemia, the results will be misleading (normal to elevated serum transferrin). Its usefulness as a measure of malnutrition has been questioned (Keller, 2019). Some of the nutritional screening tools use cholesterol as a measure of malnutrition, but the sensitivity and specificity of this is a measure is very low (Keller, 2019).

Differential Diagnosis: When determining whether a person is suffering from malnutrition, discern if any of the following conditions coexist:

- Anorexia
- Dehydration
- Dementia—alcohol related
- Dementia—Alzheimer related
- Depression—major
- Dysphagia
- Eating disorder
- Failure to thrive
- Feeding problem/older adult
- Nutritional deficiency not otherwise specified

Treatment: Identifying the contributing factors to malnutrition in each individual patient is essential to treating this condition. When possible, a 3-day diet intake should be obtained to determine the severity of the nutritional deprivation. All medications that can cause drug-induced malnutrition should be discontinued or reconsidered or an alternative should be used. Any fecal impaction should be identified and removed. Maximizing the management of chronic diseases that contribute to a decline in appetite or increase the demand for nutrients is critical. Understand that chronic disease will always challenge nutritional adequacy. Because not all factors can be treated, dietary consultation should be ordered to assist in the diagnosis of malnutrition and planning of diet supplementation. Any older adult experiencing a physiological stressor such as surgery, infection, or trauma requires an increase in protein, calories, and micronutrients. If the patient is diagnosed with protein-energy malnutrition (PEM), nutritional support will depend on the patient's medical condition and the degree of the PEM. Enteral nutritional support is considered when the patient's nutritional intake is inadequate to meet physiological requirements for more than 7 days or when the weight loss is more than 10% of the patient's pre-illness weight.

Follow-Up: Patients who are hospitalized for malnutrition or who develop malnutrition secondary to an acute-care hospitalization should be monitored daily for response to the nutritional supplementation. Prealbumin levels can be helpful in this setting. The patient's weight should also be monitored with weekly weights until the malnutrition has been corrected. If a psychosocial factor contributed to the malnutrition, periodic review of the patient's improvement is warranted.

Sequelae: An older person's initial reaction to prescribed nutrient supplements may worsen malnutrition when used as a meal replacement instead of supplementation. Patients who are malnourished can develop sarcopenia and/or cachexia. Sarcopenia, defined as a loss of muscle mass together with low strength and loss of physical performance, has been associated with inadequate intake of calories, malnutrition, and the use of certain medications (Montes et al., 2017). Cachexia is defined as a complex syndrome characterized by loss of weight, mostly due to loss of muscle mass resulting from metabolic abnormalities due to disease (Marshall & Agarwal, 2019). Long-term malnutrition increases the risk of morbidity and mortality.

Prevention/Prophylaxis: All older adults should be assessed for food insecurity and signs of malnutrition. A two-step approach for identifying malnutrition is suggested using the MNA (Haines et al., 2020). The MNA-SF has been studied and approved as an initial screening tool when undernutrition is suspected in the older adult population. The MNA-SF is highly correlated with the MNA, with a diagnostic accuracy of 98.7% for predicting undernutrition. The six-item MNA-SF can be easily used in the first step of the process because it does not require anthropometric testing. A score between 8 and 11 points indicates risk for malnutrition. For the second level of screening, the MNA is considered the most reliable and validated nutritional tool. It is appropriate for use in the outpatient and nursing home settings. It does not require invasive laboratory testing and is cost-effective. The tool consists of an anthropometric assessment, general assessment, dietary assessment, and a self-assessment that engages the older adult to assess their nutritional status. International studies have validated that an MNA score between 17 and 23.5 indicates risk of malnutrition and intervention is indicated. (Haines et al., 2020).

Referral: Referring patients who are malnourished to a specialist depends on the cause of the nutrition depletion. If food insecurity is an issue because of access to food or financial concerns, many health systems are now developing "Food Pharmacies" that allow providers to write prescriptions to meet dietary needs. A dietitian should be consulted for a nutritional support, evaluation, and patient education, including help with meal planning. Community-dwelling older adults can be referred for Meals on Wheels or provided information on the location of Agency on Aging congregate meal sites. Meal sites can serve the additional purpose of providing socialization and may combat depression and loneliness, contributors to malnutrition. If social isolation, low income, and/or functional status contributed to the development of malnutrition, the patient should be referred for social services. Patients with financial needs should be evaluated to see if they can qualify for food assistance and could be enrolled in the Supplemental Nutrition

© F.A. Davis Publishing

Assistance Program (SNAP) (Pomeranz, 2017) and/or participate in community-based food bank programs. Older adults who have difficulty with food preparation or eating can be referred to an occupational therapist for evaluation for adaptive equipment and retraining.

Patients with swallowing difficulties need to be referred to a speech therapist for evaluation and plan of care. Patients who need long-term enteral support should be referred to a gastroenterologist for consideration of a percutaneous endoscopic gastrostomy (PEG) tube or, in some cases, a feeding jejunostomy. For the patient diagnosed with a terminal illness, discuss the patient's and family's decision on nutritional support before beginning any intervention.

Education: For the alert ambulatory older adult, review the Dietary Guidelines for Americans and My Plate guidelines (www.myplate.gov). Teach family members caring for patients who are cognitively impaired or physically disabled about dietary requirements and nutritional supplementation. Caregivers and older adults can improve nutritional status by simple measures, such as preparation of an adequate diet, hand feeding, adequate-fitting dentures and oral hygiene, and adding liquid nutritional supplements between meals.

OBESITY

Signal Symptoms: Elevated body mass index (BMI), central obesity, generalized obesity.

Description: Obesity rates among older adults have been increasing over the past several decades, making it important to pay particular attention to weight and associated metrics to manage risk for chronic disease and disability. Obesity can be defined as abnormal or excessive fat accumulation that presents a risk to health. There are a variety of methods to determine whether an individual is obese; simply weighing a patient, however, does not distinguish the effect of muscle versus body fat on weight. A very muscular patient may weigh the same as an individual living with obesity. Other metrics, such as BMI, have been internationally accepted as a good indicator of percentage of fat mass at the population level. A BMI ≥25 kg/m^2 is considered overweight and a BMI ≥30 kg/m^2 is obese. Standardized nomograms or online calculators can easily determine BMI, and to further stratify health risk, obesity is often subdivided into classes (Class I: BMI=30.0–34.9, Class II: BMI=35.0–39.9, Class III: BMI ≥40.0) (Centers for Disease Control and Prevention [CDC], 2021a). Unfortunately, there are limitations to BMI because it does not take into consideration differences in age, fat distribution, sex, and ethnicity. These limitations are important to understand, particularly when interpreting and translating research data into practice. For example, the decrease in bone mineral content with increasing age leads to a decrease in height, which can lead to an overestimation (inflation) of BMI. Another aging consideration is the medical hypothesis called the "obesity paradox," which suggests that fat mass becomes less harmful or even "protective" in individuals as they age with catabolic, chronic comorbidities. New research suggests, however, that age-related redistribution of subcutaneous adipose tissue from the extremities to the trunk (and especially to the visceral organs) is not protective and that survival advantage of a higher BMI in older adults may instead be explained by a higher lean (muscle) mass (Bosy-Westphal & Muller, 2021; Carbone et al., 2019). BMI does not consider sex differences, and women tend to have greater amounts of total body fat than men with an equivalent BMI. Established BMI cut points correspond to adverse disease processes (Batsis & Zagaria, 2018); however, these cut points may not be appropriate for all individuals and populations. Individuals who are physically fit will also have a higher BMI due to increased lean muscle mass compared to fat mass (Centers for Medicare and Medicaid Services [CMS], 2011). Risk for disease may be greater at lower BMI in some populations. Among those of Asian descent, for example, there is a higher risk of developing type 2 diabetes mellitus and cardiovascular disease at lower BMI cut points currently established for overweight and obesity, and clinicians may potentially miss opportunities for earlier treatment/intervention if these differences are not recognized (Misra et al., 2018; WHO, 2004).

More recently, the evolution and implementation of body composition analysis has highlighted the limitations of BMI and obesity-associated health risk (Bosy-Wesphal & Muller, 2021). As noted earlier, BMI does not reflect the percentage of lean (muscle) mass nor the distribution of fat mass (i.e., visceral adipose tissue vs. subcutaneous adipose tissue). Although body site adiposity distribution is clinically

© F.A. Davis Publishing

important, particularly among older adults who have age-associated changes (i.e., a progressive decrease in muscle mass and increase in fat mass), the availability of more sophisticated body composition analysis equipment may not be available in all clinical settings. Hence, the inclusion of waist circumference (WC) as a screening indicator for abdominal obesity in older adults presenting with both general and abdominal obesity (Afonso et al., 2021; Bosy-Wesphal & Muller, 2021). WC is measured from the uppermost lateral border of the iliac crest and should be adjusted by age and BMI; central obesity is a waist measurement of more than 88 cm (35 inches) in females and more than 102 cm (40 inches) in males (NIH National Heart, Lung, and Blood Institute [NHLBI], 2021b). WC cut points can be standardized across all adult ethnic populations except for individuals less than 5 feet tall or individuals with a BMI more than 35. Advanced practice nurses are well-positioned to encourage healthy lifestyles among older adults that include activities to help attain/maintain lean muscle mass, regardless of BMI.

Etiology: Obesity occurs when an individual consumes more calories than they expend. The etiology of obesity is genetic as well as environmental; however, it is difficult to separate the influence of genetics versus the influence of lifestyle habits that individuals and families share. Environmental, social, and cultural influences also determine the risk of obesity. Obesity tends to occur more often when individuals eat high-calorie, high-fat, processed foods or are unable to participate in enough physical activity or exercise. Some medications may cause weight gain by stimulating appetite, affecting how the body absorbs and stores glucose, slowing overall metabolism, and/or causing fatigue (i.e., making physical activity challenging). Examples include antidepressants (selective serotonin reuptake inhibitors), anxiolytics, mood stabilizers, antipsychotics, diabetes medications (insulin, thiazolidinediones, sulfonylureas), steroid hormones, anticonvulsants, antimigraine, treatment for neuropathic pain, opioids, antihypertensives (beta blockers, alpha blockers, calcium channel blockers), antihistamines, hypnotics, and antiretrovirals (Welcome, 2017). Weight gain is often seen as patients quit smoking. A lack of sleep has also been associated with the development of obesity (Norton et al., 2018)

Occurrence: Obesity rates in the United States are on an upward trajectory. Currently, more than two-thirds of Americans are overweight (defined as BMI between 25 and 30 kg/m^2) or obese (defined as BMI greater than 30 kg/m^2).

Age: In 2017–2018, the age-adjusted prevalence of obesity and severe obesity was 42.4% and 9.2%, respectively (Hales et al., 2020). There was no significant difference in the prevalence of obesity between men and women or by age-group: among older adults, aged 60 and older, obesity rates were 43.3% in women and 42.2% in men. Severe obesity in those aged 60 and older was 5.8%.

Ethnicity: Obesity affects some groups more than others. In the United States, non-Hispanic Blacks have the highest age-adjusted rates of obesity (49.6%), followed by Hispanics (44.8%), non-Hispanic Whites (42.2%), and non-Hispanic Asians (17.4%) (Hales et al., 2020).

Contributing Factors: Obesogenic behaviors are complex and influenced by a range of genetic, individual, and environmental factors. Over-consumption of high-energy foods and a lack of physical activity are the main behavioral risk factors for people to develop obesity, but other social determinants/drivers of health, lack of sleep, high stress levels, and sedentary behavior (i.e., prolonged sitting) are just a few of the factors that can play a critical role over the course of a lifetime (Lakerveld & Mackenbach, 2017).

Signs and Symptoms: Usually, obesity can be recognized by the initial physical examination. A height and weight measurement should be obtained when medically necessary at each visit to the care provider. The use of the BMI is the most convenient method to quantify overweight/obesity in the office setting. Measurement of WC can help predict the development of the metabolic syndrome. Skin calipers can be used to measure subcutaneous fat thickness by "pinching" and measuring skinfold thickness. Unfortunately, this assessment technique requires training and strict adherence to measurement protocols that may be impractical to use in a clinical setting.

Associated symptoms that older adults with obesity often present with include feelings of worthlessness, sadness, and hopelessness; individuals should be evaluated for functional limitations, joint pain, decreased mobility, and activity intolerance (Batsis & Zagaria, 2018; Qian et al., 2021). Evidence of loss of muscle strength due to sarcopenia in sedentary older adults with obesity should be assessed, and functional ability to perform ADLs should be measured so that exercise and dietary interventions can be prioritized (Bales & Porter Starr, 2018; Batsis & Zagaria, 2018). Although being underweight significantly increases the odds of pressure injuries, skin conditions are prevalent among older adults living with obesity, making it critical to assess the skin for excoriation and pressure injury (Alipoor et al., 2021).

Diagnostic Tests: Laboratory tests are ordered based on history and clinical presentation. For example, if considered at risk for metabolic syndrome, a lipid profile and fasting glucose levels should be obtained. If hypothyroidism is suspected, a thyroid-stimulating hormone (TSH) level should be ordered. If Cushing's syndrome is suspected, a 24-hour urine cortisol and dexamethasone suppression test is recommended. Laboratory results will help guide future follow-up and/or intervention.

Differential Diagnosis: Determine the ideal body weight (IBW) for height. Patients 20% above are considered obese; those 40% above are morbidly obese. BMI can be determined with easily accessible online BMI calculators.

Treatment: In June 2013, the American Medical Association adopted a policy that recognized obesity as a disease requiring a range of medical interventions to advance obesity treatment and prevention. This policy comes after decades of various weight-loss-targeted (or bariatric/metabolic) surgeries with variable outcomes and health insurance coverage (Batsis & Dolkart, 2015; Purath et al., 2014). Obesity management includes a comprehensive nutritional evaluation and a complete history and physical examination. Important considerations include social drivers/determinants of health, dietary and physical activity patterns, and medication review for medications that may promote weight gain. There are many comorbidities associated with obesity, including but not limited to diabetes, hypertension, dyslipidemia, heart

© F.A. Davis Publishing

failure, coronary artery disease, obstructive sleep apnea, osteoarthritis, and some forms of cancer (American Society of Metabolic and Bariatric Surgery [ASMBS], 2021). The basic treatment for obesity involves a reduction of caloric intake while increasing physical activity. The goal of a standard weight loss regimen should be about 1 to 2 pounds per week; however, it is also important to have a clear understanding of a patient's expectations and degree of motivation (CDC, 2021a, 2021b; Elran-Barak & Segel-Karpas, 2020).

The initial diet should aim at reducing the caloric intake for the female patient to 1,200 to 1,500 calories per day and the male patient to 1,500 to 1,800 calories per day. This goal of caloric reduction can often be obtained by decreasing portion size and limiting high-calorie but poorly nutritious foods. Keeping a daily food diary and counting calories will often help patients to see how much they really consume each day. Commercial programs typically include prepackaged meals, meal replacement entities, or recipes with predetermined calories. Very low-calorie diets that reduce the caloric intake to less than 800 to 1,200 calories per day require strict medical monitoring through a structured program. There are few data to support the use of low-carbohydrate diets over the typical balanced but calorie-restricted diet in terms of safety or efficacy (CDC, 2021a, 2021b). A combined approach of a weight-reduction diet plus a program of exercise is generally recommended. In patients with sarcopenic obesity, an increase in dietary protein and protein supplements should be encouraged, unless contraindicated by other concomitant conditions that restrict protein intake (Bales & Porter Starr, 2018). Weight loss therapy in an older patient with sarcopenic obesity should be tailored to minimize loss to bone and muscle mass (Bales & Porter Starr, 2018).

A high-protein, modest calorie restriction diet combined with exercise for older adults with sarcopenic obesity is recommended because it helps increase caloric expenditure while preserving muscle quality and function (Bales & Porter Starr, 2018; CDC, 2021c). Before beginning any exercise regimen, older adults should determine their level of effort for physical activity relative to their level of fitness; those individuals with chronic conditions should understand whether and how their conditions affect their ability to do regular physical activity safely. In addition, older adults should participate in physical activity that includes balance training as well as aerobic and muscle-strengthening activities to improve/maintain physical function (Bales & Porter Starr, 2018). Current physical activity recommendations call for approximately 30 minutes of moderate activity 5 to 7 days per week; for weight loss without calorie restriction, 1 hour of moderate activity is required. More than 300 minutes a week of moderate-intensity activity, or 150 minutes a week of vigorous-intensity activity, results in greater health benefits. When older adults cannot do 150 minutes of moderate-intensity aerobic activity (i.e., brisk walking) per week because of chronic conditions, they should be as physically active as their abilities and conditions allow (CDC, 2021c). In addition to aerobic activity, muscle strengthening activities that work all the major muscle groups (i.e., legs, hips, back, abdomen, chest, shoulders, arms) is recommended to prevent sarcopenia (Bales & Porter Starr, 2018; CDC, 2021c).

Currently, there are three major groups of drugs used to manage obesity. Drugs work either centrally to limit dietary intake, peripherally to impair dietary absorption, or increase energy expenditure. Although pharmacological therapy is often not used for weight loss among older adults due to lack of safety and efficacy data, there are a few medications currently approved by the U.S. Food and Drug Administration (FDA) for long-term (≥1 year) chronic weight management. These include orlistat (Alli, Xenical), phentermine and topiramate extended-release (Qsymia), naltrexone hydrochloride and bupropion hydrochloride (Contrave), liraglutide (Saxenda), and semaglutide (Wegovy) (Karam & Nathan, 2021). Loraserin hydrochloride (Belviq) was withdrawn from the market in February 2020 and is no longer available in the United States. Despite the proven efficacy of FDA-approved medications, few clinicians prescribe medications for chronic weight management. It is essential to carefully review prescribing information to avoid medication-related side effects and drug/drug interactions and to consider the benefits of weight loss that improve cardiovascular and metabolic risk profiles (Carbone & Dixon, 2018). The FDA does not regulate herbal (botanical) products, vitamins, or supplements the same way it does prescription and over-the-counter medicines; therefore, the use of appetite suppressants/anorexiants (noradrenergic/sympathomimetic agents) should be used with caution because they may be contraindicated in older adults with multimorbidities.

Follow-Up: The treatment of obesity should focus on the short-term weight loss phase and the long-term maintenance phase. Weight loss has been associated with reduced risk of developing type 2 diabetes, improvement in lipid profile, and reduced blood pressure. Patients should be followed closely after they start a diet and exercise program. As patients lose weight, there should be close monitoring of potentially harmful side effects of weight loss, including fluid and electrolyte shifts, cardiac arrhythmias, exacerbation of gout, development of gallstones (cholelithiasis), mood disorders, or disordered eating. The goal is to promote the long-term management of weight with a healthy lifestyle.

Prevention/Prophylaxis: A healthy diet and active lifestyle should be encouraged. (CDC, 2021b; NIH NHLBI, 2021a, 2021b). Those who are eligible for Medicare are now eligible to receive intensive behavioral therapy counseling services for obesity management (BMI ≥30) (CMS, 2011).

Referral: The management of obesity is challenging; commercially available programs may be helpful if more structure is needed. Medically supervised, structured diets that use meal replacements or energy restriction (i.e., low or very low energy) can be effective not only in weight loss but also in improvement in comorbid conditions, depending on the intensity and duration of the intervention (Bales & Porter Starr, 2018). Referral to an endocrinologist is appropriate when dealing with such illnesses as hypothyroidism, Cushing's syndrome, or a history of polycystic ovary syndrome. Finally, referral to a bariatric surgeon may be considered for individuals who have a BMI ≥40 or have a BMI ≥35 and at least two obesity-related comorbidities who are unable to achieve a healthy, sustained weight loss (Mechanick et al., 2020). Bariatric/metabolic surgery works by restricting food intake, causing food malabsorption, or a combination of both methods (ASMBS, 2021). The most common types of metabolic/bariatric surgeries performed include the sleeve gastrectomy and the Roux-en-Y gastric bypass (ASMBS, 2021;

© F.A. Davis Publishing

Thereaux et al., 2015). Emerging evidence suggests that metabolic/bariatric surgery may establish a new body weight set point by altering the physiological mechanisms of body weight regulation, thereby causing acceptable and sustained weight loss and improved quality of life (Nor Hanipah et al., 2018; Susmallian et al., 2018). Age alone should not be a limiting factor as a surgical candidate (ASMBS, 2021; Nor Hanipah et al., 2018).

Education: Teach patients and significant others meal preparation, calorie counts, and fat gram calculation. There are commercial weight loss programs that are available for individuals who prefer individualized, group, or online methods to assist with weight loss. They range in costs so that everyone should be able to find a weight loss program that suits their individual needs. To sustain the clinical benefits of weight loss (i.e., improved insulin sensitivity), exercise training needs to be added to the weight loss intervention. It is important to encourage patients to begin a safe exercise regimen like walking, which is the most recommended exercise program (CDC, 2021b). Older adults should also be encouraged to include resistance, flexibility, and strength training in their aerobic exercise programs. Partnering with older adults to comanage the complexities of obesity will help identify individual goals and optimize care outcomes. Providers should provide the older adult with numerous safe options for increased activity and/or exercising as well as opportunities to learn, shop, prepare, and/or receive balanced nutrition to achieve weight and health-related goals.

CASE STUDY

A. D., an 80-year-old widow, is brought to see you by her concerned daughter, who reports that her mother is not eating and has lost 15 pounds in the past 8 months, "Her clothes just hang on her now." A. D. lives alone in an apartment in low-income senior housing. She has been independent in ADLs, and her daughter takes her shopping or shops for her. Recently, her daughter has noticed spoiled food in the refrigerator, and A. D. seems to be tired all the time, despite her claim that she sleeps well at night. When asked about eating, A. D. responds, "I just don't have an appetite like I used to. It seems like so much trouble to cook a meal just for me."

Past medical history: Coronary artery disease, currently stable—has prescription for Nitrostat 0.4 mg SL as needed for chest pain but has never had to use the medication. Hypertension, currently stable—takes Vaseretic 10 to 25 mg once daily. Hyperlipidemia—stable—takes simvastatin 20 mg PO daily in evening. The patient also takes vitamin D_3 2,000 IU PO daily and omega-3 fish oil daily at bedtime. The patient has no known drug allergies.

A. D. is a retired homemaker and high school graduate. Her husband has been deceased for 5 years. She has three children, all alive and well; her oldest daughter lives nearby, and her other two children live far away but keep in touch by phone. A. D. likes to play bingo at senior housing. She participates in no other activities but has friends in the building. A. D. denies any change in status or any acute health problems outside of feeling more tired than usual and having a poor appetite.

Objective: Petite, slender older woman, using a cane for support, appears her stated age; well-groomed but clothing is too large.

Blood pressure (BP) 134/78 mm Hg, pulse 84 and regular, respiratory rate 16 breaths/min and afebrile. Height 58 inches, weight 88 pounds, BMI 18.4. Last visit 6 months ago, weight was 100 pounds, BMI was 22. Physical examination unremarkable.

1. What additional subjective data are you seeking?
2. What additional objective data will you be assessing for?
3. What national guidelines are appropriate to consider?
4. What tests will you order?
5. What are the differential diagnoses that you are considering?
6. What is your plan of care?
7. Are there any *Healthy People 2030* objectives that you should consider?
8. What additional patient education may be needed?
9. Will you be looking for a consultation?

CHAPTER 5

Settings of Care

Marie Grosh and Evelyn Duffy

Nurse practitioners (NPs) caring for older adults must possess a solid understanding of different settings of care, what services are available to patients in each setting, and the risk versus the benefits of those settings. Additionally, NPs must understand their roles within different contexts, the methods and models of providing care, pertinent information for assisting patients during transitions in care, and advanced care planning. NPs are often the clinicians who can foresee and anticipate a need to change settings (such as sending a patient to the emergency department [ED] or recommending an assisted living placement). Patients and caregivers can easily become overwhelmed trying to navigate through this complex maze, and the NP must play an active role in facilitating successful transitions to and from different settings and providing ongoing care coordination, guidance, and support.

ROLES AND CARE DELIVERY METHODS

Primary Care Providers

Of the more than 325,000 nurse practitioners (NPs) certified in the United States, over 90% of them are primary care providers (PCPs). Primary care includes health promotion, wellness and prevention services, diagnosis and treatment of acute and chronic conditions, and ongoing management of patient health needs, including the needs of older adults (American Association of Nurse Practitioners, 2021). When care is well managed by primary providers, patients have statistically better outcomes. CMS has recognized this concept by initiating financial incentive programs for patients to seek care from their PCP first rather than report to acute care settings or go directly to a specialist, for example the "Primary Care First" program (CMS, 2021a).

NPs are particularly well prepared to serve as PCPs for older adults. Their initial preparation as nurses focuses on the patient's immediate health needs as well as wellness, psychosocial needs, and the patient's environment. Preparation for the role of NP adds differential diagnosis, medical decision making, and prescribing to their scope of practice.

When a patient develops any new symptom, experiences an injury, or has a chronic condition that becomes exacerbated, the NP who serves as a PCP should be the patient's first call. As PCPs, NPs also identify indications for referral and initiate consults to specialty clinicians when needed and are responsible for the overall coordination of patient care. They are essential to the safe transition of the patient from one care setting to another.

In addition to coordinating care with other providers, it is often necessary for NPs to include a family member or friend whom the older adult depends on in patient care. The role these advocates play in an older adult's care can range from minimal assistance (such as attending appointments or providing transportation) to more hands-on assistance in supporting instrumental or basic activities of daily living (ADLs).

Settings for NPs who provide primary care to older adults are not limited to the ambulatory clinic. NPs may evaluate patients using telehealth modalities or make house calls and provide care to patients in their family home or assisted living facility. Skilled and long-term care facilities are also including NPs to provide primary care to residents of those facilities. A study by Mileski et al. (2020) found that when NPs served as PCPs in long-term care, there was a decrease in unnecessary hospitalizations, an increase in access to health care, and improved overall health outcomes. They also found that NPs built relationships with residents and families and were essential to providing information essential for decision making. The study concluded that "utilization of NPs in a long-term care setting should be encouraged to improve access to care, decrease hospitalizations, and enhance quality of care" (p. 1 of 20).

During the COVID-19 pandemic of 2020, several restrictions on reimbursement for NPs were modified. Removing the requirements for telehealth had a huge impact in facilitating access to care, allowing providers additional opportunities to provide care remotely and virtually. Traditional evaluation and management of a patient can now be accomplished with live video encounters (often referred to as "real-time" or "virtual visits") or audio-only encounters. Primary care NPs can also be reimbursed for virtual check-ins and remote patient monitoring, which are additional ways for providers to receive data about patients and improve patient care management (Centers for Medicare and Medicaid Services [CMS], 2021b). Telehealth is not appropriate in all situations; if it is suspected that the health concern may require a procedure, or if the physical examination might change the treatment

© F.A. Davis Publishing

plan, the patient needs to be evaluated in person. Older adults also may have limited access to technology and/or require the assistance of another person to effectively engage in a telehealth encounter.

Acute Care Providers

Acute care providers are often caring for older adults because those older than age 65 have the highest rate of inpatient hospital use (Sun & Sosnoff, 2018). NPs in acute care settings whose scope of practice includes the care of adults should be prepared to address the challenge of diagnosing and treating patients who are unfamiliar to them and present with multiple chronic conditions. Chronic conditions often have different baseline symptomatology, which requires providers to spend more time on assessment. Older adults may present with common problems in uncommon ways, and acute providers should know the atypical presentations of common conditions in an older adult. Baseline mental status should be documented so that acute delirium is not dismissed as dementia and to ensure treatable causes for the decline are assessed. Timely follow-up and quality communication between acute care providers and PCPs are important to maintain continuity of care. Knowledge of gerontological principles and coordinating care with PCPs will improve outcomes.

Specialty Care

Some NPs choose to provide care to older adults in a specialty practice. With the increasing complexity of managing chronic conditions, primary providers depend on specialists to assist in the comanagement of patients with these conditions. Many specialties, including cardiology, pulmonology, nephrology, urology, endocrinology, dermatology, and oncology, are including an NP in the practice to improve patient outcomes and satisfaction. Disease-specific practices may include interdisciplinary teams in which an NP can play a vital role. Centers of geriatric comprehensive assessment are included in many large health-care systems. These clinics evaluate older adults who are experiencing ambiguous symptoms, a general decline, or a need for transition in care settings. NPs in these comprehensive centers should collaborate with PCPs, share the results of the assessment and the recommendations of the geriatric experts involved in the center, and coordinate the implementation.

SETTINGS AND SERVICES

There are many settings in which older adults can receive care (Table 5-1). These settings are designed to meet the needs of older adults across the health spectrum. It is often up to the nurse practitioner (NP) to identify the best option for the patient, considering not only their immediate needs but also what their needs will be going forward. Accepting some decreased independence initially may prevent further decline and support mental and functional health. The informed NP will be able to correct the patient's misconception that the only option is a nursing home, which they may envision as a facility only for frail individuals with dementia who are at the end of life. Recommendations that the NP provides to the patient regarding the best setting of care should involve joint decision making and consideration of the patient's preferences, need for autonomy, and safety. Financial considerations are an additional factor, including whether the setting is covered by the patient's insurance or accepts Medicaid.

Acute Care

The setting in which treatment for an acute issue is provided depends on the nature of the problem. Primary care providers can help patients in decision making regarding what is urgent and what is emergent or life threatening. When the patient is experiencing an acute change in condition that is not life threatening, contacting their primary care NP who is familiar with their chronic conditions and medications and has access to recent laboratory results may prevent an unnecessary visit to the emergency department (ED). Seeking care at the ED for minor conditions can put the older adult at risk for contracting healthcare-associated infections and communicable diseases. The urgency and time-sensitive nature of the problem may require a more immediate evaluation in an outpatient acute care setting or in the ED.

OUTPATIENT ACUTE CARE

Referring to outpatient settings, such as convenient care clinics and urgent care facilities, is appropriate for patients who need acute care for issues such as lacerations, which have a very low likelihood of complications or the need for a hospital admission. More serious conditions, such as an acute mental status change, should be assessed in an ED that has access to more sophisticated testing and the ability to admit the patient to the hospital if necessary. The NP must be skilled in assessing an acutely presenting issue, anticipate the potential needs, and possess an understanding of services available within outpatient acute care settings in their community. Not all convenient care or urgent care clinics have an x-ray machine or on-site laboratory, and very few have the ability to perform other imaging, such as computed tomography.

INPATIENT ACUTE CARE

Inpatient acute care may start with an evaluation in the ED. An ED, while not without its risks, does offer access to sophisticated diagnostics and consultation with specialists. If after careful assessment in the ED the diagnosis is unclear, the patient may be observed in the inpatient setting for a period of up to 48 hours. Even before the COVID-19 pandemic, this practice of inpatient observation was becoming more common. The observational period is not considered a hospital admission, which would be covered by traditional Medicare Part A; the patient remains an outpatient for insurance purposes. This delineation is important for financial considerations and availability of rehabilitation after discharge. Admission to a skilled nursing facility or to a rehabilitation unit requires a hospital admission for three overnights (Centers for Medicare & Medicaid Services [CMS] & Medicare Learning Network [MLN], 2021). Patients may be faced with a huge bill from both the hospital and the skilled nursing facility if the patient was never actually admitted to the hospital.

Inpatient hospitalization can put an older adult, especially one who is frail, at risk for harm. Providers in inpatient acute

TABLE 5-1 Common Services and Settings for Older Adults With Payment Options

	COVERAGE AVAILABLE	STIPULATIONS/RULES	DURATION	ADVANTAGES	DISADVANTAGES
Short-term rehabilitation in a skilled nursing facility	Medicare	Traditional Medicare: Hospital inpatient stay for 72 hours Advantage plans: Precertification and in-network facility	24/7 for up to 100 days	24-hour skilled nursing Daily therapy	Institutional environment Care not managed by primary care provider (PCP)
Short-term rehabilitation with home health agency	Medicare	Meet homebound status criteria Encounter with ordering provider within 30 days Advantage plans: Precertification and in-network home health agency (HHA)	Approximately 1-hour visits daily or every other day	Patient is in the comfort of their home Care managed by PCP	Intermittent visits only
Long-term care in a nursing home	Medicaid	n/a	24/7 indefinitely	24-hour skilled nursing	Institutional environment Expensive
Assisted living	Some accept Medicaid	n/a	24/7 until care needs exceed care offerings	Caregivers 24/7 Homelike environment	No 24/7 skilled nursing If patient's needs surpass the services offered, patient needs to relocate Expensive
Long-term ancillary home health	Most accept Medicaid	n/a	Hourly basis (typically 3-hour minimum), indefinitely	Patient stays in their home	Expensive
Independent living facility	None	None	Until care needs exceed care offerings	A la carte nonskilled services and meals available A true home environment	If patient's needs surpass the services offered, patient must relocate Expensive

care settings must be aware that primary care providers (PCPs) may not follow their patients in the hospital setting and may be unfamiliar with the course of events during acute care. Ideally, the PCP would be contacted whenever one of their patients is admitted to the hospital. Additionally, contacting the PCP at the time of discharge can help prevent miscommunications and medication errors. These points of contact allow for a thorough handoff.

Medicare recognized that lack of adequate communication has resulted in unnecessary rehospitalizations. Medicare's Hospital Readmissions Reduction Program (HRRP) encourages hospitals to improve communication and care coordination to engage patients and caregivers in discharge plans and, in turn, reduce avoidable readmissions (CMS, 2021h). This program links payments for the hospitalization to the quality of patient care. Additionally, the National Quality Forum (2011) developed a list of serious reportable events to educate providers regarding serious, preventable, and costly medical errors. For these events, patient readmissions that occur within 30 days of discharge are not reimbursed.

In response to the errors that occur in transitions between settings, CMS in 2015 began to reimburse for transitional care management (TCM) encounters. The TCM billing codes are based on complexity of the admission as well as the time frames for follow-up. This TCM program designates that a patient should have at a minimum a telephone encounter with their PCP within 48 hours of discharge, followed by a face-to-face or telehealth evaluation within 7 to 14 days (CMS, 2021c). Contacting the patient soon after discharge allows for any miscommunication to be addressed before there is harm to the patient.

Subacute Care

When a patient is discharged from the inpatient setting, they may need rehabilitation or continued complex skilled nursing care. Subacute care can be provided in a long-term acute care hospital (LTACH), a skilled nursing facility (SNF), an outpatient rehabilitation facility, or in the patient's home with services from a skilled home health agency (HHA). Communication between the inpatient and subacute setting is critical for safe transition of care, especially to a setting

© F.A. Davis Publishing

where the patient's previous health information may not be available. Informing the PCP of the patient's admission to these facilities is recommended for continuity.

LONG-TERM ACUTE CARE HOSPITALS AND SKILLED NURSING FACILITIES

LTACHs provide care to patients who are technologically dependent and have highly complex medical needs that may take months to resolve. Those patients who must remain on a ventilator, those patients with unhealing pressure wounds, patients with severe burns, and patients requiring nonroutine or daily dialysis that require the care of a highly skilled nurse would be candidates for admission to an LTACH.

SNFs offer the opportunity for more oversight if rehabilitation after hospitalization is required. A SNF can provide more sophisticated treatments than those available in the home setting. Common services provided in a SNF include physical, occupational, and speech therapies; wound care; postoperative management; and administration of IV antibiotics and other parenteral treatments. A hospital admission for a minimum of 72 hours is required to be eligible for SNF services to be covered by Medicare. While a patient is in a SNF, care is managed by the facility's medical director or house physicians along with NPs and physician assistants.

A SNF may be located in an acute care hospital, part of a rehabilitation facility, or part of the services offered by a nursing facility. If the SNF is located in a nursing facility and the patient does not meet the rehabilitation goals to enable them to return to their home, they may become a resident in that facility and receive custodial care (discussed below) rather than skilled care. When patients are discharged to home from LTACHs or SNFs, the TCM program applies to the primary provider's follow-up care.

OUTPATIENT REHABILITATION

Outpatient rehabilitation centers are ideal for patients who are not homebound, when rehabilitation does not require much nursing intervention, and for patients who do not have significant barriers to transportation. Many outpatient rehabilitation centers specialize in different types of surgical rehabilitation and may even partner with surgeons for very specific treatment plans (e.g., a neurosurgeon specializing in deep brain stimulator implants for Parkinson's disease). Outpatient rehabilitation centers often have interdisciplinary teams including many different types of therapists who can see a patient during one visit.

HOME HEALTH AGENCIES

HHAs provide subacute care to patients whose rehabilitation and skilled nursing needs can be met in the home setting. Home health care is overseen and managed by the patient's PCP. The PCP must certify that the patient is homebound, and recertification needs to occur every 60 days unless rehabilitation goals are met and the patient is discharged. CMS guidelines define patients as homebound if "leaving the home requires a considerable and taxing effort due to chronic illnesses and/or injuries where patient needs the aid of supportive devices including crutches, canes, wheelchairs, or walker; the use of special transportation; and/or the assistance of another person to leave their place of residence" (CMS, 2021d). The decision to discharge to home with services by HHAs is most often made by inpatient providers who are unfamiliar with the supports available to the patient at home. When evaluating the patient for home health care, communication with the PCP is critical to assess the ability of the patient to be safe when alone or with the support of a caregiver to avoid unnecessary rehospitalization.

Custodial Care

The Centers for Medicare & Medicaid Services (CMS) distinguishes the type of care provided in home health and in institutions as *custodial* or *skilled.* While skilled services may be covered by Medicare or Medicaid, custodial care is not billable to Medicare but may be covered by Medicaid. It is not a perfect distinction because even when a patient is receiving primarily custodial care provided by nonlicensed caregivers in a nursing home, licensed providers still care for wounds or provide medications. This is also true in home health, where a licensed provider oversees the care provided by a nonlicensed provider on a scheduled basis. The licensed provider may also perform skills such as changing catheters.

HHAs do not require a hospital evaluation or admission for a patient to be eligible for Medicare coverage of services. Providers seeing patients in the ambulatory setting should consider referral for any problem a patient has, such a frequent falls, wounds, or medication management, that would benefit from a HHA nursing assessment. HHAs can offer chronic long-term (versus short-term, recovery-related) services to patients in their homes. These services are separated into two categories: skilled (requiring a nurse) and nonskilled (personal services and not requiring a registered nurse). Examples of skilled long-term services in the home include a patient with a permanent indwelling catheter that needs to be changed every month or a chronic implanted central line port that needs to be flushed routinely. Nonskilled home health care is provided by nursing assistants and arranged on an hourly basis on a schedule mutually agreed upon by the HHA and the patient or family. It may be further determined by what insurance providers, including Medicaid, or the patient can afford to pay personally. These services follow an individualized care plan, which can include reminding a patient to take their medications, bathing, meal preparation, cuing and guidance through ADLs, housekeeping, and transportation to appointments. Whether the services provided by the HHA are skilled or unskilled, they do require oversight by the PCP.

NURSING HOMES

Nursing homes are licensed as Nursing Facilities (NFs) by the state and Skilled Nursing Facilities (SNFs) by Medicare. A nursing home is a strictly regulated environment that provides a greater level of clinical oversight and more complex care than a residential care facility (RCF). In addition to skilled and residential care, some facilities have special units that provide memory care or dialysis. The CMS established the Five-Star Quality Rating System (https://www.cms.gov/Medicare/Provider-Enrollment-and-Certification/CertificationandComplianc/FSQRS) to help consumers, families, and caregivers compare facilities. The system provides an overall rating and a separate score for health inspections,

© F.A. Davis Publishing

staffing, and quality measures (CMS, 2021e). Nursing homes are also surveyed by the state health department at least annually to assess compliance with the state's rules and regulations.

A patient in a nursing home can reside there permanently to have their needs met 24 hours a day. They may also receive short-term, intermittent rehabilitation after a hospitalization. Although the atmosphere of a nursing home may not be as homelike as an assisted or independent living facility, there are increasing efforts being made to address that issue. The previous image of the hospital-like institution is rapidly being revised. Patients in a nursing home are referred to as residents, and although some facilities have shared rooms, the movement is to provide each resident with their own space. Provider care in a nursing home is managed by the facility's physicians, NPs, and physician assistants (PAs), but patients may leave the facility to see specialists as needed.

ASSISTED LIVING

Assisted living facilities are licensed through their states as RCFs. They provide a place for an older adult to reside in a homelike atmosphere while receiving nursing services as needed. Residences in an RCF are like apartments, and most provide a menu of options, with options for increasing services as necessary. Patients have their own unit with their own furnishings and a kitchenette. They may choose to take all meals in a dining room or cook for themselves. Housekeeping, laundry, and medication management are optional. Professional nursing services are limited and may only include one registered nurse with additional staffing by licensed practical nurses (LPNs) for daily care from 16 to 24 hours per day. Unlicensed caregivers are available to assist patients with their ADLs and housekeeping needs. Patients in RCFs are usually given the option of whether they would like their primary care provided by their community provider or the facility's physician, NP, or PA (Ohio Department of Health, 2020).

MEMORY CARE UNITS

Memory care units are becoming a common option in many custodial care settings, including nursing homes and RCFs. Memory care units offer unique programming for patients with a low level of cognitive function. Patients diagnosed with dementia do not have to reside in a memory care unit, but the facility has a dedicated area to support those patients, especially if they also have behavioral and psychiatric symptoms of dementia (BPSD). To support those special needs, memory care units include higher staffing ratios so that patients have access to one-to-one guidance, redirection, and supervision. There may also be adaptations in the physical facility, such as locking exits and entryways equipped with alarms.

RESPITE CARE

Respite care may be an option in a nursing home or RCF. Rooms in these facilities are available for short-term stays to give caregivers temporary relief. The rooms can be any level of care that the caregiver feels is appropriate for the patient. Respite care is not typically covered by insurance, and although it is very important to the mental health and well-being of family caregivers, particularly those caring for patients with dementia and BPSD, respite stays are not widely used due to the high cost.

ADULT DAY-CARE PROGRAMS

In an adult day-care program, older adults engage in activities, receive meals, and are under the supervision of personnel. Many programs even offer personal care such as bathing. This can be a more cost-effective option for caregivers, and some adult day-care centers are even authorized to be reimbursed by Medicaid.

PROGRAM FOR ALL-INCLUSIVE CARE FOR THE ELDERLY

The Program for All-Inclusive Care for the Elderly (PACE) is a national program that provides comprehensive care to frail older adults capable of living in the community with the program's support. The participants in the program need to require a nursing home–level of care. PACE services are covered by Medicare and Medicaid with the goal of keeping patients out of nursing homes and in the community as long as possible. The program improves the quality of life for the patients and their families and saves the federal government money. PACE receives capitated funding for each life enrolled and assumes all financial risk. The program negotiates with nursing homes and hospitals for beds as needed. Individual programs may partner with pharmacies to provide a formulary of medications. Currently there are 263 PACE programs in 31 states.

Independent Living Communities

Independent living communities (ILs) are unlicensed apartment- or condominium-style buildings that offer housing to those aged 55 and older. They have the least oversight and are the least institutional of care settings. They may offer services such as restaurant-style meals in a dining room, a housekeeper, and transportation. They may not provide any nursing services, but residents may choose additional services such as medication reminders, assistance with bathing, and laundry or housekeeping service. Some communities have an on-site clinic that may be staffed by an NP or PA. Medical care is commonly provided by the patient's PCP and other specialists as needed. Patients who need a higher level of support or supervision than can be provided in the IL setting can choose from different levels of residential facilities. Each state's health department licenses residential facilities, sets forth the rules and regulations for their operations, and visits the facilities at least annually to assess compliance.

Continuing Care Retirement Communities

Continuing care retirement communities (CCRCs) are groups of facilities located on a single campus that offer all levels of care described earlier: independent living, assisted living, and nursing home services. Some may even add adult day-care services. The goal of CCRCs is to provide the full spectrum of care so that residents can move through the levels of care as their needs change without leaving the CCRC (Fig. 5-1). CCRCs may require an initial investment. If the NP's patients are considering a CCRC, they must understand what is covered by the investment and whether refunds are allowed should the resident leave early.

© F.A. Davis Publishing

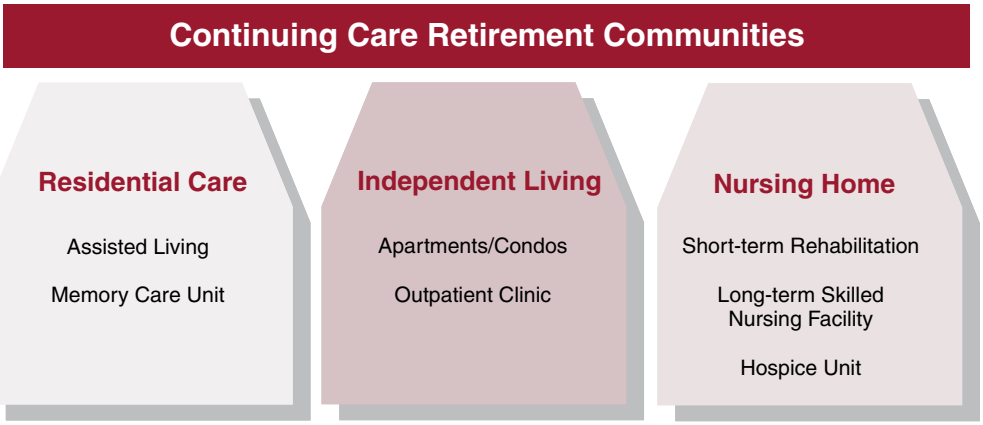

FIGURE 5-1 A theoretical setup of common continuing care retirement community (CCRC) service offerings.

Hospice and Palliative Care Services

Hospice is a Medicare reimbursement option that provides advantages in addition to classic Medicare. The service is underutilized by patients and families who envision it as an option that should be accessed only when death is eminent. Hospice is a service that is provided to a patient who has a terminal diagnosis with a life expectancy of less than 6 months, and that service can be provided in any setting where the patient resides including a private home, an assisted living facility, or a nursing home. A certificate of terminal illness needs to be signed by a physician, but a nurse practitioner can continue to be the primary care provider for their patients. Patients enrolled in a hospice program elect to forgo interventions to prolong life and sign the associated Do Not Resuscitate (DNR) order paperwork. It is not uncommon that with the support provided by hospice, patients improve and may go on what is labeled "navigator status" until their condition worsens again. Patients may also change their minds about stopping life-sustaining treatments and DNR status. Hospice agencies include registered nurses, social workers, chaplains, counselors, and nursing assistants to visit the patient wherever they are located to support the patient and provide comfort care throughout their end-of-life experience.

A referral for hospice services can be made by a patient's PCP or upon discharge from the hospital with a new terminal diagnosis (CMS, 2021f). An important but little-known service of hospice is to provide bereavement counseling to survivors for 13 months after the death of the patient.

Hospice agencies may also have inpatient units where they can admit a patient for short-term symptom management. Symptom management units can be particularly helpful for patients receiving hospice services in a private home who are struggling with pain control, BPSD, or other distressing symptoms.

Palliative care is a service offered by many hospice agencies to provide symptom management and comfort care to patients who may not have a terminal diagnosis, cannot be certified as having a life expectancy of less than 6 months, or do not want to sign a DNR or forgo other life-sustaining or curative treatments (such as a patient with cancer who wants to continue to receive chemotherapy but is having pain, nausea, or shortness of breath that is poorly controlled). Palliative care services may be provided by a physician, NP, or PA; counselor/social worker; and chaplain who may assess the patient in the inpatient setting and continue visits once a month (CMS, 2021g). Chapter 23 includes details of symptom management in hospice and palliative care.

MEDICAL RECORDS

As a patient moves from one setting to another, access to medical records is critical. Older adults may not have the ability to provide accurate history. They may never have received a clear explanation of all that occurred in a particular episode of care. When patients transition from one setting to another, continuity of care may be compromised unless there is access to important information. Miscommunication can be costly and result in duplication of services or, worse, medical errors. In 2016, the 21st Century Cures Act promoted interoperability between organizations by outlining requirements for states to begin utilizing health information exchange applications that provide authorized clinicians with secure, encrypted access to confidential patient information (Office of the National Coordinator for Health Information Technology, 2021). Although this movement has greatly improved the ability to access information, participation is not always 100%, and there are still challenges. There are many vendors that provide software for electronic medical records, and they are not all compatible, which prevents the desired accessibility to patient data.

PSYCHOSOCIAL ISSUES IN TRANSITIONS

It can be challenging to balance safety and risks while honoring patient preferences when selecting a setting of care. Older adults are reluctant to move to a setting where they must give up some of their independence or change their routines. The nurse practitioner (NP) should be aware that what matters most to the provider (medication compliance) or the patient's family (decreasing fall risks) might not be what matters most to the patient (staying in their home with their pet). Competent older adults can weigh the pros and cons of each setting and have the right to accept the risk of staying in their own home.

If a transition occurs, patients may grieve the loss of independence and changes that may require them to relinquish

© F.A. Davis Publishing

their car or to rely on strangers to help with activities of daily living (ADLs). If the change in setting was the result of the loss of a loved one who provided care and support, that compounds grief and puts patients at high risk for a new or exacerbation of existing mood disorders. The NP should be vigilant during transition periods, watching for symptoms of mood disorders and ineffective coping, even suicidal thoughts.

Caregivers need support during the process of selecting the right setting for their loved one. Feelings of guilt are a common response to the reality that they are not able to provide the care their loved one requires. Conflict may result from disagreement among family members regarding the decision to relocate the older adult. NPs should think of caregivers as an extension of the patient and support their needs by providing education on caregiver support groups or the availability of respite care.

Strategies that the NP can use to ease the psychosocial turmoil of care transitions include starting the discussion with the patient and their family early in the disease process. The NP can provide information about settings of care and what each setting offers, involving the patient and allowing them to have as much control over the decision making as possible. What matters to the patient should be the most important. Discussions about the cost of care and the possibility that Medicaid may be necessary in the future can help families in their planning. Referrals can be made to a social worker who can help provide additional information and resources.

Advanced Care Planning

Sometimes older adults, particularly those with cognitive impairments, are not able to make their own decisions about care services and settings. There are two types of advance directives that a patient can implement to ensure that their wishes are honored if they are unable to make them known themselves: (1) appointing a surrogate decision maker and (2) written directives. Advance directives do not become active unless a patient becomes incapacitated, so patients maintain their autonomy to make their own health-care decisions until they are unable to do so. Capacity is defined by the patient's ability to understand and reasonably apply information a clinician provides to them to make a choice about their care that is congruent with their values and preferences, using logic and appreciation of risks and benefits. Assessing a patient's capacity to give informed consent for any medical treatment or transfer in their setting of care is within the scope of the NP, and many tools and algorithms are available. Determination of incapacity can be transient (such as in delirium) or persistent (such as in dementia). Capacity can also vary depending on the complexity of the decisions at hand. For example, a patient with early-stage dementia may have the capacity to give consent to be sent to the emergency department (ED) after a fall but may lack the capacity to consent to a surgical procedure or to go to a skilled nursing facility (SNF) for rehabilitation (Tannou et al., 2020).

Centers for Medicare & Medicaid Services (CMS) delineates that advance care planning conversations should take place at a minimum during every annual wellness visit with an older adult and that there are reimbursements for the service, providing incentive to primary care physicians (PCPs) for specifically making time for these important discussions. Advance directive legal forms can generally be found on the Web site of each state's attorney general's office. Once signed and witnessed, the document should be kept in a safe place with the patient's will and a copy on file with the PCP's office and/or the facility where they live.

Appointing Surrogate Decision Makers

A durable health-care power of attorney (HCPOA) is both a legal document that empowers an individual chosen by the patient to make health-care decisions on their behalf if they become incapacitated and that individual. The patient must select the individual and formulate the HCPOA document during a time when they have full capacity to do so. Patients should be encouraged to give thoughtful consideration when choosing the HCPOA and be sure to select a person who they are confident would honor their wishes even if they disagree individually with them or are emotionally distraught. Older adults should have open and explicit conversations with their HCPOA about what they do and do not want in terms of care services, particularly end-of-life services.

If a patient becomes incapacitated and did not appoint an HCPOA, they become a ward of the state. A legal guardian is appointed through the patient's county probate court. The process must start with the ward being deemed legally incompetent (which differs from incapacitated, as discussed later), which requires official examination by more than one clinician and a judge's ruling. Individuals, who may be family members, can apply to be guardian, and the probate officer will typically grant them guardianship in the absence of any objections. The process of establishing guardianship can take many months to complete. If no individual applies for guardianship, the ward is appointed a volunteer guardian through adult guardianship service agencies. Guardianship is often avoidable and a main reason why advanced care planning is essential.

Written Directives

Living wills are documents that specifically outline select care services that a patient does or does not ever want. For example, a patient who feels very strongly about not wanting a feeding tube or being mechanically ventilated would put together a living will with this information. Code status, often referred to as Do Not Resuscitate (DNR) orders, is another important aspect of written advance directives. Each state creates standards for DNR orders, has specific forms to sign, and designates what type of clinician (physician, NP, etc.) is permitted to sign the forms. There are three types of code status: full code, DNR, and DNR-Comfort Care (DNRCC). A full code means that if a patient becomes noncommunicable and needs emergency care, they will receive all related treatment and/or resuscitative care available, including cardiopulmonary resuscitation. Full code status is the default status for all patients when a DNR status is not known. This is important because if a patient signs a DNR form and it is not kept visibly on file and/or the status is not communicated effectively between care providers and settings, the patient may be resuscitated in an emergency situation against their wishes.

This difference between a DNR and a DNRCC code status can be confusing, and definitions and terms vary state by

© F.A. Davis Publishing

state. When a patient signs a DNR order, they are agreeing to have all treatment-related care provided to them up until the point that they may experience a cardiac or pulmonary arrest. When arrest occurs, the patient is not resuscitated. A DNRCC order means that in addition to not wanting to be resuscitated after cardiac arrest, they also do not want all treatment-related care available; the patient only wants comfort care provided. Patients enrolling in hospice programs sign DNRCC orders as part of the admission process; however, patients who do not qualify for hospice may also sign DNRCC orders. Examples include a patient who prefers homeopathic approaches to their care or individuals who do not want to be hospitalized or participate in invasive testing/procedures. Code status documents should be kept in a safe place with the patient's will and on file with the PCP's office and/or the facility where they live. Many state health departments offer wallet cards, ID bracelets, and other identification tools to help address this issue of communicating the patient's wishes.

A common question patients ask is, "If I put my wants and wishes in writing with a living will and a DNR order, why do I need to appoint a power of attorney?" It is impossible for a living will document to outline every possible scenario that a patient could encounter throughout the rest of their life when health-care decisions have to be made, which is why having both a carefully selected HCPOA and a living will is essential and recommended.

HEALTH-CARE FINANCE

It is impossible to consider options for different settings and services without considering the financial feasibility. A patient's insurance coverage and their ability to afford care are often the determining factors of where, how, and who will provide what is needed to a patient. In the United States, the predominate third-party payers of medically necessary services to older adults are Medicare, Medicaid, and private insurance companies. The Centers for Medicare & Medicaid Services (CMS) sets the rules for these payers and administers some coverage benefits directly.

Medicare

In 1965 Medicare was passed as an amendment to the 1935 Social Security Act. It is a federal insurance program available to adults 65 years of age and older, individuals on disability, and patients with end-stage renal disease. The Medicare program initially included two parts, A and B. Part A is coverage for hospitalization and provided to everyone 65 and older who paid Medicare taxes for at least 10 years. Part B, medical coverage, is offered as an option and requires an additional premium, which is deducted from the individual's Social Security payment.

In 1997, the Balanced Budget Act provided an option for a managed care plan, Medicare Part C. These plans provide an option for those with Medicare Parts A and B to sign up for a private insurance managed care plan. These private insurance plans administer a patient's benefits, often called Medicare Advantage plans. These plans are not bound by the requirements of Medicare Part A, B, or D and can offer benefits such as dental care, eyeglasses, hearing aids, and even health club memberships. By the end of 2020, more than 40% of Medicare beneficiaries had elected to enroll in a managed care plan, increasing the privatization of Medicare. Patients who sign up for Advantage plans must receive services from the plan's network of providers and receive prescriptions from within the Advantage plan's formulary to have them covered.

The decision to keep traditional Medicare Parts A and B versus signing up for an Advantage plan has a crucial impact on the future of the beneficiary's options for care. In Ohio, for example, there are more than 20 Advantage plans available for beneficiaries to choose from. Turning 65 years old and becoming eligible for Medicare can be a daunting experience, and beneficiaries often seek the support of financial advisors to navigate through the sea of options. Because open enrollment occurs every year and changes can be made at that time, Medicare beneficiaries may change their plans. The primary care physician (PCP) may suggest the importance of making sure the current PCP is included in the plan and that the benefits offered will meet the level of care that the patient needs.

In 2003, the Medicare Prescription Drug, Improvement, and Modernization Act (MMA) was passed, establishing prescription drug coverage under Medicare Part D. For the first time the federal government was providing medication coverage. The plan was less than perfect, including a "donut hole" provision that resulted in many older adults toward the end of the year running out of coverage and paying full price for their medications. The Affordable Care Act (ACA) has a provision slowly closing that donut hole, but it can still be a problem for patients. The yearly open enrollment also applies to Medicare Part D plans. PCPs are also important resources to remind patients to select their plans carefully to make sure their medications are covered without requiring prior authorization or excessive copayments. Those with Medicare Advantage plans have their medications covered under that plan and are not required to sign up for Part D and not subject to the "donut hole."

Medicaid

Medicaid is a program for low-income individuals that is jointly administered by the federal and state governments using a system of cost sharing. Of those receiving Medicare, 21% are also receiving Medicaid. Medicaid is available to children, pregnant women, parents, and people with disabilities, as well as older adults. The ACA raised the eligibility requirement to 133% of the federal poverty level. Each state sets the conditions of participation and coverage as well as the income and asset threshold for eligibility, and not all states chose to expand coverage as provided by the ACA. The asset threshold is the criteria that results in some older adults not taking advantage of the benefit out of fear of losing their home and any bequest they hoped to leave to their families. Assets that could be used to pay medical bills cannot be gifted, sold under market value, or transferred without penalty of a period of Medicaid ineligibility. Medicaid has a look-back period of 60 months from the day of application in all states but California, which has a 30-month look-back period. Any assets transferred after that period may affect eligibility for Medicaid. Most long-term care services and, in many states, residential care facility (RCF) services are covered by Medicaid. States offering privatized Medicaid plans

© F.A. Davis Publishing

allow beneficiaries to select a private insurance company to manage their Medicaid benefit.

Older adults can qualify for and receive both Medicare and Medicaid coverage at the same time if they are older than 65 years and have low income and few assets. These beneficiaries are called "dual-eligibles." In this scenario, the payors work together to cover outpatient, acute, subacute care, and prescriptions (Medicare) and long-term care services (Medicaid). Some states administer their Medicaid benefits to beneficiaries directly, while others have transitioned to encouraging dual-eligibles to sign up for an Advantage plan. Older adults may opt out of the recommendation to sign up for an Advantage plan and keep traditional Medicare Parts A and B with Medicaid as a supplement, but many do not realize that opting out is possible. NPs assisting older adults in transitions of care must have knowledge of the benefits and restrictions of each patient's coverage.

Private Pay

Most older adults will at least have traditional Medicare Parts A and B, but there are still many uncovered costs. Medicare Supplement and Advantage plans cover some of these expenses but not everything. Medication copays can be very high if the medication is a third-tier drug. More and more medications are approved for sale without a prescription and plans generally do not cover over-the-counter medications at all. Paying privately for care, particularly long-term care services, can be profoundly expensive and therefore unaffordable for patients. In the United States, the average private pay room and board rate in 2020 was approximately $8,000 per month in a nursing home, $4,300 per month in assisted living, and $4,500 per month for long-term nonskilled home health (Genworth, 2021). The cost of long-term care services will often exhaust a patient's savings and assets and result in the need to apply for Medicaid to continue to receive the care they need. Medicaid is the largest single payer of long-term care services, with a range from 50% to 75% depending on the state. Case examples of various private pay scenarios are shown in Box 5-1.

BOX 5-1
Private Pay Scenarios

- The clinician may want a patient to go to a skilled nursing facility (SNF) for rehabilitation after a hospital stay. Medicare only covers an SNF stay if the patient has been admitted in the hospital for a minimum of 72 hours. If the patient did not meet the 72-hour admission criteria and cannot afford to pay for the SNF stay privately, they would return home with home health agency services instead.
- If a patient is rehabilitating in an SNF and does not meet their treatment goals and needs to stay for long-term care in the nursing home, Medicare stops covering the patient's stay. The patient either needs to pay the daily private pay rate and/or apply for Medicaid if they cannot afford the private pay rates.
- A nurse practitioner may order for a patient to receive skilled home health care by a certain agency, but if the agency is not in the patient's Advantage plan network, a different agency must be found, which can cause delays and communication hazards.
- Acute care providers discharging patients to their homes are often unfamiliar with coverage issues and prescribe medications that patients will not use because of the enormous expense in fulfilling the prescription.

CASE STUDY

You are the PCP for Deborah, an active 88-year-old retired teacher, and her husband, Bill, an 89-year-old with advanced rheumatoid arthritis. They reside together in an independent living community (IL) condo. Deb has well-managed comorbidities of hypertension, type 2 diabetes, and hyperlipidemia. She sustains a fall that fractures her femur and requires surgical repair. While in the hospital, Deb develops pneumonia, which prolongs and complicates her inpatient stay. She goes to a skilled nursing facility (SNF) for rehabilitation for 45 days. While there, her type 2 diabetes management requires escalation, and she is treated for deep vein thrombosis. Bill wants Deb to stay longer in the SNF because she has not returned to her baseline functional status prior to her injury, and he is apprehensive about handling her medical care at home on top of his own problems; however, her insurance will not cover any additional SNF time. They cannot afford to pay the $295 per day privately and do not meet the income level to be eligible for Medicaid, so Deb is discharged home on a Friday afternoon. When Bill goes to pick up her medications from the pharmacy, including new basal insulin and a novel anticoagulant, the cost is over $2,000 because the prescriptions were not in their drug plan formulary, so he does not get them. On Sunday, an unlicensed aide in the IL helps Deb check her blood sugar, which is 390. The aide decides to call 911. A social worker in the emergency room tells Deb and Bill before sending them back home that they should consider assisted living. Hearing this, daughter Susan comes into town, and all three of them are in your office for a transitional care management (TCM) follow-up visit to come up with a plan with your guidance. Susan has her health-care power of attorney (HCPOA) documents with her just in case you need to see them so she can make the decisions for her parents today.

1. What transitional care complications were avoidable in this scenario? How could they have been prevented?
2. What information will you obtain to be able to come up with an effective care plan for Deb and her family?
3. What services could Deb be eligible for today?
4. What conditions are Deb and Bill at high risk for?
5. Do you think that assisted living placement is the answer for this family? Why or why not?
6. Will Susan be making the decisions for her parents? Why or why not?

CHAPTER 6

Comprehensive Geriatric Assessment

Evelyn Duffy

The comprehensive geriatric assessment (CGA) has been a cornerstone of the care of older adults. Older individuals represent a richly diverse population. People age at different rates and within one person organ systems age at different rates. In addition to physiological changes with aging, older adults face many psychosocial adaptations, as well as economic and environmental challenges. How these changes impact the functional ability of the older adult is a key to the overall assessment of their health (Tran & Leonard, 2017). These changes can differ dramatically among individuals of the same chronological age. Older individuals who can benefit the most from CGA are those with multimorbidity and the older adult who is already experiencing functional decline. All older adults, but especially those with frailty, have less physiological reserve and are at increased risk of iatrogenic complications, particularly related to the multiple medications prescribed to treat chronic conditions. The disease model that applies differential diagnosis is inadequate in the setting of multimorbidity and frailty. CGA helps not only to diagnose treatable conditions and improve patient outcomes, but also to identify potentially preventable conditions.

CGA has been defined as a multidimensional, interprofessional, diagnostic process to identify care needs, plan care, and improve outcomes for older people (Palmer & Onder, 2018). A Cochrane Systematic Review of inpatient CGA versus usual care of older adults admitted to acute care or inpatient rehabilitation concluded that older adults were more likely to be alive and in their own homes if they received a CGA (Ellis et al., 2017). A systematic review of CGA in primary care (Garrard et al., 2020) concluded that there was improved adherence to medications but no improvement in survival or functional outcomes. The authors note that the interventions were widely accepted by the patients and potentially cost-effective. Garrard, et al. (2020) and Palmer and Onder (2018) suggest that a formal CGA be offered to a select category of patients—those with multimorbidity or frailty—because they may benefit most. Patients with multimorbidity are found to report lower quality of life and well-being and less satisfaction with care. Patient-centered care respects the wishes of the individual, and the result is an increased satisfaction with care and improved outcomes (Kuipers et al., 2019).

Advanced practice nurses may be a part of a team that works together to complete a CGA or may apply the concepts of CGA to their own patients. The nursing model of addressing the biopsychosocial needs of patients is reflected in the concepts of the CGA, which include function, physical health, mobility, psychological well-being, socioeconomic and environmental factors, and quality of life. Several geriatric assessment instruments are focused on these domains. These tools can facilitate the assessment, diagnosis, and evaluation processes, and those with the most clinical utility are highlighted in this chapter. Suggested dimensions within each CGA domain are identified in Table 6-1. Each of these domains is described in greater detail as follows.

PHYSICAL HEALTH

The physical assessment of the older adult includes all the components of a conventional medical history (chief complaint, history of present illness, past medical history, family and social history, and a review of systems), the conventional physical examination, and appropriate diagnostics based on the findings. Assessment begins with the first contact with the patient. Observe the patient's appearance, language, and behaviors and whether they look the stated age. Note if they are appropriately dressed for the occasion and season and if there are any signs of neglect in self-care. What is the quality of their voice and the manner and content of speech? What behaviors are observed, including facial expressions, eye contact, gestures, or abnormal movements? If a family member or caregiver accompanies the patient, how do they interact?

Interviewing begins before the physical examination and typically continues throughout the examination. In a formal CGA, it is common to send a geriatric history-taking form to the patient in advance so that they or their family can complete it and the details can be reviewed and expanded on during the visit. Any impairment in vision, hearing, speech, or cognition may affect the patient's ability to communicate effectively. Impairments should be addressed, and measures taken to accommodate them during the visit, to prevent the trap of talking to the family or caregiver, if present, to facilitate the visit rather than talking directly to the patient. In most cases, the patient's permission should be acquired

TABLE 6-1 Comprehensive Geriatric Assessment

DOMAINS OF COMPREHENSIVE GERIATRIC ASSESSMENT	DIMENSIONS OF COMPREHENSIVE GERIATRIC ASSESSMENT
Physical health	History taking
	Physical examination
	Diagnostics
	Nutritional assessment
	Medication review
Functional health	Activities of daily living
	Instrumental activities of daily living
	Sensory assessment (hearing, vision)
	Gait and balance
Psychological health	Cognitive disorders (delirium, dementia, mild cognitive impairment)
	Affective disorders (depression, anxiety)
	Spiritual well-being
Socioenvironmental supports	Social network and support
	Living situation
	Environmental safety
	Economic resources
Quality of life measures	Physical conditions
	Social conditions
	Environmental conditions
	Personal resources (mental health, life perspective)
	Preferences for care

before interviewing the family. However, the input of the family or caregiver can provide valuable information about the patient's behavioral or functional changes of which the patient may not be aware or willing to share. A change in function can be a sign of change in the patient's overall health status; it is often the first sign of illness or decompensation of an existing disease. It is important to address what the patient or their family considers significant, which often differs from what the provider considers significant.

Many older adults suffer from multiple chronic conditions that require monitoring. When two or more chronic diseases are present it is described as multimorbidity (Kadambi et al., 2020). There are no good clinical tools for measuring the burden of multimorbidity, although research tools that include the number and severity of chronic diseases, such as the Charlson Comorbidity Index (CCI), do exist (Kadambi et al., 2020). The history of chronic diseases should be identified and updated with any symptoms of decompensation. An older adult may not present with a new chief concern, but if one is reported it is important to put it into the context of the patient's previous health and illness. If a new concern is identified, a history of present illness is recorded using the seven dimensions of symptomatology as a guide (location and radiation, quantity and quality, aggravating and alleviating factors, associated symptoms and signs, absence of associated symptoms and signs, evolution and course of the symptom, and effect of the symptom on normal daily activities). After taking the history, the provider should summarize for the patient what was heard. This gives the patient the opportunity to clarify or deny any parts of the discussion.

Medication

Medication review should be completed at every encounter. Asking a patient to describe how they take a medication rather than asking if they take it is much more informative. Because older adults are the population most likely to suffer from multiple chronic diseases, they are also most likely to take more medications, both prescribed and over-the-counter. The more medications a person is taking, the more likely they are to have an adverse drug event. Polypharmacy is associated with both adverse drug events and frailty. The risk of mortality and disability is higher in patients with polypharmacy and frailty than in polypharmacy alone (Kojima et al., 2020). The most frequently used tool for evaluating drug use is the American Geriatrics Society (AGS) Beers Criteria® for Potentially Inappropriate Medication Use in Older Adults, first published in 1991 and most recently updated in 2019 (American Geriatrics Society [AGS], 2019).

A subsequent scale was developed to address some of the limitations of the Beers criteria, the Medication Appropriateness Index (Hanlon & Schmader, 2013; Hanlon et al., 1992) (Table 6-2). First published in 1992, it is a validated tool that can be used along with the Beers criteria to determine the appropriateness of prescribed medications for older adult patients. While the screening questions in Table 6-2 are applicable in the clinical setting, use of the complete instrument is more appropriate for research.

Appropriate prescribing often means that multiple medications are required for adequate management of chronic disease. Appropriate prescribing may require adding a medication, such as an angiotensin-converting enzyme (ACE) inhibitor for a patient with diabetes or chronic kidney disease. Limitations in the Beers criteria led to the development of more explicit criteria, including the Screening Tool of Older Persons' Prescriptions (STOPP) and the Screening Tool to Alert Doctors to Right Treatment (START) (Gallagher

TABLE 6-2 Medication Appropriateness Index Criteria

Is there an indication for the drug?
Is the medication effective for the condition?
Is the dosage correct?
Are the directions correct?
Are the directions practical?
Are there clinically significant drug-drug interactions?
Are there clinically significant drug-disease/condition interactions?
Is there unnecessary duplication with other drugs?
Is the duration of therapy acceptable?
Is this drug the least expensive alternative compared with others of equal usefulness?

et al., 2008). The tools address the issue of appropriate prescribing and deprescribing more specifically and are organized by organ system. They were updated in 2015 with the publication, *STOPP/START Criteria for Potentially Inappropriate Prescribing in Older People: Version 2* (O'Mahony et al., 2015). While the STOPP tool lists those that should be assessed for possible elimination the START tool includes medications that may need to be added, which is a unique aspect of STOPP/START. O'Mahony in 2020 reviewed recent research evaluating the integration of the STOPP/START criteria into the electronic medical record (EMR) showing its ongoing value in improving clinical outcomes.

Examination

Objective data collection begins with vital signs. These may be obtained by ancillary staff, but any abnormalities need to be verified by the provider. A common issue is the necessity to rule out orthostatic hypotension, which is prevalent in older adults due to volume depletion and the effects of medications. If concerns indicate the possibility of orthostatic drop, the provider needs to accurately measure the blood pressure (BP). The patient should lie down for 5 minutes and then have the BP and pulse rate measured. Have the patient stand and wait for a full minute, then repeat the BP and pulse rate measurements. Note any symptoms of light-headedness or dizziness and any drop in systolic BP greater than or equal to 20 mm Hg or diastolic BP greater than or equal to 10 mm Hg. An increase of heart rate of at least 30 beats per minute (bpm) is also abnormal. With aging, baroreceptors that are triggered by a change in position become less sensitive and vasoconstriction to maintain blood pressure is slowed, so it is important to repeat the BP and pulse rate measurements 3 minutes after standing if there was a significant drop. If BP and pulse have returned to baseline the patient has not demonstrated true orthostasis, but you may have confirmed the cause of light-headedness or dizziness.

Pulse oximetry provides a measure of oxygen saturation. The right middle finger and thumb may provide the best results. Normal readings range from 95% to 100% and any value less than 90% is considered low. A respiratory rate greater than 20 respirations per minute is classified as tachypnea and may be a sign of infection or sepsis, lung disease, heart failure, or a metabolic disorder. Weight is another measurement in which accuracy is important because it is a marker for both nutritional and fluid status. Pain is the fifth vital sign and quantifying pain can be accomplished in various ways, although older adults may prefer verbally descriptive scales.

A comprehensive physical examination of the older adult should be completed as a part of the CGA. A sample examination is identified in Table 6-3. An examination of the older adult, including a thorough assessment of functional ability, is as important as careful examination of each body system. All five senses impact functional health. Vision and hearing are commonly included in physical examination, but sense of touch, taste, and smell may not be. Among the many lessons learned from COVID-19 was the increased understanding of the importance of both smell and taste to flavor of food and subsequently to a good appetite. Addressing the health of all five senses can improve function in multiple ways because sensory loss often precludes the ability of the older adult to live independently. Both a decline in hearing and vision have been linked to cognitive decline (Ray et al., 2019). Measured visual acuity (corrected with lenses) equal to or worse than 20/40 constitutes a visual impairment. Abnormality in the six cardinal fields of gaze with nystagmus or lack of a downward gaze may reveal a neurological disease, such as progressive supranuclear palsy (PSP). Dilated ophthalmologic examinations are essential to the identification of cataracts, diabetic retinopathy, glaucoma, or macular degeneration. All of these are common diseases of the eye in older adults, and treatment can preserve vision. Although traditional Medicare does not cover routine eye examinations, it does cover examinations to assess for disease.

Screening for hearing loss can be accomplished using a handheld audiometer, which is more accurate than the whispered voice test. Otoscopic examination may reveal a cerumen impaction, which can result in a conductive hearing loss. If hearing loss is suspected, referral to an audiologist for a complete assessment is required. Although Medicare does not pay for hearing aids, it will cover a hearing assessment by an audiologist for suspected hearing loss. Many Medicare managed care plans cover both routine eye examinations and hearing aids.

Thorough neurological and musculoskeletal examinations are particularly important in the older adult. In younger adults, neurological and musculoskeletal examination may be less of a focus because health of those systems is obvious, but older adults may have unrecognized muscle weakness, limitations in range of joint motion, or contractures requiring thorough examination. Hip flexion contractures are common but can obscured by an increase in lumbar curvature. Careful assessment of range of motion of the hip is important because hip flexor contractures can increase the risk of falls. The Thomas test is an assessment technique that can help accurately evaluate the hip.

After completing the examination, discuss the general findings with the patient. Patient teaching should reinforce the positive behaviors taken to improve or maintain health and teach self-assessment and self-care management strategies. A plan for implementing recommended screening tests should be included in the discussion.

Diagnostics

Chapter 1 discusses the changes associated with aging that are reflected in laboratory values. This section provides some general guidelines on when to order testing. The reader is referred to the disease sections of this text for more specific guidelines. There needs to be a distinction between tests used to screen older adults and tests used to aid in diagnosis as these have different objectives. Screening has been defined as the presumptive identification of unrecognized disease or defect by the application of tests, examinations, or other procedures. The screening parameters for those older than 65 years, which include diagnostic testing, are covered in Chapter 2, Health Promotion.

Before ordering a test for diagnostic purposes the provider needs to assess whether the test result will alter the diagnosis, prognosis, or management of a condition. Some guidelines for use of diagnostics in decision making include: What is the prevalence of the disease being screened for with the test? What is the sensitivity and specificity of the test? Will the test

TABLE 6-3 Sample Focused Geriatric Physical Examination

SIGNS		PHYSICAL SIGN OR SYMPTOM	DIFFERENTIAL DIAGNOSES
Vital signs	Blood pressure	Hypertension	Adverse effects from medication, autonomic dysfunction
		Orthostatic hypotension	Adverse effects from medication, atherosclerosis, coronary artery disease
	Heart rate	Bradycardia	Adverse effects from medication, heart block
		Irregularly irregular heart rate	Atrial fibrillation
	Respiratory rate	Increased respiratory rate >24 breaths per min	Chronic obstructive pulmonary disease, heart failure, pneumonia
	Temperature	Hyperthermia, hypothermia	Hyperthyroidism and hypothyroidism, infection
General		Unintentional weight loss	Cancer, depression
		Weight gain	Adverse effects from heart failure, medication
Head		Asymmetrical facial or extraocular muscle weakness or paralysis	Bell's palsy, stroke, transient ischemic attack
		Frontal bossing	Paget's disease
		Temporal artery tenderness	Temporal arteritis
Eyes		Eye pain	Glaucoma, temporal arteritis
		Impaired visual acuity	Presbyopia
		Loss of central vision	Age-related macular degeneration
		Loss of peripheral vision	Glaucoma, stroke
		Ocular lens opacification	Cataracts
Ears		Hearing loss	Acoustic neuroma, adverse effects from medication, cerumen impaction, faulty or ill-fitting hearing aids, Paget's disease
Mouth, throat		Gum or mouth sores	Dental or periodontal disease, ill-fitting dentures
		Leukoplakia	Cancerous and precancerous lesions
		Xerostomia	Age-related, Sjögren's syndrome
Neck		Carotid bruits	Aortic stenosis, cerebrovascular disease
		Thyroid enlargement and nodularity	Hyperthyroidism and hypothyroidism
Cardiac		Fourth heart sound (S_4)	Left ventricular thickening
		Systolic ejection, regurgitant murmurs	Valvular arteriosclerosis
Pulmonary		Barrel chest	Emphysema
		Shortness of breath	Asthma, cardiomyopathy, chronic obstructive pulmonary disease, heart failure
Breasts		Masses	Cancer, fibroadenoma
Abdomen		Pulsatile mass	Aortic aneurysm
Gastro-intestinal		Constipation	Adverse effects from medication, colorectal cancer, dehydration, hypothyroidism, inactivity, inadequate fiber intake
Genital/rectal		Fecal incontinence	Fecal impaction, rectal cancer, rectal prolapse
		Atrophy of the vaginal mucosa	Estrogen deficiency
		Prostate enlargement	Benign prostatic hypertrophy
		Prostate nodules	Prostate cancer
		Rectal mass, occult blood	Colorectal cancer
Urinary		Urinary incontinence	Bladder or uterine prolapse, detrusor instability, estrogen deficiency

be accepted and tolerated by the patient? Does the benefit of the test outweigh the risk? Is it the least invasive test available? Will the results change the treatment of the patient? The best tests for screening have high sensitivity to decrease the risk of false negatives. For diagnosis, it is preferred that the test have high specificity to avoid the problem of false positives, which can result in additional testing and expense. This is especially true if the disease has a low prevalence. An excellent resource for providers is the ChoosingWisely.org Web site. Even tests with high sensitivity and specificity produce false results when applied inappropriately and without a firm understanding of the concepts. Most important, consider the test's acceptability to the patient. This is especially significant in the patient who cannot make a choice and give consent. In such individuals, a proxy is needed to gain permission to give the test. Although some patients may be unable to express themselves verbally, their behavior may give nonverbal expression to their feelings toward the test's acceptability.

The physical examination may reveal some indicators of malnutrition, including weight loss, muscle wasting, dry and dull hair, mental impairments, and poor wound healing. The body mass index (BMI) is commonly used to determine whether patients are underweight or obese. The proportion of fat increases with age and muscle mass decreases. Muscle weighs more than fat, so the BMI in older person may be artificially low.

There is no gold standard for biomarkers of nutritional deficiencies in the older adult, but some indicators include prealbumin, transferrin, albumin, chemistries, complete blood count, vitamin B_{12}, folate, 25(OH) vitamin D, and thyroid panel. As the understanding of the role of pro-inflammatory cytokines on the acute phase protein response, albumin cannot be used as the sole indication of malnutrition. The presence of inflammation needs to be considered when interpreting serum albumin results. This is reviewed in detail in Chapter 4.

FUNCTIONAL HEALTH

Although functional decline is common with advanced aging, the two are not synonymous. Functional decline occurs in every system, but the distinction between functional usual aging and functional successful aging remains unclear. The goal in geriatric care is to improve function, if possible, and, if not, to prevent further functional decline or slow down the process of functional deterioration. The parameters of function include both activities of daily living (ADLs) and instrumental activities of daily living (IADLs). Basic ADLs include three components: basic self-care, mobility, and continence. IADLs measure community interactions within the home and outside the home (Table 6-4). Whereas these activities are classic measures of function, physical health, mood, memory, substance use, and medications are also involved in a patient's functional ability.

Two well-established tools used to evaluate function in older adults are the Katz Activities of Daily Living Scale (Katz et al., 1963) and the Lawton and Brody Scale for Instrumental Activities of Daily Living (Lawton & Brody, 1969). It is important to be cautious about self-report of function (rather than direct observation of function) and to ask, "How do you . . .?" or "Show me how you. . . ." instead of "Can you . . .?" in order to determine whether patients actually perform the activity. Bathing is often the first ADL that poses problems for older

Ability to walk with or without assistive device	Managing finances
Continence of urine	Shopping
Continence of stool	Transportation

adults. When function is an issue involving other disciplines, physical therapy, occupational therapy, or social work can add data that will improve the planning. Since 2020 advanced practice registered nurses (APRNs) have been able to certify for Medicare home health care. Referring for a home assessment to a home health agency is an advantage. The home health nurse can assess medications, and the therapists can assess for safety hazards and observe the patient in their own environment. They can also help identify environmental risks for falling. Falls are a leading cause of death and disability in the older adult, and assessment of both intrinsic and extrinsic factors contributing to falls is important. Ask yourself the question, "Why did this patient fall today?" A valid tool for assessment of falls is the Hendrich II Fall Risk Model, which is useful in acute care, ambulatory care, assisted living, and long-term care (Hendrich et al., 2003). In addition to identifying those at risk for falls, it helps to identify appropriate interventions to reduce their fall risk. Mobility can be screened with the Timed Get Up and Go Test. This test involves observing for unsteadiness as the patient gets up from a chair without using the arms, walks 10 feet, turns around, walks back, and resumes a seated position. Timing the process, which should take less than 16 seconds, enhances the sensitivity of this test (Podsiadlo & Richardson, 1991). Patient difficulties performing this test indicate mobility issues, weakness of the extremities, and an increased risk of falling. Tinetti's Performance Oriented Mobility Assessment is a task-oriented test that measures gait and balance abilities (Tinetti, 1986).

PSYCHOLOGICAL HEALTH

Cognitive and affective disorders, specifically dementia, depression, and delirium, are more prevalent in older adults, and clinical definitions of these disorders are addressed in the *Diagnostic and Statistical Manual of Mental Health Disorders (DSM)*, 5th ed. (5th ed.; *DSM-5*; American Psychiatric Association, 2013). The *DSM-5* describes the characteristics of delirium and mild or moderate neurocognitive disorders. There are several validated tools used to screen for cognitive dysfunction. For years the gold standard was the Mini-Mental Status Examination (MMSE), but more recent tools have all been validated against that standard. Three tools used in clinical settings have comparable psychometric properties to the MMSE: the Mini-Cog, Montreal Cognitive Assessment (MoCA), and Saint Louis University Mental Status Examination (SLUMS) (Cummings-Vaugh et al., 2014; Tariq et al., 2006; Tsoi et al., 2015). The Mini-Cog is now copyrighted and details regarding its administration are available on the Web site mini-cog.com. Both the MoCA and SLUMS have comparable specificity and sensitivity to the MMSE and are better at identifying mild neurocognitive disorder. The MoCA, which has the distinction of being the most sensitive screening tool for mild neurocognitive disorder now requires registration and training prior to its use; refer to its Web site, https://www.mocatest.org. Currently the SLUMS is still accessible online, and additional requirements for administration are not preventing its use.

Older adults are at greater risk of delirium, which is underrecognized and underdiagnosed. There are several instruments designed to screen for delirium; however, the best evidence supports the use of the Confusion Assessment Method (CAM), which takes 5 minutes to administer (Inouye et al., 1990). The CAM diagnostic algorithm is based on four cardinal features of delirium: (1) acute onset and fluctuating course, (2) inattention, (3) disorganized thinking, and (4) altered level of consciousness (Shi et al., 2013).

Depression is also underrecognized in older adults. There are several screening tools for depression. The Patient Health Questionnaire (PHQ) has become the universal screen for depression across adult age-groups and is the screen included in the Medicare Wellness examination. It assesses depressive symptoms and functional impairment and screens for symptom severity. The PHQ-2 consists of two items; if positive, it is followed by the PHQ-9, a nine-item depression scale. In a recent meta-analysis by Levis et al. (2020), the combined screening had a higher sensitivity but a comparable specificity than the use of the PHQ-9 alone. In both cases, the specificity and sensitivity exceeded 80% for major depressive disorder. Still widely used in clinical practice is the Geriatric Depression Scale: Short Form (GDS:SF). It consists of 15 questions requiring a "yes" or "no" response, and it can be completed quickly in any setting (Sheikh & Yesavage, 1986).

A program to improve the quality of spiritual care validated the use of three instruments: HOPE, FICA, and SPIRIT. These tools are effective means of determining the older patient's spiritual beliefs and the comfort associated with these beliefs (Piotrowski, 2013). In that program, they chose to use the HOPE questionnaire with one additional question, "Are you at peace?"

SOCIAL DETERMINANTS OF HEALTH

Healthy People 2030 includes an emphasis on the personal, social, economic, and environmental factors that impact health. One of *Healthy People 2030*'s goals is to "Create social, physical, and economic environments that promote attaining the full potential for health and well-being for all." Social determinants of health (SDOH) include conditions and environments that affect health, function, and quality of life. An assessment of key determinants should be included in a comprehensive geriatric assessment (CGA). SDOH include five domains: Economic Stability, Education Access and Quality, Health Care Access and Quality, Neighborhood and Environment, and Social and Community Context. A safe living situation is critical to the health of older adults and includes the neighborhood in which they live, their housing, and access to reliable transportation. Older adults need an income adequate to meet basic needs and access to nutritious foods and physical activity. Literacy skills, especially health literacy, also impact health of older adults. Recently there has been an increased awareness of how racism, discrimination, and violence have a negative impact on health, and many of the most vulnerable older adults are at risk.

In community-dwelling older adults, the risk of social isolation and loneliness are all too common and are a significant health risk, affected by the SDOH. In a report by the National Academies of Science, Engineering, and Medicine (NASEM, 2020) it was noted that 24% of community-dwelling older adults are socially isolated and 35% of adults 45 and older are lonely. Social isolation and loneliness have been shown to affect overall quality of life and to contribute to all-cause mortality. Gardiner et al. (2018) in a review, cited evidence that social isolation and loneliness have been associated with depression, a decline in cognitive function, an increase in cardiovascular disease, and a decrease in overall quality of life. Social isolation and loneliness may not be detected because they are not consistently assessed in the primary care setting (Cotterell et al., 2018). Because of their broad impact on health, assessment of social isolation and loneliness should be an essential component of a CGA.

The use of screening tools in the CGA provides a framework and consistency of assessment. However, it is important to distinguish between tools useful for research and those best used in clinical practice. The NASEM (2020) identified two tools most useful in the clinical setting, the Berrkman-Syme Social Network Index, for measuring social isolation, and the three-item UCLA Loneliness Scale, for measuring loneliness. In 1995, Kane recommended including the following statements in a CGA to help improve understanding of the patient's social support:

- Is there any one special person you could call or contact if you need help? (If yes, identify.)
- In general, other than your children, how many relatives do you feel close to and have contact with at least once a month? (Number.)
- In general, how many friends do you feel close to and have contact with at least once a month? (Number.)

SUMMARY

A comprehensive geriatric assessment (CGA) is a multidimensional process designed to identify care needs, plan care, and improve outcomes for older adults. The domains of CGA include, but are not limited to, physical health, functional status, psychological health, socioenvironmental supports, and measures of quality of life. The evidence of the value of CGA in general has been inconsistent. The evidence is clear that parts of the CGA do improve certain outcomes in older patients, but continued rigorous research is indicated.

Clinical Recommendation	Evidence Rating	References
Both loss of vision and hearing have been linked to cognitive decline.	B	Ray et al., 2019
Evidence shows that the benefit of mammography screening increases with age, with women between 50 and 74 years old benefiting the most. The best balance of benefit to harm is when screening every 2 years. For women older than 75 years, evidence is insufficient; screening decisions should be on an individual basis.	A	Siu for U.S. Preventive Services Task Force (USPSTF), 2016
Patients at higher risk for glaucoma should have a dilated eye examination every 2 years. Blacks 40 years and older. All adults over 60. People with a family history of glaucoma.	B	CDC, 2021
Women aged 65 years and older and younger women whose fracture risk is equal to those 65 years and older who have no additional risk factors should be screened for osteoporosis with dual-energy x-ray absorptiometry of the femoral neck. For men, current evidence is insufficient to assess benefits and harms of screening.	B	USPSTF, 2018

AGE-FRIENDLY HEALTH SYSTEMS

The prevalence of living with multiple chronic conditions increases with age, requiring long-term treatments, complex management, and reliable continuity of care. The comprehensive geriatric assessment (CGA) requires expertise in the care of older adults and coordination across disciplines. With the rapidly growing, diverse aging population, demand for more efficient, effective, safe, and age-appropriate care of older adults is increasing (Tavares et al., 2021; Fulmer et al., 2018). Tavares and colleagues (2021) emphasize that older adults face challenges related to declining health conditions, autonomy, and independence, which may worsen due to adverse events in the health-care environment. These adverse events can extend a care period and compromise daily routines and function (Tavares et al., 2021). Application of evidence-based, age-friendly care is essential to assessment and management of older adults across health-care settings.

The Evidence for Age-Friendly Health Systems

The Institute for Healthcare Improvement (IHI) developed an approach to improve the performance of health systems. The Triple Aim model was developed by the IHI to address weaknesses in the U.S. health-care system as well as population health, experience of care, and per capita costs (IHI, 2021). When adverse events occur in health-care systems, it is commonly because of a lack of attention to the population or the experience of care, and the result is often increased cost. IHI's expertise in improving the quality of health care resulted in their partnership in 2017 with the John A. Hartford Foundation as well as the American Hospital Association and the Catholic Health Association of the United States to radically change the care received by older adults in the United States. This partnership resulted in the Age-Friendly Health System initiative. The care model focused on efficiency while providing effective, safe care for older adults. Unlike more comprehensive geriatric care models, the Age-Friendly Health System initiative easily translates into a variety of health-care settings, allowing for ease of use and reliability (Fulmer et al., 2018). The understanding is that older adults deserve safe, effective, and patient-centered care in the settings in which they receive their care.

THE 4MS FRAMEWORK

The Age-Friendly Healthcare System's evidenced-based initiative was developed by researchers, clinical geriatric specialists, and health system leaders. Methodologically, geriatric experts were convened to review 17 geriatric care models with level 1 or 2 evidence of impact. They identified 90 care elements, removed redundancies, and found 13 discrete features. That expert meeting led to the selection of a set of four core features now known as the 4Ms Framework (Fig. 6-1). The framework provides a guide for health-care providers so that the care of older adults is organized, manageable, and reliably delivered (Fulmer at al., 2018; IHI, 2021). The 4Ms include:

- What **M**atters: considering what is most important to the older adult, family, and caregivers and goals and preferences
- **M**edication: making sure all medications have clear indications, prescribed at the lowest effective dosages and frequencies
- **M**entation: assessing and managing dementia, delirium, and/or depression
- **M**obility: maintaining or improving mobility and function

The resulting age-friendly care focuses on an older adult's wellness and strengths rather than on disease. The 4Ms apply regardless of the older adult's cultural, racial, ethnic, or religious background, or the number of conditions or functional problems they may have. Many health systems found they already provide care to older adults that align with one or more of the 4Ms. The challenge to those systems is to incorporate the other elements and organize care, so that all 4Ms are used as a set to reliably guide every encounter with an older adult and their family or other caregiver (IHI, 2020).

In Age-Friendly Health Systems, healthcare-related harms to older adults are dramatically reduced and older adults get the best care possible, are satisfied with their care, and value is optimized for everyone (Mate et al., 2021). The provision of age-friendly care means that care follows an essential set of evidence-based practices, causes no harm, and aligns with what matters to the older adult and their family or other caregivers (IHI, 2020). Age-Friendly Health Systems may be applied in acute, ambulatory, long-term care, and convenient care settings.

What Matters

The Age-Friendly Health Systems initiative defines "What Matters" as knowing and aligning care with each older adult's specific health outcome goals and care preferences including, but not limited to, end-of-life care and across settings of care (IHI, 2021). Specifically asking what matters to the patient helps establish a treatment plan and a rapport with the health-care provider and allows their concerns to be the center of the visit. Research shows if what matters to an older adult is identified, it leads to decreases in inpatient utilization by 54% and intensive care unit stays by 80%, and improves patient satisfaction (Mate et al., 2021).

Understanding what matters is an ongoing process. Health-care providers should assess what matters during a series of conversations over time and use what matters as a guide for how care is delivered. What matters conversations about goals and preferences should be included in all points of care such as during annual well visits, acute and chronic disease management visits, as well as life changing events such as the death of a spouse, illness, or new medical diagnoses. What matters may include self-care, visiting family, advance care planning, and any core values of the older adults such as ideas about happiness and fulfillment. Once assessed, providers should align the care plan with what matters most to the older adult, considering their goals and preferences (Mate et al., 2018).

Medication

As adults age, the number of medications they are prescribed increases. Nearly 90% of adults 65 and older report they are currently taking prescription medication. Further, 54% of these adults report taking four or more medications daily. Polypharmacy occurs when people use multiple medications and the harm, or potential harm, of taking those medications

© F.A. Davis Publishing

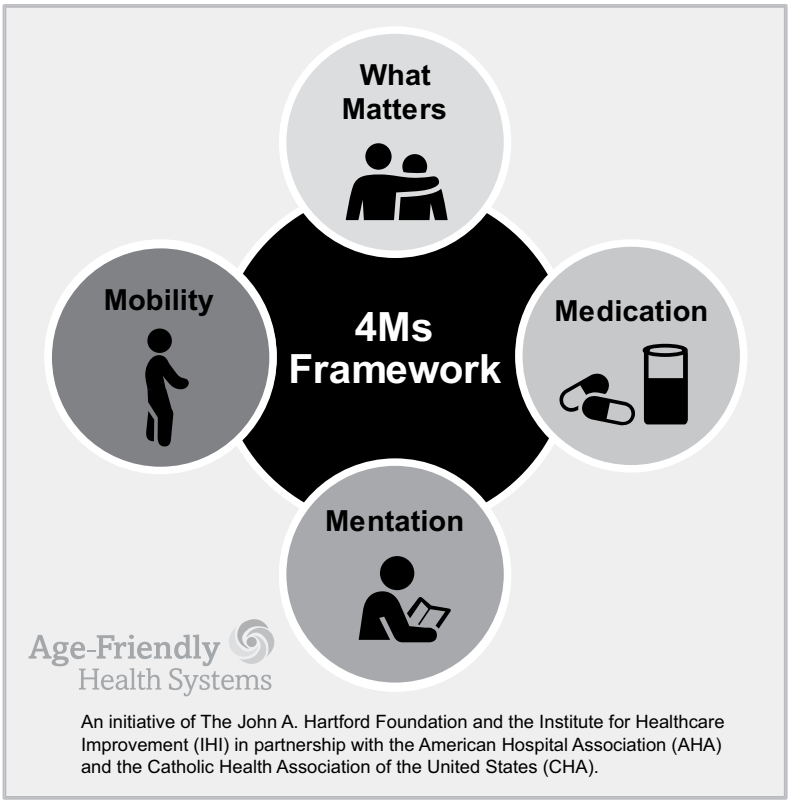

FIGURE 6-1 The 4Ms Framework. (Reprinted with permission from the Institute for Healthcare Improvement.)

outweighs the benefits (Mate et al., 2021). Problems with polypharmacy are affected by the physiological changes that occur with aging. An increase in drug excretion time, for example, may increase risk of effects on mentation and/or mobility, thereby interfering with what matters.

The Age-Friendly Health Systems movement emphasizes that if an older adult needs medication, it should be appropriate for older adults and at the lowest effective dose and frequency. In reviewing or prescribing medications for older adults, assess if any medications are currently listed on the AGS Beers Criteria® list of potentially inappropriate medication for older adults (AGS, 2019) and whether any may be safely deprescribed. These may include anticholinergic medications, benzodiazepines, opioids, muscle relaxants, tricyclic antidepressants, and antipsychotics. Across care settings, health-care providers should ensure that all medications are age-friendly and that any prescribed medications do not affect their mentation, mobility, or what matters to them. Follow-up is needed to assess tolerance to any medication changes.

Mentation

Dementia and depression as well as delirium are common psychiatric and geriatric syndromes that may occur concurrently (Leyhe et al., 2017). These syndromes may be underassessed and undiagnosed in health-care settings. Health-care providers may not be aware of the assessment or screening tools available, may have time restraints for visits depending on the setting, and may not be specialists in care of older adults. Regardless, in Age-Friendly Health Systems, assessment for cognition, delirium, and depression using evidence-based tools is expected and required. This, in turn, leads to appropriate prevention, identification, treatment, and management across all care settings. It is important to note that the Age-Friendly Health Systems movement uses evidence-based practice approaches that are also effective with patients living with dementia (Fulmer & Li, 2018). Further, the 4Ms framework centers around the patient and what matters to them, including those with dementia and their family's wishes regarding care throughout the stages of dementia.

As discussed earlier in this chapter, evidence-based assessment tools for cognition include the Mini-Cog™, SLUMS test, and MoCA. Depression screening tools may include the Patient Health Questionnaire or Geriatric Depression Scale. Delirium screening may be conducted using the Confusion Assessment Method or Ultra Brief-2 (UB-2) Screener. Actions for a positive memory-related screening tool may include assessment or testing of other potential causes or referral to a neuropsychiatrist for a more comprehensive cognitive assessment. Actions for a positive depression screen may include referral to a specialist, support group, community resources and programs, or cognitive behavioral therapy. Further assessment and emergency treatment may be indicated if a person is suicidal. Actions for delirium should focus on the underlying cause of the delirium, which may indicate a medical emergency. A follow-up plan for any abnormalities noted is important to include, and alignment of the mentation treatment plan with what matters, medication, and mobility is key.

Mobility

Mobility is a fundamental part of both basic ADLs and IADLs. Mobility, including the ability to walk and/or climb stairs, is an important predictor of quality of life among older adults

© F.A. Davis Publishing

and a measure of successful aging (Musich et al., 2018). Although increased physical strength, function, and mobility are associated with healthier outcomes, some older adults may lead a more sedentary lifestyle, which may lead to decreased health and increased risk of falls. The Centers for Disease Control and Prevention (CDC) recommend that older adults engage in physical activity of moderate to intense aerobic activity at least 150 minutes per week to have health benefits such as muscle strength (CDC, 2021). As part of age-friendly care, health-care providers should assess if there are any barriers to mobility or participating in physical activities so they may be addressed in the plan of care.

Examples of mobility assessment tools include the Timed Up and Go Test or Stopping Elderly Accidents, Deaths, & Injuries (STEADI). Actions include encouraging older adults to move safely every day and develop or continue a daily mobility goal. Older adults should receive education about appropriate physical activities, fall prevention methods such as wearing supportive, non-slip footwear, maintaining good lighting and clear walking paths in the surrounding area, avoiding use of throw rugs, and using grab bars and non-skid mats in the bathroom. As needed, patients may be encouraged to use an assistive device and/or referred to local community activities, exercise programs, or physical therapy. The mobility plan should align with what matters, medication, and mentation.

Age-Friendly Care Implementation

Becoming an Age-Friendly Health System begins with an interprofessional team developing an aim statement and articulating how it plans to operationalize age-friendly care using the 4Ms framework, including the assessment and action steps for the 4Ms. The choice of evidence-based assessment tools and frequency of use is organization-specific, and implementation of age-friendly care may vary across settings of care. For example, in acute care, assessment of the 4Ms may be done daily with delirium screening possibly every shift or every 12 hours. In ambulatory care, assessment of the 4Ms may occur annually or with a change in condition. Providers in the convenient care setting may assess and act on the 4Ms at every older adult visit, as that may be the only opportunity they have to provide age-friendly care for that patient.

The IHI offers guidebooks and toolkits to support providers in adopting the 4Ms on their Web site (http://ihi.org/agefriendly). These resources include practical guidance for various care settings and electronic health record requirements. To prepare organizations to become Age-Friendly Health Systems, the IHI holds free Action Communities that meet for 7 months and provide educational webinars, coaching, and resources.

The IHI recommends using implementation science methods, such as integrating the 4Ms into care using Plan-Do-Study-Act (PDSA) cycles to test changes to workflows, documentation practices, or other processes, before launching changes health system-wide. The PDSA steps include: (1) understand the current state, (2) describe how the care is consistent with the 4Ms, (3) design or adapt the workflow, (4) provide care, (5) study performance, and (6) improve and sustain care (IHI, 2020).

Initially launched with five pioneering health systems (Trinity Health, Ascension, Providence St. Joseph Health, Anne Arundel Medical Center, and Kaiser Permanente), as of June 2021, there are 2233 Age-Friendly Health System Participants (IHI, 2021). In 2018 CVS Health's Minute Clinic became the first convenient care setting to implement the Age-Friendly Health Systems, 4Ms model. Recognition as an Age-Friendly Health Systems Participant means that these hospitals, ambulatory practices, convenient care clinics, and nursing homes have articulated plans to implement age-friendly care into practice using the 4Ms framework. Additionally, as of June 2021, there are 537 Age-Friendly Health Systems recognized as Committed to Care Excellence, meaning they are exemplar and have at least 3 months of verified data to demonstrate early impact of using the 4Ms. The goal is to continue to scale and spread the Age-Friendly Health Systems movement across the United States and globally.

The Age-Friendly Health Systems movement was developed in response to the crucial need for an efficient, safe, effective, and reliable framework that may be easily adopted across all health-care settings. Health-care providers are expected to provide evidenced-based quality care to older adults. Assessing and acting on all 4Ms as a set in all care settings is a proven method to ensure age-friendly care is provided to all older adults.

CHAPTER 7

Symptoms and Syndromes

Evelyn Duffy

ASSESSMENT

Differential diagnosis begins when the patient presents their chief concern, or a change in condition is identified. Assessment of a symptom is based on the presentation of the concern, change in condition, or an evaluation of a geriatric syndrome in the older adult. In addition to the classic approach to defining a symptom, listening to the patient's story and asking the right questions are necessary to determine an accurate diagnosis as well as inform the development of the plan of care. Using a change in function as a measure of the impact of a symptom on the patient is an effective means of sorting out the differential. Heterogeneity increases with age, and older adults are more likely to present common diseases in uncommon ways. This requires the provider to consider a greater number of possibilities when formulating a diagnosis, and the differential diagnosis can be quite broad. It is important not to form a probable diagnosis before obtaining a full history and considering more uncommon diagnoses (Reinoso et al., 2018). Working up an older adult with a single symptom or cluster of symptoms using typical symptom analysis and clinical decision-making tools can be done, but it is often complicated by the fact that patients may ignore symptoms initially because they do not interfere with functional activities or because they attribute the symptoms to the aging process. Conversely, patients may fear loss of independence related to a subtle decline in functional abilities and thus deliberately choose to conceal certain symptoms, or they may be unaware of a subtle decline until it becomes apparent to others.

Acuity of symptoms may be blunted because of changes in the efficiency of certain physiological mechanisms (Vonnes & El-Rady, 2021). New symptoms often appear in one organ system as an offshoot of pre-existing disease in another organ system. Multiple symptoms may be present because of comorbidities. These factors can result in a delayed or atypical presentation (Vonnes & El-Rady, 2021). In many cases, the first hint of illness may be a change in cognitive function or mental status. In the case of the patient with an underlying dementia, the refusal to eat or drink, or a change in the patient's behavior, may signal an acute illness. The term *geriatric syndrome* refers to conditions that have multiple underlying factors that may involve multiple organ systems; some of the most common are delirium, falls, dizziness, and incontinence. Older adults may present with both an atypical presentation in addition to a pre-existing geriatric syndrome (Vonnes & El-Rady, 2021). The literature reflects that shared risk factors across geriatric syndromes include older age, cognitive impairment, functional impairment, and impaired mobility. For each presenting symptom, the following descriptors should be used to guide the diagnosis:

- Mode of onset of the symptom (events coinciding with onset, similar past episodes, gradual or sudden, total duration)
- Location of the symptom
- Character of the symptom
- Radiation of the symptom
- Precipitating or aggravating factors
- Relieving or ameliorating factors
- Past treatment or evaluation (when, where, who; studies done and results)
- Course of the symptom
- Effect of the symptom on normal daily activities

If the symptom or the patient's demeanor indicates a problem in function or cognition, assess these areas. Perform a thorough medication history, including the use of over-the-counter (OTC) preparations, vitamins, herbal and homeopathic remedies, and any other dietary supplements, and consider their use in formulating diagnostic possibilities. Pharmacotherapeutic or other treatment modalities can complicate or even cause illness in older patients. Diuretics, which are included in almost every older adult's medication list, were found to be the number one cause of adverse drug reactions in older adults (Brandt & Lee, 2021). In developing a differential diagnosis, an adverse drug reaction should always be a consideration. The process of differential diagnosis includes multiple decision points, and at each point, it is important to utilize shared decision making by including the patient and what matters most to them (Pel-Little et al., 2020). The nurse practitioner also should consider who else is involved in the patient's health care and whether they need to be included in these discussions. Outcomes are improved when shared decision making is utilized.

This chapter includes many of the common symptoms presented by older adults. Each section contains multiple

© F.A. Davis Publishing

differentials to consider when evaluating the patient. Regardless of what may seem like a clear presentation, in caring for older adults the compounding factors of medication side effects, geriatric syndromes, and atypical presentation of disease are essential to the final determination of evaluation and plan of care. Including the patient and their informal caregivers increases the possibility that the final plan will be successful.

BOWEL INCONTINENCE

Description: Bowel incontinence or fecal incontinence (FI) is an involuntary passage of stool, either small amount with the expulsion of flatulence or the complete inability to control stool from expulsion. There are three types of FI: (1) urge incontinence: a person feels the need to defecate but cannot make it to the toilet despite attempts to avoid defecation; (2) passive incontinence: involuntary loss of gas or stool without awareness; and (3) fecal seepage-leakage of stool after a normal bowel evacuation, usually presenting as staining of clothing (Nazario, 2020; Shah et al., 2012). On occasion bowel incontinence may be the leakage of liquid stool going around a hard mass of stool in the colon, also known as a fecal impaction. This condition can be costly because of the need to use adult briefs as well as greater incidence of nursing home placement of individuals with FI. It can also be a socially and emotionally devastating situation that interferes with quality of life and leads to diminished self-esteem and depression.

Etiology: Defecation involves a complex series of events and factors: diet, stool consistency, muscle strength and function, anorectal sensation and anal patency, as well as neurological integrity, cognition, and motivation (Nazario, 2020; Shah et al., 2012). The ability to defecate has two components: continence and defecation. Continence is the ability to hold fecal material and is under the control of the autonomic nervous system and spinal cord nerve functioning, including the internal and external anal sphincter. Defecation is the evacuation of feces when a person consciously attempts to have a bowel movement (Shah et al., 2012). FI occurs for various reasons, ranging from gastrointestinal (GI) issues to cognitive or neurological diseases. A greater concern exists in a patient who is continent of urine but incontinent of stool. See Table 7-1 for a review of causes of FI.

Occurrence: Prevalence in community-dwelling older adults is 36% and up to 65% in nursing home residents. In the hospitalized setting, there is reported to be 16% prevalence (Shah et al., 2012). FI occurs more commonly in women than men due to delivery of large babies or from obstetrical trauma related to childbirth (Shah et al., 2012).

Age: FI is found more frequently in older adults than in the general population.

Ethnicity: Not significant.

Contributing Factors: There are certain epidemiological risk factors in the older individual associated with FI. In men, kidney disease and urinary incontinence were associated with FI, and in women, depression, urinary incontinence, and chronic diarrhea were associated with FI (Nazario, 2020; Shah et al., 2012).

Diarrhea from GI disease (colitis, irritable bowel syndrome [IBS]), infectious causes such as viral gastroenteritis or *Clostridioides difficile (C. diff)*, or medication side effects can contribute to acute, short-term bowel incontinence. *C. diff* infections occur when a person is exposed to the pathogen while receiving antibiotic treatment for another illness (Connell, 2019; Keller & Surawicz, 2014). Antibiotics suppress the normal bacteria in the colon, allowing malabsorbed carbohydrates or *C. diff* to flourish, producing toxins

TABLE 7-1 Causes of Bowel/Fecal Incontinence

DISEASE	MECHANISM	COMMENTS
Central Nervous System		
Dementia	Impairs awareness of need to defecate—unable to interpret the sensation of stool in bowels Loss of inhibitory control	Manifestations depend on type and severity of dementia
Stroke	Impaired awareness of anal control Slowed motor processing communication with frontal lobe damage	Dependent on size of infarct or hemorrhage within the brain
Brain tumor	Similar to stroke	Dependent on location of tumor
Multiple sclerosis	Decreased external anal sphincter pressures leading to decreased volumes of rectal distention to inhibit the internal anal sphincter	
Peripheral Nervous System		
Cauda equina syndrome	Compression of spinal nerves	
Polyneuropathies	Various mechanisms leading to destruction of the axon and myelin	Causes include infection, autoimmune disease, hypothyroidism, vitamin B_{12} deficiency, and medications

TABLE 7-1 Causes of Bowel/Fecal Incontinence—cont'd

DISEASE	MECHANISM	COMMENTS
Diabetes mellitus	Neuropathy of sensory and motor nerves	
	Internal anal sphincter dysfunction	
Shy Drager syndrome	Multisystem atrophy	
Toxic neuropathy	Destruction of nerve cells leading to loss of sensation or motor control	Chemotherapy and radiation therapy
Traumatic neuropathy	Chronic straining during evacuation	
	External anal sphincter weakness or pudendal nerve neuropathy	
Fecal impaction	Altered rectal sensation	
	Liquid stool escaping around solid feces in colon or higher in bowels	
Gastrointestinal (GI)		
GI disease	GI dysfunction/disease with excessive stool volume and rapid gut transit	Causes include viral or bacterial gastroenteritis, colitis, Crohn's disease, celiac disease, colon cancer, irritable bowel syndrome, rectocele, and other GI diseases
		**Clostridioides difficile* can cause severe diarrhea in the elderly and can lead to death
Rectal sphincter dysfunction	Anal sphincter damage and/or pudendal neuropathy affecting sphincters, puborectalis muscle, and rectal sensation	Common causes include delivery of large baby, traumatic childbirth, anal surgery, rectal prolapse, and prolonged straining
Reservoir incontinence	Loss of compliance of the rectal wall leading to urgency, frequency, and leakage of stool	Associated with colectomy, inflammatory bowel disease, chronic rectal ischemia, and prostate/cervical radiation
		Diminished colonic/rectal capacity is a less common type of FI
Medications		
Laxatives	Medications causing increased gastric motility or increased water in stools	
Fiber products	Increase fluid in the stool to keep it soft and move easier but can lead to diarrhea and FI	
Magnesium	Draws fluid into the bowels through osmosis	Magnesium containing antacids and certain laxatives contain significant amounts of magnesium
Other medications	Antibiotics can cause destruction of the colon's natural flora, leading to diarrhea	
	Other medications that can cause diarrhea include proton pump inhibitors, SSRIs, and NSAIDs	
Other		
Physical deficits	Inability to recognize need to defecate (cognitive problems) or inability to ambulate to toilet without assistance	Common causes of cognitive problems include dementia
		Common causes of mobility problems include debilitating arthritis, hemiplegia, or any condition affecting gait
Dietary causes	Foods in susceptible individuals include a diet high in fiber, spicy foods, fatty/greasy foods, cured meats, smoked meats, dairy products, caffeine, or sorbitol	Sugar-free gum and artificial sweeteners can cause diarrhea and FI
		Avoidance of irritating foods can eliminate the FI
Obesity	Inability to ambulate to defecate	This is usually a reversible condition
Excessive fluid intake	Overhydration can lead to diarrhea and possibly cause FI	

Sources: Connell, 2019; Nazario, 2020; Shah et al., 2012

© F.A. Davis Publishing

that cause a severe diarrhea. Damage to the colon can cause the individual to become septic and possibly cause death, especially in the older patient (Connell, 2019).

Signs and Symptoms: The first step in the clinical appraisal is to inquire about bowel habits, including incidence of diarrhea and fecal continence. Determine the duration, frequency, severity, and character of the incontinence (gas, liquid, solid). Inquire if there is sensation of contents within the bowels, a sensation of rectal fullness, awareness of passing stool or gas, and warning symptoms of cramping or urgency. Associated symptoms of abdominal pain and bloating, anorexia, diarrhea or constipation, nausea and/or vomiting, rectal bleeding, and urinary incontinence should be ascertained. Review prescription and OTC medications carefully. Past medical history may be positive for diabetes, neurological and psychiatric diseases, GI disorders, cancers with radiation, and any condition limiting mobility. Surgical history may include hemorrhoidectomy, anal fissure repair, fistulectomy, anal dilation, or colon resection. Diet review may reveal high fiber intake and excessive fluid intake or foods that may cause irritation and worsen FI such as caffeine, alcohol, chocolate, greasy or spicy foods, dairy products, and various raw fruits and vegetables.

Physical examination includes assessing for significant weight loss. The abdomen should be examined for distention, hyperactive or absent bowel sounds, pain, masses, and bladder distention. The perineum is inspected for gaping of anus, an indication of severe sphincteric dysfunction, hemorrhoids, dermatitis, surgical scars, fissures, and fistulas. The clinician should check the "anal wink" (the reflex contraction of the anal sphincter when the skin around the anus is stroked bilaterally) to test sensation and pudendal nerve function. Asking the patient to bear down will reveal rectal prolapse, if present. The digital rectal examination is performed to detect hemorrhoids or masses, and evaluate baseline and squeeze sphincter tone, as well as the amount and character of stool. Neurological examination includes assessment of gait, general mobility, motor strength, and sensory testing.

Diagnostic Tests: The results of data collected from the history and physical examination will dictate if additional testing is needed. Categorize the diarrhea as inflammatory, fatty, or watery. When an infectious or foodborne cause is suspected, stool tests guided by the clinical presentation are indicated. Exclusion of fecal impaction, particularly in nursing home patients, is essential. Plain abdominal radiograph may show a high impaction when no hardened stool is felt in the rectal vault. If organic bowel disease is suspected (inflammatory disease, ischemic colitis, neoplasm), stools for occult blood, flexible sigmoidoscopy or colonoscopy is indicated. Anorectal manometry tests rectal sensation and compliance through the use of an intrarectal balloon and measures pressure, tone, and reflex contraction of the internal sphincter. It provides comprehensive information about anorectal function and is reasonable in the ambulatory and/or healthy elder who has failed conservative interventions. Other tests that may be considered include colonoscopy, electromyography, anal ultrasound, and magnetic resonance imaging (MRI).

Differential Diagnosis: The differential diagnosis includes fecal impaction, gastroenteritis, foodborne illness, ruptured diverticulum, inflammatory bowel disease, ischemic colitis, IBS, anal fistula, diabetic neuropathy, rectal prolapse, upper motor neuron lesions secondary to cerebrovascular accident (CVA), multiple sclerosis, spinal cord compression, degenerative processes, dementia, depression with self-care deficits, and functional impairment.

Treatment: Underlying causes should be treated when possible, such as administering antibiotics for *C. diff* infection, administering steroids or amino salicylate drugs (5-ASA) for inflammatory bowel disease, or implementing a gluten-free diet for celiac disease (Connell, 2019). Eliminating potentially causative agents is an important first step if diarrhea is caused by a medication or an intolerance of a diet that the individual is unable to digest such as gluten. Fecal impaction requires removal of the impaction (manually, with enemas, and/or osmotic/stimulant laxatives) and establishment of a preventive bowel regimen (see section on constipation). With loose or liquid stools, a supplement of soluble dietary fiber may be beneficial (adding more bulk to stools); the ideal amount and type have yet to be determined, and response varies greatly. Increasing fiber gradually over a period of several days can help reduce symptoms of abdominal bloating and discomfort that may be associated with increased fiber intake. In the setting of fecal reservoir incontinence, avoidance of dietary fiber may be indicated. Bowel training may be effective for elders with dementia and involves frequent and regular toileting on a timed schedule, usually after a meal to take advantage of the gastrocolic reflex and every 2 hours while awake. Once infection is ruled out, fecal impaction is excluded, and no clear cause is determined for FI with diarrhea, the antidiarrheal medication loperamide (Imodium) may be tried. For rectosphincter dysfunction, biofeedback with sphincter-strengthening exercises is an option for motivated, cognitively intact older adults who have some degree of rectal sensation. Sacral nerve stimulation is also a promising, safe, minimally invasive treatment of FI related to rectosphincter dysfunction. Surgical sphincter repair may be considered when incontinence is severe, unresponsive to conservative interventions, and clearly related to anatomical defects, with best outcomes seen with repair of defined defects in the external sphincter.

Follow-Up: Follow-up is indicated to assess resolution of FI, and the time frame will be dictated by the identified cause as well as the severity of the problem. Ongoing monitoring is needed in all cases.

Sequelae: Complications of FI include perineal irritation or dermatitis, pressure injury in the sacral/perineal area, non-healing wounds, recurrent urinary tract infections (UTIs), anxiety, social isolation, and depression. FI, along with urinary incontinence, is a leading cause of institutionalization of older adults.

Prevention/Prophylaxis: Manage constipation. Optimize treatment of underlying medical conditions, such as diabetes and GI disturbances. Adjust diet and laxative use to address loose stools. Consider physical therapy/occupational therapy (PT/OT) intervention to address mobility and toileting ability. Reinforce a regular toileting program for the cognitively impaired and physically frail.

Referral: Consider emergent spinal imaging/neurosurgical consultation for new-onset fecal/urinary incontinence with lower extremity weakness and paresthesia to rule out spinal cord compression. Additional evaluation is needed with "alarm" symptoms (change in bowel habits, rectal bleeding, weight loss) to rule out GI malignancy.

© F.A. Davis Publishing

Education: Provide clear information on normal bowel function, FI cause, and rationale for any diagnostic tests, preventive strategies, and treatments. Instruct in appropriate dilution and need for adequate fluid with fiber supplements. Direct to appropriate resources for incontinence pads and briefs as needed.

CHEST PAIN

Description: Acute, nontraumatic chest discomfort, perceived as pain or as a sensation of tightness, pressure, or squeezing in the chest or thorax area; associated with actual or potential tissue or organ damage.

Etiology: The many different pathologies of chest pain (CP) may be attributed to segmental overlap of neurons of cardiopulmonary and noncardiopulmonary origin. CP may originate from organs within or outside of the thorax; cardiac, pulmonary, esophageal, large vessel, gastric, pancreas, biliary, musculoskeletal, skin, and psychological pathology may be implicated. Life-threatening or high acuity causes include acute coronary syndrome (ACS) (includes acute myocardial infarction [MI] and unstable angina), aortic aneurysm, thoracic aortic dissection, spontaneous tension pneumothorax, pneumonia, pulmonary embolism (PE), esophageal perforation, and esophagitis. Lower acuity causes of CP can be stable angina, pericarditis, myocarditis, gastroesophageal reflux disease/gastro-peptic, biliary disease, costochondritis, rib fracture/trauma, and herpes zoster (Sanchez-Lopez & Paniagua, 2021).

Occurrence: Chest pain accounts for 5% to 10% of all emergency department (ED) visits in the United States and is one of the common complaints worldwide (Laureano-Phillips et al., 2019). Of those 6 million visits, approximately 15% are older than 65 years (Vespa et al., 2020). It is the most common reason that persons older than 65 present to the ED (Sanchez-Lopez & Paniagua, 2021).

Ethnicity: A recent study by Iacoe et al. (2018) found no statistically significant difference in the time to treatment for ACS based on ethnicity of patients seeking care.

Contributing Factors: GI causes of chest pain may mimic ACS. Gastroesophageal reflux disease (GERD) can not only mimic ACS, but in 50% of patients it can also coexist with coronary artery disease (CAD). In a 2020 study (Eisa et al., 2020) patients with GERD controlling for many other factors had a higher risk of acute myocardial infarct than a control group without GERD. Several medications and illicit substances can cause ACS. These include nonsteroidal anti-inflammatory drugs, which can cause endothelial cell damage, most prominent in COX-2 inhibitors. Antiviral therapy and highly active antiretroviral therapy (HAART) increase ACS risk by 26%. Illicit medications, including methamphetamines, LSD, cocaine, and heroin, can all lead to cardiac complications. Recent work has even correlated the use of cannabis with ACS (Richards et al., 2019). Anemia, which is frequently found in the older adult, may predispose the person to cardiac ischemia secondary to supply and demand of oxygen carrying red blood cells (Klabunde, 2020). Atrial arrhythmias, atrial fibrillation and flutter can be associated with pulmonary emboli, as a cause-and-effect relationship, as in recent orthopedic surgery, recent immobilization, deep vein thrombosis (DVT), and cancers (Ptaszynska-Kopczynska et al., 2019).

Signs and Symptoms: Pain of ACS may be midsternal, retrosternal or poorly localized; the pain may radiate to arms, back, neck, or jaw; may occur at rest; may last longer than 20 minutes; and may not be relieved with nitroglycerin. Nausea, vomiting, diaphoresis, dyspnea, weakness, fatigue, light-headedness, and/or anxiety, may accompany chest pain representing an acute coronary event or acute coronary syndrome. Chest pain may be precipitated by stress, exercise, or by mild or severe illness. Stable angina can present as substernal or precordial pressure, a feeling of constricting, or heaviness in the chest, precipitated by exertion, and may be relieved with vasodilator medication such as a nitrate. Older adults or patients with diabetes may have

© F.A. Davis Publishing

altered pain perception or inability to localize the discomfort commonly seen in typical presentations of chest pain. The average age of a patient presenting with their first MI is 65 years old for men and the average age for women is 72 years old. The incidence of MI increases with age and an absence of chest pain with ACS in older adults is common. Dyspnea is a common presenting symptom of acute MI in patients older than 85 years. Anyone older than 65 years of age who presents with the chief complaint of CP must receive an ACS work-up.

Thoracic aortic dissection has abrupt onset and severe, retrosternal tearing pain that usually radiates to the back and both arms. Pulmonary embolism (PE) may present with acute dyspnea, cough, deep pleuritic chest pain that may or may not be severe. Tension pneumothorax is associated with acute unilateral pleuritic chest pain and dyspnea and often is sudden. Esophageal spasm and GERD may mimic the pain of myocardial ischemia, can be associated with eating, consuming alcohol, improves with upright position or antacids, and is accompanied by cough, hoarseness, and dysphagia. Acute pancreatitis may present with knifelike epigastric or lower chest pain radiating to the left shoulder associated with vomiting and relieved by leaning forward. Musculoskeletal pain is usually persistent and is aggravated by movement, cough, or deep respirations and can be associated with a recent fall, or old/chronic spine injury. Musculoskeletal pain may be replicable on examination. Chest pain associated with Herpes zoster is described as sharp pain or paresthesia in the mid-thorax unilaterally and causes a vesicular rash in a unilateral thoracic dermatome. Pain may precede rash by several days.

History may be positive for CAD with or without angina or risk factors thereof, including hypertension, diabetes, and hypercholesterolemia. GI disorders, degenerative joint disease, and anxiety disorders, as well as tobacco and alcohol abuse, can also be clues to the diagnosis.

Signs of serious conditions include acute confusion or anxiety, pallor/cyanosis, diaphoresis, tachycardia, bradycardia, tachypnea, and hypotension and or mean arterial pressure less than 70. A new S_3 or S_4 gallop, new systolic murmur, or signs of HF (jugular venous distention, basilar crackles, or lower extremity edema) suggest myocardial ischemia/injury. Asymmetrical blood pressures, absent or asymmetrical extremity pulses, and aortic bruit may be present with aortic dissection. Cardiac tamponade is more common in the setting of other chronic diseases such as autoimmune disease, malignancy, or recent chest trauma. Tracheal deviation, unilateral diminished or absent breath sounds, and palpable subcutaneous crepitus may reveal pneumothorax. Rapid, irregular apical pulse suggests atrial fibrillation, whereas unilateral lower extremity swelling and tenderness suggests DVT. Fever suggests an infectious cause. Localized abdominal tenderness with guarding and rebound points to GI origins. Costochondritis pain is worse with chest movement, sneezing, or cough and is not associated with fever, shortness of breath, tachycardia, or other cardiopulmonary symptoms. Diffuse tenderness is usually seen over one or more costochondral joints.

In the older adult CP symptoms are less pronounced and may be attributed to symptoms of normal aging. This can lead to delays in care and adverse outcomes or death. Furthermore, the older adult with cognitive impairment, severe depression, delirium, or difficulty in communicating their symptoms are at a higher risk for poor outcomes and potential further debilitating manifestations (Sanchez-Lopez & Paniagua, 2021).

Diagnostic Tests: If myocardial ischemia or injury is suspected, immediate 12-lead electrocardiogram (ECG) is needed and may show ST-segment depression or elevation, T-wave inversion, new left bundle branch block (LBBB), or new Q waves. However, the ECG may not change for hours or sometimes not at all. Elevations in cardiac markers (troponins T and I) taken at hours 0, 3, and 6 after the onset of pain indicate myocardial injury (Gursahani, 2021).

Additional tests include chest x-ray (CXR), which may reveal pulmonary edema, pneumothorax, pleural effusion, pneumonia, or lung mass. A d-dimer blood test and spiral computed tomography or ventilation/perfusion scan may confirm pulmonary emboli. D-dimer levels increase with age (ADJUST-PE study; age adjusted defined as 10 times the age if >50 years old or >00 if <50 years old) and this must be taken into consideration with older aged patients (Blondon et al., 2020). Lower extremity doppler ultrasound can diagnose DVT. Additional testing is guided by the clinical situation, history, and physical findings. Older adult patients with ACS are less likely to have typical ECG findings (i.e., ST-segment elevation). Unstable angina/non-ST elevation MI shows T-wave inversion, absent Q waves, and evolving ST-segment changes.

Differential Diagnosis: The differential diagnosis includes:

Non-Ischemic	Pulmonary	GI	Chest Wall/ Musculoskeletal	Psychiatric
Cardiovascular	Pulmonary embolism	Esophageal	Costochondritis	Anxiety disorder
Aortic dissection	Pneumothorax	Esophagitis	Fibrositis	Hyperventilation
Pericarditis	Pneumonia	Reflux	Rib fracture	Panic disorder
	Pleuritic	Biliary colic	Sternoclavicular arthritis	Primary anxiety
		Cholecystitis	Herpes zoster (before rash)	Affective disorders
		Choledocholithiasis		Thought disorders
		Cholangitis		
		Peptic ulcer		
		Pancreatitis		

© F.A. Davis Publishing

Treatment: If there is high suspicion of emergent conditions such as ACS or aortic dissection, immediate transport to the ED by emergency medical services (EMS) is required. For frail older adults, conservative management of ACS in the facility may be considered. Functional older adults should receive immediate intervention and early hospital care for suspected ACS. Treatment with supplemental oxygen to maintain an oxygen saturation above 91%, aspirin 160 to 325 mg chewed (if no allergy) sublingual or IV nitroglycerin if blood pressure is greater than 90 mm Hg systolic and heart rate is greater than 50 beats per minute (bpm). Nitrates should never be administered to patients with suspected ST elevation MI (STEMI) or non-ST elevation MI (NSTEMI) who received phosphodiesterase inhibitors (sildenafil, tadalafil, vardenafil) within 24 to 48 hours of onset of symptoms. This can cause a precipitous fall in the blood pressure, leading to a potentially fatal outcome. Pursuing further treatments such as coronary artery intervention can be determined on a case-by-case basis (Mechanic et al., 2021).

Analgesic therapy may be recommended for pain control, and morphine IV can be used in a patient when not contraindicated. Treatment of stable angina includes aspirin, beta blockers, angiotensin-converting enzyme (ACE) inhibitors, nitrates, and statins. Long-acting calcium channel blockers may be used for symptom reduction if beta blockers are ineffective or contraindicated. Although only moderately successful, treatment options for esophageal spasm include calcium channel blockers, tricyclic antidepressants (exercise caution with use in older adults), nitrates, botulinum toxin, and dilation. Proton pump inhibitors (PPIs), antihistamine-1 blockers, and/or antacids are the mainstay for GERD. Weight loss is advised for the overweight and obese patient. Costochondritis may respond to conservative treatment of heat, cold, rest, topical or oral analgesics/anti-inflammatory agent. Careful examination of the skin to detect herpes zoster requires oral antiviral medications and appropriate pain management. Reassurance, cognitive-behavioral therapy, and/or antidepressants may be indicated for psychogenic causes.

Follow-Up: Follow-up is guided by diagnosis and response to treatment.

Sequelae: A 20% to 60% rate of unrecognized MI in older adults with inappropriate hospital discharge and delayed treatment results in poor outcomes and increased mortality (Acharya et al., 2019).

Prevention/Prophylaxis: Recognizing and optimizing treatment of diabetes, hypertension, CAD, hyperlipidemia, and arrythmias is essential. Encourage daily exercise and cessation of use of all tobacco products. For reflux symptoms, recommend controlling weight, elevating head of bed on blocks, staying upright after meals, and avoiding or moderating the consumption of caffeine, chocolate, spicy foods, peppermint, tobacco use, and alcohol. Encourage the patient to get age-appropriate vaccinations when indicated.

Referral: Suspected life-threatening conditions or unstable status should be referred to the ED for further evaluation and treatment. End of life and goals of care should be considered/honored per patient's wishes when life-sustaining measures may be futile to maintain one's quality of life. Establishing a person's health-care power of attorney or designee is often overlooked, making medical decisions challenging. Consultation is indicated when pain is uncontrolled, diagnosis is uncertain, and there is a poor response to usual treatment.

Education: Teach patients and families to seek immediate medical care with acute new-onset CP or when a change in chronic CP is experienced. Carefully explain causes of pain, appropriate testing and treatment, prevention strategies, and indications for follow-up. Chest pain is a common symptom found in older adults and if misdiagnosed, untreated, or undertreated, it can be life threatening and lead to high-risk complications that affect the patient's quality of life. Atypical presentations are common in this patient population which may lead to delayed care and missed opportunity to treat. It is essential to do a thorough physical examination, obtain a 12-lead ECG, cardiac isoenzymes, and CXR to establish an initial evaluation of the patient with chest pain of symptoms that may mimic cardiovascular symptoms. A careful stepwise approach is needed to assure the patient's testing is tailored to the individual's best outcome.

COUGH

Description: Cough is a preventive reflex for expelling air from the lungs involving the use of accessory muscles of the chest and constriction of the glottis (Lai et al., 2018). It is one of the most common complaints that leads people to seek medical care.

Etiology: Cough is the voluntary or involuntary mechanism used to eject aspirants or noxious substances, including fluids, solids, dust, and gases, from the body's upper and lower airways. Cough is also the body's mechanism for removing mucus from the upper or lower respiratory tracts. Involuntary cough is regulated by the vagal afferent nerve, but higher central nervous system (CNS) cortical modulation can inhibit cough or allow for voluntary cough.

Occurrence: Cough is one of the most common complaints for seeking medical attention. It is divided into three categories based on duration: acute, lasting less than 3 weeks; subacute, lasting between 3 and 8 weeks; and chronic, lasting more than 8 weeks. It can further be defined as wet or dry cough, with a wet cough producing a sputum level >10 mL per day (Lai et al., 2018). Women tend to experience heightened cough reflex sensitivity (Lai et al., 2018), and twice as many women develop a cough related to (ACE) inhibitor therapy than men (Alharbi et al., 2017).

Age: Cough occurs at any age, although in European and American countries chronic cough is more prevalent between the ages of 50 and 60 years (Lai et al., 2018). In the older adult population there is a reduced cough reflex, which is related to increased risk for aspiration pneumonia (Song et al., 2019).

Ethnicity: No direct ties to ethnicity have been documented at this time.

Contributing Factors: Any stimulation, chemical or mechanical, that irritates the receptors of the cough reflex are causes of cough. These receptors are located in the upper and lower respiratory tract, esophagus, pericardium, diaphragm, and stomach. Environmental exposure that causes cough includes multiple different types of irritants such as chemicals, dust, and pollen, along with infectious agents such as the common cold, tuberculosis (TB), or *Bordetella pertussis*. Trauma, including assault, motor vehicle accidents, or falls that lead to contusion of the lungs can cause cough. Medications may cause cough, particularly ACE inhibitors (in 5%–35% of users) (Spanevello et al., 2020).

Smoking is a primary cause of chronic cough, but medical services are often not sought by smokers. Cigarette smoking is the most significant preventable cause of disease, and lung cancer is the number one cause of cancer deaths of both men and women in the United States. Cough from chronic obstructive pulmonary disease (COPD) worsens in intensity and duration if the patient continues to smoke. Bronchogenic cancers are often associated with cough, but metastatic cancers to the lungs seldom result in cough until late in the course of the disease.

Signs and Symptoms: A thorough disease history is required because multiple chronic diseases present with cough as a symptom. Risk factors and work and home environment assessment is essential in narrowing the cause of cough. Using a systematic anatomical approach provides ease in identifying the trigger and illness. Risk factors for cough include recent exposure, smoking, stroke, immigrant status, use of ACE inhibitors, HIV-positive status, reflux and heart disease. The cough may be productive or nonproductive, and the sputum may be a variety of colors or tinged with blood. Identify the onset, including if it is episodic, continuous, or occurs only certain times of the day; the duration and character; and if it is associated with other symptoms, including red flag findings such as fever, tachycardia, dyspnea, weight loss, or pain.

The physical examination begins with vital signs that should include temperature, heart rate, respirations, and oxygen saturation. Next is a thorough examination of the nose and oropharyngeal mucosa. A pale or swollen appearance to nasal mucosa with a clear mucus in the bottom of the nasal cavity may indicate allergic rhinitis (Lai et al., 2018). A "cobblestone" appearance to the oropharyngeal mucosa and swollen eyelids are other indicators of a possible allergic origin (Lai et al., 2018). Loss of tooth enamel can indicate GERD. The chest must be assessed for adventitious breath sounds. Expiratory wheezes suggest the possibility of bronchitis or asthma caused by mucus in or constriction of the airways. Inspiratory wheezes may represent a central airway tumor (Lai et al., 2018). Rhonchi or crackles are suspicious for pneumonia or infiltrates. Diminished or absent lung sounds by auscultation and dullness to percussion are highly suggestive of pneumonia's consolidation. Rhonchi or crackles with cardiomegaly on x-ray or hypertrophy on ECG could indicate heart failure (HF) and may not be accompanied by peripheral edema or abnormal heart sounds. A velcro-like sound to the lower lung bases may suggest interstitial lung disease (Lai et al., 2018). However, most patients with chronic cough will have normal findings on physical examination (Lai et al., 2018).

Diagnostic Tests: No specific tests are indicated when the patient has a cough. The selection and extent of testing depends on the findings of the history and physical examination, cough duration (acute, subacute, or chronic), and previous evaluations.

Acute cough associated with upper respiratory infection does not require further diagnostic evaluation unless influenza or COVID-19 is suspected. In such cases, an influenza or COVID-19 diagnostic test may be beneficial. Acute cough with physical findings of life-threatening illness should be appropriately evaluated for the diagnosis of concern. A chest radiograph is appropriate for physical findings consistent with pneumonia (fever, heart rate above 100 bpm, respiratory rate greater than 24 breaths/min, altered mental status, chest examination with findings of local consolidation). Viral cultures, serologic assays, and sputum analysis should not be routinely performed in the diagnosis of acute bronchitis.

Subacute cough that has lasted more than 2 weeks without an apparent cause and is associated with posttussive vomiting, inspiratory whooping, and paroxysms of coughing should have a nasopharyngeal aspirate or polymer swab of the nasopharynx for culture to confirm the presence of

© F.A. Davis Publishing

B. pertussis (whooping cough). Bacterial isolation is the only certain way to confirm the diagnosis. Testing for TB is indicated when there is an increased risk of the population becoming infected, such as in nursing homes or prisons; in a patient with a recent visit to a country with high prevalence of TB; or in an immunocompromised patient.

Chronic cough diagnostic testing in nonsmokers is guided by elimination through treatment of the most common disorders: upper airway cough syndrome (UACS), previously known as postnasal drip syndrome, secondary to rhinosinus diseases; GERD; nonasthmatic eosinophilic bronchitis; and asthma. Medical history is crucial for determining progression of diagnostic tests for chronic cough. A chest radiograph is routinely recommended for chronic cough, though most are negative. An abnormal study would guide further diagnostics. A high-resolution computed tomography (CT) scan can identify lesions, nodules, or interstitial pulmonary disease. Bronchoscopy and biopsy can be performed to determine presence of lung cancer. HF would lead to cardiovascular evaluation via echocardiogram. Evidence of infection such as TB would direct microbiological diagnostics. Pulmonary function tests (PFTs) are valuable in diagnosing asthma or COPD. An allergen skin prick test can be beneficial in determining UACS as the underlying cause of cough (Lai et al., 2018). Chronic rhinosinusitis evaluation includes sinus imaging via sinus CT or performance of flexible nasolaryngoscopy (Michaudet & Malaty, 2017). Scans or films taken during the episode of a common cold are not diagnostic of bacterial sinus infection. Evaluation for asthma-induced chronic cough is bronchoprovocation challenge. GERD evaluation may include a barium swallow or 24-hour esophageal pH monitoring test. An induced sputum sample with eosinophilia identified can be suggestive of eosinophilic bronchitis but may also be seen in patients with cough variant asthma (Lai et al., 2018).

Differential Diagnosis: The most important first step is determining if the acute cough is potentially related to a life-threatening condition such as pneumonia, HF, or PE. Most acute coughs are related to a respiratory tract condition such as the common cold, flu, acute bronchitis, acute exacerbation of COPD, viral syndrome, or exposure to an environmental irritant.

Subacute cough is usually a cough that lingers on from a respiratory tract infection. A postinfectious cough can last 2 to 3 weeks after onset, although COVID-19 associated cough symptoms have at times been lasting longer than this. Consider UACS, transient bronchial hyper-responsiveness, asthma, acute exacerbation of chronic bronchitis, and pertussis. If it appears to be a noninfectious cough, it should be managed and further evaluated as a chronic cough.

Chronic cough most commonly is UACS, asthma, or GERD. Other potential causes may include nonasthmatic eosinophilic bronchitis, COPD, drug-induced cough, fungal infection, and mediastinal masses. A nocturnal cough associated with shortness of breath suggests HF; without shortness of breath it is more indicative of an allergy. Diagnosis of unexplained cough or idiopathic cough requires an exhaustive evaluation by a pulmonary specialist to assess the patient for uncommon causes.

Treatment: Most often the source of the cough is isolated to the respiratory system and the condition is not life threatening. The following treatments are recommended:

Common Cold. Recommendation is symptomatic treatment only; antibiotics are ineffective at decreasing the duration of symptoms and are not recommended (Lai et al., 2018). Use of first generation antihistamines alone is not recommended because of the lack of clinical benefits (Lai et al., 2018). Use of these medications is also contraindicated in patient populations older than age 65 because of the adverse reactions that can present. Combined use of a decongestant and second generation antihistamine can be considered and may significantly improve cough, sneezing, and nasal congestion. Acetaminophen is a beneficial option in those without liver disease to assist with reducing fever and improving myalgias (Lai et al., 2018). Naproxen, an NSAID, may also be used to decrease cough. It is thought to work by inhibiting the inflammatory process; however, use of naproxen should be avoided in older adults especially those with renal impairment or those at risk for stroke or MI. Antitussive agents, such as dextromethorphan, are beneficial for severe cough and come in forms that can be used by patients with diabetes. Dextromethorphan is centrally acting and should be used with caution in older adults. Expectorants, such as guaifenesin, are commonly used to help with cough and have minimal adverse reaction risk in patients older than the age of 65. Strong evidence for its efficacy is lacking, but patients often report symptom relief.

UACS. Second generation antihistamines, including loratadine and cetirizine, can be used in those older than age 65 with minimal adverse reaction risk and can be used in combination with intranasal corticosteroids, such as fluticasone, to help relieve symptoms. Improvement should present clinically within days to up to 2 months (Michaudet & Malaty, 2017). For those with severe UACS symptoms that do not respond to primary treatment, use of leukotriene receptor antagonists, such as montelukast, or immunological therapy for specific allergens is recommended (Lai et al., 2018). Immunological therapy can take a long time to manifest effectiveness (Lai et al., 2018).

Acute Bronchitis. This diagnosis is applicable in persons without signs or symptoms of acute exacerbation of COPD, acute asthma, common cold, or pneumonia. In the older adult, a high suspicion of pneumonia should be considered until proven otherwise because of the risks associated with a reduced cough reflex. Most acute bronchitis is viral and self-limiting; antibiotics do not shorten the course of the disease and should not be used. Beta2-agonists are not recommended for routine treatment unless there is wheezing or an element of pulmonary disease is present. Expectorants such as guaifenesin may be used. Dextromethorphan or codeine may be used for cough suppression for severe coughing, although research has only been done in chronic bronchitis and care must be taken when used in older adults. A cool mist humidifier in the bedroom may be helpful. If daily nicotine use is present, recommend smoking cessation.

Bacterial Pneumonia. Community-acquired pneumonia (CAP) is treated differently than healthcare-associated pneumonia. It is of particular concern in older adult patients and those who are immunocompromised because their symptoms may be less intense. In the outpatient setting, it is recommended not to obtain sputum culture; this is recommended only pretreatment in the adult who is hospitalized with CAP (Metlay et al., 2019). Prior to treatment, it is recommended to use a clinical prediction rule that is validated to aide in determining

© F.A. Davis Publishing

prognosis. The Pneumonia Severity Index (PSI) is preferred (Metlay et al., 2019). This scale assists in determining need for hospitalization versus outpatient treatment. Patients with PSI less than or equal to 90 may be considered for outpatient treatment; however, clinical judgment should also be considered (Metlay et al., 2019). See also Chapter 11 for more information about pneumonia and its treatment.

COPD. COPD embodies a variety of diseases including emphysema and chronic bronchitis (Vogelmeier et al., 2020). Treatment of these is based on the GOLD standards created by the Global Initiative for Chronic Obstructive Pulmonary Disease. Pulmonary function testing is pertinent in treating these disorders because the FEV1 and FEV1/FVC are utilized to determine severity of the airflow obstruction and the step approach to inhaler maintenance and treatment. Inhalers play a key role in the management of COPD (Vogelmeier et al., 2020). When patients with COPD experience an exacerbation they have a sudden change of symptoms with an increase in cough, shortness of breath, purulent sputum, and increase in sputum production. Treatment of exacerbations includes a SABA with or without a SAMA, systemic corticosteroids, and antibiotics for 5 to 7 days. Diagnosis and management of COPD including exacerbations is addressed in Chapter 11.

TB. Antituberculosis drugs should be initiated if the tuberculin skin test is positive, and the patient should be referred to the local health department or local infectious disease specialist.

Drug Reaction. ACE inhibitors should be stopped and only restarted if there is compelling need for the category of drug. It is recommended not to use ACE inhibitors in smokers (Lai et al., 2018). Cough will commonly subside 1 to 4 weeks after discontinuing the ACE inhibitor (Lai et al., 2018). Angiotensin receptor blockers (ARBs) can be used as an alternative treatment in those with ACE inhibitor intolerance and may also be used in smokers who may require them for kidney protection (Ding et al., 2020). ARBs are generally tolerated better and have a lower incidence of cough (Ding et al., 2020). Other medications that may cause cough include opioids, such as fentanyl, statins, omeprazole, leflunomide, interferon, and sitagliptin (Ding et al., 2020).

Postinfectious Cough. A treatment trial of inhaled ipratropium for a cough that is adversely affecting quality of life may be used. If ipratropium alone is not successful, use of inhaled corticosteroids can be considered. Antibiotics are not recommended. Severe symptoms may require use of an oral steroid for a short period while other causes of cough are being considered.

Chronic Cough Treatment. Treatment of UACS, asthma, and GERD in a stepwise, systematic approach is most likely to provide a high rate of success. Because UACS is the most common cause of chronic cough, a trial of second generation antihistamine and decongestant can be tried. Cough should improve in 1 to 2 weeks. If the response is positive, the medication should continue because it may take several weeks for marked improvement. A partial response indicates more than one cause of the cough, and evaluation and treatment for asthma or GERD is reasonable. For an unexplained cough, after evaluation and treatment for all common causes, then a referral to pulmonary medicine or otolaryngologist is recommended (Michaudet & Malaty, 2017). In some trials use of gabapentin or pregabalin along with speech therapy, or speech therapy alone have shown benefit in chronic cough (Michaudet & Malaty, 2017).

Follow-Up: The timing of follow-up depends on the severity of the illness and the impact on the patient's life. For pneumonia or bronchitis with minimal dyspnea, a call or virtual visit to check on the patient is appropriate. Rising temperature or increasing difficulty breathing requires immediate attention or ED evaluation. Patients with resolving pneumonia should be evaluated in 2 to 3 weeks; a repeat chest x-ray may be taken at that time. Chronic cough may take multiple follow-up visits, evaluation, and treatment trials.

Sequelae: If a cough is caused by lung cancer, the prognosis is ominous. Cough from COPD worsens in intensity and duration if the patient continues to smoke. In older adults, chronic cough can contribute to stress incontinence.

Prevention/Prophylaxis: Preventive measures include smoking avoidance or cessation intervention, evaluation of the work and home environment, and humidification of the sleeping area with a cool mist humidifier. Patients should be provided vaccinations following Centers for Disease Control and Prevention (CDC) guidelines, including annual flu shots, Pneumovax, and Tdap.

Referral: A referral to a specialist can be initiated anytime during the evaluation and treatment of a cough. Some results, such as lesions suspicious for cancer on radiography, require referral to a specialist immediately. A cough specialist, allergist, otolaryngologist, or pulmonologist referral is appropriate for a chronic cough that is persistent. Other specialists who may be helpful are a GI specialist for evaluation of GERD, an infectious disease specialist for infections and immunocompromised patients, and a cardiologist for heart conditions.

Education: Recommend smoking cessation classes and allergen avoidance training. Cough can last longer than the patient expects.

DEHYDRATION

Description: Dehydration, or volume depletion, is a loss of total body water caused by too little fluid intake, sodium loss, or both. It is a common condition in older adults. Balancing solutes and water aids in avoiding dehydration.

Etiology: Total body water decreases with age. Small decreases in fluid intake can cause dehydration in an older adult because of a smaller fluid reserve. Age-related pathophysiological changes make the older adult increasingly vulnerable to disturbances in fluid and electrolyte balance, particularly during periods of ill health or physiological stress (El-Sharkawy et al., 2020). The ability of the kidneys to concentrate urine declines with age, so that even when deprived of water, urination is not significantly reduced. Also, thirst, which is an important self-regulation against dehydration, decreases as a person ages.

Dehydration can be defined as a fluid and electrolyte disturbance arising from either a water depletion or a sodium depletion in which there is accompanying water loss. Volume depletion occurs from loss of sodium and water from third-space sequestration, GI, renal and skin losses. It can be classified into three different types based on the possible causes (see Table 7-2): isotonic, hypotonic, and hypertonic.

Occurrence: Dehydration has been reported to be the most common fluid and electrolyte imbalance in older adults. Estimates of prevalence of dehydration in older adults vary depending on the subgroup being measured: one-third of older adult hospital admissions, 20% to 88% of older adults in care homes and 60% of community-dwelling older adults (Edmonds et al., 2021).

Age: Adults older than 65 continue to have the highest rates of admissions for dehydration as a primary diagnosis, with those older than 75 having the highest rates (Mentes & Gaspar, 2020).

Ethnicity: Not significant.

Contributing Factors: Causes of dehydration are multifactorial and include decreased mobility and the presence of chronic diseases, such as diabetes, cancer, and cardiovascular and renal disease, which make older adults more sensitive to fluid and electrolyte imbalance. Other risk factors in older adults include dependency for eating or drinking, mouth pain, poorly fitted dentures, and difficulty swallowing. Conditions such as vomiting, diarrhea, hemorrhage, and increased metabolic states that result in excess loss of fluids (fever, infection, excess sweating, excess urination) can contribute to volume loss. The use of certain medications, such as diuretics, anticholinergics, psychotropics, or laxatives, also may increase the risk. Dehydration is the most frequent secondary condition resulting from debilitating issues such as fever, confusion, pain, or pneumonia. Cognitive impairment (delirium, dementia, depression) has been associated with dehydration in older adults.

Signs and Symptoms: Clinical diagnosis of dehydration is often based on medical history, body inspection, and blood sampling, but there is no standardized or validated method for this evaluation. Symptoms are usually vague and confounded by

TABLE 7-2 Types of Dehydration

TYPE OF DEHYDRATION	DESCRIPTION
Isotonic	A balanced loss of both sodium and water causes extracellular fluid loss that increases blood viscosity. Common causes: vomiting, diarrhea, osmotic effects of glucose.
Hypertonic	Excessive water loss results in raised sodium levels and shifts from the intracellular space to extracellular space. Common causes: renal tubular disease, osmotic diuresis, resistance to vasopressin.
Hypotonic	Excessive sodium loss results in extracellular fluid loss. Common causes: overuse of diuretics, chronic salt wasting.

© F.A. Davis Publishing

age. A rise in serum osmolality indicates the presence of a water deficit, which causes intracellular dehydration, whereas a rise in serum sodium or hematocrit better indicates extracellular dehydration (Johnson & Hahn, 2018). A dry, furrowed tongue and mucous membranes; sunken eyes; headaches; dizziness on standing; confusion; concentrated or dark urine; weight loss; and upper body muscle weakness may indicate dehydration. Clinical signs may not appear, however, until dehydration is far advanced. In addition, the usual signs of constipation, disorientation, dry mucous membranes, orthostatic hypotension, and weight loss may be caused by other factors. If one or more of these are present or are a change from baseline, dehydration may be the cause. Although poor skin turgor is an expected finding in older adults, it is also a classic sign of dehydration. Signs and symptoms of hypovolemic shock include altered mental status; hypotension; tachycardia; cold, clammy skin; and rapid, deep respirations.

Diagnostic Tests: Serum markers provide the most reliable indicators of dehydration, and these include serum sodium, increased serum osmolality, and blood urea nitrogen (BUN)–creatinine ratio. Hyperosmolar dehydration, defined as serum osmolality >300 mOsm/kg or osmolarity >300 mOsm/L may be more sensitive for the early detection of dehydration because of the challenges in detecting these signs and symptoms in older adults (El-Sharkawy et al., 2020). The serum albumin and hematocrit may be elevated when the patient is dehydrated.

Differential Diagnosis: When dehydration is identified, the clinician must identify the cause and address the contributing factors. Weight gain and edema from heart failure (HF) can conceal a patient's dehydrated status.

Treatment: Individualize treatment depending on the type of dehydration. The route of administration (oral, IV, or subcutaneous) is determined by what is safe and effective. Subcutaneous fluid administration has been shown to be as effective with similar rates of adverse effects to IV infusion (Volkert et al., 2019). Regular presentation of fluids to bedridden individuals, providing continuous verbal cues, and determining the patient's preference can maintain adequate hydration status. Older women should be offered at least 1.6 L of drinks each day, whereas older men should be offered at least 2.0 L of drinks each day unless there is a clinical condition that requires a different approach (Volkert et al., 2019).

Follow-Up: The timing of patient follow-up depends on the seriousness of the identified cause and the response to treatment.

Sequelae: Dehydration has severe consequences for older adults and can have a major impact on quality of life. Dehydration is associated with chronic health problems, including constipation, falls, medication toxicity, increased confusion, and infection. Inadequate fluid intake can have serious medical consequences such as renal failure, hyperthermia, bowel obstructions, delirium, cardiovascular symptoms, and death. Patients admitted with hyperosmolar dehydration have been shown to be four times more likely to develop AKI 12-24 hours after admission and had 60% greater 30-day mortality compared with those who were adequately hydrated (El-Sharkawy et al., 2020).

Prevention/Prophylaxis: Educate patients, families, and caregivers about the need for adequate fluid intake to prevent dehydration. All liquids are not the same in maintaining fluid balance. Water is the best and should be at least half of the daily intake of fluid. Add milk, fruit and vegetable juices, and non-salty soups for variety. Decrease coffee, tea, alcohol, colas, and liquid diet supplements because they may cause dehydration. The use of a 24-hour fluid balance chart can help determine whether the patient is at risk or is dehydrated.

Referral: Refer as indicated by source of symptom. Hospitalization is indicated when the patient has severe signs and symptoms such as dizziness, altered mental status, or lethargy; is hemodynamically unstable; or cannot tolerate oral fluids.

Education: Explain causes of symptoms and measures taken to determine cause and treatment. Allow adequate time for eating at mealtimes. Meals can provide two-thirds of daily fluids. Offer fluids regularly during the day. Encourage consumption of fluids with medications. Staff education is critical; staff should report any significant weight loss, change in fluid consumption, or other relevant symptoms, such as dry mucous membranes.

© F.A. Davis Publishing

DIARRHEA

Description: Diarrhea is the passage of increased stool frequency, liquidity, or volume. It is objectively quantified as passage of three or more loose or watery stools or increased stool weight of greater than 200 g or 200 ml per 24 hours (Connell, 2019). Most episodes of diarrhea are caused by viral gastroenteritis, are short lived (resolving within 7 days), and require no treatment other than maintaining hydration (Connell, 2019). There are three types of diarrhea: Acute diarrhea lasting 1 to 2 days. Persistent diarrhea lasting at least 2 weeks but no longer than 4 weeks. Chronic diarrhea is defined as diarrhea that lasts longer than 3 to 4 weeks and may be continuous or intermittent.

Etiology: In normal bowel motility, water is not actively transported across the intestinal mucosa, it moves passively by osmotic forces generated by solutes such as electrolytes and nutrients. Absorption and secretion take place simultaneously, but when there is either a decrease in absorption or an increase in water within the intestinal lumen, diarrhea occurs. The fundamental cause of diarrhea is the incomplete absorption of water from the intestinal luminal contents. The pathophysiological mechanisms of diarrhea include osmotic, secretory, inflammatory, and altered motility leading to food and liquids being passed too quickly through the body and being excreted through the colon as loose or watery stool. Diarrhea is often accompanied by abdominal cramping, as well as nausea. There are various causes of diarrhea (see Table 7-3). Note that *Clostridiosides difficile* (*C. diff*) infection should be suspected as a cause of diarrhea in patients with watery diarrhea during or shortly after receiving antibiotic

TABLE 7-3 Causes of Diarrhea

DISEASE	MECHANISM	COMMENTS
Physical Causes Contributing to the Incidence of Diarrhea		
Dementia	Impairs awareness of need to defecate, loss of inhibitory control	Manifestations depend on type and severity of dementia.
Stroke	Impaired awareness of anal control, slowed motor processing communication with frontal lobe damage	Dependent on size of infarct or hemorrhage within the brain.
Fecal impaction	Altered rectal sensation, liquid stool escaping around solid feces in colon	
GI disease	GI dysfunction/disease with excessive stool volume and rapid gut transit	Causes include viral or bacterial gastroenteritis, colitis, Crohn disease, celiac disease, colon cancer, irritable bowel syndrome, rectocele, and other GI diseases. *Clostridioides difficile* can cause severe diarrhea in the older adult individual and can lead to death.
Medication Causes		
Laxatives	Medications causing increased gastric motility or increased water in stools	
Fiber products	Increase fluid in the stool to keep it soft and move easier but can lead to diarrhea and FI	
Magnesium	Draws fluid into the bowels through osmosis	Magnesium containing antacids and certain laxatives contain significant amounts of magnesium.
Other medications	Antibiotics can cause destruction of the colon's natural flora, leading to diarrhea Other medications that can cause diarrhea include proton pump inhibitors, SSRIs, and NSAIDs	
Other		
Physical deficits	Inability to recognize need to defecate (cognitive problems) or inability to ambulate to toilet without assistance	Common causes of cognitive problems include dementia. Common causes of mobility problems include debilitating arthritis, hemiplegia, or any condition affecting gait.
Dietary causes	Other foods in susceptible individuals include diet high in fiber, spicy foods, fatty/greasy foods, cured meats, smoked meats, dairy products, caffeine, and sorbitol	Sugar-free gum and artificial sweeteners can cause diarrhea and FI. Avoidance of irritating foods can eliminate the FI.
Excessive fluid intake	Overhydration can lead to diarrhea and possibly cause FI	

Sources: Connell, 2019; Sweetser, 2012.

© F.A. Davis Publishing

therapy or recent hospitalization and can be especially detrimental in older adults, potentially leading to death.

Occurrence: In the United States, an estimated 179 million cases of acute diarrhea occur in the United States each year. An estimated 48 million foodborne diarrheal illnesses occur annually, resulting in more than 128,000 hospitalizations and 3,000 deaths (National Institutes of Health, 2021). The greatest risk factor is contact with another individual with diarrhea.

Age: Diarrhea occurs at any age. The severity of illness and the mortality rate is increased in individuals older than 65 years, especially if the individual has a concurrent medical illness (Khatri, 2019).

Ethnicity: No direct ties to ethnicity have been documented.

Contributing Factors: The following can be contributing factors in the development of diarrhea: recent travel, family history of inflammatory/bowel disorders, recent antibiotic use, exposures to either contacts or foods including tube feedings, whether or not the individual is immunocompromised such as with HIV, recent hospitalization, age of more than 65 years, extended stay in hospital or nursing home, recent chemotherapy, recent GI surgery including post-pyloric tube feeding, and medications. The list of medications that can cause diarrhea include diuretics, beta blockers, NSAIDs, antibiotics, quinidine, chemotherapy, colchicine, metformin, laxatives, digoxin, theophylline, prostaglandins, cholinergic agents, and phenolphthalein.

Signs and Symptoms: The initial clinical assessment is to obtain a detailed history including symptom assessment parameters, onset, frequency, amount, and character of the stool (the presence of blood, mucus, or atypical color) and any associated symptoms such as abdominal pain, cramping, fever, nausea/vomiting, or bloating. Include the patient's baseline bowel pattern, usual dietary intake, food intolerance history, exposure to others with illness, and any recent dining out experiences. A thorough medication review including any over-the-counter herbal remedies or laxatives should be conducted. A dietary history 3 to 5 days before onset of symptoms would be helpful, with particular attention to the ingestion of meat, dairy products, seafood, and products containing gluten. The associated symptoms of fever, abdominal pain and distention, vomiting, myalgias, and headache with abrupt onset suggest acute diarrhea etiology. In contrast, fatigue, muscle weakness, weight loss, alternating diarrhea and constipation, incomplete evacuation, abdominal pain, and protracted or recurring symptoms suggest chronic diarrhea etiologies.

Physical examination should include vital signs, weight, and other symptoms such as dizziness, light-headedness, or syncopal episodes, assessing for the presence of postural hypotension. Assess the skin for turgor and the condition of the tongue and mucous membranes. Check for evidence of jaundice, abdominal tenderness or fullness, rashes, or lesions. Examine the thyroid for enlargement or lesions. Perform a thorough examination of the abdomen for distention, rigidity, tenderness, bowel sounds, masses, hepatomegaly, or splenomegaly. Perform a rectal examination to check for impaction, include hemoccult testing to assess for bleeding, hemorrhoids, polyps, fissures, fistulas, or evidence of malignancy. Include a general inspection for arthritis or lymphadenopathy. Stool should be examined for mucus and the presence of blood. Depending on the results of the exam, an abdominal x-ray may be warranted. Figure 7-1 describes an algorithm to assist in determining the appropriate work-up needed for diarrhea.

Diagnostic Tests: For most cases of diarrhea of acute onset, no diagnostic testing is warranted unless the individual appears acutely ill. Hydration should be maintained. If abnormal findings are observed on physical examination or the individual has additional comorbid conditions, then diagnostic testing may be necessary. A flat plate abdominal x-ray can reveal obstruction, ischemia, or a mass. Complete blood count (CBC) and a complete metabolic panel (CMP) to include electrolytes and renal function will help identify an infectious process, any electrolyte imbalance, and the presence of dehydration. A barium enema can reveal malignancies, polyps, or abnormalities of the mucosal lining. Colonoscopy or sigmoidoscopy may be useful when symptoms are persistent and/or unexplained. If laxative abuse is suspected, consider ordering a stool laxative screen. Send a stool sample to test for occult blood, *Clostridioides difficile*, salmonella, *Escherichia coli*, lactoferrin, campylobacter, leukocytes, ova, and parasites. If the stool tests positive for leukocytes, the sample should be cultured to identify any bacterial etiology.

Differential Diagnosis: Identify the time frame for the episode(s) of diarrhea: acute diarrhea (1 to 2 days), persistent diarrhea (14 to 28 days), and chronic diarrhea (more than 28 days). In acute diarrhea, consider inflammatory bowel disease, fecal impaction, IBS, diverticulitis, antibiotic-associated pseudomembranous colitis, bowel ischemia, drug side effects, food poisoning, and virus or bacteria exposure. In chronic diarrhea consider ulcerative colitis, Crohn disease, microscopic colitis, celiac disease, IBS, bile acid malabsorption, occult neoplasm, post-radiation enterocolitis, and functional problems. A fecal specimen should be obtained for anyone in cases of severe, bloody, inflammatory, or persistent diarrhea or if an outbreak is suspected. A stool for *Clostridioides difficile* may be warranted in the older patient who has recently taken antibiotics.

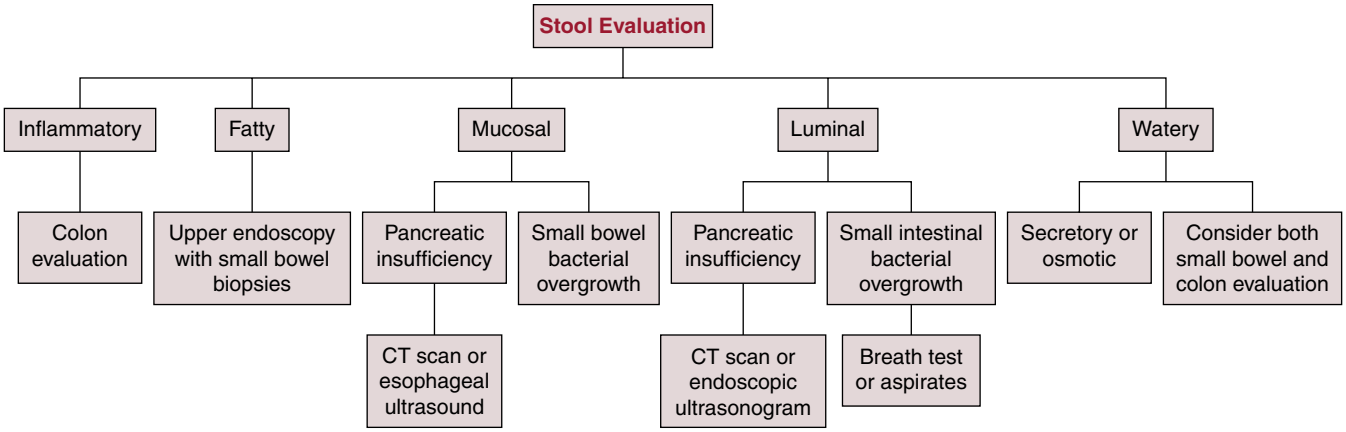
Treatment: Hydration is a priority regardless of cause or other treatments prescribed. In many cases of diarrhea, replacing lost fluid and electrolytes is the only treatment needed, but treatment is dependent on the cause. Older adults who are frail are at increased risk for dehydration, renal failure, and multisystem failure. If diarrhea is severe, refer the patient for emergent evaluation and treatment. In the hospital, the older adult patient should be treated aggressively with IV fluid therapy with close monitoring of the cardiopulmonary status, renal status, and electrolytes. In cases of acute-onset diarrhea in which a viral cause is likely, provide symptomatic treatment to maintain hydration and electrolyte balance. Use of medications can slow the intestinal motility but may also extend the time frame of the occurrence of diarrhea.

Follow-Up: Scheduling follow-up visits will be determined based on the cause of the diarrhea. In the case of acute diarrhea, reevaluate the patient after 3 to 5 days of following the initial treatment plan. If diarrhea persists, diagnostic studies may be indicated, and the patient's hydration status reevaluated.

Sequelae: Depending on the cause and extent of the diarrhea, complications may include dehydration, sepsis, shock, anemia, fluid and electrolyte imbalance, malnutrition, renal failure, and peritonitis.

Prevention/Prophylaxis: Prevention depends on the cause. Oral replacement of fluids is of highest priority, but in severe cases IV fluid replacement may be warranted. Proper

© F.A. Davis Publishing



Type of Diarrhea	Assessment	Common Causes
Inflammatory diarrhea	Frequent, small volume, bloody stools, and may be accompanied by fever and severe abdominal cramping May have leukocytes in stool Laboratory tests may demonstrate elevated C-reactive protein level or elevated sed rate (ESR), and low albumin level	Crohn's disease Ulcerative colitis Ischemic colitis Infectious processes including *C. diff*, cytomegalovirus, tuberculosis, and *Entamoeba histolytica*
Fatty diarrhea	History of weight loss Greasy or bulky appearing stools (may be difficult to flush and creates oily toilet requiring a brush to remove)	Malabsorption syndromes Celiac disease Chronic pancreatitis Inadequate bile acid concentration Small intestinal bacterial overgrowth Liver cirrhosis
Watery diarrhea	Classified as osmotic or secretory in origin Differentiate: Fasting decreases stool production in osmotic diarrhea but does not affect secretory diarrhea	Osmotic diarrhea is due to poorly absorbed ions or sugars caused by ingestion of anions such as laxatives and antacids or ions such as magnesium; or carbohydrate malabsorption of poorly absorbed sugars or sugar alcohols such as sorbitol or xylitol Secretory diarrhea is due to disruption of epithelial electrolyte transport caused most commonly by infectious processes—either viral or bacterial, as well as parasitic or peptide-secreting endocrine tumors such as in cancerous processes

FIGURE 7-1. Algorithm to assist in determining the appropriate work-up needed for diarrhea.

nutrition is important; introduce solid foods slowly, the diet should be bland, advancing from clear liquids to full liquids, to soft foods, before graduating to a regular diet. Careful cooking and storage of food is important to avoid spoilage. Check expiration dates on dairy and meat products before using. Clean cutting boards and utensils. Educate about cross-contamination when cooking, such as with raw meats, to prevent exposure to pathogens. For individuals who are traveling to a foreign country, begin appropriate prophylactic treatment (Connell, 2019). Caution travelers about avoiding undercooked foods, raw foods, buffet food, unpasteurized dairy products, untreated water, and ice. Carbonated drinks, bottled water, and boiled water are considered safe for drinking and to use for oral hygiene.

Prevention of transmission of diarrhea to or from others (including young children) in hospitals and in long-term care facilities is extremely important. Frequent hand washing by patients and health-care providers is the key to preventing transmission of infectious diarrhea. Avoidance of long-term laxative use and prudent use of antimicrobial agents are also important in preventing diarrhea.

Referral: Further work-up may be necessary in individuals who are exhibiting prolonged diarrhea, severe dehydration, or recurrent episodes of diarrhea and in individuals who report blood in stools. Refer to the hospital for consideration of an inpatient stay if IV fluids and/or electrolyte replacements are needed or if diarrhea persists. The patient may need to be evaluated by a gastroenterologist or an infectious disease specialist depending on the causative agent of the individual's diarrhea. Complications may include dehydration, malnutrition, peritonitis, sepsis, shock, anemia, renal failure, or electrolyte imbalances, which can be life threatening (such as with hypokalemia).

Education: Explain to the patient, family, and caregivers the cause of symptoms, diagnostic and treatment measures, any follow-up needs, and preventive strategies. Emphasize the need for early intervention to prevent dehydration.

DIZZINESS AND VERTIGO

Description: Dizziness is an imprecise term commonly used by laypersons, especially older adults to describe various subjective symptoms. Dizziness is an independent predictor of falls, which is the leading cause of accidental death and the leading cause of disability in individuals older than age 65 (Zanotto et al., 2017). A prompt evaluation and development of an appropriate treatment plan is essential to mitigate this risk. The practitioner must first understand the patient's personal meaning of dizziness to guide the diagnostic process to determine etiology of the dizziness. Establishing the time course, provoking or aggravating factors, concurrent symptoms, epidemiological risk factors, pre-existing conditions as well as interpreting physical examination findings are crucial in establishing a diagnosis. Despite a thorough history and physical examination, the final cause of dizziness may not be identified in some patients. For others, multiple practitioner visits may be needed to identify a cause. The ambiguity of patient descriptions as well as the multifactorial etiology of dizziness can result in significant healthcare costs from diagnostic work-up and interrupted daily activities.

The traditional clinical categories of dizziness are vertigo, unsteadiness or gait instability, light-headedness, and disequilibrium. However, there are new diagnostic approaches that do not rely on this traditional classification but rather utilize the patient's responses to determine the classification of dizziness as episodic triggered, spontaneous episodic, or continuous vestibular. This approach is referred to with the pneumonic TiTrATE: **T**iming of the symptom, the **Tr**iggers that provoke the symptom, **A**nd a **T**argeted **E**xamination (Muncie et al., 2017). The practitioner should therefore approach dizziness in the older adult population as a syndrome that requires specific strategies to recognize, evaluate, and manage to reduce significant disability and complications.

Etiology: Dizziness may result from mixed pathologies that include medications; metabolic derangement; infections; toxins; and neurological, otolaryngological, cardiovascular, or psychiatric conditions. These conditions can be divided into peripheral, central, or systemic causes. Benign paroxysmal positional vertigo (BPPV), a disorder arising from the inner ear, is the most common peripheral cause in individuals, including those older than 70 years (Balatsouras et al., 2018). The etiology of BPPV is usually loose calcium crystals in the semicircular ear, which results in the patient having a sensation of movement with any shifts in gravity and movement of the crystals. BPPV can affect the posterior or lateral semicircular canals, but posterior canal BPPV occurs in 85% to 95% of cases (Balatsouras et al., 2018). Risk factors for BPPV include head trauma and recent viral upper respiratory or inner ear infection. Dizziness associated with tinnitus or audiological manifestations is usually from Ménière disease. Individuals with dizziness and associated neurological deficits require evaluation for a central cause as this is usually due to vertebrobasilar system involvement. The most common vertebrobasilar etiologies in older adults include hemorrhagic stroke, transient ischemic attack (TIA), ischemic stroke, and vertebrobasilar insufficiency due to atherosclerotic disease. In younger adults who have a history of migraine with aura and are experiencing dizziness associated with headache but no other neurological deficits, a vestibular migraine diagnosis is high on the differential for a central etiology (Headache Classification Committee of the International Headache Society, 2018). It is not typical for older adults to have a vestibular migraine as an initial presentation of migraine so other common vestibular causes should be investigated first. Individuals with a history of migraine with aura are at increased risk for other neurological manifestations including TIA and the presence of patent foramen ovale. These patients require a referral to neurology for continued management, monitoring of their migraine, and optimization of risk factors and preventative therapy when indicated (Elbadawi et al., 2019). Dizziness associated with loss of pallor, diaphoresis, shortness of breath, or other cardiac manifestations should prompt evaluation for cardiac etiology such as orthostatic hypotension, arrythmias, ischemic heart disease, or heart failure (HF). Psychiatric disorders such as depression and anxiety can result in dizziness either due to medications utilized to treat the disorders or due to symptoms associated with the disorders. In recent years, there has been recognition of a disorder called persistent postural-perceptual dizziness (PPPD), which is a disorder on the spectrum of functional neurological disorders.

© F.A. Davis Publishing

It results in chronic dizziness with symptoms of unsteadiness and hypersensitivity to self-motion or complex visual stimuli, phobic avoidance of provocative situations similar to fear of falling, and functional gait abnormalities in the absence of other identified organic cause for the symptoms. It is believed to be caused by a long-term maladaptation to a medical vestibular event that caused the initial dizziness symptoms. Diagnosis is guided by the Bárány Society's diagnostic criteria for persistent postural-perceptual dizziness, which relies heavily on the patient's history (Popkirov et al., 2018). Individuals older than age 70 can develop presbystasis, an age-related disequilibrium not attributed to any pathology that is characterized by a gradual onset of difficulty walking (Kesser & Tucker Gleason, 2019).

Occurrence: Dizziness is common, with 45% of affected nonhospitalized patients seeking care from primary care providers (Muncie et al., 2017). The most common location to seek care after primary care is in the ED. Referral to specialists, neurologists, otolaryngologists, or cardiologists is also common if etiology is unclear or symptoms do not respond to treatment. More men than women experience BPPV; however, the condition may persist longer in women, which results in their seeking treatment more often (Álvarez-Morujo de Sande et al., 2019).

Age: Vestibular impairment is common in older adults and may affect nearly 50% of those older than 60 years (Agrawal et al., 2019).

Ethnicity: Not significant.

Contributing Factors: Contributory medications include antihypertensives, anticonvulsants, psychotropic drugs, and ototoxic drugs. Physiological changes occurring with age can affect equilibrium. Altered sensitivity of the baroreceptors, as well as diminished sensory and motor pathways over time, increase the vulnerability to syncope and gait instability.

Signs and Symptoms: The patient's description of the symptom helps determine the type of dizziness experienced.

Vertigo. Vertigo is the sensation of movement of the patient or the environment due to central or peripheral causes. Associated symptoms may include nausea, vomiting, unsteadiness, or visual disturbances that occur because of fast-beating nystagmus. The time course of vertigo assists in determining the appropriate diagnosis. Episodic vertigo following a viral illness and lasting days with nausea and no associated symptoms is usually due to vestibular neuritis. Episodic vertigo lasting for seconds and associated with position changes is probably due to BPPV. Vertigo of sudden onset lasting for minutes can be due to migraine or cerebrovascular disease, especially if neurological deficits are present. Vertigo lasting hours and when associated with endolymphatic hydrops symptoms, including tinnitus, dizziness, fluctuating hearing loss, imbalance, and a feeling of fullness/pressure in the ear, is probably caused by Ménière disease. Older adults with head or neck pain post trauma can develop cervicogenic vertigo provoked by movement or sustained positions of the neck. This cervicogenic type of vertigo requires further diagnostic work-up to rule out vascular traumatic injuries such as vertebral artery dissection.

Presyncope. In presyncope, patients have the sensation of nearly fainting. Associated symptoms include perspiration, fatigue, pallor, palpitations, dimming of auditory or visual stimuli.

Light-Headedness. Patients often describe presyncope symptoms as light-headedness. This can also be associated with anxiety or depression.

Disequilibrium. Patients with disequilibrium describe a sense of imbalance. Symptoms improve dramatically by bracing on a stationary object and are exacerbated by vision deficits or uneven surfaces. Associated symptoms may include chronic hearing loss, chronic lower extremity sensation deficits, poor coordination, and generalized weakness. However, patients with acute gait instability need further evaluation for cerebrovascular disease.

Physical Examination: The physical examination should be comprehensive and include the following components:

General. Observe how the patient moves around and any symptom reproduction with activity. Does he or she hold onto the furniture or walls? Any signs or symptoms of fever?

Head, Eyes, Ears, Nose, and Throat. Test for extraocular movement, watching for nystagmus. Rotatory nystagmus suggests a peripheral cause of dizziness, but this alone is not a conclusive finding. Vertical nystagmus suggests a central lesion and needs further investigation. In many clinical situations, rotatory nystagmus is superimposed on horizontal nystagmus. Check the patient's static monocular or binocular visual acuity and dynamic visual acuity. Evaluate visual fields. Perform a funduscopic examination, looking for papilledema and other abnormalities. Inspect the ears for accumulation of fluid, tympanic membrane abnormalities, or presence of cerumen impaction. Examine the neck for range of motion and flexibility.

Cardiovascular. Evaluate central and peripheral function. Auscultate for heart sounds; evaluate for arrhythmias and murmurs. Evaluate the carotid arteries for bruits. Check vital signs, including orthostatic vitals. A drop in systolic blood pressure of 20 mm Hg or diastolic blood pressure of 10 mm Hg is significant, especially if it reproduces the patient's symptoms.

Neurological. Test for coordination deficits with finger to nose, heel to shin, past pointing, and rapid alternating movements. If coordination tests are abnormal, keep vestibular dysfunction or cerebrovascular insufficiency in the differential. Test sensation including pain, temperature, vibration, proprioception, and Romberg. Patients with cerebellar disease have difficulty standing with their feet together. Patients with decreased position sense or other sensory deficits in their lower extremities are able to compensate with eyes open but sway with eyes closed. Perform gait assessment, including tandem gait. Complete a motor examination and evaluate deep tendon reflexes. The inclusion of psychological tests (mental status, depression, anxiety) is appropriate if a functional cause is suspected.

Special Diagnostic and Screening Tests. Forced hyperventilation involves asking the patient to breathe 20 to 30 times per minute for 2 to 3 minutes. This normally causes dizziness and

© F.A. Davis Publishing

finger and perioral numbness. If presenting sensations are reproduced, the dizziness may be related to anxiety or other functional etiology.

Have the patient march in place for 30 seconds with the eyes closed and arms extended in front. Be careful not to orient the patient with any sounds (e.g., your voice or a ticking clock). Patients with absent or reduced vestibular function (from prior vestibular damage) rotate more than 30 to 45 degrees while marching.

For the Dix-Hallpike maneuver, assist the patient to quickly lie down on the examination table with the head hanging over the back of the table at an approximate 30-degree angle with the face turned 45 degrees to the right. While holding the patient's head in place for 1 minute, observe the patient for nystagmus and ask whether this reproduces the dizziness (vertigo) symptoms. Bring the patient back to a sitting position and observe for 1 minute. Repeat the test with the head turned 45 degrees to the left. If vertigo is reproduced, the test should be repeated two or three times on the side that caused the most severe symptoms to determine whether the nystagmus and symptoms begin to disappear. Patients with benign postural vertigo experience severe vertigo 5 to 15 seconds after the head is turned and nystagmus is induced. Position change must be completed in 2 seconds, as the signs typically fade in less than 1 minute, and repeated testing causes the symptoms to disappear. The safety of this test must be considered if the patient is frail or has neck or back problems. The Dix-Hallpike test is underutilized and may be inappropriately utilized causing misdiagnosis or missed diagnosis. Thorough history taking is a key to its appropriate use (Dmitriew et al., 2021).

Diagnostic Tests: Diagnostic tests are dependent on the presenting symptoms, the history and physical examination, as well as comorbid factors. The HINTS (head-impulse, nystagmus, test of skew) examination can help distinguish peripheral from central etiologies, as well as delineate which patients may need diagnostic testing (Muncie et al., 2017). Select testing might include CBC for anemia, serum glucose for hypoglycemia, ECG or Holter monitoring for arrhythmia, audiometry if hearing loss is present, or vestibular function tests (such as videonystagmography or electronystagmography). Neuroimaging (CT, CTA, MRI, or MRA) must be ordered if neurological symptoms are present to evaluate for a central lesion, vascular stenoses or occlusions causing ischemia. For patients with psychiatric disorders or functional neurological disorders, evaluation for anxiety and depression using a standardized scale such as a Generalized Anxiety Disorder-7 for anxiety or Patient Health Questionnaire 2 or 9 to screen for depression.

Differential Diagnosis: Differentiate between vertigo (a sensation of movement), imbalance (gait instability), light-headedness (a sensation of being about to faint), and syncope (an actual loss of consciousness) to help narrow down differential diagnoses. Differential diagnoses for peripheral causes can include BPPV, vestibular neuritis, and Ménière disease. Differential diagnoses for central causes can include TIA, vertebrobasilar insufficiency, ischemic stroke, hemorrhagic stroke, vestibular migraine, and PPPD. Diagnoses for systemic causes can include orthostatic hypotension, arrythmia, HF, ischemic heart disease, infection, depression, anxiety, and other neurological disorders such as ocular myasthenia gravis. If dizziness has a predictable pattern associated with it (e.g., mid to late morning, mid to late afternoon, 2 to 4 hours after eating), suspect hypoglycemia.

Treatment: Treatment is based on the cause of the dizziness. Traditional vestibular rehabilitation is highly effective but requires face-to-face time, resulting in inconsistent completion rates. Recently, however, there are ongoing studies evaluating the efficacy of blended online and face-to-face vestibular rehabilitation protocols in the hope of improving access and promoting consistent completion rates (Van Vugt et al., 2017). Physical therapy (PT) for balance training may supplement other management approaches as well.

Patients with benign positional vertigo (BPV) can perform the Epley maneuver, which loosens and moves particles out of the posterior semicircular canal and back into the utricle. If the cause of light-headedness is medication side effects or volume deficiencies, adjustments are indicated. Support stockings may alleviate symptoms from orthostatic hypotension. Appropriate management of cardiovascular, cerebrovascular, or functional conditions is warranted.

The efficacy and mechanism of action of the common medication meclizine has not always been supported, but a recent study reported by Wibble et al. (2020) concluded that meclizine was effective in treating vertigo in "everyday activities but may not be helpful in high-acceleration environments. Benzodiazepines, despite the risk of somnolence and potential for dependency, are frequently used to treat associated symptoms of vertigo, although recent studies have shown no difference between meclizine and diazepam (Shih et al., 2017). These medications require caution because they can worsen the symptoms of dizziness and have other side effects, which are particularly problematic in older adults.

Follow-Up: Patients should follow up if symptoms worsen, change from one type of dizziness to another, or do not resolve within 2 weeks.

Sequelae: Older adults with dizziness are at high risk for falls and injury, as well as self-induced immobility due to fear of falling.

Prevention/Prophylaxis: Educate older adults to move extremities before rising from positions held for any length of time to compensate for age-related changes in vascularity. Evaluate for medication side effects before adding medications to combat the dizziness.

Referral: Persistent symptoms with unknown etiology require a referral to neurology, cardiology, otolaryngology, or psychiatry as appropriate.

Education: Explain the underlying cause, rationale for treatment, and importance of exercises like the Epley maneuver. Teach the patient the exercises and ask for return demonstration. Explain that this condition may take time to completely resolve, but that it is important to seek care for worsening or persistent symptoms. Encourage the use of assistive devices for safety until the condition resolves.

DYSPHAGIA

Description: Dysphagia is a commonly encountered problem in the older adult population and involves the inability to pass food from the mouth to the stomach appropriately. This problem can cause significant impairment in quality of life and even increase mortality risk (Tulunay-Ugar & Eibling, 2018). A problem can arise during any of the three swallowing phases and thus the specific type of dysphagia will be described based on the phase—oral, pharyngeal, or esophageal. Often a deficit exists in more than one phase (Christmas & Rogus-Pulia, 2019).

Etiology: Normal changes in the swallowing process that occur with aging are called presbyphagia. These changes often do not produce symptoms or complications for the individual. Common normal changes include increased residue after swallowing and a slower rise in swallowing pressure (Tulunay-Ugar & Eibling, 2018). Dysphagia, however, is pathological and not a normal part of aging.

Oral dysphagia involves the disruption of the normal process of chewing food, mixing the food with saliva, and moving the food to the back of the mouth. Several functional impairments can produce oral dysphagia: tongue weakness, dry mouth (xerostomia), alerted consciousness, and movement disorders. Medications that cause sedation or dry mouth, as well as presence of dementia and delirium can cause oral dysphagia. Pharyngeal dysphagia involves the disruption of the normal process of moving the food into the pharynx, through the pharynx and to the esophagus. Weakness of the tongue, pharynx, or vocal cords can contribute. Common diseases associated with pharyngeal dysphagia include Parkinson's disease, amyotrophic lateral sclerosis, stroke, or vocal cord tumor. Finally, esophageal dysphagia involves the impairment of the normal process of moving food down the esophagus using peristalsis and gravity. Mechanical obstruction from the food bolus and impairment of the esophageal muscle or lower esophageal muscle tone can contribute. Common disease processes associated with esophageal dysphagia include esophagitis, achalasia, and esophageal obstruction by the presence of a tumor, stricture, or diverticulum (Christmas & Rogus-Pulia, 2019).

Age/Occurrence: Risk of developing dysphagia increases with age. Accurate measurements of the incidence of dysphagia are difficult to quantify due to underreporting of symptoms and lack of awareness of symptoms. However, it is estimated that 10% of people older than the age of 50 have dysphagia. Dysphagia is believed to affect 40% of institutionalized older adults (Tulunay-Ugur & Eibling, 2018).

Ethnicity: Not significant.

Contributing Factors: Considering that the causes and risks of dysphagia are diverse, a multidimensional framework has been proposed for early identification of dysphagia, even in the preclinical (or unidentified) stage (Madhavan, 2021). This framework considers causative, associative, and speculated associative evidence in the development of preclinical dysphagia among community-dwelling older adults. Causative factors for the development of preclinical dysphagia include advanced age and certain diagnoses (Madhavan, 2021). The increased vulnerability to acute illness that older adults face may worsen decline in swallowing function and lead to dysphagia (Namasivayam-MacDonald & Riquelme, 2019). Neurological disease is the most common disease process associated with dysphagia (Hou et al., 2019). Dysphagia may be the first symptom identified by patients suffering from neurodegenerative disease (Tye et al., 2020). Ischemic stroke is also a major risk factor for dysphagia, with one study finding 32% of patients experiencing their first ischemic stroke having a new diagnosis of dysphagia (Stipancic et al., 2019). There are certain medications that can have a causative effect on the development of dysphagia. Anticholinergic drugs, such as those used for urinary incontinence, as well as tricyclic antidepressants can lead to xerostomia. The use of sedatives and neuroleptics often contribute to dysphagia

© F.A. Davis Publishing

because they can reduce attention and affect oral function. Steroids can weaken the strength of the tongue and mouth. Antipsychotic medications can impair the pharyngeal phase of swallowing, whereas bisphosphonate therapy can impair the esophageal phase (Christmas & Rogus-Pulia, 2019).

Risk factors that are associated with the development of dysphagia among older adults include frailty, reduced physical function, poor nutrition, cognitive decline, and poor oral health (Madhavan, 2021). A major component of frailty is sarcopenia, or the loss of skeletal muscle mass and strength, and has also been associated with an increased risk of dysphagia (Madhavan, 2021; Cha et al., 2019). Applying a multidimensional framework to the assessment of dysphagia requires including an assessment of the patient's level of social support or for the presence of sensory loss (Madhavan, 2021).

Signs and Symptoms: Symptoms typically associated with oropharyngeal dysphagia include difficulty initiating swallowing, food sticking in the throat, nasal regurgitation, and coughing during swallowing. Specifically oral dysphagia may present with pocketing or "cheeking" of food, prolonged chewing, and leftover food residue in the oral cavity. Pharyngeal dysphagia often presents with cough, throat clearing, wet sound to the voice after swallowing, nasal regurgitation of food, and even aspiration (Christmas & Rogus-Pulia, 2019). Patients with esophageal dysphagia most commonly present with a complaint that food is stuck in the chest (sternum or suprasternal area) and may report choking or a sensation of pressure and may even regurgitate food (Christmas & Rogus-Pulia, 2019).

For oropharyngeal dysphagia, a trained speech language pathologist (SLP) is an integral component of the evaluation process. Assessment begins with careful history taking through review of medical history, interview with patient and caregivers, examination of the cranial nerves, and administering of various types of foods and liquids (Christmas & Rogus-Pulia, 2019). Patients often feel symptoms of oropharyngeal dysphagia within one second of attempting swallow (Dunlap & Patterson, 2019).

Diagnostic Tests: Diagnostic tests are based on the medical history and initial examination findings (Christmas & Rogus-Pulia, 2019). Videofluoroscopy (VFSS) (modified barium swallow) is most commonly used when evaluating neuromuscular disease but is complicated by the requirement for a separate referral and appointment (Audag et al., 2019; Tye et al., 2020). The VFSS involves the administration of various amounts and viscosities of barium. The oropharyngeal area is visualized with radiography, allowing the SLP to see if swallowing difficulties are present and how well the individual is able to swallow (Christmas & Rogus-Pulia, 2019). Fiberoptic endoscopic evaluation of swallowing (FEES) is an option that can be more easily completed in office, limiting the need for additional visits (Audag et al., 2019; Tye et al., 2020). The FEES diagnostic test involves the insertion of a flexible endoscope into the nose and upper pharynx for the visualization of the swallowing process (Christmas & Rogus-Pulia, 2019).

Differential Diagnosis: It is important to differentiate whether the patient has a feeding problem or a swallowing problem or both. Cognitive impairments are frequently associated with feeding problems. Evaluation for specific motor, neurological, or obstructive causes should be performed. For the patient complaining of burning associated with swallowing, reflux esophagitis, esophageal infection, and gastroesophageal reflux disease (GERD) need to be explored.

Treatment: The purpose of early identification and treatment of dysphagia is prevention of complications such as aspiration, malnutrition, dehydration, choking, pneumonia, and death (Dunlap & Patterson, 2019; Tulunay-Ugar & Eibling, 2018). Many facilities utilize a team-based approach often lead by an SLP with coordination among nutritionists and occupational therapists. (Tulunay-Ugar & Eibling, 2018). Treatment strategies can be divided into two methods: compensatory and rehabilitative (Christmas & Rogus-Pulia, 2019).

Compensatory methods compensate for the impairment to reduce complications. Providing good oral care is one such method. Postural changes are another and can involve the chin-down position (tucking of the chin to the chest) or the head-turn position (the turning of the head toward one shoulder) (Christmas & Rogus-Pulia, 2019).

Another compensatory method of treating dysphagia is through the alteration of the thickness of swallowed foods. For example, patients with difficulty swallowing thin liquids will often be placed on a thickened liquid diet; however, this poses additional risks such as dehydration from decreased oral intake. The use of textured thin liquids can be a potential solution (Howard et al., 2018). The International Dysphagia Diet Standardization Initiative has set standards for defining textured-modified foods and liquids (Cichero et al., 2017). However, the evidence is conflicting on the clinical benefit of textured-modified foods in the treatment of dysphagia, and a patient-centered focus should be taken when determining if this approach is best for each individual (Christmas & Rogus-Pulia, 2019).

The placement of a feeding tube is a common, yet controversial, compensatory practice. The intention is to reduce the risk of aspiration and pneumonia, but the evidence as to the clinical benefit is lacking. Cellulitis and bacteremia are potential complications of gastrostomy tubes. Agitation, sinus infection, and nasal irritation are potential complications of nasogastric feeding tubes. All feeding tubes also increase the risk of diarrhea (Christmas & Rogus-Pulia, 2019). The American Geriatrics Society (AGS) published a position statement cautioning against the placement of feedings tubes in patients with both dementia and dysphagia due to the serious risks of the practice. AGS recommends careful hand feeding rather than placement of a feeding tube (AGS, 2014).

Rehabilitation methods are intended to improve the swallowing process. Exercise and training programs may help improve swallowing planning and coordination. Swallowing maneuvers may be taught to help with dysphagia. The Mendelsohn maneuver involves the patient voluntarily holding the larynx in its higher position for 2 to 3 seconds before swallowing (Christmas & Rogus-Pulia, 2019). There is only low- to very-low-quality evidence that swallowing interventions may reduce the incidence of dysphagia and chest infection or improve swallowing function. Moderate quality evidence suggests that these interventions have reduced hospital length of stay but have not reduced fatality or disability rate (Bath et al., 2018).

Esophageal dysphagia treatment depends on the cause. Esophageal dilation may be helpful for patients with achalasia (Wilkinson & Halland, 2020). Patients with esophageal spasms can be given calcium channel blockers, nitrates, or

© F.A. Davis Publishing

phosphodiesterase-5 inhibitors (Wilikinson & Halland, 2020). Esophagitis and GERD can be treated with antacids, H_2 blockers, or PPIs. More aggressive forms of treatment would involve surgical intervention such as esophageal dilation or feeding tube placement. One study found that by the time of FEES evaluation among patients with neurological disorders, almost 20% were referred for surgical intervention, thus highlighting the importance of early screening and detection to potentially reduce the need for aggressive measures (Tye et al., 2020).

Follow-Up: Patient monitoring depends on the specific etiology of the dysphagia.

Sequelae: Complications from dysphagia are caused by food or liquid penetration or aspiration. Penetration involves the movement of the oral substance—or bolus—into the laryngeal vestibule but not below the vocal cords. Aspiration involves the movement of the bolus into the trachea and lungs. Silent aspiration occurs when the patient lacks the ability to respond to aspiration through throat clearing or cough. Dysphagia in the presence of stroke and dementia is highly associated with decreased survivability (Christmas & Rogus-Pulia, 2019).

Prevention/Prophylaxis: Early detection and treatment are key in preventing complications. Patients with known disorders that are highly associated with dysphagia should be screened for symptoms.

Referral: Initial consultation with speech pathology for evaluation can be essential in deciding on further assessment. Gastroenterology should be consulted if invasive diagnostic tests are indicated.

Education: Patients and caregivers should be encouraged to provide food and fluids at appropriate consistency. Specific education is provided based on the type of dysphagia and treatment regimen used.

FALLS

Description: According to the World Health Organization (WHO), a fall is an event that results in a person coming to rest inadvertently on the ground, floor, or other lower level (WHO, 2021). In the *International Statistical Classification of Diseases and Related Health Problems (ICD-10)*, falls are coded based on the circumstance that caused an injury, such as slipping, tripping, and stumbling (ICD-10 Data, 2021). Falls are the leading cause of nonfatal injuries, and complications resulting from falls are the leading cause of death in older adults. Of serious injuries, fractures and traumatic brain injury are the most common, with falls as the cause for 95% of hip fractures, which has a 1-year mortality ranging from 12% to 37%. The total medical cost for fall-related injuries in 2015 was more than $50 billion (CDC, 2021).

Etiology: Falls are included in the list of geriatric syndromes because older adults have multiple risk factors that contribute to falls. Most falls are caused by an interaction of several intrinsic and extrinsic risk factors. Intrinsic factors include age, previous falls, weakness, gait/balance problems, poor vision, problems with feet, postural hypotension, chronic medical conditions (e.g., arthritis, dementia, arrhythmia, neuropathies), an occult medical condition (e.g., pneumonia or urinary tract infection (UTI), and fear of falling. Extrinsic factors include conditions in the environment such as lack of handrails, grab bars, improper use of assistive devices, poor lighting, obstacles, slippery or uneven surfaces, medications. Additional risk factors include inactivity and risky behavior (e.g., use of a ladder).

Eight risk factors have been identified and validated as predictors of falls in the inpatient setting using the Hendrich II Fall Risk Model. These risk factors are altered mental status, symptomatic depression, altered elimination, dizziness or vertigo, two medication categories (antiepileptics and benzodiazepines), male sex, and decreased ability to rise from a chair (Hendrich et al., 2020; Hendrich, 2021).

Occurrence: Approximately 25% of persons 65 years and older, 34% of persons older than 80 years and 50% of persons living in long-term care fall each year, although the true incidence of falling is likely to be higher due to the fact that many falls are not reported (CDCa, 2021). Although women and men are equally likely to fall, women are more likely to suffer a fracture from a fall because more women have osteoporosis.

Age: Although many sources report that falls should not be considered a normal part of aging, there are normal physiological changes with aging that can impact risk of falling.

© F.A. Davis Publishing

Age-related changes that affect postural control and increase the risk of falling include proprioceptive sensory loss in the lower extremities, impaired vestibular function, muscle activation patterns that impact balance, and visual impairment. Cognitive impairment and age-related decline in baroreceptor sensitivity, which increases heart rate with decreases in blood pressure, also increase risk of falling in older adults.

Ethnicity: Blacks are less likely to experience initial or recurrent falls than non-Hispanic Whites (Nicklett & Taylor, 2014). Among older women, the risk of having a recent fall was substantially lower for Black and Asian women when compared to White women (Geng et al., 2017).

Contributing Factors: The risk of a fall increases as the number of risk factors increases. Chronic underlying disease that impacts mobility and cognition, visual impairment, alcohol use, and environmental factors (lighting, floor covering, railings) impact the risk of falling. In addition to the assessment of medications potentially associated with falls (psychoactives, hypnotics, opioids, diuretics, vasodilators), complete a thorough inquiry about over-the-counter (OTC) medications (such as antihistamines), herbal supplements, potential drug interactions, dose changes in existing medications and if, when, and how medications are actually taken.

Signs and Symptoms: Every older adult patient or their families/caregivers should be questioned every year about falls, frequency of falling, and difficulties with gait or balance as a core component of geriatric assessment. Half of patients or families may fail to mention a fall unless there was injury. For patients who report a fall, it is important to obtain information about the circumstances of the fall, including location, what the patient was doing, how the fall occurred, symptoms at the time of the fall (e.g., chest pain, shortness of breath, dizziness/light-headedness, vertigo, diaphoresis, numbness and weakness of extremities, loss of consciousness), and presence of pain after the fall. Loss of consciousness is difficult to determine in unwitnessed falls and may not be reported from persons with cognitive impairment and those who did not sustain an injury. When possible, it is important to obtain information from someone who witnessed the fall.

In addition to asking about falling, it is important to assess tripping, slipping, or stumbling but not falling and any fear of falling because these factors increase the risk of falling. For those who report recurrent falls (two or more), difficulties with gait/balance, or presented to the emergency department (ED) because of a fall, a multifactorial risk assessment should be completed which includes history of falls, medications, gait, balance, mobility, visual acuity, neurological impairments, muscle strength, heart rate/rhythm, postural hypotension, footwear, and environmental hazards.

Diagnostic Tests: There is no routine diagnostic evaluation for individuals who fall. A complete blood count (CBC) and electrolyte panel to assess for anemia or electrolyte imbalance could be appropriate. The details about how the fall occurred, symptoms associated with a fall, comorbidities, and the physical examination will determine the need for diagnostic evaluation. Evidence of trauma to the head and loss of consciousness are predictive of intracranial injuries and should guide the decision to obtain diagnostic imaging of the brain. Intracerebral injuries should be considered in any older adult who reports head trauma or any fall in a patient on anticoagulants or antiplatelet drugs. Evaluation of syncope with Holter monitoring should be considered for those with unexplained nonaccidental falls or recurrent falls and when loss of consciousness is reported.

The decision to obtain a plain radiograph should be based on history and physical examination findings and the nature of the fall. Wrist, hip, and vertebral are the most common fractures. Femoral neck fractures should be considered in persons with any of the following: sudden onset of hip pain before or after a fall, pain in the groin region, inability to bear weight, external rotation, and shortened appearance of the leg. A plain anterior-posterior (AP) radiograph can detect fractures in most patients. Obtaining an AP pelvis radiograph allows for comparison with the unaffected hip. For patients with negative fracture on plain radiograph, ongoing pain, and inability to function at a previous level, an occult hip fracture should be suspected and evaluated with a magnetic resonance imaging (MRI) or computed tomography (CT) scan.

Differential Diagnosis: Determining the cause of a fall can be complex because most falls are multifactorial, resulting from intrinsic and extrinsic factors. A differential diagnosis can be narrowed by assessment of these risk factors, along with the history and physical examination findings. Reports of light-headedness, near-fainting, or legs giving out suggest orthostasis, arrhythmias, or other cardiovascular conditions. Difficulty standing from a chair or feeling that legs are not supportive suggests deconditioning or neuromuscular disease.

The physical examination may help narrow a differential diagnosis or identify additional factors related to a fall. It is important to initially assess for injury. The pattern of injury can help sort out the event leading to a fall. For example, a wrist fracture caused by a fall on an outstretched hand suggests that consciousness was preserved while falling. Bilateral wounds on knees could suggest drop attacks. The differential diagnosis can also be narrowed by including assessment of orthostatic vital signs, muscle tone to determine spasticity or rigidity, sensation, proprioception, vibration to determine neuropathy or a somatosensory problem, cognitive status, and visual problems. In older adults, falls are often a commonly presenting symptom of an underlying medical problem or an acute illness such as pneumonia or UTI.

Treatment: Interventions should be tailored to the cause(s) and individualized risks of falling. A framework that can be used to coordinate interventions with falls risk factors is the 4Ms, which include what Matters to the patient (incorporates patients' values and goals), Medication, Mentation, and Mobility (Institute for Healthcare Improvement, 2020). Medications can be an easily modified risk factor for falls, so it is important to consider deprescribing inappropriate medications based on Beers criteria® (American Geriatrics Society Beers Criteria® Update Expert Panel, 2019), decreasing the dosage of medications if possible, and adjusting medication dosage based on creatinine clearance. Bedrails, fall alert bracelets, chair/bed alarms and restraints have not been shown to decrease rates of falls in acute and long-term care settings (Cameron et al., 2018).

Follow-Up: For patients who have fallen and those at risk for falling, ongoing management and monitoring of medical conditions, mobility and medications associated with falling is important. Asking about the home environment and providing resources on safety interventions and exercises to improve gait, strength, and balance, reinforces the importance of decreasing the risk of falling.

© F.A. Davis Publishing

Sequelae: Persons who report a previous fall are at increased risk for subsequent falls. Approximately 20% to 30% of older adults who fall endure serious injury, including fractures and traumatic brain injury (WHO, 2021). Injuries result in decreased functional status, subsequent loss of independence, and possible nursing home placement. Falls can also have psychological and social consequences, such as fear of falling or post-fall anxiety syndrome, which can result in social isolation and loss of self-confidence. Approximately 25% to 50% of older adults will not ambulate at their previous level after a fall (CDCa, 2021).

Prevention/Prophylaxis: A baseline assessment of a patient's extrinsic and intrinsic fall risk factors is helpful for not only tailoring individual interventions but allows for assessment of subtle changes in a patient in subsequent encounters both inpatient and outpatient. Part of the baseline and subsequent evaluations should include assessment of gait, strength, and balance. Some of the most commonly used tests include the Get Up and Go Test, Functional Reach Test, and 4-Stage Balance Test. Each of these tests can be done in less than 30 seconds (CDCa, 2021).

There are many patient- and caregiver-appropriate resources available from the CDC (2021), National Council on Aging (2021), and National Institute on Aging (2017) to assess the risk of falling, safety, and fall prevention for both inpatient and outpatient use. These resources address specific environmental safety issues (e.g., inappropriate lighting, lack of grab bars, ill-fitting footwear, inappropriate assistive devices)

Although vitamin D supplementation is often prescribed for older adults with an intent to prevent falls, it has not been directly associated with decreasing fall risk (Cameron et al., 2018). Exercise in general has been shown to reduce the prevalence of falls, although evidence on specific exercise is lacking. Exercises that address balance, strength, and gait can prevent falls in community-dwelling older adults (Sherrington et al., 2019).

Referral: A home safety assessment is important for patients with falls and identified fall risks (both intrinsic and extrinsic). Based on individualized risk factors, an advanced practice registered nurse (APRN) should consider referrals to home health nursing, physical therapist (PT), occupational therapist (OT), a podiatrist, or subspecialty providers such as a cardiologist or a neurologist.

Education: Patients and their families need to be informed that many falls are preventable, but helping patients, families and caregivers understand their individual risks is important to supporting patient goals for mobility and independence. They need to be encouraged to report all falls, near falls, or fear of falling to their health-care providers so that assessment of risks, identification of appropriate interventions to decrease risk and referrals can be made.

FATIGUE

Description: Fatigue is a subjective state often described as a feeling of tiredness, weariness, lack of energy, muscle weakness, slowed responses, or exhaustion that is unrelieved or only partially relieved by rest. Fatigue can be differentiated as physical and mental and can be a symptom of or lead to depression. It often results in an inability to initiate normal activity; a reduced capacity to maintain activity; and difficulty with concentration, memory, and emotional stability (Brazier, 2020; Wasserman, 2021). Wasserman (2021) defines three classifications of fatigue:

1. New onset of fatigue or recent fatigue: Fatigue lasting less than 1 month. Occasional fatigue is common, but pathological fatigue may affect quality of life and impair independence.

© F.A. Davis Publishing

2. Prolonged fatigue: Fatigue that lasts longer than 1 month, up to 6 months.
3. Chronic fatigue syndrome: Occurs when fatigue lasts longer than 6 months and is not relieved with rest. Fatigue could also be a symptom of another illness and any older person with this complaint should obtain a medical evaluation and work-up.

Etiology: Physiological fatigue occurs normally with inadequate rest, excess exertion, or insufficient diet. Fatigue that interrupts the individual's activities of daily living (ADLs) may have a physical or psychological cause and may be acute or chronic. Fatigue in older adults may be an early indicator of the aging process, nutritional deficiencies, anemia, fibromyalgia, obstructive sleep apnea, stress, bereavement, emotional exhaustion, as well as debility or another disorder (Kalathil & Akpan, 2020). Certain disease can also cause fatigue including kidney disease, thyroid disease, electrolyte imbalances, and heart failure (HF). See Table 7-4 for common causes of fatigue.

Occurrence: Fatigue occurs in about 21.9% of the U.S. population (Galland-Decker et al., 2019). Underreporting and under recognition make the actual prevalence unknown.

Age: Fatigue is common the general population of older adults, ranging in prevalence from 27% to 50%, but the significance is difficult to quantify due to under reporting and underdiagnosing (Kalathil & Akpan, 2020). Among older adults living in the community and assisted living facilities, more than 50% report mild fatigue and 7% report severe fatigue on a chronic basis. Fatigue is more common in women than in men (Galland-Decker et al., 2019; Kalathil & Akpan, 2020).

Ethnicity: The prevalence of fatigue is more common in Blacks (Kalathil & Akpan, 2020).

Contributing Factors: Poor dietary habits, overexertion, alcohol abuse, smoking, stress, chronic illness, drug interactions,

TABLE 7-4 Common Causes of Fatigue

Infectious causes	Viral infections
	• Hepatitis A, B, C • Epstein-Barr virus (mononucleosis) • HIV
	Bacterial infections
	• Tuberculosis • Lyme disease • Occult endocarditis • Osteomyelitis
	Immunological/rheumatic
	• Rheumatoid arthritis • Systemic lupus erythematous
	Celiac disease
	Fibromyalgia
Medication related	NSAIDs
	Tetracycline
	Antipsychotics
	Antidepressants
	Sleep medications
	Pain medications
	Marijuana/cannabis
	Anxiolytics
	Statin agents
	Illicit drugs
	Alcohol
Chronic fatigue syndrome	No known cause but theories to the cause include viral infections, immune system problems, and hormonal imbalances
Physiological	Inadequate sleep
	Insufficient rest
	Overactivity
	Poor physical conditioning
	Stress
	Changes in diet, including decreased protein intake
	Relocation of one's home or change in job/retirement
	Frailty
	Weight loss
	Sarcopenia
	Parkinson's disease
	Vitamin deficiencies including vitamins B_{12} and D
Endocrine related	Hypothyroidism including subclinical hypothyroidism
	Hyperthyroidism
	Perimenopausal/postmenopausal
	Hypogonadism (low testosterone levels)
Neoplastic-related disorders	Any form of cancer
	Chemotherapy treatments
	Radiation treatments
	Anemia related to cancer, as well as its treatment
Toxin-related disorders	Exposure as well as toxicity to:
	• Carbon monoxide, possibly caused by wood-burning stove, kerosene lamps, automobile exhaust, or coal-burning plants • Lead • Arsenic
Cardiovascular/pulmonary diseases	HF
	Chronic obstructive pulmonary disease
Psychogenic	Depression
	Anxiety
	Somatoform disorders
	Substance abuse (prescribed and nonprescription drugs, alcohol)

misuse of drugs, and lack of sleep and/or sleep apnea may contribute to fatigue symptoms. In the older adult individual, it is compounded by a decrease in muscle strength, loss of muscle neurons, muscle atrophy, a decrease in hormone levels, increased sedentary lifestyles, and lack of exercise. Certain medications can contribute to fatigue symptoms including antidepressants, anxiolytics, statins, steroids, antihistamines, pain medications, and insomnia agents.

Signs and Symptoms: Obtain a complete medical history and perform a thorough physical examination when an individual complains of fatigue because it may indicate various psychological or physiological illnesses. Conduct a complete symptom assessment, including the onset; duration; severity; and precipitating, aggravating, and relieving factors. Identify other indicators or associated symptoms of fatigue, which may include decreased energy expenditure, decreased endurance, sleep disturbance, attention deficits, somatic complaints (aching body, tired eyes), dyspnea, and weakness. Carefully review the adequacy of the diet, all medications (evaluating for potential medication side effects), activity level (including degree of independence of activities of daily living (ADLs), and potential causes or contributing factors. Identify the impact fatigue is having on the person's ADLs and quality of life and current stressors. The quality and quantity of sleep should always be evaluated. Distinguish between generalized fatigue and actual weakness by testing for muscle strength, range of motion for arms, legs and the spine, and presence of localized tenderness. A thorough physical examination will include a mental status examination for depression and screening for dementia.

Diagnostic Tests: Screening tools are available for assessment of the complaint of fatigue, but there is no standardized assessment tool (Kalathil & Akpan, 2020). The benefits of diagnostic tests are limited when fatigue is the only symptom. Diagnostic tests on all patients with persistent unresolved fatigue should include complete metabolic panel (CMP), complete blood count (CBC) with differential, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), thyroid-stimulating hormone (TSH), and a vitamin D level. These tests are relatively low cost and offer significant screening capacity. Other tests that may be appropriate include urinalysis and pulmonary function tests (PFTs). If symptoms and signs indicate cardiac decompensation, a B-type natriuretic peptide (BNP) may indicate degree of HF, and an electrocardiogram (ECG) may reveal cardiac arrhythmias, enlargement of the heart, myocardial infarction (MI), or abnormalities in the conduction system. Late-life hypothyroidism or masked hyperthyroidism may present with a chief complaint of fatigue (Wasserman, 2021).

Differential Diagnosis: Fatigue can be related to many psychological and physiological etiologies. Depression was shown to be an independent predictor of fatigue in a study by Galland-Decker et al. (2019). Many psychiatric disorders affect sleep and may result in fatigue, including depression, generalized anxiety disorder, obsessive-compulsive disorder, and panic disorder (Holmes, 2021). An underlying cause of fatigue may not be definitively identified in many cases. Fatigue that cannot be relieved by rest or sleep is often a sign of disease, physical or psychological.

Treatment: Treatment depends on the etiology identified in the comprehensive work-up. Symptom management includes regular exercise, attention-restoring activities, psychosocial techniques, energy conservation measures, good sleep hygiene, eating a well-balanced diet, drinking an adequate amount of water intake, and possibly adding nutritional supplements. Pharmacological management is directed at identifying and treating the cause of the fatigue. Changing medications may be considered to diminish side effects of the medications. In extreme cases, clinicians may consider prescribing psychostimulants for opioid-related somnolence, cognitive impairment, and depression.

Follow-Up: Follow-up depends on the findings. Monitor the patient periodically as indicated by diagnosis or symptoms, symptom persistence, and disability associated with the symptom. The symptom may be a subclinical one.

The potential for complications relates to the cause of fatigue and the impact the symptom has on the person's function.

Prevention/Prophylaxis: Optimal health maintenance, including maintaining a healthy diet, adequate hydration, regular exercise, and good sleep hygiene, may prevent or enable early recognition of signs and symptoms of systemic or psychological illness.

Referral: Referral to a specialist may be indicated based on the results of the work-up.

Education: If the fatigue has a physiological cause, teaching should be related to the disease/disorder identified as the cause of the fatigue symptoms. Psychological counseling, changes in the environment, behavior modification, and stress reduction may be needed. The goal of fatigue management is to provide the patient with self-help tools to eliminate or alleviate fatigue.

HEADACHE

Description: Headache refers to a symptom that occurs in the head, neck, or face. Headaches decline with aging. Any new onset of headache in the older adult should be considered serious until proved otherwise.

Etiology: *The International Classification of Headache Disorders (ICHD), 3rd edition*, describes two categories of headache: primary and secondary (International Headache Society [IHS], 2018). Primary headaches include those in which there is an intrinsic dysfunction of the nervous system, often genetic in origin, (Robbins, 2021) which predisposes the older adult to increased vulnerability to headache attacks. Primary headaches include migraine, tension-type headache (TTH), cluster headache, and other trigeminal autonomic cephalgias. In contrast, secondary headaches are those in which the headache is secondary to an organic or physiological process, intracranially or extracranially. Medication overuse headache (MOH) is a unique headache diagnosis defined as headache occurring on 15 or more days per month developing as a consequence of regular overuse of acute or symptomatic headache medication (Berk et al., 2018). There are many possible reasons for secondary headaches. Some to consider are trauma to head or neck, nonvascular intracranial disorder such as neoplasms, substance abuse or withdrawal, infection including fever, disorders of the cranium or face, and psychiatric disorders.

Occurrence: Although the prevalence of headache decreases in the older adult, 75% to 90% of people have headaches at some point in their lives (Robbins, 2021; Taga et al., 2017). Headaches remain a problem for 35.6% of individuals aged 60 to 69 and 17.8% of individuals aged 70 to 79, with frequency decreasing after age 79 (Taga et al., 2017). Most headaches (approximately 50%) are primary, TTH, and migraine. TTH is the most common type of headache in individuals older than age 65 and in the general population, with a prevalence of 50.4% (Robbins, 2021) and 35.8% in the older adult (Berk et al., 2018). Of greater significance is that secondary headaches are more common in older adults older than 65 years, 15% of which are secondary headaches, which is significantly increased from an estimated 1.6% for adults younger than 65 years old (Phu Do et al., 2019).

Age: The prevalence of primary headaches decreases with age. The prevalence of migraine in patients older than 65 years is reported to be 5.7% to 15% (Berk et al., 2018; Burch et al., 2018). New-onset migraine in patients older than age 60 years is rare and is a red flag indicating evaluation for a secondary cause (Robbins, 2021; Starling, 2018). TTHs are generally listed as being more frequent in women (Berk et al., 2018; Feleppa et al., 2017; Taga et al., 2017) but at least one citation indicates that TTHs occur twice as often in men (Robbins, 2021). Migraine headaches, which tend to begin in early adulthood, are more common in women than in men, with 17% to 20% prevalence in women and 5% to 9% prevalence in men (Burch et al., 2018; Robbins, 2021). Cluster headaches are more common in men than in women, with a mean age of onset at age 30 years, although chronic cluster headaches may be more common in women (Berk et al., 2018; Manzoni et al., 2019). Giant cell arteritis is more commonly seen in women (Robblee & Singh, 2020; Starling, 2018).

Ethnicity: Giant cell arteritis is more common in White populations (Starling, 2018). There are some data to indicate a slight prevalence of migraine headaches in Native Americans and Alaskan Natives (Burch et al., 2018).

Contributing Factors: Depending on the type of headache, multiple factors can contribute. Poor posture, cervical osteoarthritis, ill-fitting dentures, tooth pain, and jaw disorders can contribute to tension headaches. Depression, anxiety, sleep disorders, and general pain syndromes can also contribute to most headache types. Medication side effects, particularly with estrogen, calcium channel blockers, nitrates, anti-Parkinson's drugs, indomethacin, and theophylline, can contribute to headaches. Alcohol can trigger or worsen headaches. Dehydration may be a factor. Migraines can be triggered by dietary factors such as aged or smoked cheese, chocolate, caffeine, and monosodium glutamate, as well as changes in sleep pattern, weather changes, and smoking. Genetics may play a role in migraine, cluster headache, and giant cell arteritis (Robbins, 2021; Starling, 2018).

Signs and Symptoms: Headache types, presentation, and treatment options change as patients age. Tension headaches are the most common and are due to mostly extracranial causes, such as muscle tension. Migraine in older adults may appear with sensory or motor phenomenon and may be confused with transient ischemic attack (TIA) or stroke (Burch et al., 2018; Lebedeva et al., 2020; Starling, 2018). The reported symptoms change with age bilaterally or globally with decreasing associated symptoms such as photophobia, phonophobia, nausea, and vomiting. The older adult may complain of increased neck pain, bilateral rhinorrhea, and lacrimation. Migraine in older adults is more often bilateral. In addition, older adults often have an aura without getting the headache; these symptoms need to be differentiated from a cerebrovascular accident (CVA) (Robblee & Singh, 2020). The older adult frequently has a better response to medication as compared with younger adults. Patients who report new-onset auras without a headache; that is, visual, sensory, and/or speech symptoms that may mimic those of migraine headaches, merit immediate referral for evaluation of secondary causes such as TIA, seizure, and intracranial hemorrhage (Berk et al., 2018; Starling, 2018). Two rare primary headaches occurring in older adults are hypnic (developing only during sleep, lasting several hours) and primary cough or Valsalva maneuver headache precipitated by cough or other Valsalva maneuver, lasting up to 2 hours (Berk et al., 2018).

The evaluation of an acute headache in adults is based largely on the history; the physical examination is often normal. Key responses in the history of present illness include the classic, "The worst headache in my life" or "thunderclap headache," which may suggest subarachnoid hemorrhage (SAH), a medical emergency. Ask if the headache is "typical." If the typical headache does not improve with usual treatment, consider a secondary diagnosis. The onset of the headache is very informative, a headache that has an unprovoked, sudden onset may be SAH or CVA. A headache with a sudden onset provoked by agitation, orgasm, cough, or sneeze is usually benign and transient. A subacute headache progressing over weeks may indicate an intracranial lesion, subdural

© F.A. Davis Publishing

hematoma, or hydrocephalus (Berk et al., 2018; Robbins, 2021; Starling, 2018). For the older adult with their first headache, always consider giant cell arteritis (Berk et al., 2018; Starling, 2018) Location, duration, frequency, severity, character, triggering or aggravating factors, and alleviating factors must be considered.

A focused review of systems is important. For example, fever may suggest meningitis, brain abscess, viral syndrome, or dehydration. Vomiting is less common in older adults with migraine; if present, a CVA or SAH should be considered. Visual complaints suggest a possible CVA, acute angle glaucoma, or giant cell arteritis. Other significant findings would be seizures, confusion or change in mental status, dizziness, weakness, neck pain, recent head trauma, recent travel, facial pain, tenderness, and eye pain. Ask if other contacts are ill. Past medical history should address the patient's immune status, recent change in medication, history of cancer, and hypertension. A family history of migraine or brain tumor may be significant. Alcohol consumption and smoking should be examined, as well as caffeine withdrawal. For recurrent/frequent headaches, having the patient keep a headache diary is helpful in identifying patterns and the impact the symptom has on function. Impact of the headaches on the patient's activities of daily living (ADLs) is an essential part of the history. An infection with COVID-19 may present with headache, and long COVID may also include headache.

The physical examination is often normal. Assess vital signs for extremes in blood pressure (suggestive of a neurological event) and temperature elevation, which suggests infection. Observe the patient's general appearance, including facies, and evaluation of mental status. Any sudden change in mental status or mood should be evaluated swiftly. A thorough neurological examination should include assessment of cranial nerves, gait, balance, and tactile sensation. Perform a fundoscopic examination to assess for papilledema, hemorrhages, exudates, and venous pulsations. Check for pupillary size and look at the cornea for haziness. Check extraocular movements and position of the eyelids.

Conduct an examination of the head and neck for lymphadenopathy, thyroid enlargement, carotid bruits, trigger points, meningeal irritation, or limitation in normal range of motion. Palpate the head and neck for tenderness, which may suggest TTH. Tenderness over the frontal and maxillary sinuses suggests sinusitis. Check for enlargement, tenderness, or pulsation of the temporal artery, tenderness suggests giant cell arteritis. Palpate the temporomandibular joint for alignment, mobility, and clicking. Examine the ears, nose, throat, and teeth for contributing problems. Evaluate the patient for postural alignment problems, muscle spasms, or trigger points in the back or shoulders.

Diagnostic Tests: Individualize diagnostic tests according to the suspected cause of the symptom. Neuroimaging sometimes is indicated for emergency evaluation of suspected vascular, neoplastic, or infectious disease. If red flags are present, in addition to a full neurological evaluation, neuroimaging should be considered. There are red flags that should be considered especially in the older adult. These are indicated through a mnemonic, SNOOP, originally proposed by Dodick in 2003, many versions of this are currently seen (Do et al., 2019, Walling, 2020). Dodick identified the following headache red flags: **S**ystemic symptoms including fever or weight loss, or **S**econdary risk factors such as HIV or malignancy; **N**eurological symptoms or abnormal signs such as confusion, impaired attention or consciousness; **O**nset that is sudden, abrupt, thunderclap, or positional; **O**lder age (over 50 years) at onset of a new onset or progressive headache; **P**revious headache pattern has changed in frequency, severity, or presentation. Generally, MRI is preferred to CT scan (Berk et al., 2018; Do et al., 2019). MRI is considered if the headache is of sudden onset, severe, worsening, unresponsive to treatment, and associated with neurological or constitutional symptoms. Laboratory tests generally are not helpful, unless anemia, infection, or electrolyte imbalance is suspected. However, erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) should be ordered if an inflammatory condition, such as giant cell arteritis, is under consideration. An elevated ESR warrants referral of the patient for temporal artery biopsy to confirm diagnosis. A lumbar puncture may be indicated after a negative CT scan without contrast if the patient has a "thunder-clap headache," suggesting an SAH, fever, or neck stiffness. Sinus or cervical spine x-rays may be indicated.

Differential Diagnosis: There are numerous differential diagnoses to be considered based on the history and examination. Urgent headaches as mentioned in the prior section should be delineated first. Primary headaches include TTHs, which are the most common, and may be triggered by lack of sleep, emotional or physical stress, medications, caffeine withdrawal, alcohol as delineated previously. The patient may complain of constant bilateral tightening pressure that does not worsen with ADLs. The neurological examination will be normal. Migraine headaches, as noted previously, with or without aura, are rarely new onset in the older adult. Medication-induced headache must be considered, especially with medication overuse for the treatment of either TTH or migraine headaches. Medication-induced headaches may also be the result of the misuse of barbiturate-analgesic-caffeine combinations, codeine, opioids, caffeine, acetaminophen, aspirin, and NSAIDs. These patients may present with daily or near-daily headaches. Other potential diagnoses include sinusitis and cervical spine disease.

The cluster headache is characterized by severe unilateral orbital, periorbital, or temporal pain. The attacks are relatively short (15 to 180 minutes) but can recur up to eight times in one day. Autonomic symptoms are also associated with the pain and present as ipsilateral ptosis, miosis, lacrimation, rhinorrhea, nasal congestion, and facial swelling. Cluster headaches tend to occur more often in men except in those older than age 60, when they are more common in women (Berk et al., 2018; Ljubisavljevic & Trajkovic, 2019).

Urgent diagnoses include SAH, giant cell arteritis, stroke/CVA, brain tumor, infection, and acute angle-closure glaucoma. The most common acute cerebral bleed is a subarachnoid hemorrhage, which has its highest incidence in women older than age 70 with a history including smoking, excessive alcohol ingestion, and hypertension. The patient with SAH often presents with a "thunderclap" or the "worst headache of my life," and the pain may be associated with other symptoms, such as confusion, vomiting, and seizures. This represents a medical emergency, and the patient needs to be evaluated in the emergency department with more extensive

© F.A. Davis Publishing

testing including a CT scan and consideration for possible surgery (Starling 2018).

Giant cell arteritis occurs predominantly in females older than 50 years who may also have a history of polymyalgia rheumatica. The patient may present with monocular vision loss, flu-like symptoms, and jaw claudication. On examination, unilateral blindness may be present with tenderness in the temporal area. Headache is the only presenting symptom in 1/3 of the patients with Giant cell arteritis. Optic nerve edema may be seen on funduscopic examination (Robblee & Singh, 2020).

Headache only occurs as a warning of an impending ischemic stroke in about 25% of all cases but occurs in 40% to 60% of all hemorrhagic strokes. Infectious diseases, such as encephalitis and meningitis, may also present with a headache but would include associated symptoms such as fever, altered mental status, and nuchal rigidity. When infectious disease is suspected as the cause of headache, the patient should be immediately transferred for further evaluation.

A patient with acute angle-closure glaucoma presents with acute unilateral eye and/or forehead pain, blurred vision, halos around lights, injected sclera, and nausea/vomiting. On examination, the pupil is mid-position, and the cornea appears hazy. There may be a decreased visual field, and the lack of any sign of exudate or discharge common in conjunctivitis is also significant. This presentation is considered a serious emergency, and the patient should be seen immediately by an ophthalmologist.

Treatment: Treatment of headache depends on the presumed etiology. Regardless, acute and preventive medications must be carefully scrutinized, considering the presence of comorbidities and the pathophysiological aspects of aging. The dearth of research studies including older adults limits best evidence. To avoid polypharmacy in older adults the most parsimonious option is preferred (Soni et al., 2020).

For migraine headaches, acetaminophen, NSAIDs, triptans, as well as combinations, have been established as effective for acute migraine treatment based on available evidence. Combining NSAIDs with triptans improves the efficacy. Vasoactive substances (triptans or dihydroergotamine) are contraindicated in patients with coronary arterial disease, peripheral vascular disease, or cerebral vascular disease (CVD), including a history of stroke. They should not be used in patients with uncontrolled hypertension or severe hepatic impairment, limiting their use in older adults. If the patient is at low cardiovascular risk, triptans could be considered for acute episodes. Side effects must be recognized to include cognitive and autonomic signs/symptoms. Recently, several new classes of medication for the treatment of migraines have been approved. One class of medications are the calcitonin gene-related peptide receptor (CGRP) antagonists, rimegepant (Nortek) and ubrogepant (Ubrelvy). Side effects are minimal and pain relief at 2 hours occurs more than 50% of the time. (Soni et al., 2020) Another class of medications target serotonin and 5HT1p receptors and inhibit trigeminal nerve firing. The first in this class is lasmiditan (Reyvow) (Soni et al., 2020). The mechanism of action of this class is not associated with vasoconstriction. Adjunct measures include antiemetics, hydration, and possibly magnesium. Various forms of the triptans are available in oral, injectable, and nasal forms.

Management of TTHs combines pharmacological and nonpharmacological measures. Analgesics and NSAIDs including cyclooxygenase-2 (COX-2) inhibitors are effective. All NSAIDs must be used with caution in older adults because of the risk of gastrointestinal (GI) ulceration and renal and hepatic impairment. Concomitant use of NSAIDs with aspirin or antiplatelet agents increases the risk of bleeding. Treatment should be limited to 2 days per week to avoid MOH, which is defined as headache on more than 15 days in a month (Walling, 2020). MOH respond to medication but then return when the medication wears off. Prophylactic therapy is advised for patients with MOH. Other considerations for TTH include tricyclic antidepressants (amitriptyline and nortriptyline), but they are listed on *Beers Criteria for Potentially Inappropriate Medication Use in Older Adults* (AGS, 2019) due to their anticholinergic side effects, which are a concern in older adults. Topiramate, Botox, and even corticosteroids have been used in the treatment of TTH (Walling, 2020). Behavioral intervention such as relaxation, cognitive behavioral therapy, biofeedback, and other lifestyle modifications may be helpful as adjunctive therapy.

The goal of therapy for cluster headaches is to abort the attacks after they have started. There is no evidence to support the use of NSAIDs. The uses of inhaled oxygen and subcutaneous sumatriptan 6 mg or sumatriptan nasal spray 20 mg are effective in improving headache response, as is zolmitriptan nasal spray 5 mg (Ljubisavljevic & Trajkovic, 2019). The calcium channel blocker verapamil (with an initial target dose of 240 mg per day), lithium up to 900 mg per day, and galcanezumab (Emgality, a CGRP inhibitor), 300 mg, injected monthly are preventive therapies (Robbins, 2021).

For giant cell arteritis, management requires larger doses of prednisone to prevent visual sequelae (40 to 60 mg and even 80 mg/day). The dose is maintained until remission is reached, which may take 2 to 4 weeks before tapering. The medication tocilizumab (Actemra), a disease-modifying antirheumatic drug, has also been indicated to be effective. (Robblee & Singh, 2020). Monitor blood sugar and other side effects of corticosteroids, such as changes in glucose tolerance, cognition, and mood.

Follow-Up: Monitoring depends on etiology and treatment strategies. After the diagnosis has been made and management strategies identified, patients should be monitored for effectiveness of treatment.

Sequelae: Sequelae depend on cause. Missed diagnosis of acute, life-threatening symptoms can prove fatal. Older adults are at higher risk for life-threatening headaches. Most common causes have recurrence or chronicity, which affects quality of life. Potential for side effects from medications and medication overuse must be considered.

Prevention/Prophylaxis: Preventive measures include avoidance of triggers, early intervention with medication as soon as symptoms present, and stress-reduction techniques as appropriate. Use of alcohol, tobacco, and caffeine in specific types of headaches should be monitored. For recurrent headaches, prophylactic therapy may be indicated. In addition to medication, patients should be advised to avoid triggers and to consider behavioral modification. Regular meals, sleep hygiene, hydration, and regular physical activity should be encouraged. All categories of drugs should be started at low doses and incrementally increased to therapeutic dosing.

© F.A. Davis Publishing

For older adults without predominant depression or aura, the most effective drugs are the same as those for younger adults. Medication is taken daily for a trial period (usually 1 to 2 months) to evaluate the effect on headache frequency and strength.

Anticonvulsants have been found to be among the most effective agents for prophylaxis of migraine headaches including valproic acid (250 to 500 mg in daily divided doses), topiramate (25 to 200 mg in divided doses), and gabapentin (begin with 300 mg increasing to a maximum of 3,600 mg/day). Anticonvulsants can increase fatigue, and baseline liver and kidney function studies should be obtained before initiation. Topiramate can cause kidney stones, so it is important that the patient increase fluids while taking the medication. Although beta blockers (propranolol, 80 mg orally daily; atenolol, 50 to 100 mg orally daily; or nadolol, 40 mg orally daily) have been used prophylactically for migraine and TTH, they are contraindicated in patients with a history of bronchospastic disease, asthma, diabetes, or heart failure (HF). Non-dihydropyridine calcium channel blockers (verapamil, 240 mg orally daily in divided doses, or nifedipine, 30 to 180 mg orally daily) have also been used prophylactically to prevent cluster headaches and are highly effective. Contraindications include HF, heart block, hypotension, sick sinus syndrome, and atrial fibrillation. There is moderate evidence that tricyclic antidepressants may also be effective for headache prophylaxis in low doses (amitriptyline, 25 to 50 mg orally daily, or desipramine, 50 mg orally daily). As noted above they are identified in Beers Criteria and may be contraindicated because of adverse effects on the cardiovascular system.

Referral: Refer patients to the emergency department (ED) for urgent conditions when headaches may be a result of hemorrhage, vasculitis, stroke, infectious disease, or acute angle-closure glaucoma. Any abnormal MRI or CT scan results should be referred to a neurologist. Headache red flag symptoms that indicate an urgent diagnosis, such as SAH, giant cell arteritis, stroke, brain tumor, infection, and acute angle-closure glaucoma, warrant immediate referral to the ED.

Education: Patient and family/caregiver education should be ongoing, specifically nonpharmacological management as well as pharmacological management. Evidence-based resources should be provided, as well as Web-based resources from organizations such as the American Headache Society and International Headache Society. Provide a headache journal (templates available from the American Headache Society and other sources) for the patient and instruct them on how to use it. If medications are prescribed, ensure that the patient understands proper use and safety considerations.

HEMATURIA

Description: Hematuria is the presence of red blood cells (RBCs) in the urine. It can be classified as either gross or microscopic. Gross hematuria is suspected when the urine appears either red or brown in color to the naked eye. Microscopic hematuria is identified by microscopic laboratory analysis. The American Urological Association (AUA) (Barocas et al., 2020) defines clinically significant microscopic hematuria as three or more RBCs per high-power field on a

© F.A. Davis Publishing

single, properly collected urine specimen. All patients with hematuria require evaluation because 2% to 5% of patients with microscopic hematuria are found to have a malignancy and 10% to 20% of patients with gross hematuria are found to have a malignancy. For patients with microhematuria, the AUA recommends that the clinician perform a history and physical examination to evaluate for risk factors for genitourinary, gynecological, and nonmalignant genitourinary causes as well as malignancy or medical renal disease.

Etiology: Hematuria may be renal or from contamination outside the urinary tract. Renal hematuria may result from glomerular or nonglomerular causes. The source of hematuria may be the upper collection system (e.g., renal, ureter) and/or lower collection system (e.g., bladder, prostrate, urethra). Microscopic hematuria is a common finding on routine urinalysis, and etiologies range from life threatening to benign incidental causes. The pathophysiology depends on the anatomical site from which blood loss occurred. In older adult patients the most common causes are malignancy or benign prostatic hyperplasia.

Occurrence: The prevalence of asymptomatic microscopic hematuria ranges from 2% to 31% in the adult population. In patients older than 50 years, the prevalence is estimated at 13%. There is a slightly higher incidence of hematuria in older women.

Age: Incidence of hematuria increases with age. Younger patients are less likely to have an etiology identified.

Ethnicity: Not significant.

Contributing Factors: Infection, anticoagulation therapy, renal calculi, trauma, anatomical defects such as rectocele, menstruation, atrophic vaginitis, renal disease, or recent urological procedures may all contribute to the presence of hematuria. Risk factors related to the development of a malignancy include age greater than 50 for women and age 40 for men; current or past history of smoking; degree and persistence of microhematuria; history of gross hematuria; occupational exposures to chemicals or dyes (e.g., painters, printers, chemical plant workers), irritative lower urinary tract symptoms; history of pelvic irradiation; any exposures to cytotoxic agents such as cyclophosphamide or ifosfamide; family history of urothelial cancer; or chronic indwelling foreign body, such as a catheter, in the urinary tract.

Signs and Symptoms: A thorough history is important in the assessment of hematuria. Ask all patients about the presence of visible blood in their urine, history of vigorous exercise, recent prostate examination or procedure, recent trauma to the abdomen, recent catheterization, menstruation, renal disease, viral illness, and medications (analgesics, antibiotics, anticoagulants, NSAIDs). Gross hematuria would be recognizable by the red or brownish color of the urine, but there may not be any signs or symptoms related to microscopic hematuria. Symptomatic hematuria with associated flank pain, fever, chills, nausea or vomiting, abdominal pain, or renal colic may represent kidney disease or a kidney stone. A patient may report urinary frequency, lower abdominal pain, or dysuria, which may indicate a urinary tract infection (UTI). Ask about symptoms of prostatic obstruction in males. A physical examination should focus on abdominal or flank pain, urogenital examination, prostate examination, testicular examination, and/or vaginal examination.

Diagnostic Tests: A urinalysis with microscopy should be obtained to confirm hematuria. Urine dipstick evaluation may be misleading because it lacks the ability to distinguish RBCs from myoglobin or hemoglobin. Always confirm a heme-positive dipstick with a microscopic urinalysis. Microscopic hematuria is defined as three or more RBCs per high-power field in a urine collection. The urinalysis should also include evaluation of dysmorphic red blood cells and proteinuria which can be suggestive of glomerular disease. Other analysis may include a comprehensive medical panel (CMP) to identify metabolic abnormalities. An elevated creatinine level may indicate acute or chronic renal disease. Clinicians should refer patients with microhematuria to nephrology for evaluation if medical renal disease is suspected due to an elevated creatinine level or low glomerular filtration rate. If the patient is on anticoagulation therapy, a prothrombin time, International Normalized Ratio, and CBC should be obtained. Note whether the patient is taking any other medications that would affect platelet function or decrease clotting abilities. Based on the initial evaluation, the clinician should classify the patient as low, moderate or high risk as noted on in AUA Guidelines (Barocas et al., 2020) (Table 7-5). Additional urological evaluation is dependent on the AUA risk stratification (Barocas et al.,2020). Adults aged 60 years and older, those with smoking history of more than 30 pack years, more than 25 RBCs per high-power field on a single urinalysis, and history of gross hematuria are classified as high risk for malignancy. Patients with microhematuria at low risk can participate in shared decision making to decide between repeating urinalysis within 6 months or proceeding with urological referral for cystoscopy and renal ultrasound. Evaluation for hematuria, urine cytology, and

TABLE 7-5 American Urological Association's Microhematuria Risk Stratification System

Low (patient meets all criteria)	Intermediate (patients meets any one of these criteria)	High (patients meets any one of these criteria)
Women aged <50 years, Men aged <40 years	Women aged 50–59 years; Men aged 40–59 years	Women or men age ≥60 years
Never smoker or <10 pack years	Smoking 10–30 pack years	Smoking >30 pack years
3–10 RBC/HPF on a single urinalysis	11–35 RBC/HPF on a single urinalysis	>25 RBC/HPF on a single urinalysis
No risk factors for urothelial cancer	Low-risk patient with no prior evaluation and 3–10 RBC/HPF on repeat urinalysis	Hx of gross hematuria
	Additional risk factors for urothelial cancer	

Reprinted with permission from Barocas, D.A., et al. (2020). Microhematuria: AUA/SUFU Guideline. The Journal of Urology, 204(4), 778–786.

© F.A. Davis Publishing

urine markers for bladder cancer in this low-risk group are not recommended.

Differential Diagnosis: Infection or supratherapeutic anticoagulation should be ruled out as reversible causes of hematuria. More serious causes, such as glomerular disease, renal calculi, trauma, anatomical defects, or malignancy, must be ruled out. Additional benign conditions that can cause microhematuria include benign prostatic enlargement, urethral strictures, exposure to trauma, recent urological procedures, or catheterization.

Treatment: Treatment is directed at the cause. Treatment may not be required for low-risk patients. Appropriate antibiotic therapy for a UTI should resolve the hematuria. If the patient is on anticoagulation therapy, medication adjustment may resolve the problem. If a kidney stone is present, initial treatment may be pain management and oral hydration. The patient with urosepsis, acute kidney injury, anuria, unrelenting nausea, and vomiting should be referred immediately.

Follow-Up: In patients treated for a UTI, a repeat urinalysis with microscopic evaluation must be done following treatment. Referral to a urologist is dependent on patient risk factors (Barocas et al., 2020). When patients have completed the hematuria evaluation and are confirmed to be negative, a urinalysis may be repeated within 12 months for surveillance.

Sequelae: Hematuria may be a sign of a malignancy and should not be ignored, even if it occurs transiently. Hematuria may indicate renal disease, especially when proteinuria is present and, if needed, referral to a nephrologist for a second opinion. A diagnosis of a kidney stone does not rule out the coexistence of a malignancy.

Prevention/Prophylaxis: The U.S. Preventive Services Task Force does not endorse routine screening for asymptomatic hematuria due to lack of evidence. *"No major health organization recommends screening healthy, asymptomatic patients with urinalysis for the purpose of cancer detection."*

Referral: Primary care providers can initiate testing to verify the presence of hematuria and treat if diagnosis is clear. Referral to a nephrologist is indicated if medical renal disease is suspected as evidenced by presence of proteinuria, RBC casts, dysmorphic RBCs, and/or elevated serum creatinine levels. 5% to 40% of patients referred for evaluation of hematuria or specialty care have a urological malignancy.

Education: Counsel patients and family members to seek medical advice about signs and symptoms they should report including gross hematuria, urinary frequency, dysuria, flank pain, and abdominal pain. Educate patients and families about side effects of over-the-counter (OTC) medications and prescribed medications. Educate the patient about the effects of anticoagulation therapy and to call immediately if the patient notices any hematuria which may mean drug levels are too high. Educate the patient about risk factors and recommend tobacco cessation as appropriate.

Clinical Recommendation	Evidence Rating	References
Clinicians should define microhematuria as ≥3 red blood cells per high-power field on microscopic evaluation of a single, properly collected urine specimen.	C	Barocas et al., 2020
In patients with hematuria attributed to a urinary tract infection, clinicians should obtain a urinalysis with microscopic evaluation following treatment to ensure resolution of the hematuria.	C	Barocas et al., 2020
Following initial evaluation, clinicians should categorize patients presenting with microhematuria as low-, intermediate- or high-risk for genitourinary malignancy based on the identified risk factors.	C	Barocas et al., 2020
In low-risk patients with microhematuria, clinicians should engage patients in shared decision making to decide between repeating urinalysis within 6 months or proceeding with cystoscopy and renal ultrasound.	C	Barocas et al., 2020
Clinicians should perform cystoscopy and renal ultrasound in patients with microhematuria categorized as intermediate risk for malignancy.	C	Barocas et al., 2020
Clinicians should not define microhematuria by positive dipstick testing alone. A positive urine dipstick test (trace blood or greater) should prompt formal microscopic evaluation of the urine.	C	Barocas et al., 2020
Clinicians should perform cystoscopy and axial upper tract imaging in patients with microhematuria categorized as high-risk for malignancy.	C	Barocas et al., 2020
For patients with a prior negative hematuria evaluation who develop gross hematuria, significant increase in degree of microhematuria, or new urological symptoms, clinicians should initiate further evaluation.	C	Barocas et al., 2020

HEMOPTYSIS

Description: Hemoptysis is coughing or spitting blood from the respiratory tract. This can range from blood-streaked sputum to frank bleeding. Massive hemoptysis, which is life threatening, is no longer defined quantitatively. Instead, more important is the briskness of bleeding, ability of a patient to maintain a patent airway and expectorate blood, availability of therapeutic options, and the patient's comorbidities (Davidson & Sojahaee, 2020). These more significant variables underscore the concept of the magnitude of effect definition for massive hemoptysis.

Etiology: Hemoptysis refers specifically to bleeding from the lower respiratory tract, but sometimes bleeding from the upper respiratory tract or the upper gastrointestinal (GI) tract may mimic hemoptysis (pseudohemoptysis). There are multiple potential causes for hemoptysis including, but not limited to, airway disease and trauma, pulmonary infections or inflammation, bronchiectasis, lung neoplasms, cardiac disease, cocaine use, pulmonary embolism (PE), and medication use (anticoagulants, antithrombotics, NSAIDs). Massive hemoptysis is uncommon, and causes include tuberculosis (TB), bronchiectasis, mycetoma, and cancer (Davidson & Sojahaee, 2020).

The lungs receive blood from the pulmonary and bronchial arterial systems. Bleeding involving the low-pressure pulmonary system produces small-volume hemoptysis, whereas the high-pressure bronchial system produces more profuse bleeding. Infection causes mucosal inflammation that can lead to blood vessel rupture. Neoplasms can cause mucosal invasion, eroding into the blood vessels. In the primary care setting the most common causes of hemoptysis are acute and chronic bronchitis, pneumonia, TB, and lung cancer.

Occurrence: The most common cause of hemoptysis is airway disease. There is a strong seasonal trend with peak incidence in the spring and decreased incidence in late summer. The most common causes of life-threatening hemoptysis include bronchiectasis from infectious and noninfectious etiologies, bronchogenic carcinoma, and lung infections including TB (Kathuria et al., 2020).

Age: Hemoptysis may occur at any age, although the age range can vary based on etiology of the hemoptysis. The mean age of occurrence is 62 years.

Ethnicity: No direct ties to ethnicity have been documented, but immigrants and persons living in poverty are at higher risk for TB and other pulmonary infections.

Contributing Factors: Smoking history (active or passive exposure), alcohol use, cocaine use, any history of trauma, environmental exposures, hypertension, comorbidities including diabetes or immunocompromised status. Medications such as aspirin, NSAIDs, or anticoagulants can either be causative or contributing factors. Risk factors associated with an increased risk of lung malignancy include male sex, older than 40 years, greater than 40-pack-per-year smoking history, and duration of hemoptysis longer than 1 week.

Signs and Symptoms: The quantity, characteristics, and duration of the hemoptysis should be established first when assessing the patient. It is important to know if it has increased in severity, if the cough is worse at night, and if there are any other associated symptoms. The amount of hemoptysis is potentially overestimated or underestimated by patients and practitioners, but it is important to at least attempt to determine the volume and rate of blood loss. Hemoptysis of more than 100 mL in less than 24 hours is potentially life threatening and requires immediate assessment in an emergency department. Any sudden onset of hemoptysis with or without associated symptoms can be caused by a PE and needs emergency assessment. A comprehensive history, including the patient's known risk factors and work and home environment, is helpful in narrowing the cause of the hemoptysis. Establish if there are any signs and symptoms of infection (fever, cough, sputum production), malignancy (cachexia, weight loss, smoking history), trauma or foreign body aspiration, or any history of immune deficiency. A thorough medication review should also be completed.

Assess any risk factors such as smoking, cocaine use, long-term alcohol abuse, stroke, older age, immigrant status, immunocompromise, and heart disease when trying to identify the cause of bleeding. Use of tobacco with long-standing or increasingly severe hoarseness may indicate cancer of the mouth or throat. A history of persistent "heartburn" may be a clue to possible esophageal erosion as the source of bleeding. Chronic cough, dyspnea, and/or sputum production may suggest pulmonary disease.

Vital signs should include oxygen saturation. Tachypnea, tachycardia, use of accessory muscles, cyanosis, fatigue, or altered mentation are signs of respiratory distress and should be treated as a medical emergency regardless of the amount of hemoptysis described or observed. The physical examination should begin with a thorough examination of the nose and oropharyngeal mucosa. The neck, supraclavicular area, and axillae should be palpated for any enlarged lymph nodes, a possible sign of infection, lymphoma, or other malignancies. Auscultation of the lungs may reveal a focal abnormality consistent with pneumonia (crackles, rhonchi, wheezing); egophony is suggestive of consolidation and is often present in pneumonia. Heart sounds should be auscultated specifically for a murmur because mitral regurgitation or mitral stenosis can be associated with pulmonary edema or decompensated HF, especially in the setting of clinically apparent volume overload; this sputum is classically described as pink and frothy rather than frank bleeding. An abdomen distended with ascites may be accompanied by esophageal varices.

Diagnostic Tests: The initial test of choice is the chest x-ray or chest computed tomography (CT) scan (Davidson & Sojahaee, 2020). Diagnostic work-up may also include these laboratory tests: complete blood count (CBC) with differential, prothrombin time/partial thromboplastin time/International Normalized Ratio, comprehensive medical panel (CMP), arterial blood gas, sputum culture and smear, TB skin testing or quantiferon gold panel, d-dimer, and ESR. If initial imaging suggests the need for further testing, a CT angiogram or bronchoscopy may be the next step. If no cause of hemoptysis can be isolated and the radiographic

© F.A. Davis Publishing

studies are normal, a flexible bronchoscopy for airway examination is still useful to rule out an endobronchial source of bleeding.

Differential Diagnosis: Determine first whether the blood is coming from the respiratory tract (hemoptysis) or from the GI tract (hematemesis). Patients with hematemesis typically have nausea and vomiting and a history of gastric or liver disease, and the sputum more likely will be coffee ground in texture and a brown-black color. In hemoptysis, however, the sputum is bright red or pink and a frothy liquid or clotted, and the patient may have a history of lung disease. If the source of bleeding is determined to be the lung, possibilities include infection, inflammation, malignancy, trauma, autoimmune disease, cardiovascular disease, and coagulation disorders.

Treatment: The goals of management include bleeding cessation, aspiration prevention, and treatment of the underlying cause. If the source of the bleeding has been reasonably isolated to the respiratory system, the condition is not life threatening, and if an infectious or inflammatory etiology is diagnosed, the following diagnoses might be considered:

Acute Bronchitis. Acute bronchitis is predominantly viral, and antibiotics do not shorten the course of the disease. If the patient smokes, they should be counseled to quit or to cut back significantly. Bronchodilators help open the airways; expectorants such as guaifenesin used to mobilize secretions are about as effective as drinking two additional glasses of water per day. Cough suppressants should be avoided except to help the patient sleep. A cool mist humidifier in the bedroom is useful for loosening secretions.

Chronic Bronchitis. Chronic bronchitis needs a combination bronchodilator as an inhaler or as a nebulizer. Because chronic bronchitis is usually a result of smoking, the patient should be counseled to stop. A short course of prednisone is often helpful to treat an acute exacerbation of chronic bronchitis. Antibiotics should be reserved for acute exacerbations heralded by increasing shortness of breath, change in color of the sputum to dark yellow or green, or fever.

Bronchiectasis. Permanent enlargement of some of the airways in the lungs caused by chronic infections, trauma, or immune system problems can cause intermittent hemoptysis. The hemoptysis usually results from dilation of bronchial arteries. Because this is a chronic illness, antibiotic selection is generally based on previous sputum culture/susceptibility results.

Bacterial Pneumonia. Community-acquired pneumonia is most often caused by *Streptococcus pneumoniae. Hemophilus influenza, Chlamydia pneumoniae, Mycoplasma pneumoniae*, and *Legionella pneumophila* are other major bacteria that cause pneumonia in the otherwise healthy individual. If pneumonia is suspected, a chest x-ray should be obtained, and broad-spectrum antibiotics should be initiated empirically. Immunocompromised patients, patients with any respiratory distress, and older adult patients with significantly elevated or decreased white blood cell (WBC) counts may need to be hospitalized.

Fungal Infection. A fungal infection should be suspected if the pneumonia does not respond to conventional antibiotic therapy. The provider should attempt to collect a sputum specimen for analysis and culture. Appropriate antifungal therapy may be initiated, and the patient should be referred to a pulmonologist and/or infectious disease specialist.

TB. If TB is suspected based on history, signs/symptoms, and chest imaging, the diagnostic work-up should focus both on detecting the bacteria in sputum (acid-fast bacteria culture and smear) and on protecting other individuals from contracting the infection. This may include admission to a negative pressure hospital room with airborne isolation for the diagnostic work-up. Treatment with an antituberculosis regimen can be started by the hospital or outpatient clinic; however, these patients need to be referred to the health department who will often manage treatment through directly observed administration of the antituberculosis regimen.

Follow-Up: Follow-up depends on the severity of the illness. For pneumonia or bronchitis with minimal dyspnea, a call to check on the patient is appropriate. Worsening temperature, bleeding, or difficulty breathing requires immediate attention or emergency department evaluation. Patients with resolving pneumonia should be evaluated in 2 to 3 weeks, radiographic resolution may take 6 to 8 weeks, especially in older adult patients or those with underlying lung disease. Mild hemoptysis recurring sporadically over a few years is common in smokers who have chronic bronchitis punctuated with superimposed acute bronchitis.

Sequelae: Death can occur if the etiology is not identified quickly and treated, particularly if it causes cardiovascular collapse or acute respiratory insufficiency. The mortality rate depends on the etiology, and in patients with a malignancy and massive hemoptysis (more than 1,000 mL per 24 hours) the rate is 80%. Chronic lung disease may also result.

Prevention/Prophylaxis: Counseling patients and their families about the benefits of smoking cessation and decreasing alcohol intake are worthwhile. Discussions to promote a healthy lifestyle are important, stressing activity and weight loss.

Referral: Massive hemoptysis requires treatment in the intensive care unit including pulmonary and cardiovascular/cardiothoracic surgery consultation. In cases of non-massive hemoptysis when bleeding persists or increases, the patient should be referred to a pulmonologist for bronchoscopy or to an otolaryngologist for direct laryngoscopy. If diagnostic imaging such as chest CT suggests malignancy, the next step would include a biopsy, requiring referral to a pulmonologist or cardiothoracic surgeon. In the setting of known or prior malignancy, referral to an oncologist, if not already established, is an important consideration.

Education: Discuss risk factors associated with PE, such as immobility or hormone replacement therapies. Provide patient education related to smoking cessation and cessation of street drugs and/or alcohol abuse. Patients with chronic obstructive pulmonary disease (COPD) or bronchiectasis should be aware of their own clinical signs/symptoms of worsening or acute exacerbation and have an action plan should any of these symptoms occur.

© F.A. Davis Publishing

INVOLUNTARY WEIGHT LOSS

Description: Weight loss is common among older adults and is associated with poor health outcomes and functional decline. Involuntary or unintentional weight loss is a condition in which the patient does not purposefully set out to lose weight for any reason (Kim et al., 2018). It may be a presenting concern of the patient, reported by the family, or first noted by the provider. There is a well-established association between weight loss and mortality in older adults (Cox et al., 2019). The Centers for Medicare and Medicaid Services (CMS) defines involuntary weight loss (IWL) that must be clinically investigated as 5% in 1 month, 7.5% in 3 months, or 10% in 6 months.

Etiology: The causes of IWL are not always clear. With aging there is a decline in bone mass and a decrease in muscle mass, which is responsible for a small decline in weight after the seventh decade of life (0.2 to 0.4 pounds per year). Another age-related phenomenon is a reduction in appetite called anorexia of aging (Cox et al., 2019). Sarcopenia is a geriatric syndrome that includes decrease in muscle mass and strength and decline in physical performance related to aging. The resulting increased ratio of fat to muscle may contribute to further weight loss because of the relationship of adipose tissue to inflammatory cytokines, which have been linked to cachexia and weight loss, including tumor necrosis factor-α (TNF-α), interleukin-1β, and interleukin-6. Cachexia is a metabolic disease characterized by the loss of muscle mass with or without the loss of fat. It may be difficult to distinguish cachexia from sarcopenia, and the two may coexist. Causes of weight loss may be the result of physiological factors, psychological factors, social factors, or a combination of these (see Table 7-6). While often the primary concern is an undiagnosed malignancy, nonmalignant causes are the most common. Many medications can interfere with appetite and result in weight loss, but often medications are added as treatment rather than removed.

Occurrence: Involuntary or unintentional weight loss occurs in 15% to 20% of older adults (Kim et al., 2018). Using the CMS criteria, the yearly incidence of weight loss is about 7% in the community. From 30% to 50% of long-term care residents have below-average body weight, but CMS nursing home data using their criteria reported a 6% incidence when patients with end-stage disease or on hospice were excluded (CMS, 2021).

Age: Old age is a risk factor for IWL because of the normal physiological changes with aging combined with a higher prevalence of physiological, psychological, and social factors associated with involuntary weight loss.

Ethnicity: Not significant.

Contributing Factors: When considering all causes of IWL, nonmalignant causes are most common, but in up to 38% the cause is a malignancy. Nonmalignant gastrointestinal (GI) disease is next, followed by psychiatric, endocrine, and cardiopulmonary conditions; alcoholism; dementia; medications; loss of taste and smell; decreased functional status; chronic infection; dentition; and smoking. Social factors such as isolation, abuse or neglect, location of residence (food deserts, safety concerns), lack of transportation, and financial issues have an influence on adequate nutrition with resulting weight loss as well. Many medications contribute to factors related to weight loss and a careful review should be initiated (see Table 7-7). Because weight loss can cause skeletal muscle loss there is an increased risk for falls, functional impairment, protein calorie malnutrition, immune system compromise, anemia, and decreased cognition, all of which increase morbidity and mortality.

Signs and Symptoms: Weight loss may be reported by the patient, their family, or noted by the provider. If clinical documentation is not available, a classic guideline introduced by Martson et al. (1981) suggests that a change in clothing size, confirmation of history by a family member, or ability of the patient to report exact weight change can be substituted. A thorough history and complete physical examination are required to identify any treatable underlying cause of the weight loss. History should include a review of cardiac,

TABLE 7-6 Causes of Unintentional Weight Loss

PHYSIOLOGICAL FACTORS	
Disease	
Malignancy	Lung, GI, pancreatic, hematological, prostate
Acute illness	Influenza, pneumonia, *Clostridioides difficile*
GI disease	Malabsorption, autoimmune, oral health
Endocrine	Diabetes, hyperthyroidism
Cardiovascular	HF
Respiratory	COPD, interstitial lung disease
Infectious disease	HIV, TB
Neurological disease	Dementia, stroke, Parkinson's disease
Rheumatological disease	RA, sarcoidosis, inflammation
Renal disease	Uremic cachexia
Previous surgery	Malabsorption, pain
Chronic pain	
Medications	
See Table 7-7	
Functional Issues	
Decline in ADLs and IADLs	Feeding, purchasing, and preparing food
Dysphagia	Food avoidance, dietary restrictions
Sarcopenia	Muscle weakness, decreased mobility
Falls	Fracture, fear of falling
Psychological Factors	
Depression	
Anxiety	
Grief	
Substance abuse and dependence	Alcoholism, tobacco, cocaine
Social Factors	
Social isolation	
Limited income	
Abuse or neglect	
Environment	Food desert, transportation, safety

TABLE 7-7 Medications That May Cause Weight Loss

MEDICATION	EXAMPLES
Neurological Psychiatric	Antidepressants, lithium, anticonvulsants, stimulants, levodopa, dopamine agonists, selegiline, phenothiazines, haloperidol, benzodiazepines, cholinesterase inhibitors, NMDA receptor antagonists
Cardiovascular	Digoxin, ACE inhibitors, CCB, β blockers, α agonists, hydralazine, statins, diuretics, amiodarone, procainamide, spironolactone
GI	Cimetidine, interferon, diphenoxylate-atropine, proton pump inhibitors, laxatives
Anti-infective	Metronidazole, griseofulvin, most antibiotics, amantadine
Nutritional	Calcium carbonate, iron, potassium, bile acid sequestrants
Musculoskeletal (including pain)	NSAIDs, bisphosphonates, colchicine, penicillamine, aspirin, opiates, allopurinol, colchicine, gold, hydroxychloroquine, methotrexate
Pulmonary	Theophylline, pseudoephedrine, antihistamines
Endocrine	Levothyroxine, Armour thyroid, metformin
Other	Anticholinergics

respiratory, GI, genitourinary, endocrine, hematological, or infectious disease symptoms. An assessment of depression, anxiety, cognitive impairment, substance abuse, and functional decline begin with the history. There should be a focus on oral concerns such as poor dentition, new dentures, mouth lesions, dry mouth, dysphagia, or loss of taste. A review of medications both prescribed and over-the-counter (OTC), including supplements, is necessary.

A functional cause of weight loss may be primary or secondary to a physiological or psychological etiology. Determine whether the patient has functional limitations that affect the ability to prepare and eat an appropriate diet and if adequate help is consistently available to assist with activities of daily living (ADLs) if necessary. The Mini-Nutritional Assessment (MNA) is supported by evidence as useful in measuring nutritional risk. The tool is accessible at www.mna-elderly.com where you can download the forms and the user guides at no charge. There is a training video and the possibility of integrating it into the electronic medical record. There are three versions of the MNA: Self MNA, the MNA for clinical use, and the original full MNA. They all include anthropometric measurements and general, dietary, and functional assessments.

Physical examination should include the cardiovascular, respiratory, GI, genitourinary, dermatological, and musculoskeletal systems. A comprehensive neurological examination and a mental status examination that includes assessment of mood, cognitive ability, and substance use are essential components. Patients with significant weight loss appear pale and cachectic, with signs of malnutrition such as hair loss, muscle wasting, and loss of subcutaneous fat. Look for evidence of loose skin, petechiae, cyanosis, clubbing of the fingers, and edema. There may be temporal wasting, icterus, dry mucous membranes, and flattened papillae of the tongue. The oral examination should note denture fit; tooth and gum disease; and oral lesions such as ulcers, stomatitis, and candidiasis. Examination of the cardiorespiratory system may reveal loud or palpable murmurs and diminished breath sounds. The liver or spleen may be palpable. Check for masses in the abdomen, breasts, and rectum. Muscle wasting may be apparent on the extremities, and deep tendon reflexes may have a prolonged

© F.A. Davis Publishing

relaxation phase. Patients may have diminished position and vibratory sense. Check women for ovarian masses, cervical lesions, and any obvious neoplasia. In men, examine the prostate gland for enlargement.

Diagnostic Tests: History and physical examination findings guide the choice of diagnostic tests. It has been shown that 70% of the diagnosis can be made with history alone and the physical examination increases this rate to 90%. Emphasis is placed on evidence-based practice and testing that supports findings from the history and physical examination.

Additional diagnostic tests serve to confirm the assumptions. A nutritional or diet history and calorie counts add objective data to evaluate the amount and quality of food intake. After the results of the diagnostic work-up are available, consider a neoplastic origin when benign causes of weight loss appear unlikely. Malignant and nonmalignant GI disorders are the most prevalent cause of involuntary weight loss. Evidence of microcytic anemia on the complete blood count (CBC) or a positive fecal occult blood result is a reason to refer for colonoscopy. With frail older adults it is important to address the question of treatment options with the patient and family before further invasive and expensive work-up is initiated. If the cause of weight loss is not clear from the diagnostic evaluation, watchful waiting is recommended; watch for further weight loss or specific symptoms and reconsider a functional cause of weight loss. If no abnormalities are detected from the history, physical examination, and diagnostic tests, an organic cause is unlikely (less than 5%). When the findings from the initial work-up are negative, psychological problems, particularly depression and anxiety, are among the most common reasons for weight loss.

Differential Diagnosis: For weight loss that occurs with increased food intake, consider diabetes, thyrotoxicosis, malabsorption, leukemia, lymphoma, and adrenal insufficiency. For weight loss that occurs with normal or decreased food intake, consider alcoholism; malignancy; infection; GI, hepatic, renal, dental, endocrine, respiratory, cardiac, or psychological causes; anorexia nervosa; malnutrition; or a functional origin. After investigation, the cause of weight loss remains unknown in 16% to 28% of patients. Table 7-8 lists causes of weight loss in the older adult.

Treatment: Treat or manage the identified underlying cause. This will likely involve the inclusion of other disciplines. Regardless of the cause, a referral to a nutritionist should be a priority. Medicare offers specific nutritional benefits to patients with diabetes or chronic kidney disease. Dentistry to assess oral health, speech to evaluate swallowing, occupational therapy (OT) or physical therapy (PT), and social work are all key to addressing the problem of IWL. Nonpharmacological options should be initiated first. Diet modifications should minimize dietary restrictions, address patient preferences, and accommodate problems of dentition or swallowing. Smaller, more frequent meals can be useful if the patient reports early satiety. Patients with dementia tend to consume most of their daily energy at breakfast, so high-energy foods should be served at this meal, and varying dietary texture can be helpful. Eating with assistance and in the company of others increases calorie intake. For older adults in the community, home delivered meal programs are beneficial. Oral nutritional supplements, such as high-energy and high-protein drinks, if initiated, should be consumed between meals. Evidence supports that their short-term use improves weight and diagnostic parameters, but data in support of their long-term use is lacking. Regular exercise, especially resistance training, stimulates appetite and can prevent increasing sarcopenia. Use of a multivitamin supplement should not be a first-line intervention; nutrient-dense foods and improving intake are preferable. Oral supplements are rich in micronutrients and when added to the treatment plan are superior to a multivitamin. Multivitamins are preferred over individual vitamin supplements.

It is common in clinical practice for clinicians to order mirtazapine and other pharmacological agents to stimulate appetite; however, evidence underlying their use is limited, particularly in older adults, and none has gained approval from the U.S. Food and Drug Administration (FDA). Megestrol acetate has evidence for use in cancer or HIV, but studies in older adults have had equivocal results. The risk of deep vein thrombosis (DVT) and pulmonary embolus is alarming and increasing in patients who are sedentary. Dronabinol is a synthetic form of tetrahydrocannabinol (THC), a naturally occurring component of cannabis sativa (marijuana), which is FDA approved for chemotherapy-induced nausea and vomiting, and anorexia from AIDS or cancer. Only one study has been conducted in older adults, patients with dementia who were refusing food. The central nervous system (CNS) side effects are a major risk in a population who has a more vulnerable CNS.

TABLE 7-8 Meals-on-Wheels Mnemonic for Causes of Weight Loss in the Older Adult

MNEMONIC	CAUSES OF WEIGHT LOSS
M	Medications
E	Emotional problems (depression, anxiety)
A	Alcoholism, anorexia tardive, abuse
L	Late life paranoia
S	Swallowing disorders (dysphagia)
O	Oral problems
N	Nosocomial infections
	No money (poverty)
W	Wandering and other dementia-related behaviors
H	Hyperthyroidism, hypercalcemia, hypoadrenalism
E	Enteric problems (malabsorption)
E	Eating problems (inability to feed oneself)
L	Low-salt, low-cholesterol diet
S	Social problems
	Shopping and meal preparation
	Stones (cholecystitis)

© F.A. Davis Publishing

Follow-Up: If results of the standard tests listed earlier are negative, and the history and physical examination are negative, the recommended approach is to watch for further weight loss and to reconsider functional causes. Have the patient or caregiver keep a daily record of food intake, activity levels, and symptoms, and schedule a return visit in 2 to 4 weeks. Supplements may be added with the emphasis that they should be used between meals.

Sequelae: Malnutrition (Sanchez-Rodriguez et al., 2017) is the first complication to consider in IWL. Long-term unexplained weight loss may indicate failure to thrive and the beginning of a downward spiral in health and function. Many patients in acute and long-term care have unrecognized protein-calorie malnutrition. Protein-calorie malnutrition is a common iatrogenic complication of hospitalization.

Prevention/Prophylaxis: Discuss proper nutrition and the need for dental care, if appropriate. Address functional, financial, and social issues that may affect nutrition (e.g., address depression; arrange for socialization at mealtime, if feasible; arrange home delivered meals).

Referral: IWL often has multiple factors and may require the assessment of multiple specialties to derive a diagnosis and plan for treatment. Include the patient and their family in discussions about goals of care. Referral for palliative care may be appropriate. Adult failure to thrive can no longer be used as the primary diagnosis for hospice admission; however, consultation with hospice teams can help in determining the primary diagnosis. Always consult a specialist for rapid or acute decline; for positive diagnostic test results indicating malignancy, thyrotoxicosis, or other acute organic illnesses requiring sophisticated diagnostic work-up or management; or for a patient condition beyond your current scope of practice. Refer patients for assistance if social or functional issues may be contributing to weight loss. Refer to an appropriate specialist as noted previously.

Education: Instruct patients about proper nutrition and hydration. Encourage exercise to improve strength or function and to stimulate appetite. Teach patients about medication side effects that may affect nutrition and about signs or symptoms of overmedication or undermedication.

Clinical Recommendation	Evidence Rating	References
There is a relationship between depressive symptoms and weight loss. Patients with weight loss should be screened for depression.	A	Ji et al., 2020
Oral nutritional supplementation is associated with weight gain and reduced mortality, and should be given between meals.	A	Morley, 2018
Loss of weight in obese older adults is associated with greater morbidity than in non-obese older adults	A	De Stefani et al., 2018
If clinically documented weight loss is not available, a change in clothing size, confirmation of history by a family member, or ability of the patient to report exact weight change can be substituted.	B	Martson et al., 1981 (classic study)
Optimize caloric intake, minimize dietary restrictions, eat in the company of others.	B	Gaddey & Holder, 2021 Morley, 2018
No medications have been shown to reduce mortality. Few studies have been done to determine effectiveness in older adults with involuntary weight loss, and all have considerable side effects.	B	Gaddey & Holder, 2021

JOINT PAIN

Description: Joint pain can be inflammation, irritation, pain, or discomfort from any joint and/or the surrounding structures including bone, muscle, cartilage, bursa, tendons, or ligaments. Joint pain is commonly referred to as arthralgia or arthritis, which is more specifically pain or inflammation within the joint.

Etiology: Joint pain can be the result of many different causes including injury, infection, inflammation, degenerative, autoimmune, cancer, or genetic. It can be an acute, chronic, or a recurring problem. The description, location, onset, and associated symptoms are important to diagnosing the cause of joint pain. Clarifying the etiology of the pain depends on the clinical presentation, history of illness, findings from physical examination, and appropriate diagnostic testing. Joint pain can be mild (e.g., sprain or strain), chronic (lasting more than 3 months), inflammatory (e.g., joint effusion, inflammatory arthritis), or severe and/or acute (e.g., trauma or infection). Acute joint pain may become a chronic pain if exacerbating factors are not relieved such as overuse, inflammation, or physical activity contributing to joint deterioration. For example, knee pain from osteoarthritis (OA) may initially occur intermittently with weight-bearing and evolve into chronic pain. Systemic causes of joint pain include autoimmune diseases such as type 1 diabetes, rheumatoid arthritis (RA), psoriatic arthritis, and inflammatory bowel disease

© F.A. Davis Publishing

as well as infectious causes such as hepatitis and Lyme disease. Drug-induced arthralgia can occur with some medications, such as antibiotics, statins, and breast cancer and osteoporosis treatments (Havelin & King, 2018; Treede et al., 2019; Villa-Forte, 2021).

Occurrence: Pain is one of the leading reasons patients seek medical attention, particularly for low back pain as well as other musculoskeletal pain (Treede et al., 2019). It is estimated that 54 to 92 million U.S. adults have either provider-diagnosed arthritis or report symptoms consistent with arthritis (Arthritis Foundation, 2019; Guglielmo et al., 2019). In the United States, arthritis reportedly limits the activities of approximately 24 million adults and more than 25% of individuals with arthritis consider the pain to be severe (Guglielmo et al., 2019). Chronic low back pain is the greatest contributor for years lived with disability (Treede et al., 2019).

Age: In older adults, the most common cause of acute nontraumatic monoarticular joint pain is osteoarthritis (Villa-Forte, 2021). Approximately 33% of men and women 18 to 64 years old, report having symptoms of joint pain consistent with an arthritis diagnosis and/or have provider-diagnosed arthritis (Arthritis Foundation, 2019). Prevalence of age-specific arthritis increases with each decade of life, ranging from 8.1% for those 18 to 44 years old to 50.4% of those 65 years and older (Guglielmo et al., 2019). RA typically affects adults between 30 and 40 years of age, but in approximately 33% of cases the patient is older than 60 years. Polymyalgia rheumatica (PMR) should be considered in any adult 50 years and older who is experiencing hip and/or shoulder girdle pain and stiffness often with acute onset and particularly notable in the morning (Villa-Forte, 2021). Rates of age-standardized arthritis among women are significantly higher at 25.4% compared to men at 19.1% (Guglielmo et al., 2019). For people older than the age of 65, more than 50% of men and 66% of women may have arthritis (Arthritis Foundation, 2019). Older women with distal interphalangeal (DIP) joint pain should be screened for gout as well as nodular OA (Villa-Forte, 2021).

Ethnicity: Prevalence of joint pain and arthritis varies based on specific etiology. Generally, the prevalence of joint pain and arthritis among Hispanics and non-Hispanic Asians is lower than other racial/ethnic groups. Conversely, the incidence of age-standardized arthritis, at 29.7%, was significantly higher among non-Hispanic American Indian/Alaskan Natives compared to other racial/ethnic groups. Incidence of arthritis is inversely related to the federal poverty level and education. Additionally, rates of arthritis are higher amongst those living in rural areas versus in urban settings (Guglielmo et al., 2019).

Contributing Factors: Factors that may lead to joint pain include overuse or strain, past injury or trauma to the joint, alterations in gait or balance, known history of joint disease, or past surgery. In a younger individual or an athlete, injury, obesity, or occupational activities are the main factors that contribute toward developing osteoarthritis (Arthritis Foundation, 2019). Injury, obesity, and occupation as well as infection and smoking are modifiable risk factors. Genetics, age, and sex are non-modifiable risk factors for joint pain and arthritis (Centers for Disease Control and Prevention [CDC], 2020).

Signs and Symptoms: Assessment of joint pain requires the history of present illness (HPI), review of systems, past medical, social, and family history; and a thorough physical examination. It is important that the HPI include a pain assessment tool such as the PQRSTU assessment that addresses the following measures regarding pain: provocative/palliative, quality/quantity, region/radiation, severity, timing/treatment, and understanding (Gregory, 2019). Questions on timing should elicit if there is prolonged morning stiffness, which would possibly indicate an inflammatory nature or if pain is worse later in the day or with increased activity, which may indicate a degenerative cause. Evaluation of joint pain should include the "red flags" of joint warmth and/or erythema, open skin areas, fatigue, weight loss, fever or other systemic or extra-articular symptoms and any use of anticoagulants or underlying bleeding disorder (Villa-Forte, 2021).

Both the HPI and examination should assess for any swelling, deformity, decreased range of motion (ROM), crepitus or popping/ clicking of the joint and whether there is one or multiple joints involved. The physical examination should include inspection and palpation of each joint, assessing range of motion, noting any pain, limitations in movement or contractures. Additional diagnostic maneuvers, if indicated, should be performed such as the drawer test for ligament injury of the knee, the McMurray test for meniscal tear, or the Thomas test for hip flexion contracture. The patient's posture, gait, and balance should be assessed for any guarding, compensatory mechanisms, or deficits.

Diagnostic Tests: X-rays are useful to detect arthritic changes such as joint space narrowing or destruction, erosions, or degenerative changes as well as to diagnose pseudogout or fracture or to rule them out. For swelling and painful soft tissues surrounding the joint, ultrasound can be beneficial. In the setting of new acute monoarticular joint pain with a joint effusion, arthrocentesis is necessary to distinguish between a noninflammatory and an inflammatory process to rule out infection and to help diagnose a crystalline arthropathy. The specimen should be sent for synovial fluid analysis that includes cell count, crystal analysis, and culture (He et al., 2020). Joint aspiration likely will also offer symptomatic relief. If examination, x-rays, and arthrocentesis fail to adequately diagnose joint pain, then a magnetic resonance imaging (MRI) scan may be needed to rule out uncommon etiologies such as osteonecrosis, occult fracture, metastasis or other musculoskeletal anomalies (Villa-Forte, 2021).

Laboratory testing can help diagnose infection, inflammation, and metabolic problems. A complete metabolic panel (CMP) and complete blood count (CBC) will detect abnormal calcium, alkaline phosphatase, glucose levels as well as an elevated white blood cell (WBC) count. Hypercalcemia and elevated alkaline phosphatase levels can be seen with malignancy and Paget disease. Undiagnosed or poorly controlled diabetes causes more musculoskeletal injuries, joint pain, and fibroproliferative disorders than for those without diabetes (Sözen et al., 2018). Serum creatine kinase (CK) isoenzymes can be elevated with musculoskeletal trauma and myositis. If the joint pain is polyarticular, it may be reasonable to check inflammatory markers such as C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR). More specific laboratory tests would depend on suspected etiology. Checking uric acid during a gout flare is not useful because it is likely that urate will be sequestered in the affected joint and the laboratory level may result artificially low (Villa-Forte, 2021).

© F.A. Davis Publishing

Differential Diagnosis: The diagnosis of joint pain can best be narrowed by considering if it is monoarticular (injury, infection/cellulitis/septic arthritis) or polyarthricular (RA, PMR), if it appears to be infectious (hepatitis, Lyme disease), inflammatory (gout, pseudogout, psoriatic arthritis), or mechanical (OA, spinal stenosis) in nature; if the pain is from the actual joint or from surrounding soft tissue structures (bursitis, tendonitis, ligament injury). The differential diagnoses can further be narrowed by considering whether joint distribution is symmetric (RA, PMR), and if any extra-articular symptoms (sarcoidosis, spondyloarthropathy, connective tissue diseases) are present. Acute polyarticular joint pain is most often due to a systemic inflammatory disease flare, an infectious cause or in some cases severe gout; however, malignancy should be ruled out. If persistent weakness is present the differential should include degenerative and radicular causes; in inflammatory diseases joint weakness tends to improve through the day. Fibromyalgia should be considered for clinical presentation of pain that is more generalized and muscle related (myalgia) than specifically joint pain (Villa-Forte, 2021).

Treatment: Treatment of joint pain is directed toward the underlying cause, first ruling out acute injury/fracture or infection and if suspected treating accordingly. In the process of working up joint pain, it is reasonable and necessary to address pain however glucocorticoids should not be initiated until inflammatory markers are tested if pertinent to the differential. Management of joint pain is multifactorial, utilizing oral, topical, and intra-articular medications as well as physical, surgical, behavioral, educational, and psychosocial interventions (Kolasinski et al., 2020).

Both acute and chronic joint pain can benefit from nonpharmacological treatment modalities such as intermittent cold or heat therapies and short-term wrapping/splinting. It is important, however, to avoid prolonged splinting, which can result in contractures such as of the elbow or adhesive capsulitis (frozen shoulder). PT/OT can assist patients with splints, braces, assistive devices and help to maintain joint function, flexibility, and reduce risk of falls in older adults. Exercise and PT are first-line treatments for chronic and persistent joint pain. Other than gout and pseudogout, most inflammatory joint pain is worse with extended rest as opposed to injury and mechanical joint pain, which improve with rest (Kolasinski et al., 2020; Rice et al., 2019).

Acetaminophen can be useful to alleviate noninflammatory joint pain, particularly at higher therapeutic doses (3 g/day); however, it is important to avoid alcohol and other medications that contain acetaminophen due to possible liver toxicity. Oral NSAIDs can be particularly effective at reducing pain and inflammation; however, caution is advised due to risk of renal and cardiovascular side effects and gastrointestinal toxicity/bleeding. NSAIDs are best prescribed at the lowest effective dose, used symptomatically instead of scheduled, and with routine monitoring. As a selective NSAID, cyclooxygenase type 2 (COX-2) inhibitors offer the anti-inflammatory benefits with a better gastrointestinal (GI) risk profile; however, they carry a higher cardiovascular risk and still require routine labs. Duloxetine, tramadol, and opioids are only conditionally recommended by the American College of Rheumatology although duloxetine can help with different types of pain (Kolasinski, 2020). As with any opioid, patients should be closely monitored due to the increased risk of falls and the lowest dose and shortest duration should be prescribed to avoid complications. Topical NSAIDs are not quite as effective, but they offer a better safety profile. Over-the-counter (OTC) topical preparations include lidocaine 4% and capsaicin, both of which offer variable patient responses (Villa-Forte, 2021).

Any joint with suspected infection should never be injected, only arthrocentesis should be performed; and a joint with surgical hardware should not be punctured with a needle (Sen & Hurley, 2021). Intra-articular (IA) joint injections can offer localized relief without extensive systemic effects. Corticosteroid injections work well in the setting of acute OA pain, and they are relatively low cost and low risk. As with any injection, the risk of infection is possible and intra-articular glucocorticoids can briefly elevate blood glucose (Kloppenburg & Berenbaum, 2020). Systemic inflammatory joint pain will likely require immunosuppression (Villa-Forte, 2021).

Follow-Up: Monitoring of patients depends on etiology and the course of the disease/condition. If joint pain persists for longer than a couple weeks, the patient should be seen for further work-up and referrals as appropriate. Management of chronic joint pain requires routine visits to monitor the effectiveness of treatments and for follow-up laboratory testing if necessary. Providers should also monitor patients for depression, poor sleep, and impaired coping skills as joint pain and possible subsequent disability contribute to these (Deveza et al., 2019).

Sequelae: The prognosis of joint pain is affected by the etiology. Falls are always a concern for older adults and any damage from injury or disease can potentially affect movement as well as cause pain.

Prevention/Prophylaxis: The best prevention of joint pain is to reduce or eliminate modifiable risks, including injury, infection, obesity, smoking, and occupation hazards (CDC, 2020). Weight loss is recommended when appropriate. It is also important to participate in a moderate level of exercise throughout one's life; doing so helps to maintain physical fitness and muscle strength, which helps to ensure proper joint function and flexibility. Tai chi is strongly recommended for older adults because it helps to maintain function and flexibility while also reducing risk of falls (Kolasinski et al., 2020; Rice et al., 2019).

Referral: For acute joint pain related to injury or infection, refer the patient for needed treatment. For joint pain that requires further work-up, specialized treatment, or is resistant to treatment modalities already tried, a referral to a specialist such as rheumatology or orthopedics may be necessary. Many patients with joint pain benefit from referral to PT/OT.

Education: It is important to educate patients on proper follow-up and to have them report any new or persistent problems related to joint pain or any systemic/extra-articular symptoms. Patients also require understanding of medications prescribed, avoidance of duplicate therapy, the necessary monitoring, and possible adverse effects. Patients will have the best outcome by incorporating nonpharmacological modalities, so the importance of these need to be emphasized. Patient participation in the plan of care will offer the best chance of recovery or minimizing the impact of joint pain including slowing progression, avoiding disability, and preventing falls. This includes the use of assistive devices, which some older adults are hesitant to use.

MUSCLE CRAMPS

Description: Muscle cramps are unintentional, and often painful, sudden contractions of a muscle or muscle group. They can range from intermittent and mild to frequent and severe, at times debilitating. There is often gradual resolution after seconds to minutes and most often muscle cramps present in calf and foot muscles. Muscle cramps can reduce quality of life.

Etiology: Muscle cramps present when the body's motor system is stressed by either a physiological stress, such as dehydration, electrolyte imbalance, or extreme exercise, or by a neuromuscular disease (Katzberg, 2020). They are caused by abnormal discharges from nerves or nerve terminals (Katzberg, 2020).

Occurrence: It is a common outpatient complaint with as many as 50% of older adults reporting frequent cramps, more than three times per week, and sleep disturbance from cramps (Katzberg, 2015, Lorenzo et al., 2018). Muscle cramps are 1.5 times more likely to present in women (Lorenzo et al., 2018), and they are at higher risk for muscle cramps related to statin therapy (Thompson et al., 2016).

Age: Muscle cramps can occur at any age, although in the younger population it is more often related to vigorous exercise and in the older population reported more at bedtime or related to an underlying disease process (Swash et al., 2019).

Ethnicity: No direct ties to ethnicity have been documented at this time.

Contributing Factors: A variety of neuropathic conditions are associated with muscles cramps, such as amyotrophic lateral sclerosis (ALS), peripheral neuropathies, and cramp-fasciculation syndrome. Medical conditions can also be associated with muscle cramps and can include hypothyroidism, hypocalcemia, hypomagnesemia, hypokalemia, deep vein thrombosis (DVT), restless leg syndrome (RLS), and renal and liver disorders. Some medications can cause muscle cramps, including statins, furosemide, hydrochlorothiazide, donepezil, nifedipine, and raloxifene. If no underlying cause is found for recurrent muscle cramps, then they are referred to as idiopathic muscle cramps.

Signs and Symptoms: A comprehensive disease history is key to identifying underlying differentials because multiple chronic diseases and medications can cause muscle cramps. A detailed assessment of risk factors, history, current illnesses, and medications must be obtained. Use of a systematic approach facilitates in identifying the underlying causes and disease processes present. Risk factors for muscle cramps include military exposures, liver or kidney disease, vigorous exercise, electrolyte imbalances, smoking, diabetes, use of statins, venous insufficiency, cancer treatments, pregnancy. A thorough review of systems should take place. Muscle cramps can be unilateral or bilateral, localized or generalized, painful or nonpainful, intermittent or consistent, present with other symptoms such as fatigue and red flag symptoms such as swelling, pain with movement, muscle wasting, or weakness. The description of cramp symptoms helps to differentiate from other underlying conditions. Claudication may be described as aching with occasional cramping, noted more during exercise and activity, then relieved with rest. Those with RLS may describe an irresistible urge to move their legs with a cramp-like feeling noted more at night. Intolerance to statin therapy may present as deep aching cramps and can present in any muscle group. In peripheral neuropathy a

© F.A. Davis Publishing

person may complain of numbness and tingling and possible secondary cramps (Allen & Kirby, 2012). Patients with ALS may present with muscles cramps and weakness to extremities, along with loss of muscle mass. A person with exercise-induced cramps or electrolyte imbalances may complain of discomfort after the activity, which then improves with rest and hydration. A patient with DVT can present with unilateral cramping to an extremity, often with pain along a major vessel and possible edema and erythema to area.

Most often cramps will not be present at time of visit, so it is important to assess all physical areas that may be included in differentials (Allen & Kirby, 2012). The physical examination can start when patient enters exam room, by assessing their posture and gait, looking for any muscle imbalances. Vital signs should be obtained, including temperature, heart rate, respirations, and oxygen saturation. If capability is present in office setting, then a blood pressure should be obtained on all extremities, if a weak pulse or low ankle: brachial pressure ratio is present then ischemia needs to be considered. Next is a complete examination, starting with the head and neck, assessing for decreased hair pattern or loss of eyebrow hair and palpating thyroid assessing for enlargement. Assess for changes in skin turgor or moisture of skin, examining for increased dryness of skin which can appear with hypothyroidism. Cardiovascular examination should include palpation of all extremity pulses. Examination of the gastrointestinal (GI) system may include assessing for liver enlargement or jaundice, which may present in cirrhosis. Thorough neurological and musculoskeletal physical examinations must be obtained in patients presenting with muscle cramps, this should include assessing reflexes, strength testing, and sensation to extremities. Two clinical signs may present in those with low calcium, Chvostek and Trousseau, and these should be assessed. The Trousseau sign is more specific because in healthy individuals it is only positive about 1% of the time (Pepe et al., 2020). The provider should be on alert for red flag findings such as muscle weakness, loss of sensation, hyperreflexia, tenderness along area of major veins, or significant incongruency in calf diameter. Homan sign is not considered a reliable test to assess for DVT. Lower extremities should be assessed for skin discoloration, decreased hair pattern, or edema, which may indicate venous insufficiency.

Diagnostic Tests: The testing obtained for muscle cramps depends on the suspected underlying causes, associated differentials, and pertinent findings on physical examination.

When electrolyte imbalance is a concern, pertinent laboratory studies may include a comprehensive metabolic panel (CMP) to look at potassium, sodium, and calcium, plus checking magnesium level. Low levels of these electrolytes can lead to subsequent muscle cramps presenting. An imbalance may be a differential when a patient is undergoing dialysis, vigorously exercises, was out in extreme heat, has poor nutritional status, had recent fluid loss via diarrhea or vomiting, or is taking certain medications, like a diuretic or a proton pump inhibitor (PPI). Severe hypocalcemia, hyponatremia, or hypokalemia frequently require admission to the emergency department (ED) setting and would benefit from an electrocardiogram (ECG) to ensure no life-threatening arrythmias are present (Pepe et al., 2020). A CMP can also assess functional status of the liver, as underlying liver disease can cause muscle cramps.

If concern for peripheral neuropathy is present, then obtaining glycosylated hemoglobin (A1c), HIV antibody, B_{12} level with a methylmalonic acid, and a complete blood count (CBC) may assist in determining whether this is an underlying cause of muscle cramps (Allen & Kirby, 2012). In patients with symptoms concerning for hypothyroid, a thyroid-stimulating hormone (TSH) test would offer value. A d-dimer assay can be obtained on those in whom there is concern for DVT, although this test varies in sensitivity it is a recommended test, with the enzyme-linked immunosorbent assay (ELISA) offering 94% sensitivity (Linkins & Takach Lapner, 2017).

Imaging studies can offer benefit. Venous doppler ultrasounds are obtained to assess circulation in patients in whom there is concern for DVT or venous or arterial insufficiency. In patients who present with muscle weakness, wasting, and cramps, where there is concern for ALS, there remains to be no specific diagnostic test for this disease, and it continues to be primarily a clinical diagnosis (Oskarsson et al., 2018). For ALS the clinical standard for diagnosis remains the revised El Escorial World Federation of Neurology criteria (de Carvalho et al., 2008). Electromyography (EMG) testing is used to assess for abnormalities within the muscle, by recording electrical activity of muscle tissue. It is a cornerstone in assessment of underlying neuromuscular disease (Whittaker, 2012). This testing can be utilized to determine the presence of underlying disease, such as ALS or polyneuropathy, by showing abnormal nerve activity and reduced recruitment of motor units (Chung et al., 2014). Neuroimaging, such as magnetic resonance imaging (MRI), can be obtained to assist in ruling out other possible causes for muscle cramps, such as cervical or lumbar spine degeneration. Specialists may obtain other testing to further determine diagnosis for muscle cramps, these include single-fiber electromyography (EMG) and transcranial magnetic stimulation, both which look at nerve and muscle response with stimulation. The diagnosis of underlying cause for muscle cramps can be a lengthy process and may require a multidisciplinary approach.

Differential Diagnosis: When assessing a patient who complains of muscle cramps it is important to immediately assess those who have red flag symptoms, such as swelling, pain with movement, muscle wasting, chest pain, or weakness. In older adults, an alteration in mental status may also present with an acute illness or electrolyte imbalance; this should immediately be examined.

Some of the most prevalent electrolyte imbalances seen are hypocalcemia, hypokalemia, hyponatremia, and hypomagnesemia (Table 7-9). Diagnosis of electrolyte imbalance is determined by obtaining blood work and assessing levels.

TABLE 7-9 Electrolyte Balances Related to Muscle Cramps

Calcium	*Hypocalcemia:* Below 8/5 mg/dL
Potassium	*Hypokalemia:* Less than 3.5 mmol/L
	Moderate hypokalemia: 2.5 to 3.0 mmol/L
	Severe hypokalemia: <2.5 mmol/L
Sodium	*Hyponatremia:* serum sodium <135 mEq/L
Magnesium	*Hypomagnesemia:* Below 1.6 mg/dL

© F.A. Davis Publishing

Each electrolyte imbalance has a variance in presentation from asymptomatic to life-threatening, this presentation will guide the practitioner's treatment as more serious symptoms may need further evaluation in an emergency room setting. Other causes include amyotrophic lateral sclerosis, chronic venous insufficiency, peripheral neuropathy, restless leg syndrome, and some medications (primarily statins).

Treatment: Treatment of electrolyte imbalances is dependent on the severity and type of imbalance that is present. Treatments for other disorders listed as differential diagnoses are discussed in their respective chapters.

Follow-Up: Follow-up depends on the severity of the muscle cramps and the impact on the patient's quality of life. For electrolyte imbalance, it is important to follow-up within a week to recheck levels or after discharge from hospital. If you have been treating imbalance on an outpatient basis and the patient becomes symptomatic, it is important for them to be seen sooner. With underlying chronic disease such as ALS, RLS, and neuropathy, comanaging with a specialist is important. If medication changes are made to help improve muscle cramps, a 4-week follow-up after changes is reasonable.

Sequelae: ALS has an ominous prognosis and requires a multidisciplinary approach, including hospice involvement as disease progresses. Neuropathy, venous insufficiency, and RLS may take several months to find a beneficial treatment regimen. Good outcomes can be expected when muscle cramps are the result of a medication side effect or an electrolyte imbalance and those problems are corrected.

Prevention/Prophylaxis: Preventive measures include frequent medication reviews to screen for medications that can cause muscle cramps and laboratory testing to check for imbalances. Neuropathy and venous insufficiency can be caused by diabetes. Good diabetic control can help prevent these from developing or worsening. Smoking cessation can aid those with venous insufficiency to help prevent disease or slow down progression.

Referral: A referral to a specialist can be initiated anytime during the evaluation and treatment of muscle cramps. Referral to a nutritionist can facilitate an assessment of dietary deficiencies and recommend improvements. If concern is present for the diagnosis of ALS, then immediate referral to neurology should take place as a multidisciplinary approach is important early on. For those with neuropathy a referral to podiatry for annual foot exams can help with wound prevention and regular foot care. A referral to vascular medicine can be of help to those with venous insufficiency to aide in further assessment and obtaining proper compression stockings. Consultation with a dietitian may aid those with chronic electrolyte imbalances, to assist in understanding dietary supplement needs. Pain management may be needed in patients who fail conservative or initial treatment for pain relief.

Education: Recommend smoking cessation support and discuss options to aide in quitting. If there is risk for electrolytes imbalances, then teach about dietary supplementation. It is important to educate patients on all prescribed medications and side effects, such as muscle cramps and statins, ensuring they present to office if these effects present.

Diagnosis	Clinical Recommendation	Evidence Rating	References
Electrolyte imbalances	Correct the imbalance either via outpatient oral supplements or, if imbalance is severe or the patient is symptomatic, hospitalization with IV replacement. Discontinue medications that may be causing imbalances.	B	Ahmed & Mohammed, 2019 Hoorn & Zietse, 2017 Pepe et al., 2020 Van Laecke, 2019
Amyotrophic lateral sclerosis	Symptom management is key, including use of muscle relaxers for cramps	A	Oskarsson et al., 2018
Chronic venous insufficiency	Risk reduction is initial treatment, including weight loss, smoking cessation, and good diabetes control. Compression hose and Tylenol for discomfort and prevention of worsening are recommended. If poor response with initial treatment, then referral to vascular for more invasive therapy may be needed.	A	Youn & Lee, 2019
Peripheral neuropathy	Prevention is key initial treatment, including good diabetes control. If B_{12} deficiency, replace B_{12} via supplement. If initial treatments do not work then use of gabapentin, pregabalin, duloxetine, amitriptyline, and venlafaxine offer benefit, but for some of these attention must be given to renal function and age of patient. Poor response to initial treatments may require a referral to pain management and discussion of opioid treatment.	A	Katzberg, 2020

PERIPHERAL EDEMA

Description: Peripheral edema is swelling due to an increase in the interstitial fluid volume and may not be evident until the interstitial volume has increased by 2.5 to 3 L. This is generally associated with an increase in weight of up to 10% (Goyal et al., 2021). Lymphedema, or lymphatic obstruction, occurs when a compromised lymphatic system causes localized fluid retention and tissue swelling. There are numerous etiologies for peripheral edema ranging from benign to life-threatening clinical conditions.

Etiology: Normally, the distribution of water between the blood and interstitial tissues is maintained by hydrostatic and oncotic pressures in each compartment. Starling's principle—the osmotic pressure of the plasma proteins balances the hydrostatic pressure in the capillaries—helps in the understanding of fluid dynamics (Michel et al., 2020). Fluid flows from the vessels to the interstitial area in response to intravascular hydrostatic pressure and the colloid osmotic pressure of the interstitial fluid. In the opposite direction, fluid enters the blood because of the interstitial tissue tension and the oncotic pressure of the plasma proteins. Interstitial fluid also is returned to the blood as lymph. Under steady-state conditions, net fluid flux out of the capillary is balanced by lymph flow back into circulation. Alteration in any of these compartments (intravascular, extravascular, lymphatic) upsets the equilibrium, and edema occurs. Two basic steps occur in edema formation: sodium and water are retained, and capillary hemodynamics are altered.

Peripheral edema may be due to increased capillary hydrostatic pressure, decreased plasma oncotic pressure, increased capillary permeability or lymphatic obstruction. An increase in capillary hydrostatic pressure may be the result of an increase in localized venous pressure (e.g., deep vein thrombosis [DVT]), a systemic increase in venous pressure (e.g., heart failure [HF], liver failure), or an increase in plasma volume (e.g., pregnancy, renal failure, or certain medications). A decrease in plasma oncotic pressure may be the result of protein loss (e.g., pre-eclampsia nephrotic syndrome), decrease in protein synthesis (malabsorption, malnutrition, or liver disease). Capillary permeability increases in burns, cellulitis, or allergic reactions. Lymphatic obstruction may be the result of malignancy or postoperative effects on lymphatic drainage (Goyal et al., 2021). The swelling that results from lymphedema is nonpitting. It may be primary due to congenital or inherited conditions, or secondary caused by damage to the lymphatic system; cancers (especially breast, ovarian, and prostate); infection; inflammation; or obesity.

Occurrence: The frequency of occurrence depends on the underlying etiology. Lymphedema and venous insufficiency are more common in women.

Age: Edema can occur in any age, but is more common in older adults, has diverse etiologies, and more than one disorder can be causing edema in the same patient. In patients older than age 50, venous insufficiency is the most common cause of peripheral edema (Goyal et al., 2021)

Ethnicity: While moderate edema does not have a notable ethnic difference, severe venous insufficiency is most common in Whites (Pappas et al., 2020).

Contributing Factors: Physiological age-related changes increase the vulnerability to fluid retention. The older adult has a smaller amount of total body water overall (75% to 85% of body weight for an infant, 60% to 65% for an adult male, 50% to 55% for an adult female, less than 40% for an older adult) (Khatun et al., 2020), and of this, two-thirds of the fluid is intracellular and one-third is extracellular. As more intracellular fluid is lost over time, extracellular fluid volume starts to comprise more body water. Risk factors for peripheral edema from age-related changes include a decrease in:

- Serum albumin—less than 2 g/dL can cause edema
- Glomerular filtration rate
- Hepatic blood flow

© F.A. Davis Publishing

- Sodium-concentrating ability of the kidney
- Myocardial contractility and cardiac output
- Baroreceptor sensitivity
- Medications that are used to treat conditions common in older adults can cause peripheral edema:
- NSAIDs cause increased sodium absorption in the kidney due to the blockage of prostaglandin (Trayes et al., 2013).
- Thiazolidinediones are used as treatment for diabetes (pioglitazone or rosiglitazone) and stimulate sodium reabsorption in the kidney; worsening HF is a known side effect (Lebovitz, 2019).
- Antihypertensives with mechanisms that cause vasodilation or activation of the renin-angiotensin-aldosterone sympathetic nervous system may increase peripheral edema (e.g., hydralazine, dihydropyridine calcium channel blockers, and alpha blockers) (Vouri et al., 2019).

Additional contributing factors include dependent positioning of the lower extremities, excessive intake of sodium, and hot weather. Patients who normally live at high altitude may develop lower extremity edema when they transition to lower altitudes. This differs from those who move from sea level to higher altitudes who may develop pulmonary or cerebral edema (Zubieta-Calleja & Zubieta-DeUrioste, 2017).

Signs and Symptoms: The patient may complain of swelling, fullness, discomfort, aching pain, shoes that are too tight, wounds, gait disturbance, self-image issues, or weight gain. The history should elicit the seven dimensions of the signs and symptoms of edema, emphasizing location (unilateral or bilateral) and chronological evolution (acute or chronic progression). Associated symptoms need to be elicited, particularly shortness of breath or awakening at night with difficulty breathing. The presence or absence of pain is helpful in determining the differential diagnosis. Ask about aggravating and alleviating factors, including positional changes, the effect of prolonged sitting or standing, and determine the effect of passive leg elevation. A history of malignancy, pulmonary, cardiac, renal, hepatic, endocrine disorders, or peripheral vascular disease is important. Ask about recent weight loss or gain, changes in diet, salt intake, and alcohol use. A thorough review of medications (both prescribed and over-the-counter [OTC]), particularly new medications or a recent change in dosage is essential. Has the patient been on a trip recently or had periods of prolonged standing or sitting?

The physical examination begins with general appearance, assessing for any distress or apparent discomfort. evaluate the patient's weight for change. Assess skin changes, including pigmentation and thickening, lesions, discoloration, texture, temperature, and induration. Evaluate the venous and arterial circulation, checking pulses throughout; capillary refill; and dependent rubor. Varicose veins are usually readily apparent with the inspection of the legs while the patient stands. Assess the extremity for local or diffuse tenderness and for pitting or nonpitting edema. Measure and compare the circumference bilaterally from a fixed reference point above the ankle to the area of maximal edema (e.g., patella, calf, midcalf). Assess any localized enlargement.

Pitting edema has no universal scale for measurement. When assessing for edema of the lower extremity, the provider applies pressure anterior to the tibia to check for pitting. If pitting is present, this is a positive Godet sign. (Zubieta-Calleja & Zubieta-DeUrioste, 2017). It is generally defined on a scale of 1+ to 4+ or brawny edema (which is chronic and may not be pitting). Edema is assessed by applying firm pressure with your thumb over the area of swelling. A commonly used scale for grading edema refers to the depth of the impression: 2 mm = 1+, 4 mm = 2+, 6 mm = 3+, and 8 mm = 4+ (Brodovicz et al., 2009). Another method adds the amount of time it takes for the impression to return to normal: 30 seconds or less = 1+, 30 to 60 seconds = 2+, 60 to 90 seconds = 3+, and 90 to 120 seconds = 4+. To assess whether nonpitting edema represents the presence of lymphedema, a technique that is recommended was defined by Kaposi and later by Stemmer. The Kaposi-Stemmer sign suggests lymphedema when there is an inability to tent the skin over the dorsum of the foot at the base of the second toe. This sign has high specificity but not sensitivity (Jayarah et al., 2019).

The examination should also include body systems as indicated by the history, particularly pulmonary, cardiac, peripheral vascular, hepatic, renal, and endocrine. If arterial insufficiency is suspected, an ankle-brachial index (ABI) measurement should be performed. In unilateral edema, a 1-cm difference in size above the ankle or a 2-cm difference at the calf is significant and should lead to further investigation.

Diagnostic Tests: Diagnostic tests depend on the probable etiology of peripheral edema. Cardiac causes may warrant a chest x-ray, electrocardiogram (ECG), or echocardiogram. Laboratory studies also depend on the diagnostic considerations: complete blood count (CBC) for suspected anemia, with a differential if infection is a possibility; complete metabolic panel (CMP), which includes electrolytes, glucose, blood urea nitrogen (BUN), creatinine, albumin, phosphorus, aspartate aminotransferase (AST), alanine aminotransferase (ALT), and bilirubin. More targeted chemistries may be reasonable—for example, a basic metabolic, renal, or hepatic panel. Thyroid function can be assessed with a high sensitivity thyroid-stimulating hormone (TSH) with a reflexive addition of free thyroxine if abnormal. Additional studies could include ultrasound, venogram, venous Doppler studies, lymphoscintigraphy, or the more invasive lymphangiography. Computed tomography (CT) scans or ultrasound for pelvic masses and lymphoma may be indicated, as well as a cancer antigen 125 (CA-125) test. Urine studies quantify protein losses and urine electrolytes.

Differential Diagnosis: Peripheral edema is an important clinical sign, and its causes are diverse. The differential diagnosis is facilitated in part by noting if edema is unilateral or bilateral and recognizing distinctions between lymphedema, lipedema, and venous stasis. Lipedema is a bilateral, symmetrical deposition of fat in the lower extremities that spares the feet (a distinguishing feature) and occurs exclusively in obese women. A multisystem approach that excludes major organ system dysfunction is useful, especially pulmonary, cardiac, endocrine, hepatic, and renal disease. An accurate diagnosis is important because the mainstay of treatment is reversing the underlying disorder, if possible.

Treatment: Always direct treatment at the cause of peripheral edema: diuretics for HF, a high-protein diet for hypoalbuminemia, angiotensin-converting enzyme (ACE) inhibitors for proteinuria, and thrombolytics for acute DVT. Any drugs known to cause edema should be discontinued or decreased

© F.A. Davis Publishing

in dosage. Adding a diuretic to manage edema due to medications such as dihydropyridine calcium blockers may result in polypharmacy; consider deprescribing the offending agent, if possible (Vouri et al., 2019). Many patients expect that any edema should be treated with a diuretic, but if fluid overload is not the issue, diuresis can cause tissue death. Edema due to venous stasis, for example, should focus on that specific etiology, which may not require diuretics.

Compression Stockings. Compression stockings decrease the capillary filtration rate, thus decreasing edema. They are especially useful in patients with venous insufficiency. There is no evidence to indicate that high compression (30 to 40 mm Hg) is clinically more advantageous than medium compression (20 to 30 mm Hg), and patients are more compliant with medium compression. The stockings can be difficult to pull on, and a stocking donner can be helpful. Give the patient a prescription for two sets to allow for laundering. They need to be replaced every 6 months because the compression properties decrease with wear. Stockings that zip are available. Send the patient to the medical supply store where trained fitters will ensure the proper fit. Compression stockings are not recommended for patients with peripheral artery disease (PAD), and if suspected, an ABI can be ordered to screen for PAD.

Behavioral modifications include intermittent periods of recumbency, the avoidance of environmental heat, exercise, weight loss, and sodium and water restriction as indicated (Tennison et al., 2018). Exercise improves the muscle pump action and strengthens leg muscles.

Follow-Up: Closely monitor patients for effectiveness of therapy and adverse events. Monitor the weight and limb circumference measurements using the same reference points because a patient's weight may increase 10% before pitting edema is clinically evident.

Sequelae: When administering diuretics, the health-care professional must be alert to potential volume depletion. Older adult patients are very sensitive to diuretics, and their administration may result in falls, weakness, confusion secondary to sodium and other electrolyte abnormalities, urinary incontinence, gout attacks, volume depletion, and acute renal failure. Patients with edema as a result of deep venous insufficiency are prone to recurrent ulceration.

Prevention/Prophylaxis: For patients with recurrent lymphangitis and cellulitis, prescribe intermittent long-term antibiotic prophylaxis. For patients with leg swelling secondary to DVT, thrombolytics may limit the tissue loss, pulmonary embolus, and more extensive thrombosis of the deep venous system.

Referral: Referral to specialists depends on the diagnosis. It would be rare to hospitalize a patient for most causes of peripheral edema, thus treatment is almost always outpatient. Even DVTs can be treated in consultation with a vascular medicine specialist in the outpatient setting with low-molecular-weight heparin (enoxaparin), warfarin, or direct oral anticoagulants (DOAC) (rivaroxaban, dabigatran, apixaban, and edoxaban). The DOACs offer benefits above warfarin because they do not require routine monitoring, have predictable pharmacokinetics, fewer drug-drug interactions, and limited drug-food interactions.

Education: Patients need specific information related to the edema and the management of symptoms. Typically, the patient with edema is instructed to avoid highly salted foods (follow a 2 to 3 g sodium diet). If compression stockings are recommended, emphasize the importance of proper sizing and application technique to avoid excessive pressure. Instruct patients to elevate the legs above heart level to decrease peripheral vascular pressure for 10 to 15 minutes three to four times a day. Periodic active muscle contraction exercises are important for individuals who must sit for long periods. Teach patients with peripheral vascular disorders to avoid excessive heat and reduce weight if indicated. Special care of the skin, including proper shoes and prevention of trauma, is important.

PRURITUS

Description: Pruritus is a localized or generalized unpleasant, irritating, or itching sensation on the surface of the skin that may lead to the desire to scratch. Pruritus may be acute or chronic (>6 weeks) and is a symptom of an underlying disease process.

Etiology: Pruritus does not always present with visible inflammation or skin lesions. Other causes associated with pruritus include systemic illness, neuropathic and psychogenic processes, and the aging process itself (Butler, 2020; Chung et al., 2020). The itch sensation is a result of immune and neural

© F.A. Davis Publishing

dysfunction. The sensation begins in the dermal layer through triggering the inflammatory immune response. This creates a signal transmitted to the dorsal horn through C fibers. This signal travels up to the thalamus and then it is transmitted to several areas of the brain. The route of pruritus pathways is similar to pain pathways, but the specific pathways differ. The cause of pruritus in older adults is often multifactorial due to aging of the skin and neurological, immunological, and psychological changes associated with aging. In fact, stress can exacerbate itch and vice versa (Golpanian et al., 2020). Additionally, medications are a common exogenous trigger of pruritus, including antihypertensives, antibiotics, opioids, and psychotropics. Drug-induced pruritus may be localized or generalized and may start after the first dose of a drug or many weeks or months after being on the drug.

Occurrence: Pruritus is the most common symptom seen in dermatology and is caused by various skin and systemic diseases. Women are likely to experience and have more intense chronic pruritus symptoms compared to men (Kursewicz et al., 2020; Whang et al., 2019). Additionally, women are more likely to have comorbid autoimmune and psychiatric conditions and for pruritus to have a more negative impact on quality of life (Kursewicz et al., 2020; Whang et al., 2019).

Age: Pruritus is relatively common but increases with age. In older adults, chronic itch is a distressing and debilitating condition associated with a decreased quality of life (Butler, 2020; Chung et al., 2020; Kremer et al., 2020).

Patients who are Black are more likely to experience pruritus and use special lotions, soaps, and clothes than patients who are White (Shaw et al., 2017; Whang et al., 2019). Patients who are Black also report more significant emotional distress from pruritus, but are less likely to seek specialty care (Huang et al., 2019; Shaw et al., 2017).

Contributing Factors: Once a pattern for pruritus has been initiated, continued scratching causes a cascade of inflammatory mediators that provoke the itch sensation and repeat scratching. Additional factors that contribute to dryness include winter weather with low humidity, daily use of cleansers, and bathing without replacement emollients. Sleep deprivation can cause an increase in the release of an inflammatory mediator which results in and contributes to pruritus.

Signs and Symptoms: A thorough history following OLD CARTS (Onset, Location/radiation, Duration, Character, Aggravating factors, Relieving factors, Timing, and Severity) format and physical examination should be done in all patients with pruritus. Find out about allergies and if there was an exposure to new creams or detergents. Ask about systemic-associated symptoms such as weight loss, fever, heat/cold intolerance (thyroid or hepatic disease), nausea and vomiting (chronic renal failure), and polyuria/polydipsia (diabetes). Document past medical history including previous skin conditions, skin care routine, and current medications. A complete physical examination is warranted, examining all surfaces of the skin, including the hair and nails. Assess texture, temperature, moisture, and turgor of the skin. Assess lesions and document the location, shape, and characteristics. A thorough physical examination is required to identify potential systemic causes and contributors to pruritus.

Diagnostic Tests: Skin biopsy or scraping may be needed to establish a diagnosis for a non-recognizable skin lesion. Depending on the results of the history and physical exam appropriate tests might include a comprehensive metabolic panel, complete blood count (CBC), erythrocyte sedimentation rate (ESR), C-reactive protein, thyroid-stimulating hormone (TSH), and HIV. If paraneoplastic itch is suspected, a chest x-ray and/or and computed tomographic scan of the chest and abdomen should be considered. Magnetic resonance imaging may be helpful when addressing itch found along a particular dermatome. Psychiatric assessment can be considered after cutaneous, systemic, and neuropathic causes of itch have been ruled out.

Differential Diagnosis: The differential diagnosis is broad and includes dermatological causes, hypersensitivities, allergic reactions, mite infestation, neuropathic and neurogenic causes, and psychiatric causes, including pruritus associated with systemic diseases. There may be more than one cause, and frequently a cause is never determined.

Treatment: Goals of treatment include alleviating the itch and maintaining skin integrity. Treatment is aimed at the cause. For example, xerosis (dry skin), a common cause of itch in older adults, is treated with emollients that rehydrate the skin and reduce inflammation, and some may include a mild anesthetic or menthol that helps decrease the sense of itching.

Topical Treatments. Most useful with localized forms of pruritus. Topical steroids reduce inflammation, though are avoided for generalized itching or prolonged periods because they cause thinning of the skin. An antihistamine topical cream may be used for localized urticaria. Topical immunomodulators (calcineurin inhibitors) have good evidence to treatment of atopic dermatitis and recently, ceramide emollients and pine tar preparations have been shown useful for itch relief (Harrison & Spada, 2019). Local anesthetics or capsaicin cream can decrease transmission in sensory fibers.

Systemic. These treatments are frequently used for generalized pruritus. Systemic medications with antipruritic properties can be very useful and include serotonin and norepinephrine reuptake inhibitors (SNRIs), selective serotonin reuptake inhibitors (SSRIs), and tricyclic antidepressants. Mirtazapine, paroxetine, and doxepin have antihistaminic and serotonergic effects. Mirtazapine may be particularly useful for underweight patients with nighttime itch because it may also enhance appetite (Khanna et al., 2019). The antidepressants may also be helpful in psychogenic causes. Depending on the cause, antihistamines, neuroleptics, and opioid agonists and antagonists can help. First generation antihistamines may help patients experiencing nocturnal pruritus to sleep better because of their soporific effects. These medications are included in the Beers list of Potentially Inappropriate Medications because of their anticholinergic properties; therefore, second generation antihistamines are recommended as first line. Gabapentin/pregabalin and opiate antagonists has been shown to be useful for neuropathic or systemic causes of pruritus (Chung et al., 2020).

Nonpharmacological Measures. Remove any identified environmental allergens. Consider occlusive dressing (reduces scratching), cool compresses, psychotherapy, and acupuncture.

© F.A. Davis Publishing

Phototherapy has been used for decades to treat various pruritic dermatoses.

Follow-Up: Monitor the patient frequently to evaluate the effectiveness of treatment and reinforce adherence. Assess for secondary complications.

Sequelae: Secondary infection is a risk when the skin is broken. Neglecting pruritus can have a negative effect on the patient's quality of life and lead to anxiety, depression, and insomnia.

Prevention/Prophylaxis: Avoid triggering or exacerbating factors. Additional recommendations regardless of the cause of pruritus include increasing the humidity in the home, drinking plenty of water, and eliminating triggering food. Bathe less often, use warm (not hot) water, and use a soft towel to gently pat skin dry rather than vigorously rubbing. After bathing, apply emollients gently to avoid overstimulating the nerve endings.

Referral: Depending on the result of your assessment, refer to a specialist to manage systemic disease if indicated. If no specific diagnosis is identified and first-line treatments are ineffective, refer to a dermatologist or an allergist.

Education: Includes an explanation of the diagnosis plus triggering/exacerbating factors. Discuss bathing techniques and use of moisturizers. Counsel to keep fingernails short, wear light/loose clothing, avoid alkaline and alcohol-based cleansers, maintain comfortable temperature and humidification, and alleviate stress. Discussion about breaking the itch-scratch cycle is important.

SYNCOPE

Description: Syncope is a sudden and transient loss of consciousness and postural tone resulting from a reduction in oxygen to the brain with immediate spontaneous recovery. Although of short duration, it can result in physical injury, accidents, and a decreased quality of life.

Etiology: Etiologies for syncope range from trivial to lethal. In most instances, the loss of consciousness reflects a temporary decrease in cerebral blood flow that is usually secondary to a fall in the systemic arterial blood pressure influenced by metabolic regulation, chemical regulation, and autoregulation. Syncope is categorized as reflex or neurally mediated in 45% of cases, cardiac related in 20% of cases, and orthostatic hypotension (hypotension occurring after standing up) in 10% of cases. Reflex or neurally mediated and orthostatic causes are usually more benign, whereas cardiac and neurological causes are more concerning. Vasovagal syncope is the most common type of reflex syncope and commonly has prodromal symptoms such as sweating, nausea, vomiting and pallor. The second most common reflex syncope that has the highest incidence in older adults is carotid sinus syncope, which is more common in men and reproducible with carotid massage. Other reflex syncope is more situational, triggered by cough, micturition, or defecation. Cardiovascular syncope is associated with underlying cardiac conditions such as arrythmias or structural heart disease. Heart failure (HF) has been associated with syncope in 12% to 14% of patients. Cardiac syncope is associated with increased mortality. Orthostatic hypotension, which is particularly common in older adults, is associated with antihypertensive medications and dehydration. Studies show that the cause of syncope remains elusive in 30% of cases of patients admitted for syncope (Geer, 2021; Runser et al., 2017; Shen et al., 2017).

© F.A. Davis Publishing

Occurrence: Syncope prevalence has been reported as high as 40% and recurrent syncope occurring 13.5%. Syncope accounts for 1% to 1.5% of all emergency room visits and of those experiencing a syncopal episode 30% to 50% will be hospitalized for further evaluation (Runser et al., 2017; Shen et al., 2017). Among younger adults, women have nearly twice the rate of syncope as men; among older adults, men have the greater incidence. This likely reflects the most common etiologies in the different age-groups.

Age: Syncope incidence is increased in older adults. Among patients older than 80 years of age presenting with syncope, 58% were hospitalized. Among older adults, syncope is associated with increased falls. The lifetime incidence of syncope may be 25% in older adults, and 80% of all emergency department (ED) admissions for syncope are individuals older than 65 years of age. Some forms of syncope (i.e., vasovagal, carotid sinus hypersensitivity) are more common in younger persons than in older persons; other forms of syncope (i.e., cardiac, orthostatic, micturition related) occur more often in older than in younger individuals.

Ethnicity: Not significant.

Contributing Factors: Cerebral blood flow has been reported to decline 25% with physiological aging, which is thought to be related to vascular stiffening. Hormonal regulation of extracellular volume may become impaired with age. Cardiac reflexes and baroreceptor sensitivity also may become impaired. The kidneys' ability to conserve sodium and water declines. Chronic diseases, such as heart disease, diabetes, renal insufficiency, hypertension, and chronic pulmonary disease, are predisposing conditions. Medications used to treat these chronic diseases, such as diuretics, beta blockers, vasodilators, nitrates, antiarrhythmics, and antihypertensives, also may be offenders. Alcohol is a contributing factor in vasovagal syncope. An emotional response can cause neurally mediated syncope in susceptible individuals in stressful circumstances. Dehydration and orthostatic hypotension may be factors. Autonomic nervous system dysfunction, such as Parkinson's disease can cause orthostatic symptoms. Situational syncope can occur when the Valsalva maneuver is produced (micturition, defecation, cough, lifting heavy objects, or after meals related to postprandial hypotension). Prolonged recumbency can contribute to micturition syncope, especially in men with prostate enlargement who awaken from a supine sleep and stand to urinate.

Signs and Symptoms: Sudden collapse with loss of motor tone, with or without injury, is the most common presentation of syncope. The American College of Cardiology (ACC), the American Heart Association, and Heart Rhythm Society (2017) developed recommendations for risk stratification to evaluate the syncope type and each individual's risk factors for future cardiac events. The initial syncope evaluation includes history, physical examination, and resting 12-lead electrocardiogram (ECG). Risk categories are low, intermediate, and high risk (Shen et al., 2017). Standardized risk stratification tools guide appropriate evaluation and management of syncope. Helpful risk stratification tools include the Boston Syncope Pathway, CHADS2 score, the FAINT score, and the San Francisco Syncope Rule (Geer, 2021).

Self-report and eyewitness accounts of transient loss of consciousness are often unreliable—even when the eyewitness is a health-care professional. The most important first step is determining if it is true syncope. Obtain the patient's description of symptoms preceding the event and of activities that may have precipitated the event. Cardiac-related syncope may be sudden and without warning. A brief prodrome of symptoms, such as nausea, pallor, or diaphoresis, may suggest a vasovagal episode or a seizure. Many older adult patients report presyncopal episodes along with true syncopal events. In adults older than age 65, only 5% of the causes of syncope can be determined by history alone as compared to 25% of cases in patients below age 65. Determine whether any focal neurological symptoms were present (i.e., diplopia, motor and sensory symptoms). Review significant past medical history, prior history of an event, all medications being used, and alcohol intake. Evaluating the timing of the syncopal event to meals, physical activities, and length of the prodromal symptoms help in determining neurally mediated syncope from cardiac etiology. Ask about family history for sudden cardiac events. Rapid onset and complete recovery are key diagnostic symptoms along with loss of motor tone. If any one of these symptoms is absent, nonsyncopal causes must be considered. It is possible to have generalized jerking movements with syncope that occur after the loss of consciousness. Rapid reorientation can distinguish this presentation of syncope from a seizure disorder. The physical examination should start with checking the patient for evidence of trauma, then focus on the cardiovascular and neurological components. Check blood pressure in both arms and positionally. Determine the compensatory pulse rate. Check the carotids for bruits. Carotid sinus compression sometimes is used to provoke symptoms, but this should be done cautiously and selectively and is contraindicated in patients with a bruit or a history of stroke or myocardial infarction. Examine the heart, assessing for murmurs, signs of arrhythmia, vascular disease, and left ventricular dysfunction. Check oxygen saturation rates. Perform a thorough neurological examination, paying particular attention to focal abnormalities that may suggest neurological syncope. Generalized anxiety disorders can cause hyperventilation and trigger a vasodepressor reaction; this should be evaluated during the physical examination.

Diagnostic Tests: The ECG is the most important diagnostic test with a focus on the rate and rhythm. Diagnosis of cause from the ECG is very low at 2% to 9%, but it is inexpensive and when positive for disease, critical to proper intervention. Positive findings may include sinus bradycardia, prolonged PR interval, a bundle branch block, or ventricular ectopy. Additional laboratory and imaging studies should be ordered only if clinically indicated by the history and physical examination. Extensive diagnostic testing of patients with syncope contributes to increased health-care costs with low diagnostic yield. Additional diagnostic work-up frequently is required in older adult patients (Geer, 2021; Runser et al., 2017; Shen et al., 2017). Cardiac diagnostic studies may include echocardiogram (valuable in estimating ejection fraction and valvular heart disease), ambulatory ECG monitoring, particularly implantable loop recorders, and electrophysiological studies. A stress test is not indicated unless the event occurred during exercise or was accompanied by chest pain. A chest x-ray, which may reveal cardiomyopathy, is indicated in patients with new abnormal findings and in patients with dyspnea. Electroencephalogram and computed tomography (CT) scan of the head are reserved for patients with focal neurological abnormalities. Vasovagal syncope may be induced with tilt-table testing, which may be done with or without isoproterenol.

© F.A. Davis Publishing

It is useful in patients with syncope of unknown etiology or patients with recurrent syncope. Laboratory evaluation is generally of low yield but may include a complete blood count (CBC) with differential if infection or anemia is suspected. Renal function studies and electrolytes may also be considered.

Differential Diagnosis: Distinguish syncope from seizures, dizziness, drop attacks, orthostasis, postprandial hypotension, carotid sinus sensitivity, and arrhythmias. Atypical presentations include myocardial infarction (MI) and pulmonary embolism (PE). Dizziness does not involve a loss of consciousness and is often characterized further as vertigo, light-headedness, disequilibrium, or presyncope (sensation of impending loss of consciousness). Drop attacks are sudden drops without warning and may be due to transient basilar artery insufficiency at times precipitated by head movement or neck hyperextension. Metabolic disorders (hypoglycemia, hypoxemia) cause coma/somnolence rather than syncope. Orthostatic hypotension reflects a drop in blood pressure of 20 mm Hg systolic or 10 mm Hg diastolic after changing from a lying to a standing position and is taken 1 minute after standing and again 3 minutes after standing. Consider the relationship to meals with a drop in blood pressure. Carotid sinus sensitivity and arrhythmias (atrioventricular block, sick sinus syndrome, and supraventricular arrhythmias) increase with age. Supraventricular arrhythmias rarely cause syncope, but ventricular tachyarrhythmias, especially those with decreased ejection fraction, are a major concern.

Treatment: When you identify the specific cause of syncope, you can initiate the appropriate treatment. Hospitalization may be required when there is a high risk of death, recurrence, or injury. Twenty-four-hour observation may be an option for patients with confusing presentation. Vasodepressor syncope is best addressed with volume expansion. Six factors predictive of adverse outcomes were noted in almost all research focused on risk stratification: acute coronary syndrome, HF, structural heart disease, abnormal ECG, anemia, or hemodynamic instability. Antiarrhythmic therapy is initiated, if indicated, and drug-induced or idiopathic orthostatic hypotension is treated appropriately. Cardiac pacing may be appropriate. Cardiac surgery is the treatment of choice for obstructive heart disease. Always correct underlying anemia and metabolic imbalance and optimize cardiac and pulmonary status in the older adult patient. Address any age-related, disease-related, or disuse-related changes that impair the patient's compensation for hypotensive stressors, such as dehydration, deconditioning, and orthostatic hypotension. Nonpharmacological approaches to vasodepressor syncope include tilt-table training and lower extremity muscle tensing.

Follow-Up: Unknown causes precipitate a high incidence of syncopal events and in one-third of patients, syncope is a recurring event. Because recurrences may reflect lack of effective therapy or a failure to diagnose correctly, close monitoring is indicated.

Sequelae: Syncope from cardiovascular causes tends to be more dangerous. Sudden death with syncope has been attributed to arrhythmia. Patients with syncope are at risk for fall-related injury (fracture, subdural hematoma) and reduced functional capacity.

Prevention/Prophylaxis: Patients with vasovagal syncope are taught to avoid triggers and, if premonitory symptoms occur, to lie down immediately and elevate the feet higher than the chest. Adequate fluid intake is a precaution, and for selected individuals with vasovagal syncope, a higher salt intake may be advised. Support hose may help prevent reduction in central plasma volume. Patients are encouraged to avoid a sudden change in position. For syncope caused by atrial fibrillation, low-dose warfarin or aspirin therapy may be prescribed. Micturition syncope can be avoided by advising men to sit down to urinate.

Referral: Hospitalization is necessary for patients in whom you suspect an arrhythmia or MI as the cause of the syncope and for patients who sustain significant injury during the syncopal event. Consultation may be appropriate with a cardiologist for managing cardiac syncope and with a neurologist for managing neurally mediated syncope. Primary care providers can facilitate urgent referrals for patients to specialists for further syncope evaluation (Shen et al., 2017).

Education: In addition to teaching preventive strategies and the avoidance of triggering events, teach individuals with recurrent syncope safety precautions related to driving or the use of dangerous machinery. It is prudent for the health-care professional to understand the driving laws of the state relative to loss of consciousness/syncope.

TREMOR

Description: Tremor is the most common form of involuntary movement and is characterized by an intermittent or continuous rhythmic oscillation of a body part that can be classified according to the circumstances under which it occurs. Tremors may result from physiological or pathological processes.

Etiology: Tremor can be classified as genetic, acquired, or idiopathic. It can be an isolated symptom such as a physiological tremor or a symptom associated with a neurological or medical disorder. Although many people experience a physiological tremor or enhanced physiological tremor, they often do not seek medical care. Therefore, the two most commonly diagnosed causes of tremor are essential tremor (ET) followed by tremor related to Parkinson's disease (PD). Other causes of tremor include but are not limited to multiple sclerosis, Wilson's disease, dystonia, brain injury from stroke or trauma, hyperthyroidism, alcohol abuse or withdrawal, some medications, and liver or kidney failure. Some individuals may also experience a functional tremor, not to be confused with malingering.

Occurrence: Tremor is the most common movement disorder encountered in clinical practice. Enhanced physiological tremor is very common and may surface with anxiety, fatigue, caffeine, or other medications and normalizes when the contributing cause is removed or managed (Bhatia et al., 2018). Eight times more common than PD, essential tremor affects 10 million Americans (International Essential Tremor Foundation, 2021).

In 50% of those with ET, the disease is familial (autosomal dominant, meaning their child has a 50% chance of also having ET). Approximately 1 million Americans have PD (Parkinson's Foundation, 2021), but not all people with PD have a tremor. Less common types of tremor are cerebellar tremor, functional tremor, dystonic tremor, and tremor associated with Wilson's disease or other medical conditions or diseases. Essential tremor occurs in both sexes equally, with Parkinson's disease more common in men than in women.

Age: Most studies report a significant age-associated increase in the prevalence of essential tremor. It may start at any age with a median age of 45 years old (International Essential Tremor Foundation, 2021) and will most likely intensify with age. Tremor in older adults is more likely to be of the essential or parkinsonian type than other tremor types noted. While the average age of onset is 62, 4% of individuals with PD are younger than 50 (Parkinson's Foundation, 2021).

Ethnicity: Tremor is most prevalent in Whites, followed by Black, Asian, and Hispanic individuals, though the latter ethnic groups are often underrepresented.

Contributing Factors: During times of stress, the amplitude of a tremor may increase. Fatigue, anxiety, hyperthyroidism, systemic illness, use of medications, drug withdrawal (especially from alcohol), use of methylxanthines, and excess caffeine intake can exaggerate tremors of all types as well. Medications that can cause or exacerbate tremors include those that stimulate the sympathetic nervous system and psychoactive medications.

Signs and Symptoms: Terms used to describe the clinical phenomenology of tremors include rest tremor and action tremor. *Rest tremor* occurs when a muscle is not activated voluntarily, and the relevant body part is fully supported against gravity, whereas *action tremor* is present with voluntary contraction of a muscle. Action tremors can be subclassified further into postural, kinetic, and isometric tremor. *Postural tremor* is present while voluntarily maintaining a position against gravity. *Kinetic tremor* may occur during any form of voluntary movement of the affected body part. *Isometric tremor* occurs with muscle contraction against a rigid stationary object. The first step in evaluating tremors is categorizing the tremor based on activation conditions, distribution, and frequency. Determine the duration and age of onset of symptoms, exacerbating or alleviating factors such as alcohol (some individuals with essential tremor have a temporary improvement when drinking alcohol), and any family history of tremor or other neurological disorders. Include any associated symptoms, such as bradykinesia or rigidity (suggesting PD) or ataxia and nystagmus (suggesting cerebellar disease). The patient's medication history, any exposure to toxins, and the presence of illness should be noted. The impact of the tremor on the patients' ability to perform their ADLs and IADLs, as well as their self-assessment of their quality-of-life, will further help quantify the impact of the tremor.

It is critical to conduct a thorough tremor-focused neurological physical examination. When assessing for rest tremor, patients should be evaluated while supine and seated with the hands dangling or in a relaxed position with the forearms fully supported. (If patients are in a position that does not provide complete support, certain muscles may be active against gravity, producing a tremor that may be classified improperly as a resting tremor.) After rest tremor is identified or ruled out, the patient performs other maneuvers to assess for action tremor.

The upper extremities are examined in an outstretched position with the hands supine (palms up), sideways (semiprone), and then prone (palms down). Having the patient spread their fingers can help to identify myoclonus, a symptom that is often mistaken for tremor. In the wing-beating position (i.e., with opposing fingers held close to each other but not touching in front of the mouth), proximal tremor may be identified. Goal-directed activities are performed, such as finger-to-nose, heel-to-shin, pouring water between cups, writing, and drawing. The latter is done by obtaining handwriting and drawing samples (e.g., script, numbers, Archimedes spirals). Patients with essential tremor typically have shaky and large handwriting, whereas the handwriting of patients with PD initially may be of average size and progressively becomes smaller (micrographia). Archimedes spirals drawn by individuals with essential tremor tend to illustrate natural fluctuations in tremor magnitude. Cranial structures (including the mouth and jaw) are examined at rest and in action, and the tongue is observed during rest and protrusion to assess for vocal tremor. This can be done with normal conversation, or the patient is asked to recite a standard paragraph and enunciate a sustained vowel. Abrupt changes in tremor, entrainment and distractibility are signs the tremor may be functional.

© F.A. Davis Publishing

Careful evaluation is also performed, looking for signs associated with tremor syndromes. Muscle tone is checked throughout the body. Bradykinesia and postural abnormalities are evaluated by observing difficulty rising from a seated position, decreased arm swing, and masked facies. Gait is evaluated for shuffling and unsteadiness, and Romberg (station) and balance testing are conducted.

Diagnostic Tests: The diagnosis of tremor is primarily clinical; however, laboratory testing may be necessary to exclude certain conditions associated with tremor, such as metabolic disturbances, including hyperthyroidism (e.g., through thyroid function tests) and Wilson's disease. Brain imaging may be indicated for select patients, particularly patients with unilateral tremor, sudden onset, or atypical clinical features. For complex cases, nuclear imaging such as a DaT-SPECT scan or, more rarely, an F-DOPA PET scan can differentiate essential tremor from PD, but these tests do not always differentiate PD from atypical parkinsonism.

Electromyography can be but is not frequently used to subdivide tremors according to their rate and relationship to the posture of limbs and volitional movement. Genetic testing may be done if indicated.

Differential Diagnosis: The differential diagnosis, in general practice, is often between PD and essential tremor, but there are many causes of tremor as previously noted, and a few are discussed further below. Other symptoms such as myoclonus, dystonia, and ataxia may be mistaken for tremor.

Physiological Tremor. A normal phenomenon, physiological tremor may occur in all contracting muscle groups. Although seldom visible to the naked eye, physiological tremor often may be detected when the fingers are firmly outstretched with a piece of paper placed over the hands.

Enhanced Physiological Tremor (or an Intensification of Physiological Tremor to Detectable Levels) (8–12 Hz). Physiological tremor may be enhanced under conditions of stress, anxiety, fatigue, exercise, cold, hunger, stimulant use, alcohol withdrawal, or metabolic disturbances such as hypoglycemia or hyperthyroidism. It is often difficult to distinguish it from essential tremor clinically.

Essential Tremor (4–12 Hz). Essential tremor is a persistent postural and kinetic tremor that predominantly affects the hands and forearms. A resting component is present only rarely and typically occurs in the most advanced cases. Although less frequently involved than the hands, tremor in the head or voice is a strong indication of essential tremor and is especially useful in differentiating the syndrome from PD. Head tremor, which is also postural, disappears when the head is supported. Listening to the patient speak or holding a musical note as long as possible may reveal a quivering intonation. The legs are affected less often.

Parkinsonian Tremor Syndromes (4–7 Hz). Parkinsonian tremor syndromes involve resting tremor that is often asymmetrical. Tremor may be observed when muscles are relaxed, such as when the hands are resting on the lap, and may affect the upper and lower extremities, the mandible, and lips. Tremor may disappear during sleep. Typical is an alternating tremor of the thumb against the index finger—*pill-rolling tremor.* Although rest tremor is a diagnostic criterion for Parkinson's disease, tremor in other positions may also be present.

Treatment: Only a small fraction of persons with tremor seek medical attention. However, tremor should be treated if it causes disability or affects their emotional well-being, as, for many, tremor can cause significant social distress. When there is a lack of response to medical treatment or when tremor results in severe disability, a patient may be considered for a referral to neurosurgery. Specific treatments for the most common causes are noted next.

Physiological Tremor. Usually, no treatment is required for physiological tremor. When exaggerated, however, it may interfere with activities requiring extreme precision or cause social embarrassment. Identify and remove precipitating and contributing causes. If the precipitating cause cannot be removed, propranolol may be effective.

Essential Tremor. According to the 2019 International Parkinson and Movement Disorder Society commissioned task force's evidence-based review of treatment for essential tremor, primidone, propranolol, and topiramate (greater than 200 mg daily) are the only medications considered efficacious (Ferreira et al., 2019). Alprazolam and Botulinum toxin type injections for certain types of tremors were found to be likely efficacious. Many other medications are often tried, but the task force found them either inefficacious or with insufficient evidence to determine the effectiveness.

If a medication is documented to be beneficial, it may be continued at the regulated doses, and the subsequent medication may be added to the drug regimen. If the response to a drug is adequate and the dose is well tolerated, monitor tolerance and possibly increase the dose. If the medication is of no benefit at a dose that causes adverse effects, dose levels should be tapered down gradually and eventually discontinued. Although the response to alcohol may help diagnose essential tremor, alcohol should not be used as a treatment. Not only does it cause a rebound tremor, but tolerance can be developed, and it can cause alcoholism, accidents, and damage to the body.

Parkinsonian Tremor. The tremor of PD results from a loss of striatal dopamine, and this is the rationale for treatment with either the dopamine precursor levodopa or dopamine receptor agonists. Anticholinergic medications such as trihexyphenidyl (Artane) are also used but may have undesirable cognitive and other side effects in older adults. The combination of carbidopa with levodopa reduces levodopa-induced nausea. There are other formulations of levodopa, including a levodopa-carbidopa intestinal gel (brand name Duopa) that is dosed for 16 hours during wakefulness. It is administered via a PEG-J tube supplied by an external pump. This dosing route decreases tremor by reducing plasma fluctuations that patients on oral levodopa and carbidopa might experience. See Chapter 17 for further discussion on the treatment of PD.

Functional Tremor. A comprehensive approach involving a movement disorders neurologist, a psychologist, and a physical therapist (PT) provides the best treatment for those experiencing a functional tremor. Patients with severe tremors resistant to pharmacotherapy may benefit from deep brain stimulation (DBS), or magnetic resonance imaging-guided focused ultrasound thalamotomy (product name ExAblate Neuro) is successful in treating essential tremor. Many consider this approach noninvasive because it is incisionless, but it creates an irreversible lesion in the brain.

© F.A. Davis Publishing

Follow-Up: Patients should be evaluated for therapeutic effects and side effects within one week of starting treatment. Routine monitoring for weight loss, depression, and decline in functional status are necessary.

Sequelae: Functional disabilities may occur in activities of daily living (ADLs), including compromised eating, drinking, and preparing food. Decreased caloric intake and weight loss may be observed. Ambulation, especially on stairs, maybe hazardous as many people with tremors also have balance problems. Withdrawal from social situations may occur, and depression is common.

Prevention/Prophylaxis: Reduce factors that can exacerbate the tremor. Continue medication regimen.

Referral: A neurologist, specifically a movement disorder specialist, should be consulted for cerebellar tremors, mixed tremors, parkinsonian tremors, challenging to treat essential tremor, or when a focal neurological deficit is identified. Physical therapy and occupational therapy (OT) should be initiated early on and may continue to be helpful throughout all stages. These specialists often make recommendations to improve functionality and quality of life, such as weighted silverware, special writing tools, and other adaptive devices. Some patients may experience benefits with biofeedback, relaxation methods, and other behavioral techniques by alleviating anxiety or stress that may exacerbate tremors.

Education: When a diagnosis has been established, the natural history of the condition should be explained to patients. They should be encouraged to learn as much as possible about their disease to empower them throughout the progression of the disease. Referral to appropriate disease-specific support organizations is helpful for many patients. It also may be appropriate to recommend counseling. Appropriate coping strategies may reduce stress substantially, preventing possible augmentation of tremor owing to anxiety and may also prevent depression.

URINARY INCONTINENCE

Description: Urinary incontinence (UI) is an involuntary loss of urine (Davis et al., 2020). It is common in the older adult. Urinary incontinence is often underreported and can lead to significant consequences, such as falls from attempting to reach the toilet before incontinence occurs or slipping on a wet floor from the incontinence, dermatitis and skin breakdown due to constant moisture, social isolation due to trying to stay near a toilet, depression, and increased caregiver stress. It can be distressing and affect a person's overall quality of life (Batmani et al., 2021; Davis et al 2020).

The detrusor muscle of the bladder is an interlacing bundle of smooth muscle. It relaxes to store urine and contracts to empty the bladder. Alpha-adrenergic activity causes the urethral sphincter to contract (sympathetic activity) and beta-adrenergic innervation causes relaxation of the urethral sphincter (parasympathetic activity). The person's anatomical position can assist in bladder control and is another factor to consider.

There are five types of urinary incontinence: stress, urge, overflow, mixed, and transient (sometimes referred to as functional) (Kolodynska et al., 2019). The most common type is stress incontinence, or outlet incompetence, which occurs in a reported 55% to 88% of all types of incontinence. Urge incontinence, or detrusor overactivity, results when there is an imbalance of inhibitory and excitatory activity and affects 17.4% of women and 15.6% of men (Kolodynska et al., 2019). Overflow incontinence, commonly due to outlet obstruction or detrusor underactivity, results in a loss of urine when the amount of urine exceeds the capacity of the bladder. Mixed incontinence is a combination of UI and overactive bladder and is not uncommon in older adults which can make management more challenging. When there is a normal urinary system but incontinence occurs, it is often due to problems with immobility or cognitive impairment and is referred to as transient or functional UI. It may also be a result of acute illness or the effects of medications and is self-limiting when the cause is determined and addressed. Table 7-10 describes the various types of UI and management strategies.

Etiology: The causes and management of UI are multifactorial, depending on the type of incontinence and the severity

© F.A. Davis Publishing

TABLE 7-10 Types of Urinary Incontinence

TYPE OF URINARY INCONTINENCE	DESCRIPTION/SYMPTOMS	PATHOPHYSIOLOGICAL CHANGES CAUSE UI	COMMON CAUSES	
Stress Incontinence [accounts for up to 88% of all UI]	Leakage of urine caused by increased abdominal pressure associated with standing, bending, lifting heavy objects, sneezing, coughing, laughing, etc.	Weakening of the pelvic floor muscles and failure of complex musculo-ligamentous-fasciocutaneous tissues	Childbirth, trauma, hormonal disorders and a reduction in reproductive organs in abdominal cavity (uterine shrinkage or absence), and surgeries	Lifestyle interventions Behavioral therapies
Urge Incontinence [affects 17.4% of women and 15.6% of men]	A result of an imbalance between inhibitory and excitatory mechanisms' detrusor activity which results in a disorder of micturition Urine leakage associated by or immediately preceded by the feeling of an urgent need to void.	a) CNS damage above bridge – causing detrusor overactivity while reducing the capacity of the bladder b) Spinal cord at the level of S_2–S_4 – at this level there is a micturition center-the bladder is autonomous in relation to the nervous system and has lost the ability to effectively cause shrinkage of residual urine c) Damage to the spinal cord above the level of S_2–S_4 – urination reflex depends on the Parasympathetic nervous system, and the bladder compresses effectively, but is done rather unexpectedly and involuntarily	a) Stroke, dementia, Parkinson's disease b) S_2–S_4 spinal cord damage causing the individual to lose the capacity for reflex emptying c) Spinal cord damage above the level of S_2–S_4 affecting the parasympathetic nervous system	Lifestyle interventions Behavioral therapies Consider trial of antimuscarinic medications
Overflow Incontinence (OI)	The bladder accumulates a urine volume greater than the maximum capacity of the bladder Urine leakage occurs when the bladder is over-distended and may result in incomplete bladder emptying Symptoms can present as constant dribbling, frequency, hesitation when initiating urination, and nocturia	Increased pressure in the bladder causes the urine to flow through the urethra-may occur as a result of the presence of an outflow obstruction (such as prostate hypertrophy)	Associated with bladder outlet obstruction, such as benign prostatic hypertrophy in men and pelvic organ prolapse in women. Neurogenic bladder can also present as overflow UI	Assess for the cause such as medications and fluid intake Double voiding to empty residual urine from bladder
Mixed Incontinence (MI)	A combination of symptoms of UI with stress and urge incontinence, marked by involuntary leakage associated with urgency and also with exertion, effort, sneezing, or coughing.	Same mechanisms as SI & UI	see SI & UI	See Management of Stress Incontinence and Urge Incontinence
Transient Incontinence (TI) and Functional Incontinence	Acute onset of urinary incontinence associated with an illness, an injury, or a new medication. The inability to hold urine due to reasons other than neurological and lower urinary tract dysfunction including delirium, psychiatric disorders, UTI, or impaired mobility	Any temporary change in the patient's ability to identify the sensation of a full bladder and the need to urinate, such as an acute delirium or the result of a medication	Acute confusion, a side effect of a medication such as diuretics, or damage to the nerves affecting muscle control of the urination process	Treat the underlying cause.

and impact on quality of life for the individual. Anatomical changes, factors related to the individual's medical history, lifestyle, and acute and chronic illnesses, in addition to medications, can result in incontinence that can be either reversible or evolve into a permanent condition. Cognitive as well as chronic mental illness, depression, and functional barriers to continence can also affect an individual's ability to maintain urinary continence.

Occurrence: Urinary incontinence affects 43.8% of Americans older than 65 living in the community and 70.3% of long-term care residents (Davis et al., 2020). It is often underreported because it is accepted as a normal part of the aging process (Kolodynska et al., 2019).

Age: Urinary incontinence affects all age-groups, with the highest prevalence in older adults who live in residential facilities, have cognitive impairment, and have functional limitations including but not limited to frailty. UI is twice as prevalent in women as in men, and the incidence increases with age, with those living in residential facilities, and those who have at least one deficit in activities of daily living (ADLs) (Davis et al., 2020; Kolodynska et al., 2019). In males, prostate enlargement may cause urinary obstruction and a weaker bladder stream due to a partial outflow obstruction leading to urinary retention and overflow incontinence. In males who have had a radical prostatectomy, frequently there is a transient UI for up to 12 weeks with an average of 7% having long-lasting UI (Cleveland Clinic, 2021). In females there are decreased estrogen levels which weakens bladder muscles and increases more space in the pelvic cavity as the uterus atrophies or has been surgically removed. Women are at higher risk for stress incontinence and overflow incontinence is more prevalent in men.

Ethnicity: In a meta-analysis of multiple studies in older adults who experience UI in the age range of 55 to 106 years, the highest prevalence of UI was among women in Asia with 45.1% (Batmani et al., 2021).

Contributing Factors: There are many physical changes that occur with aging, and these changes may contribute to the predisposition for UI including decreased bladder capacity, increased involuntary bladder muscle contractions, increased nighttime urine production, and alterations in immune function. Cognitive losses that frequently present in this population can affect a person's ability to recognize bladder distention and determine the appropriateness of voiding at a specific time and place. The many contributing factors for UI include pelvic muscle weakness, multiparity, estrogen depletion, pelvic organ prolapse, diabetes, stroke, multiple sclerosis, Parkinson's disease (PD), spinal cord injury, benign prostatic hyperplasia, urinary tract infection (UTI), fecal impaction, poor fluid intake or excessive fluid intake, smoking, cognitive impairment, depression, immobility or impaired mobility, environmental barriers, impaired dexterity, visual impairment, obesity, and high-impact physical activities. Incontinence can be a side effect of many medications, including cholinergics, anticholinergics, diuretics, antispasmodics, opiates, hypnotics, calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, alcohol, and caffeine.

Signs and Symptoms: In screening for UI it is important to evaluate whether symptoms are transient or persistent in nature. A thorough history should include:

- The severity and quantity of urine lost, including use of pads or adult briefs
- Onset and duration of the problem and whether the UI is worsening
- Triggering factors or events, including sneezing, coughing, laughing, or during activity
- Constant versus intermittent urine loss
- Associated frequency, urgency, dysuria, pain with a full bladder
- History of UTIs
- Association with fecal incontinence or pelvic organ prolapse
- Additional medical problems, including current or past cancers of the pelvic organs (prostate or uterus), congestive heart failure (HF), chronic obstructive pulmonary disease (COPD), cognitive impairment, and connective tissue disorders
- Obstetrical history, including difficult deliveries, multiparity, and large babies
- History of pelvic surgeries or other urological procedures, including use of indwelling urinary catheters
- History of spinal or central nervous system (CNS) problems and/or surgeries
- Lifestyle issues, including use of tobacco, alcohol, or caffeine; occupational or recreational factors causing severe or repetitive increases in intra-abdominal pressure
- Medications, including use of the following medications that have been associated with UI: cholinergic or anticholinergic agents, alpha blockers, over-the-counter (OTC) allergy medications, estrogen replacement, beta-mimetics, sedatives, muscle relaxants, diuretics, and ACE inhibitors
- Effect of these symptoms on ADLs, socialization, and relationships, including sexual activity

Considering that approximately 10% of nursing home admissions are a result of UI, discussion with patients and caregivers before long-term care placement about symptoms has the potential to prolong the individual's ability to remain at home for a longer period of time.

Physical examination should include functional assessment with special attention to mobility, including ability to ambulate to the toilet, and dexterity, including the person's ability to remove necessary clothing in time to use the toilet. Vital signs should be assessed, looking for the presence of an elevated temperature. Respiratory rate and the presence of dyspnea on exertion may affect continence due to limited stamina to complete necessary tasks for maintaining continence. Mental status, including cognition and evidence of depression, should be assessed. The abdomen should be examined for clues such as bladder distention, pelvic masses, inguinal lymphadenopathy, or tenderness in the suprapubic region. Bladder distention can be found in overflow incontinence secondary to obstruction. In women, malignancy, uterine fibroids, or organ prolapse in the pelvic region creates pressure on the bladder seen in urge, stress, or mixed incontinence. A vaginal examination may also reveal poor perineal hygiene, skin breakdown from urine soaking, or redness and thinning of tissue typical of atrophic changes. Prolapse of genitourinary structures or the rectum may also be seen.

To assess for pelvic floor muscle strength and relaxation, instruct the patient to bear down as though having a bowel

© F.A. Davis Publishing

movement, then tighten or squeeze by pulling up with the pelvic floor muscles. In patients with pelvic floor relaxation, you can see the inability to contract or weak contractions and feel a lack of muscle tone when testing during the vaginal examination. Have the patient cough and determine whether leakage occurs. Urethral discharge in male patients should also be assessed. Positive neurological findings in the perineal area include hypersensation, hyposensation, or absence of the bulbocavernosus (anal wink) reflex. A rectal examination may reveal fecal impaction, rectal prolapse, hemorrhoids, masses, or, in men, prostatic enlargement. Whenever possible, the examiner should observe the patient voiding, having the patient void into a measurable receptacle. This should be followed by evaluation of a post-void residual (PVR) urine by ultrasound of the bladder or catheterization. Studies are inconclusive with respect to the amount of PVR that is significant, with values ranging from greater than 50 mL to greater than 200 mL.

Diagnostic Tests: Initial evaluation for UI should include a urinalysis to rule out UTI and renal abnormalities. This has great significance when UI has an acute onset. Older adults have a high rate of asymptomatic bacteriuria. Referring to the McGeer definitions for UTI can increase accurate diagnosis and avoid antibiotic misuse or overuse (Ryan et al., 2018). In addition to the presence of nitrites and leukocyte esterase in the urinalysis, the McGeer definition includes new-onset incontinence and the presence of symptoms including hematuria, pain and or fever. When a UTI is suspected, a culture and sensitivity should be ordered to assess if the bacterial colony count is high enough to qualify as a UTI and to ensure appropriate antimicrobial therapy. Hematuria may indicate a number of diagnostic possibilities including infection, obstruction, kidney stones, or malignancy. Proteinuria is revealing for renal disease and is often associated with poorly controlled diabetes. When renal, metabolic, or obstructive causes of urinary tract dysfunction are suspected, a basic metabolic panel is recommended to evaluate elevated blood urea nitrogen (BUN) and creatinine levels and calculate estimated glomerular filtration rate (eGFR) to evaluate for renal disease. Measurement of PVR may reveal incomplete bladder emptying.

When symptoms and basic noninvasive evaluation does not clearly indicate the type of urinary tract dysfunction, and the individual indicates that UI is problematic enough to warrant further treatment, referral to a urologist or urogynecologist for urodynamic testing is indicated. Urodynamic testing evaluates all stages of lower urinary tract function, including filling and storage, as well as bladder outlet abnormalities. Subjective reporting by the patient of sensation such as urgency can also be evaluated with respect to bladder wall compliance, detrusor overactivity, pressure, and flow measurements during testing. Cystoscopy is indicated for evaluation of hematuria to visualize the bladder wall when cancer is suspected, or when a stricture or prostate enlargement is suspected with symptoms of urinary retention.

Differential Diagnosis: UI is a symptom, not a diagnosis. The two mnemonics DRIP and DIAPERS often are used to differentiate transient (acute) from persistent urinary incontinence:

Mnemonic: DRIP
- **D**elirium
- **R**estricted mobility
- **I**nfection
- **P**harmaceuticals, polyuria

Mnemonic: DIAPERS
- **D**elirium
- **I**nfection, impaction, inflammation
- **A**trophic vaginitis
- **P**sychological, pharmaceuticals, psychotropics
- **E**ndocrine problem
- **R**estricted mobility
- **S**tool impaction

Treatment: Management of UI will depend on the type of incontinence; the patient's preference regarding their perception of how UI affects their lifestyle; and the patient's ability to tolerate treatments, surgical procedures, and risk for adverse effects, as well as complications of medications or treatment regimens. For transient UI, treating, eliminating, or modifying the cause usually alleviates the symptom. Delirium or a mild elevation in temperature from the patient's baseline, rather than a fever, may be the first indication of a UTI in the older adult. Appropriate treatment includes increasing water intake and examining a urinalysis with a culture and sensitivity if indicated (i.e., if the bacterial colony count is greater than 10,000, antimicrobial treatment may be indicated if symptoms persist after increasing water intake, it is warranted that assessing the bacteria's sensitivity to antibiotics guide antibiotic therapy choices due to widespread antibiotic sensitivity).

Lifestyle management using behavioral therapies and pelvic muscle exercises (Kegel exercises) can be an effective treatment for stress and urge incontinence, performed alone or in combination with biofeedback, to help strengthen periurethral muscles. A referral to a physical therapist (PT) who specializes in pelvic floor exercises is an excellent choice to support treatment. Toileting programs (see Table 7-11) can be effective interventions for decreasing the impact of or controlling UI, even in patients with cognitive impairment. Nocturia can be a very annoying problem and cause significant issues where quality of life is concerned. Control of comorbidities and symptoms of fluid overload such as HF and other causes of edema, in addition to limiting fluids before bedtime, can be helpful to improve sleep hygiene.

Pharmacological treatment for urge incontinence with anticholinergic drugs is effective for symptoms; however, they are not without potential side effects, especially constipation, blurred vision, gait abnormalities, and cognitive changes in older adults. These medications, such as tolterodine (Detrol) and oxybutynin (Ditropan), seem to be better tolerated in long acting and transdermal forms. Drugs that are more selective for muscarinic-3 receptors, such as darifenacin (Enablex), solifenacin (Vesicare), and trospium (Sanctura), which do not appear to cross the blood-brain barrier, appear to have a better side-effect profile, and are better tolerated in the older adult population. Patients need to be informed that these medications may take 4 to 6 weeks to experience the full benefit.

Comorbidities such as narrow-angle glaucoma and potential interactions with other medications are always a concern in the older adult population and should be considered before prescribing a drug regimen for UI. In certain situations, estrogen replacement therapy may be considered in women younger than age 65 but caution should be used due to the potential for increasing the risks of developing or worsening

© F.A. Davis Publishing

TABLE 7-11 Lifestyle Measures and Behavioral Therapies for UI Management

Lifestyle measures	Weight loss
	Fluid management-restricting fluids
	Avoiding alcohol, caffeine, and carbonated beverages
	Avoiding constipation
Behavioral therapies	Pelvic floor exercises including Kegel exercises: • Identify the muscle that starts and stops urination through attempts to start and stop urinating • Contract the identified muscle for approximately 8–10 seconds, and then relax the muscles • Perform 8 to 12 contractions • Repeat 3–4 sets of repetitions daily
	Bladder training: • Prompted toileting: Ask the individual to void more often • Habit training: Identifying the toileting pattern including UI episodes, schedule toileting routine to prevent UI episodes • Timed toileting: Scheduled toileting at fixed intervals • Combined toileting and exercise therapy: Incorporates pelvic floor strengthening exercises and bladder training interventions • Double voiding: Empty bladder, relax for 1–2 minutes, then lean forward and/or press on bladder and attempt to void again, emptying the remaining urine from the bladder

Source: *Batmani et al., 2021.*

dementia and increasing the risks of breast cancer. Vaginal or topical estrogen therapy can be an effective remedy for UI as a result of vaginal atrophy. It has a low systemic absorption, but still should be used with caution in women who have a history of breast cancer. Studies have also indicated that the antidepressant duloxetine (Cymbalta) when used in combination with pelvic floor exercises can be an effective treatment for stress UI (Davis et al., 2020).

For patients with overflow incontinence secondary to prostatic hypertrophy, 5-alpha-reductase inhibitors, finasteride (Proscar), or dutasteride (Avodart) are effective to reduce prostate volume by preventing the conversion of testosterone to dihydrotestosterone. These medications take up to 6 months to achieve their maximum benefit. A baseline prostate-specific antigen (PSA) is recommended because the reduction in size of the prostate decreases the PSA and may mask an actual increase. These drugs should not be handled by women of childbearing age because they can be harmful to the development of a male fetus. Selective alpha-adrenergic antagonists such as tamsulosin (Flomax) relax smooth muscle to reduce urethral resistance and improve urine flow. Nonselective alpha-1 blockers such as doxazosin (Cardura) and terazosin (Hytrin) are effective for UI and can also be used in patients who also require antihypertensive therapy. The provider should consider, however, the cardiovascular side effects due to their nonselectivity. Orthostatic hypotension is an adverse reaction that can have serious consequences, such as increased fall risk and injuries, in the older adult patient. Daily tadalafil (Cialis) 5 mg was approved for the treatment of benign prostatic hypertrophy in 2011. It works by increasing the blood flow to the prostate and improving lower urinary tract symptoms. It should not be taken with an alpha adrenergic antagonist, but it may be used with a 5-alpha-reductase inhibitor.

Other treatments for UI include bulking agents such as collagen for stress incontinence, botulinum toxin, sacral nerve stimulation for urge incontinence, and surgical interventions for stress incontinence in women and for prostatic hypertrophy in men. Referral to urology or urogynecology for surgical intervention is appropriate if the patient is inclined to consider surgical intervention and is physically able to tolerate the procedure. Surgical management for pelvic organ prolapse to improve organ support, such as retropubic suspension, sling procedures, and vaginal mesh, are viable options; however, patient education with regard to the high failure rate (10% to 20%) should be discussed when considering these options. In 2008, the FDA warned of potentially serious complications associated with the use of surgical mesh, and in July 2018 they placed it on a "High Vigilance Pause" for pelvic organ prolapse, a frequent cause of stress incontinence (Dawson et al., 2020). When surgical treatment for UI because of pelvic organ prolapse is contraindicated, a pessary is a viable option. In addition to incontinence pads and briefs, pessaries, when properly fitted within the vaginal vault to correct organ prolapse and reduce stress UI, can typically be managed by the patient or cared for by a qualified nurse at regular intervals. Nonsurgical management of persistent urinary overflow incontinence includes clean intermittent catheterization initially and ultimately may require an indwelling suprapubic catheter. Although the Centers for Medicare and Medicaid Services now reimburses for a single-use sterile catheter, there is no evidence to support a reduction in UTIs with the use of sterile versus clean urinary catheters.

Follow-Up: Follow-up visits will depend on the acuity and severity of symptoms. Treatment of infection and symptoms related to urinary retention requires closer and more frequent follow-up due to renal complications that can result. Initially, medication management should be attempted but monitored closely for adverse effects, especially with anticholinergic medications. These medications can increase the risk of falls and side effects can result in other significant complications such as blurred vision, dizziness, acute delirium, and somnolence. Long-acting medications appear to have a lower risk profile, but individual monitoring is necessary to ensure patient safety. Additionally, cognitive impairment and dementia exacerbation can occur with the use of anticholinergic medications, resulting in hallucinations, psychosis, or changes in behavior that can lead to injury to the individual or others. Constipation, a common adverse effect of anticholinergics, can exacerbate UI by causing a fecal impaction. Polypharmacy issues also need to be monitored closely with any medication change, requiring close follow-up when starting a new drug regimen.

Sequelae: Possible complications include UTI, hydronephrosis (with overflow or obstruction), renal failure, adverse drug events, or failure of behavioral therapy. Skin breakdown is a significant complication with persistent UI. Falls due to UI result from environmental factors or as a side effect of medication management. Social isolation may be a result of uncontrolled UI having a significant impact on quality of life and may lead to depression.

© F.A. Davis Publishing

Prevention/Prophylaxis: Ways to help prevent incontinence include:

- Early identification of acute or transient UI
- Teaching patients and family members/caregivers that UI is not a normal part of the aging process and that treatment options are available
- Referral to appropriate specialists for treatment options
- Regular rectal examination in men to detect and treat early prostatic hypertrophy
- Recognition of polypharmacy and adverse reactions when initiating new medications in the geriatric population

Referral: Referral to urogynecology for the female patient to explore treatment options is appropriate if behavioral interventions and medication management are unsuccessful. It is also appropriate to refer to a specialty practice if the diagnosis is uncertain. Refer men with overflow incontinence for urological evaluation urgently if PVR urine volume is significant, to prevent renal complications, and for surgical intervention, if indicated. Referral to certified continence nurse specialists or PT may be appropriate for behavioral therapies, such as biofeedback or for electrical stimulation treatments to improve continence. Further work-up and referral to urology would be indicated if abnormalities in the urinalysis do not resolve after treatment for infection, such as persistent hematuria or proteinuria, and if the patient has a past medical history that includes surgeries for genitourinary diagnoses or a history of pelvic cancer with or without radiation therapy. Patients with neurogenic bladder because of injury or a chronic neurological condition should be followed by a neurologist in collaboration with the primary care provider.

Education: Teach patients, family, caregivers, and health-care providers, as well as the community, that UI is *not* a normal part of aging, and it is a treatable medical problem in many individuals. Behavioral therapy can be provided in the primary care setting, such as Kegel exercises, as well as self-catheterization techniques. When starting a new medication, the patient should be given written instructions that include details regarding possible adverse drug effects to prevent serious consequences of complications. Also, it is important to teach patients with bladder outlet obstruction the signs and symptoms of a UTI, including delirium as an indication of acute illness, and that a fever may not occur with infections in an older adult. Additional topics to address include having an adequate fluid intake, limiting bladder irritants such as caffeine and alcohol, and prevention of constipation to avoid fecal impaction and help to avoid bladder symptoms and infections. The importance of good perineal hygiene, especially for women and patients who do self-catheterization, should be emphasized. When incontinence cannot be completely avoided, attention to skin care and instruction in the use of skin barriers such as zinc oxide or dimethicone-based products should be taught to the patient or caregivers to prevent skin breakdown.

WANDERING

Description: Wandering in older individuals, whether it appearing to be intentional to a specific destination or aimless, often occurs in individuals who have disorders that cause cognitive impairment. It is characterized as locomotion either ambulation or propelling in a wheelchair. The wandering behavior is often described as having observable patterns such as lapping, pacing, or random movements. The wandering behavior may be frequent, repetitive, temporally disordered, and possibly spatially disordered in nature. A more recent definition, critical wandering, includes elopement which can

© F.A. Davis Publishing

lead to the individual getting lost either in or outside the person's living setting. Once lost, the wandering older adult is at risk for injury from falls, fatigue, and even death from head injury, hip fractures, other accidents, and exposure to the elements of the environment (e.g., temperature extremes, moving vehicles, or injury from animals) (Adekoya & Guse, 2019; Neubauer et al., 2018; Silverstein & Flaherty, 2021). Moser (2019), however, cites statistics that show injury or death due to wandering is actually a rare event.

Etiology: Although poorly understood, there are many hypotheses regarding the causes of wandering behaviors. A medical hypothesis suggested right parietal dysfunction, which leads to spatial perception and memory lapses resulting in these types of behaviors. Another theory is the individual has unmet needs or environmental triggers leading to wandering behaviors (Neubauer et al., 2018) (Table 7-12).

Wandering behaviors occur in individuals who experience confusion—either temporary in states of delirium or in individuals with a dementia, most commonly during the middle to later stages of the dementia process. Delirium is an extreme confusion, an acute episode of fluctuating attention, worsening of cognition, and change in level of consciousness, which frequently results in agitated and wandering behaviors (Neubauer et al., 2018). Most delirium is reversible but occurs more often in individuals with dementia. Common causes of delirium include illness, medications, and environmental factors (Table 7-13).

Occurrence: Wandering behaviors occur in one out of every five individuals with dementia at some point during their illness (Neubauer et al., 2018). In 2016, 46.6 million people globally were living with dementia, and this number is projected to increase to 75 million by 2030 (Neubauer et al., 2018).

Age: Wanderers do not differ in age (although some studies suggested it occurs more frequently in the younger old) or sex (although some reports suggested it occurs more frequently in males) (Cipriani et al., 2014). Women are diagnosed more often with Alzheimer's disease. Women generally live longer than men and therefore are more likely to live to the age when Alzheimer's disease is more common.

Ethnicity: Numerous studies have documented differences in dementia prevalence among racial and ethnic groups in the United States. African Americans and Hispanics are found to have a higher risk of dementia compared to European Americans (Chen & Zissimopoulos, 2018). Prevalence related to ethnicity showed frequency of occurrence to be 58% in European Americans, 67% in African Americans, and 63% in Hispanics.

TABLE 7-12 Potential Causes of Wandering Behaviors

Unmet personal needs	• Internal discomfort: need for toileting, hunger, thirst • Loneliness • Perceived threat to the individual's safety • Past history of walking behaviors
Environmental triggers	• Noisy environment • Increased visual distractors • Visualizing other individuals leaving • Shadowing a caregiver

Source: *Neubauer et al., 2018.*

TABLE 7-13 Common Causes of Delirium in the Older Individual

Illness	• Urinary tract infection • Upper respiratory infections including pneumonia • Sepsis • Severe constipation as well as intestinal obstruction • Meningitis • Dehydration • Electrolyte imbalances, especially low sodium and low calcium levels • Severe malnutrition • Hypoxia • Terminal illness
Medications*	• Medications with anticholinergic properties • Certain antipsychotics • Pain medications, especially when the individual is toxic
Overstimulation	• Loud noises or multiple conversations • Bright or blinking lights • Large number of people • Change in routine of an individual with cognitive impairment • Overly tired individual with a diagnosis of dementia

Sources: AGS, 2019; Neubauer et al., 2018.
**See the Beer's list of potentially inappropriate medications frequently prescribed in the older patient*

Contributing Factors: Wandering behaviors occur in more than one-half of individuals with a diagnosis of dementia in the moderate to late stage of this cognitive impairment process. The greatest percentage of wandering occurrence has been reported in older adults residing in a nursing home setting or during hospitalization when the patient is experiencing an episode of delirium (Adekoya & Guse, 2019; Neubauer et al., 2018). The most frequent occurrence is between 5:00 and 7:00 p.m., which is often referred to as "sundowning," but occurrence has also been reported as early as 2:00 p.m. and late into the night (Neubauer et al., 2018).

Signs and Symptoms: The older adult may be anxious or agitated or exhibit symptoms prior to an episode of wandering, causing the individual to be difficult to redirect. Individuals who are anxious and those who are delusional appear to exhibit wandering behaviors more frequently. The consequences of wandering may include falls, exhaustion, malnutrition, anxiety and aggression, elopement, and becoming lost from the individual's home environment (Adekoye & Guse, 2019; Cipriani et al., 2014; Lin et al., 2019; Tilly, 2015).

Diagnostic Tests: In an older person who seems to wander aimlessly or become confused or lost, a full medical evaluation should be conducted, including an evaluation for dementia,

© F.A. Davis Publishing

particularly Alzheimer's disease. A work-up includes a review of the individual's medications; diet, nutrition, and use of alcohol; as well as medications (prescription and nonprescription/street drugs); vital signs and pain level; laboratory tests (blood and urine); and a thorough physical examination including an in-depth geriatric neurological examination. Although no singular test is available for dementia, multiple cognitive assessments are recommended, including the Mini-Mental State Exam (MMSE), the Montreal Cognitive Assessment, the St. Louis University Mental Status Exam, Mini-Cog test, Clock Drawing test, and Memory Impairment Screening. The Mini-Cog test is a short screening test that incorporates a three-item recall within 5 minutes and a clock drawing test. Although used less often now because the MMSE is proprietary, it had been the most widely used to assess an individual's level of cognitive functioning. In one study wandering behaviors were noted to be common in individuals who scored a 13 or less on the MMSE (Cipriani et al., 2014).

Treatment: Determine whether the wandering behaviors are troublesome or placing the individual at risk for harm. If wandering is benign—consider providing a safe environment for the individual to wander. If intervention is warranted—a person-centered approach to assessment, planning, and delivery of care is the key to managing wandering behaviors (Tilly, 2015). Examine the frequency of wandering occurrences, the time of day, and any triggers that may be the cause of the wandering behavior. When possible, attempt to identify why the person is wandering, and when developing a plan of care, involve the person with dementia in decision making. If able to identify triggers to the behavior, attempt to modify the individual's routine to minimize these triggers; decrease distractions, especially in the afternoon and evening hours or when the person is tired; and do not vary the day-to-day routine. Attempt to engage the individual in nondemanding activities during the time of day the wandering behaviors most frequently occur. Nonpharmacological interventions should be attempted, but when the individual is severely agitated, aggressive, exhausted, or otherwise at risk for harm to self or others, and distraction and redirection are unsuccessful, pharmacological intervention may become necessary.

Sequelae: Consequences of wandering behaviors include accidents, getting lost, fatigue, sleep disturbances, social isolation, falls, injury, and death (Neubauer et al., 2018). Falling with hip fractures and head injuries are common consequences in these individuals. Malnutrition can also occur as a result of an inability to sit for a meal or excessively wandering, which increases caloric requirements and leads to weight loss. Wandering behaviors often lead to early admission to a dementia facility when families are unable to manage the individual in the community setting. Disruptive activities are associated with wandering including agitation, screaming, physical aggression, and disturbed nighttime sleep.

Prevention/Prophylaxis: Care is aimed at balancing a person's need for autonomy with the need to minimize risks. The goal is to provide a pleasant and safe environment where an individual will not wander away, fall, or become exhausted. Wandering is not always problematic if the person is able to ambulate without falling, the behavior does not lead to aggression, or the person does not wander away and become lost. To maximize safety, the living environment needs to be surveyed and modifications made, when necessary, and the area is familiar (minimize changes) and uncluttered. Assure ample lighting, maintain clutter-free walkways, and keep harmful objects out of reach from the confused individual. Other considerations may include putting locks on cabinets and ovens, unplugging dangerous appliances when necessary, removing wall hanging mirrors (the confused individual may misinterpret the reflection as another person in the room), and providing exits with safety mechanisms. Wandering behavior can be diminished with the installation of simple childproof doorknob covers, possibly more complex door locks, or even in-house alarms or bells.

If an individual wanders, identify to where the person usually wanders, what activity the person is usually engaged in when wandering occurs, and at what time of day it usually occurs. Identification bracelets or necklaces may help minimize the hazardous consequences if wandering off does occur and the individual becomes lost. Many Medical Alert necklaces/bracelets have GPS tracking and can be of assistance in locating an older adult who has wandered away. Also include identification in clothing and keep a recent photograph of the individual when assistance is needed to locate the person (Moser, 2019). When wandering occurs, caregivers should approach the individual slowly, speaking softly, in a monotonous and nonthreatening manner. Act in a nonjudgmental, matter-of-fact manner. Validate the person's feeling with positive, open statements or questions such as "You look concerned" or "What can I do to help?" Distract the individual by refocusing the person's attention on something different, such as looking at old pictures or discussing the weather. Redirect the person in a reassuring manner by saying, "I know you are concerned; let's sit and talk and have a cup of coffee." Possibly suggest going for a walk in the direction you wish the person to go instead of the individual leaving that environment. Avoid asking the person to explain the behavior. In summary, validate, redirect, distract, and redirect the wandering or confused person to abort the behavior (Sollito, 2021).

Referral: Caregivers need to determine the abilities of the wandering individual and create an environment that provides for autonomy as much as possible and ensures safety. Referrals may be made to geriatric care specialists for evaluation and management, home health agencies for assistance in the home setting, and community resources for support groups and available educational resources. When necessary, consideration for a more structured living arrangement may be advised when safety becomes a major concern. Options include sitters in the home setting, adult day cares, assisted living facilities, and nursing homes. In extreme situations, when the elder is at risk for harming self or others, referral to a psychiatrist may be indicated for evaluation.

Education: Educating caregivers, both family and friends, of the wanderer, as well as paid caregivers (nurses, aides, staff), is essential to provide optimal care. The essential information includes the causes of dementia and wandering behaviors and how to identify triggers of this behavior, create a safe environment, and manage wandering individuals while promoting quality of life and patient autonomy.

WEAKNESS

Description: Weakness is "loss of strength" (Cortes-Vicente et al., 2020), but this definition can further be qualified by objective and subjective characteristics. Complaints of weakness could be localized muscle weakness or overall weakness, which is better described as malaise or frailty. Weakness is described usually as an extremity that will not move to its full potential against gravity. Weakness is a risk factor in the decline of independence in instrumental activities of daily living (IADLs) and activities of daily living (ADLs) (McGrath et al,2020).

Etiology: Infections, such as the flu or urinary tract infection, are the most common cause of acute generalized weakness. Acute extremity weakness is most commonly from trauma and typically associated with pain (Levin, 2019). Post-surgery or procedure pain can also result in weakness. Neurological issues, such as multiple sclerosis, myasthenia gravis, or stroke, can cause unilateral weakness or weakness in cranial nerves that can be acute or generalized and even wax and wane (Cortes-Vicente et al., 2020). Hormone levels, such as thyroid levels, or electrolyte imbalances can occur with dehydration and can also cause weakness (Levin, 2019). Weakness may be experienced as the result of an acute infection such as polio, Lyme disease, or other tick-borne illnesses.

Occurrence: Weakness can be acute (seconds to minutes) resulting from an injury, trauma, or stroke. Subacute weakness (hours to days) can result from an infection, inflammatory process, or autoimmune condition such as multiple sclerosis or myasthenia gravis. Chronic weakness may result from a previous injury or trauma, a metabolic or muscle disorder, or a congenital or degenerative condition. Weakness due to multiple sclerosis, myasthenia gravis, or thyroid dysfunction is higher in women because these conditions are generally more predominant in women. Weakness related to stroke is higher in older women (Bushnell et al., 2018).

Age: Weakness can occur at any age. At birth it could be related to trauma, congenital issues, or cerebral palsy. Some types of muscular dystrophy can progress as one ages. Lack of regular exercise, injuries, degenerative changes, obesity, and comorbidities that occur as one ages can also contribute. Neurological causes of weakness such as multiple sclerosis and myasthenia gravis are usually diagnosed between ages 20 to 40 (Cortes-Vicente et al., 2020). Strokes can occur at any age, but incidence doubles for each decade between ages 55 and 85 (National Institute of Neurological Disorders and Stroke, n.d.).

Ethnicity: Certain neurological conditions can be related to ethnicity, and stroke may be seen more in people of color (Hooman et al., 2020).

Contributing Factors: Having a compromised cardiopulmonary system can cause acute or chronic weakness depending on degree of issues and activity level/cardiac demand of patient. Vitamin B_{12} deficiencies, alcoholism, and certain medications such as statins can also cause muscle weakness and/or nerve damage. Obesity and diabetes can contribute to weakness due to glucose levels or calories needed for expenditure.

Signs and Symptoms: Weakness is described as an extremity that will not move to its full potential against gravity. Over time atrophy of the muscle can be visualized or measured. Weight gain or loss may be seen in subacute or chronic weakness. Weight gain may occur because of a lack of calorie expenditure and injury, pain, or hormonal issues can cause weight loss (Levin, 2019).

Generalized weakness is described as trouble moving from point A to B or even the inability to get out of bed or perform ADLs. Cognitive fatigue from poor sleep quality, obstructive sleep apnea, or mental health issues can also result in generalized weakness.

Physical examination should first start with evaluating distress of the patient, especially in an acute situation such as a stroke where facial droop or slurred speech may occur. If not in an acute setting, use of the reported weak extremity should be witnessed during initial intake. Additional factors to consider include:

- Does the patient need assistance with ambulation? Did they require a wheelchair when usually they are fully ambulatory?
- Are they guarding the extremity if having pain?
- Does the patient report or show signs of pain with ambulation or palpation of the extremity?
- Is hygiene compromised because they are unable to get into the shower or bath? Do they spill food or drink on themselves due to upper extremity weakness?
- Is there increased tone or lack of tone? Hyporeflexia or hyperreflexia?
- Is swelling or atrophy present?

© F.A. Davis Publishing

When considering the scale of weakness in isolated muscle groups, motor strength is commonly rated as:

- 0/5: No visible muscle contraction
- 1/5: Visible muscle contraction with no limb movement
- 2/5: Limb movement but not against gravity
- 3/5: Movement against gravity but not resistance
- 4/5: Weakness against resistance
- 5/5: Full strength

Measurement of handgrip strength (HGS) can be done in any setting. HGS provides and assessment of overall muscle strength, and low HGS is associated several poor health outcomes (McGrath et al., 2020).

Diagnostic Tests: The patient's report of acute, subacute, or chronic weakness helps establish next steps for testing. Determination of localized weakness or generalized weakness will further differentiate appropriate testing (Table 7-14).

Differential Diagnosis: Differential Diagnosis is broad for weakness, which is why the patient's reported history of their symptom is crucial. *Acute or subacute:* Injury or reinjury, infection, neurological cause, cancer, electrolyte disturbance. *Chronic:* Nerve damage, alcoholism, eating disorder, cancer.

TABLE 7-14 Diagnostic Testing for Weakness

STAGE	LOCALIZED	GENERALIZED
Acute	• X-ray of extremity if injury occurred • Computed tomography (CT) or magnetic resonance imaging (MRI) of head if stroke causing unilateral weakness is suspected • CT or MRI of extremity, if warranted	• Laboratory tests: complete blood count (CBC), complete metabolic panel (CMP), urine • Consider swabbing for flu, strep infection, or COVID-19. • Head CT
Subacute	• Review of medications and recent activities (excessive exercise) that could cause rhabdomyolysis • Labs: CBC, CMP, AChR antibodies • Electromyography (EMG) or nerve conduction test to help evaluate health of muscles and nerves.	• Laboratory tests: vitamin B_{12}, thyroid-stimulating hormone (TSH), CBC, CMP, urine, erythrocyte sedimentation rate ESR, CRP, ferritin, Hgb A1c, AChR antibodies • Check medication list
Chronic	• EMG or nerve conduction of extremity • Muscle biopsy if indicated	• Laboratory tests: vitamin B_{12}, TSH, ferritin, Hgb A1c, AChR antibodies • Monitor weight. • Screen for depression. • Consider a sleep study. • Determine whether the patient is up to date on cancer screenings, including low dose CT if patient is smoker.

Treatment: Treatment for most types of weakness will likely involve exercise or physical therapy (PT). Locating a physical therapist who specializes in the etiology of the problem can increase success of recovery.

Medications for chronic generalized weakness or fatigue include stimulants or wakefulness medications. These will not help with muscle strength, but they may help the patient feel more energized. There are no medications to make muscles stronger. Sometimes B vitamins have been prescribed to help with weakness or fatigue, but clinical trials have been mixed in terms of true benefit (Levin, 2019). There is one medication with proven efficacy for patients with multiple sclerosis, dalfampridine (Ampyra), a potassium channel blocker that in clinical trials helped patients improve their walking by increasing nerve conduction. If the patient is diagnosed with multiple sclerosis or myasthenia gravis, there are a variety of medications available to stabilize the disease process.

Assistive devices such as canes, rollators or various braces can help with extremity weakness. These may help a patient maintain ambulation to avoid further sequelae from their weakness. A physical or occupational therapist would be the best resource to outfit a patient with the correct device. Diet should be evaluated for nutritional value as well as appropriate caloric intake. Hydration needs to be emphasized especially in certain climates and times of the year.

Follow-Up: Follow up depends on the etiology and treatment and the level of patient distress. Follow up in weeks or months should be determined with the patient in shared decision making.

Sequalae: Sequelae from weakness, even when treated, can still result in atrophy of muscles, pain, falls, deep vein thrombosis (DVT), and osteoporosis. Sequalae can cause poor sleep due to pain or positioning. Weakness can lead to social isolation.

Prevention/Prophylaxis: Weakness from neurological or congenital issues cannot be prevented but can often be improved with therapy and assistive devices. The best prevention for weakness is regular, safe exercise and avoidance of injuries or falls. Eliminating use of tobacco and limiting alcohol use can be beneficial. Risk factors for stroke, such as obesity, hypertension, and diabetes, should also be addressed.

Referral: After the etiology of weakness if diagnosed, the patient should be referred to a specialist in that field as appropriate, such as neurology or orthopedics. Referrals can also be made to PT, occupational therapy (OT), or physical medicine and rehabilitation. Referral to an endocrinologist should be made for management of thyroid disorders. For generalized chronic weakness it may be helpful to refer to a mental health provider.

Education: Patients should be educated on the etiology of their weakness as well as preventive measures. Expectations of treatment should be outlined. Discuss realistic treatment outcomes with the patients, understanding that they may not return to their baseline strength depending on the etiology of their weakness. Education should be done regarding the benefits of a regular exercise program. If initiating medication therapy that has risk of rhabdomyolysis or an electrolyte disturbance that could cause weakness (such as diuretics), patients should be educated on symptoms and what to do immediately should they experience issues.

CASE STUDY

J. B. is a 77-year-old man who is known to your practice. He is brought in today by his daughter, who reports a new onset of confusion accompanied by UI (first noticed bed was wet a few nights ago). When you see the patient today, he is oriented to place and person (knows you and your office), but not to time, and does not recall much about events of the past few days. He says that he is eating and drinking as usual (but daughter is shaking her head to the contrary). He denies any change in bowel function, but is fearful of sleeping because he might "wet the bed." Daughter states that he has been drinking a lot more water than usual and urinating more frequently. He denies any pain, other than arthritis. He was a regular attendee at the local senior center but has not been there for a week and seems to have forgotten about it.

Past medical history: Known CAD, hypertension, hyperlipidemia, impaired fasting glucose, osteoarthritis of knees.

Medications: Lisinopril 20 mg orally PO once daily in evening; hydrochlorothiazide 12.5 mg PO once daily in morning; metoprolol 50 mg PO once daily in morning; simvastatin 20 mg PO once daily. OTC medications include Aleve, 2 tablets every 12 hours when needed for severe knee pain (infrequent use); topical Icy Hot for knee pain daily; glucosamine-chondroitin preparation daily for joint health; multivitamin for male more than 50 years daily.

Vital signs: Blood pressure (BP) 130/84 mm Hg; heart rate (HR) 60 beats per min, regular; respiratory rate 16 breaths/min; temperature 99.2°F orally; BMI 38.

Physical findings are unremarkable.

Using the guide to characterizing a symptom located in this chapter, focus on the following questions:

1. What additional subjective data are you seeking?
2. What additional objective data will you be assessing for?
3. What national guidelines are appropriate to consider?
4. What tests will you order? How will you decide on prioritizing in this patient with multiple symptoms?
5. What are the differential diagnoses that you are considering? For each one, map out your clinical reasoning for and against it and make a tentative plan to confirm it or rule it out.
6. Will you be looking for a consultation?

CHAPTER 8

Dermatological Disorders

Laurie Kennedy-Malone

CHANGES WITH AGING

The largest organ of the body, the skin, undergoes certain normal changes with age. The number of cells in the epidermis, such as Langerhans cells, which are responsible for immune surveillance, begin to decline. Melanocytes also decrease, thereby reducing the skin's natural protection from the sun (Russell-Goldman & Murphy, 2020). As people age, the skin tends to be very thin, fragile, and often transparent (Burr, 2018). Skin renewal turnover time increases to approximately 87 days in older adults, compared with 20 days during youth. This fact becomes an important consideration in surgical and dermatological healing. The subcutaneous tissue that houses the eccrine, sebaceous, and apocrine glands thins, thereby providing less protection from heat exposure and less insulation, energy storage, and shock absorption (Golpanian & Yosipovitch 2020; Russell-Goldman & Murphy 2020). Secretions aiding temperature control, moisturization, and odor production are also reduced. The skin of older adults therefore tends to be very dry (xerosis) and with accompanying pruritis (Russell-Goldman & Murphy, 2020). Fat is generally redistributed to the abdomen and thighs, leaving bony surfaces, such as the face, hands, and sacrum, exposed to potential injury, especially skin tears from shearing and friction forces and pressure injury development (Farage et al., 2013). The skin's repair system becomes impaired, with delayed cell regeneration and poor circulation (Russell-Goldman & Murphy, 2020).

Common benign skins lesions in older adults include seborrheic keratoses, cherry angiomas, acrochorda (skin tags), and senile lentigo (Russell-Goldman & Murphy, 2020). Aging skin is also susceptible to develop contact and allergic dermatitis, eczema, and nonmalignant skin cancers and malignant melanoma (Farage et al., 2013). Older adults are also prone to developing many pigmentary disorders not common in younger adults (solar lentigo, lentigo maligna, stasis dermatitis, purpura, poikiloderma) (Armenta et al., 2019).

Although the capillaries in older adults tend to be fragile, making the skin of older adults more susceptible to bruising, it is important to discern the cause of the ecchymosis, whether it is trauma-, pressure-, or medication-induced, as in patients taking anticoagulants or corticosteroids. It is important to note, however, that sudden appearance of numerous seborrheic keratoses, telangiectasia, or pigmented warty lesions (known as Leser-Trelat sign) may suggest internal malignancy (Bernett & Schmieder, 2020).

All of these tissue changes represent a near-catastrophic scenario of aged skin poorly protected from the environment (especially the sun, heat, and cold) and slow to respond to immunological challenges, producing minimal or delayed urticaria and swelling (Shah & Kennedy, 2018). Changes to the skin that occur at the end of life during the dying process (loss of tissue and declining organ function) increase the risk of patients developing pressure injuries (Burr, 2018).

ASSESSMENT

A thorough dermatological assessment should include the presenting concern/compliant with the skin, history of the presenting concern/compliant, past medical history, family history, social history, medicines (including topical treatment, over-the-counter [OTC]), and known allergies. Also determine the patient's routine exposure to ultraviolet (UV) light (Burr, 2018; Czerkasij, 2010). Equally import it to determine the impact of the dermatological concern on the patient's quality of life (Linos et al., 2018). Family history should address any familial tendencies for dermatological conditions, including any predispositions for psoriasis or eczema, or familial atypical multiple mole melanoma (FAMMM) (Lynch & Shaw, 2016). Concurrent and recent conditions experienced by family members may reveal a contagious or environmental etiology. Patients should be questioned about occupation and/or hobbies to consider exposure to chemicals, travel to include exposure to insects (bites, stings), past dermatological allergic reactions (plant-based, food, drug, environmental, animal dander), whether or not the patient smokes (to include prior history), alcohol consumption, medications (including any new prescription or OTC medications. Review with the patient any current psychological stressors that may have triggered a new dermatological response or an exacerbation of a previously diagnosed condition (Willacy, 2019).

When exploring the chief complaint and history with the patient, review the dermatological problem's onset, duration, location, size of lesion, color, associated pain, or itching, and lost or heightened sensation to touch. Has there been a

© F.A. Davis Publishing

previous episode of the lesion in the past that resolved (Burr, 2018; Czerkasij, 2010; Willacy, 2019)?

- Investigate associated symptoms such as wheezing, loss of appetite, fever, malaise, joint pain, headaches, and change in temperature perception. Skin conditions can be clinical signs of underlying malignancies with the most common to metastasize to the skin are "breast, lung, colon, stomach, sinus laryngeal, oral, thyroid, renal, and uterine" (Hall, 2017, p. e287).
- Question current and chronic medication history, complete a focused nutritional assessment, and ask about relevant childhood diseases (especially asthma, atopic dermatitis, and varicella).
- Ask about contact with chemicals, lifetime occupations, hobbies, level of lifetime UV light exposure, family history of skin cancer, contact with animals, change in environmental habits (e.g., exposure to plants, insects, or water) or internal habits (e.g., change in soap or laundry detergents, use of any lotions or creams, recent travel, change in diet and cooking products, and exposure to new clothing items or metals such as nickel).
- Question about smoking history and alcohol use.
- Ask whether the person has been treated for a similar condition in the past and, if so, ask about the treatment (self-administered or provider prescribed).
- Note whether the patient appears uncomfortable or pruritic.
- Observe overall hygiene and grooming
- Is the patient incontinent?
- Has the patient had two doses of the Shingrix? Did they have the Zostavax vaccine?
- Is the patient taking any anticoagulation medications?

To conduct a thorough skin assessment, patients should be asked to gown except for underwear (Wheatley, 2018). Proper equipment for inspection includes good overhead and tangential lighting, a magnifying glass, blades, and collection devices for biopsies and microscopic study. Gloves should be readily available. A total body skin examination is warranted to assess the skin for skin cancers (Linos et al., 2018). During the examination, inspect the skin for possible signs of neglect, abuse, or decreased function. Poorly healing wounds or chronic pressure injuries may signal a problem not only with the patient but with the caregiver's ability to provide adequate care. Welts, lacerations, burns, and distinctive markings may indicate a need for intervention (Earlam et al., 2018).

Inspect the hair and nails. The hair may be graying and thinner than in youth. Normally, nails start to form ridges after age 80. A recent (in the past year) change in quality of hair and nails is a significant finding. For example, the hair may have become dryer, duller, and thinner or the nails pitted or brittle, which may be indicative of a systemic condition or nutritional deficiency (Burr, 2018).

Inspection of the skin for even color and overall quality and care is important. Lesions require close scrutiny, description, and classification. Description by type, shape, arrangement, and distribution is a widely accepted and usable format.

- Type: Is the lesion a macule or papule? Is it a nodule? Is it vesicular? Is it eroded, excoriated, or hyperpigmented or hypopigmented?
- Shape: Is the periphery of the lesion round, ulcerated, or linear?
- Arrangement: Are multiple lesions grouped (serpiginous, zosteriform, arciform, iris, or bull's-eye pattern) with or without definable borders (Suneja et al., 2020)?
- Distribution: Is the extent of the lesions isolated, regional, or generalized? Is the pattern symmetrical or over pressure sites, hairline, or sun-exposed areas? Is the distribution characteristic of scabies, seborrheic dermatitis, contact dermatitis, herpes zoster, or lupus?
- Is there any inflammation around the lesion? Is the lesion or surrounding area tender to the touch?
- Is there bleeding or discharge? (Bleeding may be indicative of a malignancy; discharge may be a sign of an infection.)
- Any noted fluctuation in the presence of the lesion?
- Is there any unexplained bruising that could be indicative of elder abuse or neglect (Earlam, 2018)?

The lesion may be classified as primary or secondary. Primary lesions (vesicles, tumors, burrows) arise from normal tissue. Secondary lesions (infections, crusts, and lichenification) arise from changes to the primary lesion and may be the result of trauma, scratching, or infections (Suneja et al., 2020). Palpate for moisture, temperature, mobility, and turgor. Testing skin turgor in older patients can be done by pinching the skin on the sternum or forehead. The skin should move easily and return back to place after release; a slower return of the skin may be indicative of dehydration. Lax skin may indicate weight loss, whereas fixed skin may be associated with sclerotic or scarred tissue. Lesions should also be palpated to check whether they are fluctuant, hard, or fixed. "Lesions that are crusting, changing, itching, bleeding, burning or otherwise new in recent months require immediate attention" (Czerkasij, 2010, p. 646).

At the end of the examination, consider associated pathology, especially thyroid disorders, diabetes, autoimmune conditions, anemia, and malignancies. Provide wellness instructions, including those concerning proper nutrition, moisturizing, and year-round UV light protection. Awareness of the high susceptibility of the older adults to hyperthermia and hypothermia secondary to reduced thermoregulation in the skin should be emphasized (Farage et al., 2018).

Lesions that concern you or the patient should be examined through biopsy. Lesions that warrant biopsy are those that have changed, bleed, or are painful. Treatment for skin lesions must take impaired absorption, duration, dosage, and delivery method (e.g., cream, powder, ointment, lotion) into consideration. Patients for whom treatment plans fail initially should be referred to a dermatologist.

Guidelines for Prescribing Topical Medications

When prescribing topical treatments, it can be a challenge to determine the quantity necessary to dispense. A guideline for determining the quantity was first described by Long and Finlay in 1991 with the introduction of the "fingertip unit." One fingertip unit (FTU) is the amount of ointment or cream dispensed from a tube with a 5-mm opening from the tip of the finger to the first crease. One FTU is equal to approximately 0.5 g. Along with the concept of FTUs, the "Rule of Hand" was developed. This rule says that the body surface of the front and

© F.A. Davis Publishing

back of an adult hand requires 1 FTU for coverage. Each body part is described by its equivalent surface area in hands. Each arm is equal to three hands, the front torso is seven hands, and so are the back and buttocks. Each leg is equal to six hands, and each foot is two hands. So, if you are treating lesions on one foot, a total of 2 FTUs will be required, or 1 g per treatment. For treatments that are prescribed as twice a day (bid) for 2 weeks, a total of 28 g will be necessary. This guideline results in a more quantitative prescription than writing "dispense 1 week's supply" (Long & Finlay, 1991).

BURNS

Signal Symptoms: Erythema, edema, blistering, serous exudate, eschar, pain, pruritis; carbonaceous sputum, singed nasal hairs, hoarseness, dyspnea (for inhalation injury).

Description: Burns are tissue injuries caused by heat. Beyond the classic thermal injury definition, "burns" may refer more broadly to tissue injury caused by exposure to chemicals, electricity, friction, or radiation. Given the integumentary system's role as the primary physical barrier to the external environment, burns most often affect skin and other superficial tissues. However, burn injuries may extend to deeper tissues, may evolve over time, may be concomitant with inhalation injury and/or multisystem trauma (polytrauma), and may be compounded by significant comorbidities. Optimal long-term outcomes depend upon appropriate referral for definitive care and specialized resources for ongoing recovery and rehabilitation.

Etiology: According to the American Burn Association (ABA) National Burn Repository (2019), flame burns remain the dominant cause of burn injury in the United States, followed by scalds, contact burns (direct exposure to a hot object), electrical burns, and chemical injuries. However, the relative frequency distribution of burn cause and severity varies by age, sex, ethnicity, and numerous other demographic and/or contributory risk factors. Some vulnerable subgroups are at greater risk of burn injury and/or worse outcomes from burn injury.

It must be emphasized that etiology of the original thermal injury to tissue is only part of the equation. Dysregulated host response to injury is a hallmark of burn injury. Severe burns often elicit a heightened and sustained inflammatory response and hypermetabolic state that may exacerbate the original injury, prolong time required for wound healing, and lead to additional tissue damage and/or organ dysfunction (Nielson et al., 2017).

Occurrence: Most burns occur in the home (72.5%), in industrial settings (6.6%), or on street/highway (5.5%) (ABA, 2019). The setting of initial medical treatment may vary (e.g., emergency department [ED], urgent care, private medical office, specialty clinic, hospital), and reporting systems are not integrated. As a result, burn injury incidence estimates vary, but rates may approach 2.5 million injuries annually. Approximately 500,000 individuals receive medical treatment, and approximately 10% of those treated require hospitalization (ABA, 2019). Mortality rate for all cases was 3.0%, though mortality increases with advancing age, burn size, and presence of inhalation injury (ABA, 2019). Annual fire deaths in the United States have fallen steadily from nearly 6,000 in the 1980s to fewer than 3,500 by 2020 (Ahrens & Messerschmidt, 2021).

Age: The overall number of fire fatalities in the United States has fallen substantially over the past 40 years, but the reduction has not been uniform across all age-groups. The greatest reductions have been among younger age-groups, but the annual number of home fire fatalities among those 50 and older has remained largely unchanged; this has caused the percentage of home fire fatalities in those who are 65 or older to increase from 19% to 36% (Ahrens & Messerschmidt, 2021). Worldwide, the incidence of burn injury in older adults is increasing (Jeschke et al., 2020).

Age-related changes to the skin, such as thinner skin, decreased vascularity, and diminished nerve function often result in a higher incidence of deeper burns. Advanced age also imposes an increased burden of comorbidities, weakens the immune system, and prolongs or delays wound healing. Thus, older adults are at particular risk for burns.

Males sustain a higher rate of burn injury than women across all age-groups, except for those individuals 80 years and older (ABA, 2019). Conversely, female sex was related to higher mortality (Bedri et al., 2017). There are some differences in cause of burn injury and location of occurrence; compared to women, a greater proportion of burn injuries for men occur outside or in the workplace.

Ethnicity: National Burn Registry data (ABA, 2019) outlines the following distribution of reported ethnicity in burn injuries: 60.3% White, 20.6% Black, 9.5% Hispanic, 6.0% other, 2.7% Asian, and 1.0% Native American. Race/ethnicity factors may influence injury risk differently across age-groups: people of color younger than age 16 (especially those younger than age 5) are overrepresented among those with burn injuries, but this phenomenon is not observed in older age-groups (ABA, 2019). There are complex interactions between race/ethnicity, gender identity, sex, age, and socioeconomic status—with subsequent effects on burn outcomes. Multivariate analysis by Bedri et al. (2017) found that burn mortality was related to such factors as being Black, being female, and being uninsured in addition to burn severity (total body surface area [TBSA] and depth) and inhalation injury. In addition, people of color were more likely to have complications such as urinary tract infections and septicemia, and they had a higher risk of morbidity and mortality compared with Whites.

Contributing Factors: The major causes of home fires and fire deaths are cooking, home heating, electrical distribution and lighting, and smoking (Ahrens & Messerschmidt, 2021). Smoking is the leading cause of home fire deaths and has been found to increase the risk of burn injury sixfold—even further when compounded by use of home oxygen (Ahrens & Messerschmidt, 2021).

Human judgment plays a large role in activities that are related to burn injury. Older adults may have slower response times and may show impaired judgment due to illness or medications. The ability to sense fire decreases, and disabilities may impede escape. Many older adult individuals live alone or are

© F.A. Davis Publishing

dependent on an aging spouse for support; this isolation further increases the risk of injury. Comorbidities such as cardiac disease, renal disease, diabetes mellitus, dementia, or psychological impairment may complicate outpatient care; these individuals may require initial hospital admission for burn assessment and stabilization (Voight et al., 2018).

Signs and Symptoms: Burn injury constitutes trauma, and as such, the initial evaluation should consist of a primary survey including the ABCs (airway, breathing, circulation), followed by a secondary survey including a comprehensive patient history and thorough head-to-toe examination. Ascertain the time and mechanism of injury, duration of contact with the offending agent, and any steps taken to manage the injury. This will assist in determination of wound depth and suitability for outpatient management.

Skin is the largest organ in the body and performs myriad protective, sensory, and regulatory functions. It is composed of three layers: the epidermis, the dermis, and the subcutaneous tissue or hypodermis. The epidermis is the thin outermost layer of the skin. At this level of the skin, melanocytes produce melanin, which affects skin color and provides protection from UV radiation. The dermis consists of a dense connective tissue that forms the bulk of the skin. This layer is vascular, with its deeper layer containing hair follicles, associated muscle fibers, cutaneous glands, and nerve fibers. The hypodermis is largely composed of adipose tissue, which provides padding and thermal regulation. Burn injury can affect all these skin layers in addition to deeper structures such as muscle and bone. A graduating zone of damage may evolve over time, making it difficult to estimate the depth of a burn when first evaluated.

- First-degree burns involving the epidermis are erythematous and painful, but do not blister. Most sunburns fall into this category and are not considered when estimating total burn size.
- Second-degree (partial-thickness) burns
- Superficial dermal burns involve the dermis and are characterized by blisters. The underlying tissue is pink, moist, and hypersensitive to touch. The tissue will blanch with pressure and is associated with dilation. Superficial dermal burns will often heal within 2 to 3 weeks.
- Deep dermal burns extend further into the dermis, present with blistering, but the tissue surface appears mottled, pink, and white immediately after injury. Capillary refill is slow and usually by the second day from injury the wound bed appears white and dry. Pain is often described more as pressure. Partial-thickness burns that are not healed by 3 weeks should be excised and grafted.
- Third-degree (full-thickness) burns involve the full dermis extending into the subcutaneous tissue. The burn appears dry, white, charred, and leathery. There is no sensation to pinprick in the wound bed. There may be mottling that does not blanch with pressure. There may be visible coagulated vessels on the surface. Full-thickness burns require early excision and autograft.
- Indeterminate burn wounds may hold components of both partial-thickness and full-thickness; they should be evaluated daily over a period of days to determine the need for excision and autograft (Jeschke et al., 2020; Voight et al., 2018).

After determining the depth of tissue injury, estimate the TBSA of second- and third-degree burns. Note that superficial (first-degree) burns are not included when calculating TBSA. The Lund and Browder technique, first published in 1944, considers body surface area relative to age. The estimated surface area stabilizes by 15 years of age through adulthood (Table 8-1). An adjunct method used for scattered or irregularly shaped burns is the Palmar method: the patient's palmar surface (palm, digits, and thumb in adduction) correlates to approximately 1% of TBSA.

Emergency care for burns greater than 20% TBSA should include IV fluid resuscitation to correct ongoing fluid and electrolyte losses and to prevent further tissue injury secondary to hypovolemia and tissue hypoperfusion. Advanced Burn Life Support (ABLS) guidelines recommend use of the Modified Brooke/Parkland Formula to estimate 24-hour fluid volume of Lactated Ringer to be administered: 2 mL × %TBSA × weight in kilograms (Woodson et al., 2018). However, in practice, IV fluid rates are titrated to

TABLE 8-1 Adult Burn Size Estimation

achieve adequate perfusion as indicated by physical examination, vital signs, and urinary output of 30 to 50 mL/hr (Jeschke et al., 2020). Effective fluid resuscitation of acute burns is best accomplished in consultation with the nearest burn center or trauma center.

After initial patient assessment is completed, a decision must be made to transfer to a higher level of care or to continue management in the outpatient setting. The ABA has established criteria for burn center referral to improve patient outcomes (Table 8-2). An important caveat is that any case of suspected elder abuse should be transferred via the emergency medical system (EMS) to the appropriate emergency department to ensure proper follow-up and reporting. Suspicion of abuse should be triggered by any of the following:

- Burn patterns that do not match the reported event
- Straight or smooth transitions between the area burned and healthy skin, resulting in a stocking- or glove-like appearance
- A long delay between burn injury and request for treatment

Diagnostic Tests/Tools: Laboratory and diagnostic testing should be guided by patient presentation and, if warranted, may be an indication for hospital-based evaluation. Of note, standard pulse oximetry devices may fail to detect smoke inhalation injury; many devices cannot differentiate between saturation of hemoglobin by oxygen versus carbon monoxide, resulting in misleading saturation levels (Jeschke et al., 2020). When in doubt, or if inhalation injury is suspected, obtain an arterial blood gas (ABG) including a carboxyhemoglobin (COHb) level.

Differential Diagnosis: Many exfoliative and necrotizing skin disorders can present in a similar fashion and must be ruled out. Although these skin disorders are not true burns, they are often referred to burn care facilities for definitive treatment. These may include but are not limited to:

- Erythema multiforme
- Necrotizing fasciitis
- Purpura fulminans
- Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN)
- Staphylococcal scalded skin syndrome (SSSS)

TABLE 8-2 American Burn Association Referral Criteria

1. Second-degree (partial-thickness) burns greater than 10% of Total Body Surface Area (TBSA)
2. Third-degree (full-thickness) burns of any size
3. Burns involving face, hands, feet, genitalia, perineum, or major joints
4. Electrical burns, including lightning injury
5. Chemical burns
6. Inhalation injury
7. Burn injury in patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
8. Any patient with burns and concomitant trauma in which the burn injury poses the greatest risk of mortality or morbidity; if trauma poses the greater immediate risk, the patient may be stabilized in a trauma center before transfer to a burn unit
9. Burned children in hospitals without qualified personnel or equipment for the care of children
10. Burn injury in patients who will require special social, emotional, or rehabilitative intervention

Burn Center Referral Criteria list from Resources for Optimal Care of the Injured Patient, Committee on Trauma, American College of Surgeons, Chicago, IL, p. 101. Copyright © 2014 American College of Surgeons.

Treatment:

Initial Care. First, stop the burn. Remove and isolate the causative agent while protecting the patient and staff. If a scald has occurred, remove all soaked clothing. If chemical exposure is suspected, contact Poison Control for guidance; in industrial or workplace settings, also refer to corresponding Material Safety Data Sheet (MSDS) if available. Unless contraindicated by the MSDS or Poison Control, irrigate wounds with copious amounts of water to dilute and remove contaminants (Jeschke et al., 2020). Isolate clothing to be sure that others are not contaminated.

In evaluating burns in older adult patients, it is imperative to consider their physiological differences from younger adults, along with any associated comorbidities. If transfer to a higher level of care is appropriate, activate the EMS promptly; do not delay for wound debridement. Cover wounds with dry, clean sheets or towels. Maintain a warm environment to minimize the risk of hypothermia. Provide supplemental oxygen as needed to maintain adequate oxygenation. In cases of suspected inhalation injury, administer 100% oxygen via a nonrebreather mask.

Wound Care. Burn wounds are frequently colonized with bacteria from the local environment. These wounds are routinely managed with topical antibiotics; systemic antibiotic therapy is not generally indicated (Table 8-3). Wounds may be doused briefly (30 seconds) with cool water to disperse any remaining heat in the tissue. Continuous use of cool or cold water for pain relief is not advised, because this may cause further tissue damage due to vasoconstriction, as well as hypothermia. Wounds should be cleaned with a mild soap and rinsed. Antibacterial soaps are not necessary. Although small (<2 cm) blisters may be left intact, any loose or devitalized tissue should be removed. Wounds should be washed daily. However, care must be taken to remove exudate and nonviable tissue while also not disturbing the process of reepithelialization.

The goal of wound dressings is threefold: absorb drainage, provide protection, and decrease pain. Dressings used for small burn wounds should be simple, affordable, and manageable by patients and caregivers. For small burns without infection, use simple petroleum-infused mesh with or without antibiotic ointment. When wrapping a burn wound, it is important to consider function. Digits should be wrapped individually to allow for both active and passive range-of-motion exercises. Elevate extremities at rest and utilize compression garments or elastic bandage wraps (lower extremities only) to prevent edema.

Burn wound care utilizes clean rather than sterile technique. Patients and families should be taught proper cleaning techniques, including frequent hand washing and

© F.A. Davis Publishing

TABLE 8-3 Topical Agents and Dressings for Burn Wounds

NAME	USAGE	APPLICATION
Topical antibiotic ointment (bacitracin, mupirocin, triple-antibiotic ointment, Polysporin®)	Small area, partial-thickness burns: prevention and treatment of infection with gram-positive and some gram-negative bacteria. Mupirocin is active against most strains of MRSA.	For facial burns, apply ophthalmic preparations without a dressing and leave open to air (OTA); reapply thin layer as needed to keep wound slightly moist. For burns to other areas, apply a thin layer daily to wound, and cover with a petroleum-impregnated mesh and sufficient outer gauze to absorb exudate. Change outer gauze more often as needed for excess exudate.
Hydrocolloid dressings	Provide a moist protective covering and barrier against exogenous bacteria. Effective for small-area, partial-thickness burns. Not indicated for wounds with large amounts of exudate.	Occlusive dressings may be left in place for 5–7 days for patients with low risk for complication.
Silver sulfadiazine 1%	Prevention and treatment of infection in second- and third-degree burns with eschar burden. Can delay wound healing by impeding epithelialization. Discontinue use once necrotic tissue has sloughed from wound. Contraindicated in those with sulfa allergies or pregnant women.	Do not apply to face. Cover burn area with a layer approximately 1/16-inch thick, wrap with sufficient gauze to absorb exudate, and change daily or more often as needed for excessive exudate.
Petroleum gauze/mesh (Adaptic®, Xeroform®)	Protective covering, 3% bismuth tribro-mophenate in a petrolatum blend (Xeroform®) has bacteriostatic action, can be used with topical antibiotic ointments. May be used in cases of sulfa allergy.	Apply daily, cover with gauze wrapping sufficient to manage exudate. Change external gauze wrapping more often as needed to manage excess exudate.
Aquacel Ag Hydrocolloids Mepitel Ag Silverlon Suprathel TheraBond 3D	Synthetic wound dressings designed to reduce pain, reduce healing time, and manage exudate by either absorbing or transferring exudate to secondary dressing (varies by type). Appropriate for superficial, partial-thickness burns.	Apply primary dressing after thorough wound cleansing, and cover with secondary dressing such as gauze, hydrogel, or foam dressing. Primary dressing may be left in place for 3-7 days between dressing changes (Hydrocolloids, Mepitel Ag, Silverlon) or up to 14 days (Aquacel Ag, Suprathel, TheraBond 3D); change secondary dressing as needed if saturated with exudate.

Adapted from Care of outpatient burns *by C. D. Voight, M. Celis, and D. W. Voight (2018), in D. N. Herndon (Ed.),* Total burn care *(5th ed., pp. 50–57). Saunders Elsevier.*

management of supplies within their environment. Wounds should be examined daily during care for redness, swelling, purulent drainage, or odor. This should be reported promptly to the health-care provider, and the addition of systemic antibiotics should be considered for any signs or symptoms of infection.

Patients should be instructed to minimize exposure to UV light by using protective clothing and applying sunscreen over healed burn wounds. Patients should also be instructed to continue using compression garments in the rehabilitative phase to minimize swelling and scar formation.

Follow-Up: Outpatients should be reevaluated 24 hours after the burn injury. Examine the condition of the wound and surrounding tissues for signs of healing or impending infection. Reexamine respiratory status of patients with an inhalation injury to detect diffuse wheezing and rhonchi. Determine the adequacy of the current pain management regimen. Have the patient or significant other demonstrate proper dressing techniques. Patients should return periodically about every 4 to 6 weeks to determine healing, assess progress/compliance with any physical therapy or occupational therapy if required, and assess coping mechanisms. Depending on the severity of the burn and/or presence of complications, more frequent visits may be necessary at first, until progressive healing is noted.

Sequelae:

Pain. There is benefit in utilizing medications with different mechanisms of action to address pain in burn patients. This is especially true for burn patients undergoing any type of procedure that can include wound care or physical therapy (Romanowski et al., 2020). It should be anticipated that for small burns the need for narcotics will be short lived as the wound heals. With deeper or larger burns, there may be a benefit to adding pharmacological agents that act on neuropathic pain, such as gabapentin and pregabalin. Acetaminophen and NSAIDs have a good safety profile and may help to manage pain and inflammation, if not contraindicated by comorbidities (Romanowski et al., 2020). Evaluation of renal and liver function should be assessed with dosages adjusted accordingly.

Pruritis. The process of healing triggers the mobilization of multiple agents such as cytokines and histamine into the wound bed. Patients may experience intense pruritus, but scratching can cause significant disruption to wound healing. This can be particularly challenging for older adults

© F.A. Davis Publishing

because antipruritic agents, such as diphenhydramine or hydroxyzine, can be sedating. Adequate analgesia in conjunction with these agents can be effective, but care must be taken to avoid oversedation. Consider scheduling agents that selectively block H_1 receptors, such as cetirizine or loratadine, to limit sedating effects. Moisturizers, massage, and pressure garments on healed wounds can aid in management of pruritus and are essential to prevent drying and cracked skin. Pruritus tends to diminish over a period of approximately 6 months as the burn scar begins to mature, but some patients may need additional interventions.

Hypertrophy and Contracture. Collagen production increases during wound healing. This may be more exaggerated with prolonged wound healing, infected wounds, or in individuals prone to keloid formation. Wounds that remain open for 2 weeks or longer tend to be particularly prone to the development of hypertrophic scarring (Jeschke et al., 2020; Voight et al., 2018). Hypertrophy can lead to pain and loss of function through distortion of normal anatomy. The utilization of appropriate topical agents and dressings that act to facilitate timely wound closure will help prevent and/or minimize hypertrophy. In addition, the use of pressure garments over nearly closed or healed wounds will aid normal scar progression.

Hypertrophic scars may compromise the web spaces of the fingers and toes, and contractures and underlying tendon damage in the hands may result in impairments. The resulting loss of function may be restored through surgical intervention, but early and continuous consultation with specialized occupational therapy services is vital for optimal long-term outcomes. Bands and contractures can continue to develop many years after injury, so scars should be monitored periodically for progression.

Prevention/Prophylaxis: Injuries occur when the host, the environment, and vector converge. For example, an older adult falls asleep while smoking, the sheets ignite, and the individual is burned in a house fire. It is the relationship between this person, their environment, and a potentially hazardous agent that can result in injury. The nurse practitioner can affect each of these components (person, environment, agent) and possibly prevent the initial burn injury from occurring. The nurse practitioner, by virtue of education, clinical expertise, and anticipatory guidance, plays a vital role in burn prevention (Grant, 2004).

Primary prevention constitutes product design, regulation, and legislation. This also includes educational programs designed to educate the public on safety. In the previous example, the individual smoking in bed may benefit from a community smoking cessation program. Regulation of product design would affect the combustibility of clothing, linen, and housing materials exposed to the smoldering cigarette. During annual physical examinations, the nurse practitioner should include discussion and education on healthy lifestyle habits (smoking cessation) and home safety priorities such as proper use of smoke alarms, practicing a home escape plan, removal of hazards such as frayed electrical cords, visual aids for those with impaired sight, and the appropriate temperature setting for home hot water heaters.

Secondary prevention includes actions to limit the extent of damage done by an injury, such as cooling wounds initially to mitigate deeper tissue damage. Occupational therapists provide compression garments and ensure proper splitting technique to maintain function. Physical therapists assist with mobilization through stretching and exercise programs.

Lastly, tertiary prevention addresses recovery and rehabilitation. Individuals continue to work with therapists to maximize function. Management of healed burn scars with moisturizers and sunscreen can prevent further skin damage. Through tertiary prevention, the individual optimizes his or her level of functioning and minimizes disability resultant from the burn injury.

Nurse practitioners are instrumental in developing and/or referring clients to community-based programs that promote home safety for older adults (Grant, 2004). Excellent educational programs are available through agencies such as the National Fire Protection Association (NFPA), the Centers for Disease Control and Prevention (CDC), the ABA Prevention Campaign, and verified burn centers.

Referral: Burns often require complex care and the involvement of multiple disciplines. In the older adult population, even a small burn may require complex fluid resuscitation due to extensive comorbidities and influence of polypharmacy. The absence of support systems or the suspicion of elder abuse should prompt considerations for hospitalization and possible referral to a specialized burn care facility. The ABA has developed a list of criteria that should signal the need for referral to a burn center (see Table 8-2). A burn center verified by the ABA can provide services to a burn patient through all phases of the patient's care.

For rehabilitation concerns related to nerve compression, development of scar bands, or contractures, consider referral to a plastic and reconstructive surgeon. Reconstruction after burn injury should also include evaluation of mature scars that have remained hyperemic and hypertrophic for possible photoablation with laser therapy. Occupational therapy and physical therapy are crucial in preserving and maintaining form and function for burn victims (Voight et al., 2018). Referral for these services should be made early in the care of the burn patient. A referral for social services or in-home assistance may be indicated to promote safe return to a living environment. Contact your nearest burn center for referral information. An excellent resource for patient and family support is the Phoenix Society, a national nonprofit organization dedicated to empowering those affected by a burn injury (https://www.phoenix-society.org/).

Education: Education is an ongoing component of patient care. Clinicians should identify who will provide wound care and assist with recovery. The patient or caregiver should demonstrate the ability to perform wound care before leaving the clinic or hospital setting. Provide appropriate written instructions in clear language for wound care, indicators for infection or tissue compromise, and contact information should questions arise. In addition, provide written instructions on medications, including dosing and possible side effects.

CELLULITIS

Signal Symptoms: Erythema, warmth, local tenderness/pain, and edema.

Description: Cellulitis is an infection of the deep dermis and subcutaneous tissues of the skin; most commonly caused by groups A, B, C, and G beta-hemolytic streptococci, *Staphylococcus aureus* (both methicillin-susceptible [MSSA] and methicillin-resistant [MRSA]), and occasionally a gram-negative organism (Bystritsky, 2021; Infectious Disease Society of America [IDSA], 2014). Cellulitis can also be caused by human or animal bite pathogens.

Etiology: Cellulitis usually occurs when an organism enters the skin through an open area. However, a clear site of entry may not be evident in patients with obesity, edema, or lymphedema (Bystritsky, 2021; Silverberg, 2021)

Occurrence: In the United States, the cases and cost of cellulitis have continued to increase; more than 14 million outpatient cases (Silverberg, 2021) and 10% of the infectious disease hospitalizations are related to cellulitis, (Neill et al., 2019). Most cases occur in the summer months (Bystritsky, 2021)

Age: Cellulitis can occur at any age but most commonly in middle-aged and older adults (Bystritsky, 2021). Lower extremity cellulitis is more common in older adults because they may have poor vascular supply masking the common signs of cellulitis (Gbinigie et al., 2019). Cellulitis occurs equally among men and women.

Ethnicity: Cellulitis occurs in all ethnic groups.

Contributing Factors: Predisposing factors include arterial or venous insufficiency, diabetes mellitus, lacerations, obesity, lower extremity edema, lymphedema, human or animal bites (cat bites), tinea infections, recurring cellulitis, burns, trauma, stasis ulceration, ischemia, toe web maceration, IV drug use, and puncture wounds (Bystritsky, 2021; Silverberg, 2021). Any break in the skin or mucous membranes is a port of entry of bacteria (Rrapi et al., 2021). Acute and chronic sinusitis can lead to periorbital or orbital cellulitis. Consider cellulitis in patients who are immunocompromised or on immunosuppressive medications, immunocompetent (HIV infection and AIDS), have drug or alcohol abuse issues, or are prescribed long-term use of corticosteroids or cancer chemotherapy (Silverberg, 2021). The fragile, thinning skin of the older adult can increase the risk of trauma and bacterial infections (Gbinigie, 2019).

Signs and Symptoms: Cellulitis in older adults often presents atypical symptoms, making a diagnosis difficult (Gbinigie et al., 2019). History of trauma or injury to the skin, preexisting skin conditions, recurrent cellulitis, with the signs including warmth, erythema, edema, and localized tenderness/pain of the affected skin (Neill et al., 2019; Rrapi et al., 2021). Cellulitis is typically unilateral. Systemically patients may present with fever, chills or malaise, hypotension, tachycardia, leukocytosis, lymphadenopathy, and lymphangitis (Neill et al., 2019; Bystritsky, 2021). Cellulitis may

© F.A. Davis Publishing

include drainage that can be purulent or nonpurulent (Bystritsky, 2021).

Diagnostic Tests: Unless purulent drainage has formed in the wound, tissue culture is usually not necessary (Silverberg, 2021). In cases of extensive infection or suspected systemic toxicity, blood cultures and a complete blood count (CBC) with differential should be obtained to determine the severity of illness and to identify the organism, including MRSA (Silverberg, 2021). C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) may be elevated in patients with severe cellulitis (Silverberg, 2021). Patients with diabetes mellitus should have a radiograph of the area and an ESR to rule out the presence of osteomyelitis or necrotizing infection (Bystritsky, 2021). Ultrasounds could detect abscesses or fascial inflammation if strongly suspected (Silverberg, 2021). Skin biopsies may be necessary to rule out the presence of fungal, viral, parasitic, or mycobacterial etiologies if suspected (Silverberg, 2021).

Differential Diagnosis:

- Lipodermatosclerosis (tender red plaque on the medial lower legs with venous stasis or varicosities)
- Stasis dermatitis (bilateral redness, irritation of lower extremities)
- Acute severe contact dermatitis (superficial edema, itching)
- Acute gout (synovial fluid aspiration contains monosodium urate crystals)
- Deep vein thromboses (DVTs) (lower extremity Doppler ultrasound)
- Pseudogout (synovial fluid aspiration contains calcium pyrophosphate crystal deposition)
- Early herpes zoster
- Atypical drug eruptions
- Erysipelas (superficial dermis cellulitis represented by demarcated erythematous area)
- Venous or varicose eczema (limited or localized erythema, absence of systemic symptoms)
- Diagnoses determined by radiographs, magnetic resonance imaging (MRI) or computed tomography (CT)
  - Necrotizing fasciitis (diffuse swelling of an arm or leg with bullae [clear or serosanguineous fluid], crepitus, and intense pain)
  - Osteomyelitis
  - Pyomyositis

(IDSA, 2014; Rrapi et al., 2021; Silverberg, 2021)

Treatment: Ask when the patient's last tetanus toxoid booster was given if an open wound is present. If the most recent booster was 10 years ago and the wound is grossly contaminated, the tetanus immune globulin should be administered immediately followed by the tetanus booster (CDC, 2020). If the wound is grossly contaminated and the patient's last tetanus booster was 5 to 10 years ago, the practitioner should consider giving another booster at this time (CDC, 2020). An older adult who has not had primary immunizations requires tetanus booster and tetanus immune globulin (CDC, 2020).

Patients with mild-moderate cellulitis may be given oral antibiotics (IDSA, 2014; Silverberg, 2021). The drugs of choice (typically for 5 to 7 days) include one of the following: dicloxacillin 500 mg qid; clindamycin 300 mg qid; amoxicillin/clavulanate 875 mg/125 mg bid; and a first-generation cephalosporin such as cephalexin 250 to 500 mg qid. (Bystritsky, 2021; ISDA, 2014). For streptococcal cellulitis, penicillin is the drug of choice (Bystritsky, 2021; IDSA, 2014). Treatment of MRSA (total duration of therapy is 7 to 14 days) should be guided by wound culture results of open wound and/or considered when the patient has higher risk factors for MRSA or cellulitis is nonresponsive to primary choice of treatment (Bystritsky, 2021; ISDA, 2014). Antibiotic choices include one of the following: clindamycin 300 to 600 mg four times daily; doxycycline 200 mg once followed by 100 mg every 12 hours; trimethoprim-sulfamethoxazole 160 mg/800 mg 1 to 2 tablets twice daily; or linezolid 600 mg every 12 hours (Bystritsky, 2021; ISDA, 2014). Newer oral agents are available for treatment of cellulitis but are reserved for when other agents cannot be used (Bystritsky, 2021). Consider the patient's renal function before prescribing any medication. For patients with complications or severe symptoms (especially systemic), hospitalization is recommended for monitoring and to receive IM/IV antibiotics (IDSA, 2014; Silverberg 2021).

Follow-Up: Symptoms of cellulitis may get worse within the first 24 hours to 48 hours after starting treatment but should begin to improve after that time (Bystritsky, 2021). Outpatients should be requested to contact their health-care providers within 1 week if no improvement with antibiotic use or within 48 hours if fever or inflammation continues.

Sequelae: Further issues caused by cellulitis include bacteremia, bullae, lymphangitis, and necrosis of the affected area (Bystritsky, 2021). Older adults have associated increased mortality from cellulitis so appropriate diagnosis and treatment is imperative (Kumar et al., 2020).

Prevention/Prophylaxis: Prevention of cellulitis includes good hand washing, avoidance of injury/trauma, minimizing edema, prevention of peripheral vascular disease, and controlling diabetes. Daily use of compression therapy to lower extremities prone to recurrent cellulitis reduces the risk of recurrence (Webb et al., 2020).

Referral: Patients with high fever, diabetes, alcoholism, HIV, anaerobic cellulitis, necrotizing fasciitis, or cellulitis of the orbit or face, or those experiencing extreme pain should be referred to an infectious disease specialist. A surgical consultation may be required for incision and drainage of abscesses and debridement of necrotic tissue.

Education: Patients with cellulitis must adhere to antibiotic dose, frequency, and duration of antibiotic treatment for optimal results. Avoid trauma to the area, keep the area clean, and elevate the affected area if able (especially if edema is present). If there are no contraindications, patients may use NSAIDs and acetaminophen for pain relief. If there is no DVT, suggest compression bandages to decrease edema (especially if edema causes recurrent cellulitis). As with any infection, blood glucose levels may need to be monitored in those with diabetes. There is an increased risk of DVT associated with cellulitis, and education should include signs and symptoms of DVT (report immediately if they occur). Treat underlying conditions that predispose the cellulitis, such as tinea, maceration, fissuring, chronic venous stasis, or lymphedema (Bystritsky, 2021).

CORNS AND CALLUSES

Signal Symptoms: Thickened skin or hyperkeratotic area on the foot or hand that is often painful. This section will focus on those occurring on the foot.

Description: Corns and calluses are benign skin lesions on the foot. Corns (helomas) can be soft (heloma molle) or hard (heloma duram). They have distinct borders as compared to callosities. Soft corns are spongy and most often found between the fourth and fifth toes. Hard corns form from calluses over time. They have a central core that is painful with weight-bearing. They occur on the plantar surface of the foot at the metatarsal heads and on the interphalangeal joints. A callus (tyloma) is a hardened area on the foot's plantar surface. Calluses usually are seen at the metatarsal heads, medially to the first metatarsal head and laterally to the fifth metatarsal head. Melo and colleagues (2015) report lesser-toe deformities, including hammer toes, claw toes, and mallet toes, predispose individuals to callus formation on the second through fifth distal surface of the toes.

Etiology: Mechanical forces of compression, shear, and torsion (Hashmi, 2013) put stress on the stratum corneum of the epidermis. This triggers a protective and inflammatory response. The stratum corneum cells form either a plaque (callus) that is superficial or cone shape (corn), which is pointed and deep (Hashmi, 2013).

Occurrence: Corns and calluses, the leading cause of foot pain, are prevalent in older adults with reports of at least 60% of the population experiencing plantar hyperkeratotic lesions (Spink et al., 2009).

Age: Corns and calluses are common with increasing age (Feldman, 2017). Older adults have a higher incidence because the aging process reduces fatty tissue and bones become more prominent (Nordqvist, 2014).

Ethnicity: Blacks report 30% greater occurrence than Whites (Feldman, 2017).

Contributing Factors:

Intrinsic. Bony prominences, foot deformity, mobility alterations, obesity, diabetes, peripheral neuropathy, peripheral arterial disease, anhidrosis, and hyperhidrosis.

Extrinsic. Poor fitting shoes, not wearing socks or wearing socks that fit poorly, high heels, thin-soled shoes, walking barefoot and standing, walking, or running for prolonged periods of time.

Signs and Symptoms: Pain can be the cardinal symptom of both lesions; however, calluses are usually asymptomatic, although they may be of cosmetic concern. Corns are often painful and interfere with daily activities, which is frequently the chief complaint in podiatry practices (Farndon et al., 2015).

Diagnostic Tests: Clinical examination and history taking is usually the method of discovery. A way to distinguish corns from plantar warts is the absence of capillary dotting, known as the Auspitz sign (Al Aboud & Yarrarapu, 2021). Radiographs may be ordered to assess bone anatomy and foot deformity. Hashmi (2013) reported ultrasound has been used but resolution is poor. Dermatology practices are using optical coherence tomography (OCT) to assess before and after treatment (Baillie et al., 2011; Hashmi, 2013). Dermatoscopy may be used to observe and analyze skin lesions. Pressure studies may assist in identifying areas of high pressure on the plantar surface.

Differential Diagnosis:

- Plantar wart
- Poroma
- Warty dyskeratoma
- Gout and pseudogout
- Hypertrophic lichen planus
- Foreign body granuloma
- Porokeratosis
- Underlying ulcer
- Fungal infection (Al Aboud & Yarrarapu, 2021; Feldman, 2017)

Treatment: Self-maintenance of minor calluses can be done by soaking the feet in warm water and sanding the affected area with a pumice stone. Calluses may be softened with emollients (with and without urea). Homeopathic preparations from clove, garlic, aloe vera, barleria prionitis, lantana camera, moringa oleifera, and tecoma capensis provide

© F.A. Davis Publishing

medicinal benefits (anti-inflammatory, antimicrobial, antioxidant, and analgesic properties) for wound healing and can be applied topically (Anil et al., 2020). Barrier creams and occlusive materials, such as silicone sleeves may reduce friction (Hashimi, 2013) and prevent callus and corn formation. Crest pads (off-loading pressure with padding) will reduce pressures (Curran et al., 2015). Salicylic acid plasters and mechanical debridement or paring with a 15-blade scalpel are two successful treatments for removing corns (Farndon et al., 2013). One study of self-perception of pain following three scalpel debridement of painful calluses versus partial debridement was the same in older adults, thus patients need to be aware that there may be a level of pain with debridement (Garcia & Soler, 2020). High-risk patients with some toe deformities may require surgery. Percutaneous digital flexor tendon tenotomy, which is used to straighten a toe when conservative treatment has been unsuccessful (Bus et al., 2016), and electrosurgery (Hashmi, 2013) are two other recognized methods. Ablative laser surgery is available now and is favored by some over sharp debridement (Al Aboud & Yarrarapu, 2021). Microwave therapy has shown positive results for hyperkeratotic lesions (Bristow & Webb, 2020). Patients with diabetes and those with neuropathy should be advised to never use a chemical treatment on their feet. This could damage normal skin without them knowing it (Al Aboud & Yarrarapu, 2021).

Follow-Up: Follow-up is determined by the intervention type. Use of salicylic acid plasters usually demand a follow-up appointment within 1 week to assess the progress of the chemical debridement, the need for mechanical debridement of affected skin, and to assess for any complication (Farndon et al., 2013).

Sequelae: Untreated corns and calluses usually result in extended periods of pain, possible alteration in mobility that could result in falls, and a general decline in quality of life. There is the potential to develop septic arthritis and osteomyelitis (Al Aboud & Yarrarapu, 2021). According to Bus et al. (2016), patients with diabetes are especially at risk as these lesions may ulcerate, become infected, and worst-case scenario, require amputation.

Prevention/Prophylaxis: Encourage self-awareness and inspection of the feet as a basic self-care measure. Providers should inspect the feet of patients with diabetes at every visit. Proper footwear is essential. The shoe must be the proper size and not cause any friction. If a problem area is identified, inspect the inside of the shoe for problems. Lamb's wool and toe pads of felt or silicone may be used to protect the affected area. Prescribed orthotic inserts or therapeutic shoes may be necessary.

Referral: Primary care providers can address the problems associated with corns and calluses; however, podiatric, orthopedic, or neurology referral for patients with complicated corns and calluses should be made when treatment prescribed has not alleviated or improved the problem (Al Aboud & Yarrarapu, 2021).

It is recommended that patients with diabetes see a podiatrist annually (Bus et al., 2015) and with more frequency if high risk factors or problems exist.

Education: Advise patients to maintain good foot hygiene: washing feet regularly, keeping toenails clipped, and wearing clean socks and shoes that fit properly. Diabetic patients should be instructed to wash and inspect their feet daily, looking for problematic areas, and to seek medical assistance when lesions are apparent. Counsel patients on the prevention measures mentioned previously.

HERPES ZOSTER

Signal Symptoms: Cutaneous eruption of a dermatome distribution; burning, itching, or tingling skin sensation.

Description: Herpes zoster (HZ) is an acute vesicular eruption caused by a virus histologically identical to the varicella (chickenpox) virus—human (alpha) herpes virus 3 (varicella-zoster virus [VZV]), a member of the herpes virus group.

Etiology: Recurrent VZV infection causes herpes zoster. All patients with HZ have incurred some version of primary VZV exposure, usually in childhood, either from contact with a

© F.A. Davis Publishing

person who is sick with the virus or from the primary vaccination (Rosamilia, 2020). The DNA virus resides within the neurons. VZV migrates to adjacent sensory dermatomes. Vesicles with pustulation begin to form within 7 days of the rash onset. Pustulated vesicles form scabs/crusting within 10 days of onset (Le & Rothberg, 2019). Older adults have a decrease in cell-mediated immunity, which contributes to the risk of developing herpes zoster and postherpetic neuralgia (PHN). The incidence of HZ increases with age in persons older than 80 years (Dooling et al., 2018).

Although chickenpox is one of the most readily communicable diseases, HZ has a much lower rate of transmission. Nonimmune persons are considered contagious 8 to 21 days after exposure to VZV. Transmission occurs upon contact with the vesicle fluid. Patients with herpes zoster may be sources of infection for 1 week after the appearance of vesicle lesions.

Occurrence: HZ occurs worldwide, more commonly in older adults. Incidence increases markedly in those 60 years old or older as a result of impaired cell-mediated immunity. One case of herpes zoster occurs for every 100 older adults (Centers for Disease Control and Prevention [CDC], 2020). In the United States, more women are diagnosed with HZ than men (CDC, 2020).

Age: This infection is most common in adults older than 55 years old. It is estimated that the risk of contracting HZ is greater than 50% for those 85 years of age or older. (CDC, 2020).

Ethnicity: Herpes zoster is 50% less common in the African American population (CDC, 2020).

Contributing Factors: Individuals are more likely to develop herpes zoster if they are more than 55 years old, have diabetes mellitus, have had an organ transplant, are immunosuppressed (e.g., patients infected with HIV), have certain malignancies, are receiving long-term corticosteroids, are receiving chemotherapy, or are taking radiation treatments (CDC, 2020).

Signs and Symptoms: Patients usually experience hyperesthesia with an itching, burning, or tingling pain at the site 4 to 5 days before the eruption appears. Pain in a dermatomal pattern may precede the appearance of the vesicles by weeks, however. Allodynia, the presence of pain without a painful stimulus applied to the area, may also be experienced (Ganty, 2014). Patients often experience a sense of anxiety, malaise, headache, fever, and flu-like symptoms with the onset of HZ. Patients may report sleep disturbances, decreased appetite, and depression. There may be reported pain around the eye if ophthalmic HZ later develops. A rash, initially erythematous, forms into vesicular lesion when the VZV reactivates in the dorsal ganglia. The vesicles are clear at first and then become cloudy within 3 to 5 days. T1 to L2 are the most common vertebral dermatomes involved, followed by cervical and sacral dermatomes (Le & Rothberg, 2019). As vesicles age, they become pustular, then crust over after 7 to 10 days, finally healing in 2 to 4 weeks (CDC, 2020; Ganty, 2014).

Lesions may appear in irregular crops and are typically unilateral. Scarring and change in pigmentation may occur following the healing of the crusted vesicles. The most common distributions are on the trunk or face in elderly. The pain can last 6 to 12 months after disappearance of the rash (PHN). Ocular complications occur in about one-half of patients with involvement of the ophthalmic division of the trigeminal nerve. These complications may include keratitis, anterior uveitis, and corneal ulceration. Vesicles on the tip of the nose, known as Hutchinson sign, have been found to be a precursor to ocular involvement in HZ (Sampathkumar et al., 2009). Cutaneous or visceral dissemination, the appearance of numerous varicella-like lesions in extradermatomal sites, may cause pneumonitis, encephalitis, meningitis, myelitis, and hepatitis (CDC, 2020; Fashner & Bell, 2011). The reactivation of VZV in the geniculate ganglion produces vesicles in the mucocutaneous distribution of the peripheral nerves. Known as Ramsey-Hunt syndrome, patients may experience vesicles in the pharynx and external auditory canal, tinnitus, vertigo, one-sided hearing loss, nausea and vomiting, involuntary eye movements and often paralysis on one side of the face (Sampathkumar et al., 2009).

Diagnostic Tests: Diagnosis usually is based on clinical appearance and distribution of the eruption and on a careful history of when the rash appeared. The direct immunofluorescence with fluorescein-tagged antibody (DFA) or polymerase chain reaction (PCR) is preferred over the old standard Tzanck smear. The PCR has the highest sensitivity and specificity. It detects DNA in fluids and tissues (Le & Rothberg, 2019).

Differential Diagnosis:

Pain
- Migraine
- Trigeminal neuralgia
- Myocardial infarction
- Acute abdomen
- Renal colic
- Pericarditis
- Pleuritis
- Pulmonary embolism
- Cholecystitis

Rash
- Contact allergic dermatitis
- Herpes simplex (Le & Rothberg, 2019)

Eye Symptoms
- Ulcerative keratitis
- Acute angle closure glaucoma

Treatment: Antiviral agents are recommended in the presence of significant pain, serious HZ, or involvement near the eye. PHN is not prevented by antiviral therapy, but these agents may decrease PHN duration. Give acyclovir 800 mg five times a day for 7 days: famciclovir 500 mg orally every 8 hours for 7 days, or valacyclovir 1,000 mg orally every 8 hours for 7 days (Saguil et al., 2017). These drugs must be given within 72 hours after onset of rash to be effective, and their use must be monitored in patients with reduced renal function (Beuscher et al., 2017; Tyring et al., 2000). Patients with disseminated disease and those who are immunocompromised may need IV antiviral medications.

Glucocorticoids are used at times as an adjunct to antiviral therapy; these agents have been said to reduce acute pain and can speed healing (Saguil et al., 2017). However, in three adequately powered random controlled studies, evidence was insufficient to support this (Dvorin & Ebell, 2020). Topical

© F.A. Davis Publishing

agents are also effective in treating the initial symptoms of herpes zoster. The use of cool compresses with 1:20 Burrow's solution, calamine lotion, and topical lidocaine (Xylocaine) is recommended for the soothing local effect. Topical antivirals are not recommended (Le & Rothberg, 2019).

Analgesics may be necessary for the initial prodromal pain associated with HZ. Acetaminophen and NSAIDs are recommended initially, but around-the-clock dosing is needed for optimal pain control. Tramadol may be used for moderate pain, and stronger opioids are used for severe pain.

The capsaicin 8% cream and 5% lidocaine patch have been recommended for first-line pain management of PHN. Capsaicin cream is not recommended for acute HZ but is more economical compared to the lidocaine patch. Both are available over the counter (Derry et al., 2017; Saguil et al., 2017; Schmader, 2018).

Gabapentin and pregabalin are also recommended for the treatment of PHN. The initial dose of gabapentin is 300 mg on the first day and is titrated up gradually until pain relief is safely reached. The maximum does of gabapentin is 3,600 mg per day (Chou et al., 2009).

Pregabalin is also recommended for the treatment of PHN and can be administered 50 mg three times a day or 75 mg twice a day. The dosage can be increased to 300 mg daily after 3 to 7 days as tolerated, followed by 150 mg every 3 to 7 days. The maximum recommended dose is 600 mg per day. Caution is advised when prescribing gabapentin and pregabalin to older adults, given probably reduced renal function and the side effects of dizziness and ataxia.

The secondary amine tricyclic antidepressants, nortriptyline 10 mg orally or desipramine 10 to 25 mg orally, have been used in the past; however, because of the anticholinergic side effects in the older population, caution is warranted. Studies show that pain relief with gabapentin and tricyclic antidepressants were the same (Chou et al., 2009). The use of Magnesium sulfate for chronic PHN has proven to be as effective as ketamine. (Shin et al., 2020). Alternative methods of pain management include transcutaneous electrical nerve stimulation, acupuncture, cupping, and meditation.

Follow-Up: Patients should be reexamined in 2 to 4 weeks to monitor progression of rash and as needed for follow-up of PHN.

Sequelae: PHN is the primary complication, occurring almost exclusively in people over 60 years old. Twenty percent of people older than the age of 85 years diagnosed with HZ develop PHN (Ganty, 2014). This pain persists at least 6 weeks after skin lesions. The pain, characterized as constant, severe, sharp, or burning, may develop into a long-standing, debilitating problem. PHN usually lasts 1 year or less. Another possible consequence of HZ is a secondary bacterial infection leading to cellulitis. There is also an increased risk of an acute cardiovascular event, such as a cerebrovascular accident or myocardial infarction in the weeks to months after an episode of HZ (Kim et al., 2017).

Prevention/Prophylaxis: The newest vaccine for herpes zoster (Shingrix) is available and is recommended for patients aged 50 years and older (CDC, 2020; Dooling et al., 2018). People who have had HZ should receive the vaccine to help prevent future occurrences of the disease. The immunization is also recommended without any serologic testing, history of varicella, or history of HZ. The vaccine is given in two doses, with the second dose to be given 2 to 6 months after the first dose. Patients should be scheduled for the second visit (Dooling et al., 2018; Resnick, 2017). With the protection of the Zostavax vaccination waning within the first 5 years and protection uncertain (CDC, 2019; Dooling et al., 2018), it is recommended that patients be protected with the Shingrix vaccination even if they have had the Zostavax vaccine in the past (Dooling et al., 2018; Resnick, 2017). Practitioners are advised to review the listed contraindications before administering the HZ vaccine. High-risk individuals, such as immunosuppressed patients and individuals who may not be able to receive the Shingrix vaccine or have not had chickenpox, may benefit from low-dose acyclovir which could prevent HZ (Schmader, 2018). These individuals should also distance themselves from patients with HZ.

Referral: Because of probable ocular involvement, patients with lesions on the nose or in the eye area should be referred to an ophthalmologist. Patients with disseminated HZ in need of IV antivirals should be referred to an infectious disease specialist. Patients with severe uncontrollable PHN should be referred to a pain management clinic, and a neurology referral may be necessary for HZ with neurological complications such as vasculopathy or neuritis (Schmader, 2018).

Education: Emphasize to the patient the need to stay home and get plenty of rest. Patients are to be advised to keep area clean and dry to prevent superimposed infections that may be caused by excessive scratching. Proper infection control measures and proper disposal of dressings should be encouraged, especially in regard to items of clothing that contain vesicle fluid. This fluid may infect known contacts that are vulnerable for developing varicella; therefore, patients should avoid direct body contact with individuals who are immunocompromised or have not had chickenpox. Covering open, wet lesions may decrease transmission. The respiratory tract of infected people may also shed virus from the respiratory tract (Le & Rothberg, 2019).

PRESSURE INJURIES

Pressure injuries are classified through the use of staging systems. These systems describe the degree of tissue loss and the clinical presentation of the injury caused by pressure and/or shear. Pressure injury staging has become the basis for treatment, comparison of outcomes, and, if applicable, reimbursement. It is noteworthy that in April 2016 the National Pressure Ulcer Advisory Panel (NPUAP, now National Pressure Injury Advisory Panel, NPIAP) updated the Pressure Injury Classification System after a rigorous literature review by an appointed task force, soliciting input from stakeholders and the public, and hosting the consensus conference with over 400 stakeholders in attendance. The revisions reflect current scientific and clinical understanding of the etiology of pressure injuries, as well as clarify and make the system more accurate and easier to use (Edsberg et al., 2016).

Only pressure injuries should be staged with the NPIAP Staging System. Non–pressure-related ulcers and wounds are subject to unique staging or classification systems based on wound type; these include diabetic foot ulcers (Wagner Classification System), venous leg ulcers (Clinical Etiology Anatomy Pathophysiology [CEAP]), skin tears (International Skin Tear Advisory Panel [ISTAP]), medical adhesive or tape injuries (Medical Adhesive Related Skin Injury [MARSI] categories) and burn classification (TBSA). It is essential to confirm the presence of pressure and/or shear as a causative factor prior to using the NPIAP Staging System for an injury. Because the NPIAP Staging System is based on the extent of tissue damage, an understanding of anatomy is required prior to evaluating tissue types found in wounds. Finally, to ensure an accurate assessment, pressure injury staging should take place only after a wound has been thoroughly cleansed. In 2016, several revisions, which follow, were made to the NPIAP Staging System.

Signal Symptoms: Intact skin with a localized area of nonblanchable erythema may be present, which may appear differently in darkly pigmented skin. It is usually over a bony prominence or related to a medical device. Presence of blanchable erythema or changes in sensation, temperature, or firmness may precede visual changes. Partial-thickness involves loss of skin with exposed dermis, intact serum-filled blister. Full-thickness loss of skin with visible adipose (fat) tissue and/or deeper structures such as fascia, muscle, tendon, ligament, cartilage, or bone may be exposed. Wound edges may be open or present with epiboly (closed or rolled edges). Depth may be obscured by the presence of necrotic tissue, resulting in an unstageable pressure injury until such time when the wound bed becomes visible, and the degree of tissue damage can be determined. Intact or nonintact skin may be present with a purple or maroon discoloration and/or an epidermal separation revealing a dark wound bed or blood-filled blister (European Pressure Ulcer Advisory Panel, National Pressure Injury Advisory Panel, and Pan Pacific Pressure Injury Advisory Panel [EPUAP/NPIAP/PPPIAP], 2019)

Description: A pressure injury is localized damage to the skin and underlying soft tissue usually over a bony prominence or related to a medical device. The injury can present as intact skin or an open ulcer and may be painful. The injury occurs as a result of intense and/or prolonged pressure or pressure in combination with shear. The tolerance of soft tissue for pressure and shear may also be affected by microclimate, nutrition, perfusion, comorbid conditions, and condition of the soft tissue. Common terms for pressure injury include *pressure ulcer, decubitus ulcer, bedsore*, and *pressure sore.* There are six pressure injury stages and two categories pertaining to etiology based on anatomical location (Edsberg et al., 2016):

- Stage 1: Intact skin with a localized area of nonblanchable erythema, which may appear differently in darkly pigmented skin. Presence of blanchable erythema or changes in sensation, temperature, or firmness may precede visual changes. Color changes do not include purple or maroon discoloration; these may indicate DTPI.
- Stage 2: Partial-thickness loss of skin with exposed dermis. The wound bed is visible, pink or red, moist, and may also present as an intact or ruptured serum-filled blister. Adipose (fat) is not visible and deeper tissue is not visible. Granulation tissue, slough, and eschar are not present. These injuries commonly result from

© F.A. Davis Publishing

adverse microclimate and shear in the skin over the pelvis and shear in the heel.

- Stage 3: Full-thickness skin loss in which adipose (fat) is visible in the ulcer and granulation tissue and epibole (rolled wound edges) is often present. Slough and/or eschar may be visible. The depth of tissue damage varies by anatomical location: areas of significant adiposity can develop deep wounds. Undermining and tunneling may occur. Fascia, muscle, tendon, ligament, cartilage, or bone is not exposed. If slough or eschar obscures the extent of tissue loss, this is an unstageable pressure injury.
- Stage 4: Full-thickness skin and tissue loss with exposed or directly palpable fascia, muscle, tendon, ligament, cartilage, or bone in the ulcer. Slough and/or eschar may be visible. Epibole (rolled wound edges), undermining, and/or tunneling often occur. Depth varies by anatomical location. If slough or eschar obscures the extent of tissue loss, this is an unstageable pressure injury.
- Unstageable: Full-thickness skin and tissue loss in which the extent of tissue damage within the ulcer cannot be confirmed because it is obscured by slough or eschar. If slough or eschar is removed, a stage 3 or stage 4 pressure injury will be revealed. Stable eschar (i.e., dry, adherent, intact without erythema or fluctuance) on ischemic limbs or heels should not be softened or removed.
- DTPI: Intact or nonintact skin with localized area of persistent nonblanchable deep red, maroon, purple discoloration, or epidermal separation revealing a dark wound bed or blood-filled blister. Pain and temperature change often precede skin color change. Discoloration may appear differently in darkly pigmented skin. This injury results from intense and/or prolonged pressure and shear forces at the bone-muscle interface. The wound may evolve rapidly to reveal the actual extent of tissue injury or may resolve without tissue loss. If necrotic tissue, subcutaneous tissue, granulation tissue, fascia, muscle, or other underlying structures are visible, this indicates a full-thickness pressure injury (unstageable, stage 3, or stage 4). Do not use DTPI to describe vascular, traumatic, neuropathic, or dermatological conditions.

Ulcer Versus Injury. The 2016 NPUAP Pressure Injury Staging System used the term *injury* instead of *ulcer.* After an intensive review, the panel determined that the term *ulcer* did not accurately describe the clinical presentation of a stage 1 pressure injury or a deep tissue pressure injury (DTPI). In short, an ulcer cannot be present without an injury, but an injury can be present without an ulcer.

Roman Versus Arabic Numerals. Roman numerals were changed to Arabic numerals in each of the numbered stages. This change was made to clarify and reduce the potential for confusion between similar terms used in health care, such as stage IV and intravenous (IV).

Artwork. Artwork was created to illustrate the features of each stage of pressure injury. It is a graphic representation of the tissues present and is to be used for teaching about the extent of injury and the tissues present or absent within each stage of pressure injury. A color version of the artwork is available as a free download on the NPIAP Web site at (https://npiap.com).

Suspected Removed, Pressure Inserted in DTPI. The word *suspected* has been removed from the term *deep tissue injury* and the word *pressure* inserted for consistency with the revisions of the other terms.

Teaching Points. Teaching points (key elements of understanding) have been included with each stage. Educators and those responsible for the accuracy, as well as the interrater reliability of serial assessments, can use these teaching points as elements of an orientation or skills competency program for bedside care providers.

Etiology: Although the science regarding the etiology of pressure injuries has supported the role of tissue deformation, microclimate, nutrition, perfusion, and tissue tolerance, the exact mechanism of pressure injury development is poorly understood (Edsberg et al., 2016). Classic references by Kottner and colleagues (2009) describe four causation theories: ischemia caused by occlusion of the capillaries leading to vascular insufficiency, tissue anoxia, and cell death; reperfusion injury (i.e., cellular injury resulting from the reperfusion of blood to previously ischemic tissue); impairment of lymphatic function leading to a build-up of metabolic waste products; and mechanical deformation of tissue cells (Kottner et al., 2009). The type of tissue involved is also important, with epidermis and dermis being more resilient to the effects of pressure than muscle (Kottner et al., 2009). Also, the type of force or combination of forces (i.e., pressure, shear, friction) exerted on the tissue is important. Pressure and shearing forces mainly affect deeper tissue layers, with moisture, pressure, and friction affecting primarily superficial layers (Kottner et al., 2009). Consequently, pressure is believed to be the major causative factor in pressure injury formation. Several factors play a role, however, in determining whether pressure is sufficient to create an injury. Bergstrom and colleagues (2013) studied the pathological effect of excessive pressure on soft tissue and determined pressure injuries can be attributed to intensity of pressure, duration of pressure, and tissue tolerance (the ability of skin and its supporting structures to endure pressure without adverse sequelae). Injury occurs to the skin and underlying tissues. Ischemia and hypoxia result as the pressure is applied to the area. Waste products accumulate as the ischemia continues, which produces toxins that cause further tissue breakdown.

Medical Device-Related Pressure Injury. Medical device-related pressure injuries result from the use of devices designed and applied for diagnostic or therapeutic purposes. The resultant pressure injury generally conforms to the pattern or shape of the device. The injury *should* be staged using the 2016 NPIAP Pressure Injury Staging System (Delmore & Ayello, 2017).

Mucosal Membrane Pressure Injury. Mucosal membrane pressure injuries (MMPI) are found on mucous membranes with a history of a medical device in use at the location of the injury. Mucosal tissues are especially vulnerable to pressure from medical devices such as oxygen tubing, endotracheal tubes, bite blocks, orogastric and nasogastric tubes,

© F.A. Davis Publishing

indwelling urinary catheters, and fecal containment devices. Because the 2016 NPIAP Pressure Injury Staging System for cutaneous injuries is based on the anatomy of the skin, it *cannot* be used to stage mucosal pressure injury. Development of a classification system for MM pressure injuries has been undertaken with testing of reliability performed in an intensive care setting (ICU). The Reaper Oral Mucosa Pressure Injury Scale (ROMPIS), which described three stages of MM pressure injury, showed moderate interrater reliability. This classification system is undergoing further validation. (Reaper et al., 2017).

Occurrence: Definitive information on the occurrence of pressure injuries is limited. Studies to date have been encumbered by methodological issues such as variability in describing the lesions and in differentiating pressure injuries from lesions of other etiologies. Consequently, pressure injuries are common; increase patient morbidity and mortality; and are costly for patients, their families, and the health-care system (Bauer et al., 2016).

The incidence in hospitalized patients ranges from 2.7% to 29% and the prevalence in hospitalized patients ranges from 3.5% to 69%. Patients in critical care units have an increased risk of pressure injuries, as evidenced by a 33% incidence and 41% prevalence. Older adults admitted to acute care hospitals for nonelective orthopedic procedures, such as hip replacement and treatment of long bone fractures, are at even greater risk, with a 66% incidence (Engels et al., 2016)

In the nursing home environment, the prevalence of pressure injuries is in the range of 2.6% to 24%. The incidence has been as high as 25% in residents admitted from an acute care hospital. Patients with preexisting pressure injuries demonstrate a 26% incidence of additional pressure injury formation over a 6-month period. The incidence in chronic care hospitals is reported to be 10.8%, whereas 33% of those admitted to a chronic care hospital have pressure injuries. Long-term follow-up demonstrates that most injuries healed within a year. Persons with spinal cord injury and associated comorbidity are also at increased risk. The incidence of pressure injuries in this population is in the range of 25% to 66%.

Age: It has long been believed that comorbid conditions are associated with pressure injuries, and age is considered a comorbid state. Recent literature reviews suggest, however, that age is a confounding factor and a general indicator of likely deficits in the main areas of risk, including mobility/activity, skin status, perfusion and oxygenation, nutrition, and skin moisture (EPUAP, 2019). Prevalence of pressure injuries in the older adult population is 11.6% to 27.5%, with the increased risk being assigned to those of advancing age. The incidence in skilled care and nursing home facilities is approximately 25%. Patients admitted to a hospital geriatric unit have similarly high prevalence rates: of patients under 70 years of age, only 6% have pressure injuries; of patients older than 70 years of age, the prevalence almost doubles to 11.6%.

Ethnicity: Cited in the literature and mentioned in the NPIAP 2016 Staging System Update is that there may be some difficulty in detecting stage 1 pressure injuries in persons with darker skin pigmentation because the red-hued changes may appear more subtly in persons with darker skin tones. Thermography has been shown to improve skin assessments in patients with dark skin tones. (Black and Simende, 2020).

Contributing Factors: The main contributing factors to pressure injury development are pressure, shear, adverse microclimate, and malnutrition. Moisture is cited as a related condition because it alters the resiliency of the epidermis to external forces. The primary offending source of moisture is incontinence, and more fecal incontinence than urinary incontinence due to the significantly higher pH of feces (liquid greater than solid) when compared to that of urine. The skin's pH is an acid mantle (i.e., 5.5). Understanding the concept and presentation of moisture associated skin damage (MASD), particularly the two subcategories of incontinence associated dermatitis (IAD) and intertriginous dermatitis (ITD), are essential in the differential diagnosis of pressure injuries from those partial-thickness tissue injuries that are not resultant from pressure (Gray et al., 2011).

Signs and Symptoms: A detailed history of the pressure injury should be obtained from the patient or caregiver, including chronic illness, hygiene, nutritional status, immobility, presence and type of prolonged moisture, ability to perform activities of daily living (ADLs), psychological impact of injury, and sources of available support. Ask the patient if they have pain over or near bony prominences or beneath medical devices.

Clinical presentation can vary from nonblanching erythema to partial-thickness tissue loss and frank tissue necrosis. Nonblanching erythema results from damage to blood vessels and extravasation of blood into the tissue. Its presence suggests that more extensive tissue damage is imminent or has already occurred. The color of the skin can be varying hues of pink to red to darker toned hues of maroon or purple. Pressure-induced nonblanching erythema is occasionally misdiagnosed as a hematoma or ecchymosis. When DTPI is also present, the area is often either indurated or boggy when palpated. Note the injury size; obtain serial measurements of length, width, and depth; note the characteristic of the wound edge (open or epibole [rolled]); note the presence and character of exudate, epithelialization, granulation tissue, deeper structures, and findings such as necrotic tissue, sinus tracts, undermining, tunneling, and other signs of infection, such as induration, warmth, and/or advancing erythema (McNichol et al., 2022)

Diagnostic Tests: General laboratory tests for the patients with a pressure injury include wound culture and sensitivity. Particularly look for any of the following:

- Signs of local infection (erythema, edema, change in exudate to include purulent or foul-smelling drainage, pain, crepitus)
- Signs of systemic infection (fever, leukocytosis); bone involvement (due to risk of osteomyelitis)
- Presence of chronicity to determine whether there is a causative, elusive organism

Evaluation of nutritional status should include total protein, albumin, and prealbumin; in patients with a pressure injury, often these clinical indicators are decreased because of inadequate nutritional stores present for tissue repair. A CBC may reveal increased red blood cell distribution,

© F.A. Davis Publishing

decreased lymphocyte count (malnutrition), and elevated leukocyte count (osteomyelitis). The erythrocyte sedimentation rate will be increased. X-rays of the appropriate area often reveal bony rarefaction (decreased density), periosteal elevation, and new bone formation. New ICD-10-CM diagnosis codes for Moisture-Associated Skin Damage (MASD) have been approved by the ICD-10 Coordination and Maintenance Committee and will take effect on October 1, 2021. These codes will improve patient care and outcomes, resource allocation, clinician education, data collection, and facilitate research.

Differential Diagnosis:

- Skin cancers (neoplasms)
- Fungal or yeast infections
- Herpes simplex (HSV-2)
- HZ (shingles)
- Lower extremity wounds (venous, arterial, mixed etiology, and neuropathic etiology in origin)
- MASD, particularly IAD and ITD
- Burns (thermal injuries) (McNichol et al., 2015)

Treatment: Effective pressure injury treatment with topical dressings requires consideration of numerous factors. Consider use of the mnemonic I DIP A MOP:

- **I**nfection (eliminate, reduce bioburden)
- **D**ebride necrotic tissue (consider surgical/conservative, sharp, mechanical, enzymatic, biologic, autolytic)
- **I**nsulate the wound
- **P**rotect periwound tissue
- **A**bsorb excess exudate
- **M**aintain a constant moisture level
- **O**bliterate dead space
- **P**revent further injury

Pharmacological Management. Most moisture-retentive dressings are available without a prescription. Some antimicrobials (e.g., silver sulfadiazine, mupirocin), some antifungals (e.g., fluconazole), and some enzymatic debriding agents (e.g., collagenase) are prescriptive.

Follow-Up: Practitioners need to objectively evaluate the patient's progress toward healing at least weekly using standardized methods of assessment (e.g., wound measurements in three dimensions, amount of exudate, patient comfort, etc.). Immediate intervention is indicated if wound deterioration is observed sooner. If the wound deteriorates, is it in accordance with a decline in the patient's overall condition? It is important to communicate this decline as an expected result to patient, caregivers, and staff. The patient's general health and nutritional intake, the stability of the comorbid conditions, the need for psychological support, and the patient's comfort level should be monitored. Signs and symptoms of complications need to be reported and recorded accurately (McNichol et al., 2022).

Sequelae: Complications include, but are not limited to, cellulitis, bacteremia, osteomyelitis, and sepsis (secondary to pressure injuries).

Prevention/Prophylaxis: Use a valid and reliable risk assessment tool (e.g., Braden, Norton) at the first encounter and at regular intervals thereafter for patients at risk. Specific interventions are to be directed at the first encounter and at regular intervals following initial appraisal of skin and should be targeted toward improving subscale scores in any areas in which the patient's score falls below normal. Enlist the support of an interdisciplinary care team (e.g., nurse, physician, physical therapist, caregiver, dietitian, pharmacist) to ensure all goals of care are addressed adequately. Consider support surfaces for bed and/or chair when decreased mobility and moisture are risk factors (McNichol et al., 2020).

Referral: Consider referral to a wound care specialist (wound, ostomy, and continence [WOC] nurse, plastic surgeon, infectious disease practitioner, dermatologist) if wounds fail to progress in spite of evidence-based interventions consistent with the overall plan of care.

Education: Practitioners should provide patients and their caregivers with information that highlights the applicable contributing factors to the development of pressure injury formation and information about techniques being used (or those attempted, but not tolerated by the patient) pertaining to mitigation of those contributing factors.

- Review available and appropriate treatment modalities for each identified stage of wound progression, as well as expected outcomes and anticipated time frames for healing.
- Discuss reportable signs and symptoms of infection and complications.
- Discuss advances in technology and dispel myths that may exist regarding wound care.
- Identify informative Web-based resources and explain that information available via electronic means and/or from well-meaning individuals may not be evidence based.
- Discuss hand hygiene and disposal of soiled dressings.
- Review the importance of positioning, sources of dietary protein, and the amount to be consumed during the wound repair process.

Clinical Recommendation	Evidence Rating	References
When conducting a pressure injury risk assessment: • Use a structured approach. • Include a comprehensive skin assessment. • Supplement use of a risk assessment tool with assessment of additional risk factors. • Interpret the assessment outcomes using clinical judgment.	C	EPUAP/NPAIP/PPPIA, 2019

PSORIASIS

Signal Symptoms: There are several forms of psoriasis. The most common is plaque psoriasis, with erythematous patches, papules, and plaques with silvery scales that may be pruritic. Other forms include inverse psoriasis in intertriginous areas that appears as a smooth plaque; guttate, which is a rare form that presents with pustules; pustular, a rare pustular eruption which can occur in association with another form of psoriasis or independently; and erythrodermic, which can be deadly with generalized rash. Up to 30% of those diagnosed with psoriasis will develop psoriatic arthritis, which shares features of both rheumatoid and spondyloarthritis (Ritchlin et al., 2017).

Description: Psoriasis is a common inflammatory skin disease that results from a combination of environmental triggers and genetics. Well-defined, erythematous plaques with an overlying silvery scale are characteristics of the most common variant, chronic plaque psoriasis (Bolognia et al., 2018). If the scale is removed traumatically, the presence of bleeding points, Auspitz sign, is noted. When the lesion is present in intertriginous areas, the moist environment macerates the scale, so the lesion appears as a smooth plaque. This is referred to as inverse psoriasis. Guttate psoriasis presents as an acute eruption of generalized round or raindrop-like, scaly papules. Pustular psoriasis, in contrast to papular types, include pustular psoriasis of the palms and soles or generalized pustular psoriasis (Zumbusch psoriasis). The least common, yet the most life-threatening variant is erythrodermic psoriasis. It occurs most often as an acute eruption of large, red patches with desquamation in those diagnosed with plaque psoriasis. Less often, it can occur as the first sign of psoriasis (Bolognia et al., 2018). Frequently, those with psoriasis have involvement of either the fingernails or toenails. Fingernail involvement is more common (Habif, 2016; Wolff et al., 2017).

Psoriasis can also affect the joints, causing a seronegative inflammatory arthritis, psoriatic arthritis. It is also associated with other chronic diseases such as cardiovascular disease, metabolic syndrome, and nonalcoholic steatohepatitis (Botelho et al., 2020; Miller et al., 2014). Generally, the symptoms of psoriasis occur in those aged 30 to 39 years and 50 to 69 years. Joint symptoms occur before skin psoriasis in about 15% of cases. Symptoms include early morning stiffness; warm, red joints; and effusions.

© F.A. Davis Publishing

Etiology: Genetic susceptibility, an altered immune response, and a variety of environmental triggers drive the pathogenesis of psoriasis. Interactions between T cells, cytokines, keratinocytes, neutrophils, and dendritic cells play a role in the initial onset and duration of skin inflammation (Armstrong & Read, 2020). Approximately 40% of patients with psoriasis or psoriatic arthritis have a family history of the disease. In addition to the genetics, environmental factors are often the trigger, including skin trauma (Koebner phenomenon), streptococcal or viral infection, stress, medications, smoking, and alcohol consumption (Patterson, 2016).

Occurrence: Psoriasis affects about 2% of the world's population and as high as 4.6% in the United States, or about 15.5 million Americans (Michalek et al., 2016). Chronic stable plaque psoriasis is the most common type, affecting up to 80% of those with psoriasis. Guttate psoriasis most often occurs in younger adults and represents about 8% of patients with psoriasis (National Psoriasis Foundation, 2021). There is an equal incidence of the disease in males and in females.

Age: Psoriasis can have a bimodal age presentation with the peak incidence at age 22.5 with a late onset occurring between 55 to 69 years of age. Women tend to have earlier onset, and earlier onset is associated with more severity of the disease. Psoriatic arthritis occurs most often in those between the ages of 30 and 50 years (National Psoriasis Foundation, 2017).

Ethnicity: Prevalence is highest among Scandinavians, with low incidence in West Africans, Japanese, and Inuits. There is a very low incidence among North and South American Indians. African Americans also have a low incidence of 1.3% compared with 2.5% of European Americans.

Contributing Factors: In addition to genetics, medications, and infections, potential triggers for psoriasis include environmental, medical, and behavioral risk factors. Approximately 40% of those with psoriasis or psoriatic arthritis report a family history of the condition (Lopez-Estebaranz et al., 2015). A streptococcal or viral infection often precedes the onset of guttate psoriasis by 2 weeks. Drugs that may precipitate or exacerbate psoriasis include lithium, beta blockers, antimalarial agents, tetracyclines, and NSAIDs. Several lifestyle factors or behaviors have been associated with a higher rate of psoriasis. The likelihood of developing psoriasis was doubled for smokers compared to nonsmokers (Armstrong et al., 2014). Psoriasis is more prevalent in those who abuse alcohol and may increase the severity of the disease. Multiple studies have noted a relationship between obesity and the development of psoriasis (Menter et al., 2011).

Signs and Symptoms: The characteristic features of psoriasis vary by subtype with chronic plaque psoriasis being most common. Typical findings include symmetrically distributed round or oval well-defined, pink/red plaques with overlying white scale. These plaques are commonly found on elbows, knees, gluteal cleft, and the scalp. Chronic plaque psoriasis may involve a few plaques or may have many plaques scattered over the entire body.

Inguinal folds, umbilicus, axillae, and inframammary folds are often affected areas of inverse psoriasis. Plaques lack scale due to the moist environment, and are typically shiny, thin, and well-defined. This inverse-pattern psoriasis may be difficult to distinguish from *Candida* or tinea. The distinct demarcated border is helpful in differentiation.

The lesions of guttate psoriasis are distinct small papules with overlying fine scale that have a drop-like, or guttate, appearance. The eruption is usually generalized, sparing the palms and soles. The eruption is often preceded by a streptococcal infection and its clinical course is unpredictable.

Most subtypes share other common clinical manifestations. Pruritus is a common complaint of most subtypes. Nail psoriasis may occur concurrently or prior to a cutaneous eruption. Tiny pits scattered in the nailbed, nail plate thickening or crumbling, and tan or brown spots (oil drop sign) are abnormalities associated with psoriasis (Klaassen et al., 2013).

Pustular psoriasis may present as an acute eruption of generalized inflammation, desquamation, and pustules. Similar characteristics are seen in erythrodermic psoriasis, but pustules will not be present. Both can have life-threatening complications.

Diagnostic Tests: The distinct presentation of the lesions of psoriasis makes a clinical diagnosis possible. When fungal infections are a possibility, potassium hydroxide (KOH) tests are the gold standard. There are no laboratory tests to confirm diagnosis. Challenging cases can be confirmed with a skin biopsy. If required, a referral to a dermatologist will ensure accurate testing.

Psoriasis is now considered a chronic inflammatory disease involving multiple systems. In addition to psoriatic arthritis, comorbid conditions should be assessed once diagnosis is confirmed and periodically thereafter. Associated comorbidities include metabolic syndrome, hypertension, atherosclerosis, dyslipidemia, diabetes, and pulmonary disorders (Danielsen et al., 2014; Rodríguez-Zúñiga & García-Perdomo, 2017; Samarasekera et al., 2013; Wu et al., 2020).

Differential Diagnosis:

Plaque Psoriasis:
- Seborrheic dermatitis
- Nummular eczema
- Tinea corporis
- Lichen planus
- Pityriasis rubra pilaris
- Mycosis fungoides
- Atopic dermatitis

Guttate Psoriasis:
- Secondary syphilis
- Pityriasis rosea
- Maculopapular drug eruption

Inverse Psoriasis:
- Candidiasis
- Tinea

Psoriatic Nails:
- Tinea unguium
- Onychomycosis caused by yeast or molds

Treatment: Although treatment decisions will generally be made by the dermatologist or, in the case of psoriatic arthritis, by the rheumatologist, the primary care provider is always responsible for the oversite of the patient's care.

© F.A. Davis Publishing

Knowledge of contraindications, side effects, adverse drug reactions, and drug-drug interactions are all a critical responsibility of the advanced practice nurse provider. Establishing good communication with the specialist is a necessity. It is also crucial that comorbidities that are common with psoriasis are optimally managed.

Treatment options should be evaluated on a case-by-case basis and according to patient preference, type and severity of disease, comorbidities, cost, and medication response. To ensure the appropriate choice of treatment, referral to a dermatologist should be initiated. Dermatologists are the experts who treat and manage the multiple nuances of this disease. Due to comorbidities associated with psoriasis, a multidisciplinary approach to management should be implemented. Team members may include dermatology, rheumatology, cardiology, behavioral health, and nutritionists. Primary care providers are key to ongoing assessment for early recognition of comorbid conditions.

Topical Treatments. For most patients with mild disease, topical treatments are safe and effective (Table 8-4). These treatments are also used as adjunctive therapy for patients with moderate to severe disease who need phototherapy or systemic therapy. Patients may be on concurrent topical therapy with the use of more than one topical agent. Topical agents include corticosteroids, vitamin D analogues, retinoids, calcineurin inhibitors, salicylic acid, anthralin, coal tar, and emollients. A combination of topical corticosteroids (TCS) and corticosteroid-sparing agents are typically used by dermatology (Elmets et al., 2021).

The use of class 1–7 TCS is recommended for twice daily application up to 4 weeks on the body and scalp, not including the intertriginous areas. Low-potency agents (class 6 or 7) should be used on the face and intertriginous areas. Common adverse effects of TCS include striae, atrophy, telangiectasia, and folliculitis. To reduce the risk of adverse effects of TCS, transitioning to lower-strength agents or intermittent use after improvement is recommended. In addition, combining treatment with nonsteroidal agents, such as tacrolimus, pimecrolimus, or crisaborole should be considered (Elmets et al., 2021).

Phototherapy. Phototherapy requires treatment by a dermatologist. Narrow-band ultraviolet B (UVB) is often used in combination with topical therapies and offers the possibility of home therapy. A more aggressive treatment is photochemotherapy with psolaren (an oral medication) and ultraviolet A (PUVA) light. The treatment inhibits mitosis by stopping DNA replication. It increases the risk of squamous cell carcinoma and possibly melanoma. It also induces photoaging. Although it has more risk than UVB, it is more effective (Elmets et al., 2021).

Systemic Therapy. Systemic therapy is reserved for those patients with severe disease and requires management by a dermatologist with expertise in treatment of psoriasis. Common oral medications include methotrexate, cyclosporin, and apremilast. Biologic agents are subcutaneous injections that are well tolerated and have excellent efficacy. Although both oral and injectable medications are effective for treating psoriasis, biologics are costly compared to oral nonbiologic medications. Biologic therapies include etanercept, infliximab, adalimumab, ustekinumab, secukinumab, and ixekizumab, just to name a few.

TABLE 8-4 Topical Treatment for Psoriasis

TOPICAL TREATMENT	MECHANISM OF ACTION	SIDE EFFECTS/ PRECAUTIONS
Corticosteroids	Anti-inflammatory, antiproliferative, immunosuppressive, vasoconstrictive	Skin atrophy, telangiectasia, striae distensai, acne, folliculitis, and purpura
		May exacerbate some superficial skin conditions: rosacea, tinea
		Rebound of psoriasis
		With high potency, possible systemic side effects
Vitamin D analogues	Binds to vitamin D receptors	Burning, pruritus, edema, peeling, dryness, erythema may improve with continued treatment
Calcipotriene topical	Inhibition of keratinocyte proliferation and enhancement of differentiation	Rarely systemic effects of hypercalcemia and parathyroid suppression; apply after UVA therapy
Retinoids Tazarotene topical	Normalizes abnormal keratinocyte differentiation, diminishes hyperproliferation	Local irritation, may be reduced with lower concentrations; combine with moisturizers or topical steroids
	Decreases inflammation	
Calcineurin inhibitors Pimecrolimus topical	Block the synthesis of inflammatory cytokines	Burning and itching reduced with continued therapy
		Cautious use with light therapy
		Not FDA approved for psoriasis
Salicylic acid	Keratolytic; reduce keratinocyte-to-keratinocyte binding	Risk of systemic toxicity; do not use with oral salicylates
	Reduce pH stratum corneum	Use after UVA therapy
Anthralin	Prevent T lymph activation	Skin irritation and staining
	Normalize keratinocyte differentiation	

Methotrexate has direct immunosuppressive effects by its ability to decreases lymphoid cell proliferation. Apremilast reduces the inflammatory response involved in underlying psoriasis. Cyclosporine blocks proinflammatory signaling. Due to its list of serious adverse effects, cyclosporine should not be considered for long-term treatment. Both methotrexate and cyclosporine require close monitoring due to their

© F.A. Davis Publishing

risk factors, the most serious being hepatotoxicity for methotrexate and renal toxicity for cyclosporine. Drug interactions are common with all systemic therapies (Stiff et al., 2018).

Biologics target cytokines including TNF-alpha, interleukin 12 (IL-12), interleukin 17 (IL-17) and interleukin 23 (IL-23). Biologic agents have a high benefit-to-risk ratio and can be used as monotherapy or combination therapy. Baseline and annual screening for latent tuberculosis is mandatory for all biologics due to their potential to activate the disease. Monitoring parameters vary according to drug. All age-appropriate live vaccines should be given at least 2 weeks prior to starting a biologic, inactivated vaccines are safe (Le & Vender, 2021). Coordinating the care of older adults on systemic therapy with the dermatologist is essential to adequate management (Menter et al., 2020).

Follow-Up: Follow-up should be on a case-by-case basis. A key to follow-up is coordination with the dermatologist, who, in other than the mildest cases, should be managing the disease process. It is important to consider the "heartbreak of psoriasis." The incidence of depression and suicidal ideation is higher in psoriasis and may not be directly related to the severity of the disease. All patients should be screened for depression. Patients with psoriasis have a higher incidence of arthritis, heart disease, diabetes, cancer, and hypertension, and all of these are increased in older adults as well (Menter et al., 2020).

Sequelae: Psoriasis is a chronic disease with exacerbations and remissions. In a small percentage of those with psoriasis, more serious types, such as psoriatic erythroderma or generalized acute pustular psoriasis, may occur. These diseases have much higher morbidity and may even result in death. Five percent of those with psoriasis will develop psoriatic arthritis.

Prevention/Prophylaxis: Triggers should be avoided: smoking, excess alcohol use, and skin trauma. Keeping the skin dry but well hydrated may decrease pruritus and the urge to scratch. Drugs known to exacerbate psoriasis should be avoided. Stress management, adequate rest, and a well-balanced diet to achieve ideal body weight are all important.

Referral: Except in the mildest cases of psoriasis, the patient should be comanaged with a dermatologist.

Education: In addition to ways to avoid triggers that can cause exacerbations, patients need to understand the treatment options and partner with providers to make choices that increase adherence. Teaching needs to include information regarding medication side effects and special considerations, such as the importance of not getting live vaccines if currently being treated with biologics. In the current health-care environment, retail clinics and pharmacies are offering vaccines, so patients need to be especially conscious of the recommendations related to their treatments and the guidelines regarding vaccines. The emotional toll of this disease needs to be acknowledged, offering patients connection to support groups. Patients also need to be informed of reputable Internet sources on psoriasis.

SKIN CANCER

Signal Symptoms: Poikiloderma refers to telangiectasia, reticulate hyperpigmentation, and atrophy. These are signs of long-term sun exposure and indicate significant risk for development of skin cancer. Basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) are common cancers most often found on sun exposed areas of the skin. The SCC type of skin cancer may evolve from actinic keratosis, which present as discrete lesions or a cluster of crusted, scaly papules on sun-exposed skin. These are called actinic keratosis and may be tender or itchy. Melanoma, the fifth most common cancer in the United States is the most serious type of skin cancer (Siegel et al., 2019). Any lesion with changing pigment, abnormal symmetry, crusting, bleeding, or tenderness is a possible skin cancer.

Description: Nonmelanoma skin cancers (NMSCs) include BCCs, which arise from the basal keratinocyte layer of the

© F.A. Davis Publishing

epidermis, and SCC, which originates in the squamous cells of the epithelium. Malignant melanoma (MM) is a tumor arising from pigmented cells. Melanoma causes abnormal proliferation of specialized cells that produce melanin in the skin, eyes, and hair.

Etiology: The major risk factor for the development of nonmelanoma skin cancers is exposure to UV radiation (Bolognia et al., 2018).

Occurrence: Skin cancer is the most common form of cancer in the United States. The worldwide incidence of NMSCs has been rising by 3% to 10% annually for the past 30 years. In the United States, BCC incidence rate has increased between 20% and 80% in the same period (Apalla et al., 2017). Each year, more than 1 million new cases of skin cancer are diagnosed in the United States. SCCs carry a 9% to 14% lifetime risk for men and 4% to 9% for women (Nehal & Bichakjian, 2018). Melanoma occurs less frequently but is responsible for more deaths. It is estimated that over 9,000 persons will die of MM each year (Guy et al., 2015; U.S. Cancer Statistics Working Group, 2016). MM is equally prevalent in men and in women until the age of 40 when incidence nearly triples for males (Apalla et al., 2017). Melanoma, though deadly in the later stages of development, has an excellent prognosis if treated early (Guy et al., 2015).

Age: The incidence of all types of skin cancers increases with age and the degree and intensity of sun exposure.

Ethnicity: Skin cancers are more prevalent in fair-skinned persons who tend to burn instead of tan, reflective of sensitivity to sunlight. In the United States, residents of states where year-round sunshine is abundant and those who live closer to the equator are at a high risk. Although SCC rates are low for those with darker skin types, if they do occur, they tend to arise on skin not exposed to sun. Acral lentiginous melanomas (ALMs) are the most common melanoma subtype in dark skinned persons (Marchetti et al., 2015). They are characterized by location and are found on the palms, plantar surface of feet, and nail matrix (subungual).

Contributing Factors: Skin phenotype and UV exposure, including tanning beds, are major risk factors for all types of skin cancer. Other factors related to the development of BCC include and SCC include age, ionizing radiation, arsenic exposure, genetics, and immunosuppression (Bolognia et al., 2018). Additional risk factors specific to melanoma include a family or prior personal history of melanoma, high numbers of normal nevi (moles), and the multiple atypical nevi (Caini et al., 2009; Pampena et al., 2017). Risk factors for NMSC and MM include skin pigmentation, genetics, age, occupation, chemical exposures, and immunosuppression. BCC is the most common skin cancer in the United States, followed by SCC with a ratio being roughly 4:1.2 (Apalla et al., 2017). Both are treatable with low metastatic potential.

Signs and Symptoms: Question patients about any new or changing lesions. Is the lesion painful? Does it itch or bleed? Has it healed and then reappeared? Ask about past history of any previous actinic keratosis, excised or treated lesions, and prior diagnosed skin of cancer. Question patients about any family history of skin cancers. Ask about their history of sun exposure, severe sunburn, burns, scars, ulcers, radiation dermatitis, use of tanning beds, current and prior occupations, and family history of skin cancer. Palpation can help with subtle skin changes, scale, and depth (firmness) of lesions.

Presentation of the skin cancer will depend on the type of tumor. There are several subtypes of BCCs including nodular, morpheaform, and superficial. Nodular BCCs account for 80% of all subtypes. It often appears on the face favoring the nose, cheeks, nasolabial folds, and forehead. They can present as smooth, pearly papules or nodules with rolled borders with or without central ulceration. Occasionally, brown or black blotchy pigment can be seen. Patients may describe this lesion as a pimple that did not heal. Superficial BCC often appears on the trunk as well-circumscribed, light red or pink patch with slight overlying scale. This type of BCC resembles other chronic skin conditions such as psoriasis, eczema, discoid lupus erythematous, and Bowen disease. The least common type of BCC is the sclerosing or morpheaform tumor. Found on the head and neck and occasionally the trunk of the body and can present as atrophic plaques which may be flesh-colored or light pink (Bolognia et al., 2018). A close examination from several angles with redirection of lighting may help due to the subtle appearance of these types of BCC.

Actinic keratoses, precursors to SCC, appear as round or irregular-shaped erythematous or pink plaques with a scaly or rough surface. Other precursor lesions of SCC include cutaneous horn, leukoplakia, and keratoacanthoma. Clinical presentation can vary from skin colored, pink or red, well-demarcated patch with scale to thick, firm nodules that may be smooth or ulcerated. SCC often originates at sites of chronic inflammation or old scars in individuals with darker skin types. For the immunocompromised, SCC often present with multiple lesions in areas of previous sun damage but can also occur on oral, genital, and anal mucosa. The progression of these lesions varies over time, and they can be painful, pruritic, or tender (Bolognia et al., 2018).

For patients with suspected melanoma, the mnemonic ABCDE guides the clinician in determining if the clinical characteristics of a suspicious lesion warrant close surveillance and/or biopsy for histological evaluation.

- Asymmetry
- Border irregularity
- Color variation
- Diameter greater than 6 mm
- Elevation of a previously flat lesion, evolving, and enlarging (Bibbins-Domingo et al., 2016)

It is important to note that the classic ABCDE pattern of MM development is not always present. The tool is used to alert patients and nondermatologists about suspicious lesions (Rastrelli et al., 2013). Melanoma can appear to have little or no color (amelanotic) and can mimic benign lesions. Approximately 65% to 70% of melanoma lesions arise on normal skin, the remaining from an existing nevus (Pampena et al., 2017)

Major Signs. Change in size, change in shape, change in color. If one or more major signs exist, refer for expeditious biopsy.

Minor Signs. Inflammation, crusting or bleeding, sensory change, diameter of greater than 6 mm. If three or four minor signs exist with a major sign, consider referral.

Patients may be concerned about a new, pigmented lesion or a change in an already existing one. Patients may report associated itching, burning, or pain in a mole. Superficial

© F.A. Davis Publishing

spreading accounts for nearly 70% of all melanoma subtypes. It presents as a flat to slightly raised pigmented lesion with irregular borders, commonly found on the trunk of men and the lower extremities of women. Lentigo maligna melanoma presents as an irregularly light brown, brown, or black pigmented patch with ragged borders on sun-exposed areas, especially on the faces of older adults. Nodular melanoma, the second most common subtype, presents as brown or black papules usually located on the trunk, head, and neck (Elder et al., 2020).

Diagnostic Tests: Skin cancer is diagnosed through biopsy. Biopsy of the suspected lesion is necessary to confirm the diagnosis via histological examination of the tissue. If the lesion is suspicious for melanoma, the entire lesion should be removed. An excisional biopsy is necessary for larger lesions. (Swetter et al., 2019).

Differential Diagnosis:

- Actinic keratoses
- Seborrheic keratoses
- Keratoacanthoma
- Atypical nevi
- Blue nevus
- Dermatofibroma
- Venous lakes
- Pyogenic granulomas
- Intradermal nevus
- Sebaceous hyperplasia
- Molluscum contagiosum
- Psoriasis
- Bowen disease (Nolen et al., 2011)

Treatment: Several factors need to be considered before skin cancer therapy begins: tumor pathology, the patient's age and general health, immune status, size and location of the tumor, and the cosmetic concerns of the patient. BCC and low-risk SCC may be treated by excisional surgery, electrodessication and curettage, cryotherapy, ionizing radiation, and Mohs micrographic surgery. Treatment for high-risk SCC is often guided by clinical and pathological factors. A TNM staging system, which assesses the primary tumor (T), regional lymph nodes (N), metastatic (M) sites, guides melanoma treatment (Elmore et al., 2018).

A number of different treatment options are available for the management of actinic keratosis (AK), including cryotherapy, topical medications, and photodynamic therapy, all of which have been shown to reduce lesion count in patients with AK. Cryotherapy, topical 5-fluorouracil, imiquimod, and photodynamic therapy are the most commonly used treatments for AK (Bolognia et al., 2018). Combination therapies can include both field-directed and lesion-directed therapy (Cornejo et al., 2020).

Follow-Up: Follow-up for a patient with diagnosed skin carcinoma is essential because the recurrence rate of skin cancer is high; 50% to 70% of persons with BCC and SCC have a reappearance of a cancerous lesion within 2 years (Bolognia et al., 2018). A person who is susceptible to skin cancer may develop another cancerous lesion at any time. Precancerous lesions should be examined regularly every 6 to 12 months using a head-to-toe skin examination, including a careful inspection of the previous site of a lesion. In patients with SCC, palpation of regional lymph nodes is suggested. During subsequent visits of patients with malignant melanoma, a thorough review of systems is imperative to elicit clinical signs and symptoms of metastasis.

Sequelae: BCC rarely metastasizes; however, if it is not treated early, the carcinoma may invade the surrounding tissue and bone. Advanced SCC lesions of the lips, ear, and genitalia often recur. Those that occur on the ear, genitalia, within a chronic wound or scar, or on irradiated skin have a higher rate of metastasis. The initial size, depth, and host factors of those diagnosed with NMSC can also influence recurrence and metastasis rate. Five-year prognosis for MM is primarily determined by the thickness of the tumor. Tumors that are thin (<0.8 mm) and caught early are associated with a 97% 5-year survival rate, whereas more advanced melanomas with distant metastasis have a very poor prognosis of 33% for 1-year survival rate (Elmore et al., 2018).

Prevention/Prophylaxis: Because the incidences of all skin cancers increase with age, it is important to discuss sun care protective behaviors with all older adults (Lin et al., 2011). The CDC recommends easy options for sun protection. UV radiation increases the risk for skin cancer with all skin types; therefore, individuals need to seek shade when UV radiation is strongest, during the hours of 10:00 a.m. to 4:00 p.m., and avoid burning. According to the Skin Cancer Foundation, sunscreen should have a sun protective factor (SPF) of at least 30 or higher, broad spectrum, and water resistant for extended outdoor activity. Tanning beds or booths should be avoided, as they pose a significant risk for the development of melanoma and nonmelanoma skin cancers (Boniol et al., 2012; CDC, 2016).

Sunscreen should be applied to sun-exposed skin daily. Approximately 1 teaspoon of sunscreen should be applied to the face and neck, 2 teaspoons to the torso, 1 teaspoon to each arm, and 2 teaspoons to each leg (Isedeh et al., 2013). Sunscreen should be reapplied after toweling off from swimming or exercise and after heavy sweating. Wide-brim hats that shade the face, head, ears, and neck; long-sleeved shirts; and long pants are recommended. Sunglasses that are wraparound type should be worn and can be purchased to block up to 100% of UV radiation (U.S. Cancer Statistics Working Group Department, 2014).

Patients need to be routinely asked about their ability to conduct skin self-examinations. Recommending partner participation can enhance one's thoroughness in examining hard-to-reach areas of the body. Providing individuals with printed directions on how to position mirrors to examine the body, the use of good lighting, and suggesting magnifying lenses for those with impaired eyesight can help ensure a thorough examination has been carried out by the patient. Taking the time to give patients adequate instructions in skin self-examination has been found to be a successful strategy in ensuring older adults routinely conduct or seek assistance in regular skin examinations and the use of sunscreen (Janda et al., 2011). High-risk patients can be provided body maps to record areas of suspicious lesions to bring with them at the time of clinical examinations. These patients should be questioned if they are regularly being followed by a dermatology practice. If not, primary care providers are well positioned to begin triaging (to include referring patients to a dermatologist) patients who present with suspicious skin lesions (Goulart et al., 2011).

© F.A. Davis Publishing

Yearly physical examinations should include assessment of the head, scalp, and skin, and an accurate recording of descriptions of any suspicious lesions. Patients should be fully undressed, to complete an accurate physical. New, unusual, symptomatic, or changing lesions or moles should be evaluated by a dermatologist. Immunosuppressed solid organ transplant recipients are at high risk for developing skin cancer at rates faster than the general patient population and should be scheduled for regular skin examinations.

Referral: When a suspicious lesion is found, referral to a dermatologist for evaluation and possibly biopsy is necessary. Whole-body photographs and dermoscopy may be used to follow patients with suspicious lesions. A tutorial on dermoscopy is available at https://dermoscopedia.org/Main_Page. Oncology referral is needed for metastatic SCC and MM.

Education: Advise older patients that skin cancers are a common occurrence as one ages, especially for patients at risk. Older adults should perform a monthly self-evaluation of the skin. Any suspicious lesion that does not heal in a reasonable time needs to be examined by a primary care provider. Patients also need to report any slow-growing, flesh-colored, or pigmented lesion, noting if the lesion has irregular borders, changes in color, ulceration, bleeding, or horn formation. Sun exposure, especially during the hours of 10:00 a.m. to 4:00 p.m., should be avoided. Year-round broad-spectrum sunscreen that blocks UVA and UVB light is recommended. Vulnerable areas, such as the head and neck, should be covered with protective clothing.

SUPERFICIAL FUNGAL INFECTIONS

Signal Symptoms:

Dermatophyte Infection (Tinea). Erythema, scale, raised border, clearing center, may present with vesicles if inflammatory.

Candidiasis (Moniliasis). Pustules, red, denuded, glistening surface with a scaling border and satellite pustules that often occurs on mucosal surfaces and skinfolds. In the oral cavity candidiasis forms white plaques on the oral mucosa or tongue. Angular cheilitis presents as inflamed skin with crust formation at the angles of the mouth. The scale and inflammatory cells form the classic "cottage cheese curds" within the vagina.

Tinea Versicolor (Pityriasis Versicolor). Hypopigmented macules and patches or scaly red or shades of brown macules or patches may be slightly pruritic. The condition typically occurs on the neck, upper trunk, and proximal arms.

Description: Dermatophytes (*Trichophyton* and *Microsporum*) and yeasts (*Malassezia* and *Candida*) are the primary groups of fungi that cause the most common superficial fungal infections of the skin (Ameen, 2010). Dermatophyte infections are referred to clinically as *tinea* followed by the region of the body that is infected: tinea capitis (the head), tinea barbae (the beard area), tinea facea (the face except for the beard area), tinea manuum (the hand), tinea corporis (the body), tinea cruris (the groin), tinea pedis (the foot), and when there is nail involvement, tinea unguium or onychomycosis. Lay terms for the dermatophytes include ringworm, jock itch, and athlete's foot.

Candidiasis may be termed monilia, yeast, or thrush and generally presents in intertriginous areas or on mucous membranes. Tinea versicolor, often referred to as pityriasis versicolor, is caused by a yeast in the *Malassezia* genus. *Malassezia* is a part of normal skin flora; however, when disrupted tinea versicolor may result. Common factors leading to this disruption include immunosuppression, heat, humidity, oral contraceptives, and genetics (Passeron et al., 2019). Clinical manifestations include macules and patches of varying pigmentation with slight overlying scale on the trunk and upper arms.

Etiology:

Dermatophytes. Dermatophytes are the predominant cause of fungal infections of the skin, hair, and nails. (Ameen, 2010). The dermatophytes are a group of fungi that survive on a protein called keratin which is found in the skin, hair,

© F.A. Davis Publishing

and nails. Patients who are chronically infected may have a genetic predisposition to dermatophyte infection. Dermatophytes are classified by the origin of the infection: anthropophilic, transmission from person to person by fomites or direct contact; zoophilic, transmission from animal to person by fomites or direct contact; or geophilic, from the soil. The latter two sources result in a more rapid and more severe inflammatory response. Clinical subtypes are based on the tissue primarily involved. Epidermal involvement is classified as either tinea corporis, tinea cruris, tinea pedis, tinea faciei, and tinea manuum. Tinea capitis and tinea barbae are infections of the hair and hair shaft, and tinea unguium involves nails. The dermatophytes within the stratum corneum disrupt the horny layer, lead to scaling, and create an inflammatory response. Three fungal species are primarily responsible for the infection: *Trichophyton, Epidermophyton*, and *Microsporum. Trichophyton rubrum* is the most common cause of skin and nail infection, with *Trichophyton* responsible for 80% of infections (Wolff et al., 2017).

Cutaneous Candidiasis. *Candida albicans* is an oval, yeast-like fungus that lives in the normal flora of the mouth and gastrointestinal tract. It reproduces through budding, the development of pseudohyphae, and true hyphae. Conditions that compromise the immune system or alter the normal body flora contribute to the development of *Candida* infections. The yeast infects the outer layer of the skin with the primary lesion, a pustule that dissects under the outer skin layer and peels it away. The result is a glistening surface with a scaling, advancing border and often the presence of satellite lesions. *Candida* grows best in warm, moist environments, and often the lesions end as they meet the area of dry skin.

Tinea Versicolor. Although termed "tinea," this condition is caused by yeasts in the *Malassezia* genus (formerly Pityrosporum, not dermatophytes (Kang et al., 2019). The organisms are lipophilic yeasts that reside in the keratin and hair follicles, areas with increased sebaceous activity (Habif, 2016; Wolff et al., 2017). Tinea versicolor is an overgrowth of normal skin flora and is not contagious. As sebum production declines later in life, the incidence of tinea versicolor also declines.

Occurrence: Immunosuppressed patients are at higher risk for fungal infections of all kinds and are more likely to have infections that do not resolve. Older adults are at higher risk for many fungal infections because of the decline in the immune system with aging, as well as the increased incidence in comorbidities and the use of multiple medications. Functional compromise can lead to a decline in personal hygiene, which also increases the risk factors for fungal infection. Tinea versicolor is more common in young adults due to its link to sebum production (Wolff et al., 2017).

The feet and nails are the most common areas of the body affected by dermatophytes in the older adult. Onychomycosis due to dermatophytes (tinea unguium) account for 60% to 70% of nail infections, the remaining 40% to 30% of nail infections are caused by yeast or nondermatophyte mold (Lipner & Scher, 2019). Incidence of onychomycosis increases with advancing age, while toenail onychomycosis due to *Candida albicans* declines with age. *Candida* most often causes intertriginous infections in those older than 65 years and is also the most common cause of fingernail onychomycosis in this age-group.

When the dermatophytes are inaccurately diagnosed and treated with topical steroids, a phenomenon called tinea incognito may occur. The rash initially disappears, but when treatment with steroids is discontinued, the rash returns with much more extensive involvement and may appear without scale. It is not responsive to subsequent topical steroid treatment, and a thorough history is necessary to make the proper diagnosis of tinea.

Tinea versicolor thrives in heat and humidity. It has an estimated prevalence in the United States population between 2% and 8%; however, the actual prevalence may be much higher because many of those with the disease do not seek medical evaluation.

Tinea barbae is an infection that only occurs in males and is more common in rural areas. Males also more often experience tinea cruris and tinea pedis and are more likely to have toenails infected with dermatophytes than females, whereas females are more likely to have *Candida*-infected fingernails. Differences between sexes have not been found in cases of *Candida* in other parts of the body or in cases of tinea versicolor.

Age: Tinea of the scalp and face (tinea capitis and tinea facialis) are primarily diseases of children. Tinea of the body, trunk, and extremities (tinea corporis) can occur at any age. The initial presentation of tinea pedis (athlete's foot) is most common in adults aged 20 to 50 years, and the initial presentation of tinea unguium (onychomycosis) commonly occurs in those aged 45 to 54 years. Tinea unguium can affect any age, but the incidence in toenails increases with aging and is most common in the oldest old. Approximately 50% of those older than 70 years are affected (Kang et al., 2019)

Candida of the skin occurs more often in older adults because of the decline in immune response with aging, as well as a decline in hygiene among many older adults. Although not a common cause of toenail infection, when it occurs it is more likely in an older adult, whereas fingernail fungus is rarely seen in older adults.

Tinea versicolor is more common when sebaceous glands are most active during puberty and in young adults ages 15 to 24 years. Tinea versicolor is less common in those older than 65 years because sebum production declines with age (Kang et al., 2019).

Ethnicity: African Americans are less likely than other races to be diagnosed with dermatophytosis. Ethnic differences have not been noted for either *Candida* or tinea (pityriasis) versicolor (Habif, 2016; Wolff et al., 2017).

Contributing Factors: Fungal infections are more common in warmer climates. Excessive sweating increases risk. Any of the diseases that compromise the immune system, atopy, and topical and systemic steroids increase risk. Individuals with diabetes are noted to have a higher risk as well as those with abnormalities of the keratin, as in psoriasis and ichthyosis (Nenoff et al., 2014). Age alone increases the risk, particularly of onychomycosis. Tinea manuum is rare in individuals who do not also have tinea pedis. A common presentation is two feet–one hand syndrome, which is believed to be a result of the patient touching or scratching the infected feet. Tinea pedis occurs more frequently in those who wear occlusive

© F.A. Davis Publishing

footwear that promotes warmth and sweating, the perfect environment for fungal growth. Socioeconomic status also appears to contribute to the incidence of dermatophyte infections, with tinea pedis more prevalent in developed countries and tinea capitis more prevalent in countries with fewer resources.

Cutaneous candidiasis is more common in adults with diseases that compromise the immune system, those taking medications that cause immune decline, adults treated with broad-spectrum antibiotics, and those with poor hygiene that results in moisture in intertriginous areas (Habif, 2016; Wolff et al., 2017). Other contributing factors include hot, humid weather; tight underwear; poor hygiene; and inflammatory diseases occurring in skinfolds.

Like other fungal infections, tinea (pityriasis) versicolor is more common in an environment of heat and humidity. It grows best where sebaceous activity is highest and may be more common in those with oily skin. Immune-compromised individuals and those on steroids are also more susceptible. Although the color change may be more noticeable on darker colored skin, there is no noted racial difference (Habif, 2016; Wolff et al., 2017).

Signs and Symptoms: It is not uncommon to have more than one fungal infection simultaneously; therefore, a full examination of hair, skin, and nails is recommended. Well-defined borders with scale are a hallmark of each of the superficial fungal infections. Tinea is often dry and scaly, whereas *Candida* presents with initial pustules that become eroded, confluent, and evolve into patches with sharply demarcated borders and fine scale, surrounded by satellite pustules.

Tinea capitis presents as scaly, round patches with generalized or localized hair loss (alopecia), and broken hairs. Affected areas of the scalp may have inflamed, crusted pustules and papules. Black dot tinea capitis occurs when hairs break off near the surface and give the appearance of dots. The dots may be scattered over the scalp and may not form a classic round patch.

Tinea corporis affects sites other than face, hands, feet, or groin. It presents as the classic ringworm pattern with a clearing center and a raised, scaling leading edge. Tinea cruris presents as an erythematous pruritic rash that begins on the medial upper thigh that centrifugally spreads to the perianal area, gluteal cleft, perineum, and buttocks. The scrotum is often spared, and the rash borders are well-defined. It is usually symmetric, pruritic, and can easily spread from the feet (tinea pedis) to the inguinal folds. The lack of scrotum involvement can help to differentiate tinea from *Candida* of the groin, where scrotum involvement is common (Habif, 2016).

Tinea pedis, athlete's foot, is a common dermatophyte infection and presents with a variety of signs and symptoms. The three main clinical types are interdigital, moccasin type, and vesicular.

- Interdigital tinea pedis results in erythema and scaling present between the third and fourth toes, although any interdigital space can be affected. Secondary infection with bacteria is more common in the macerated toe space.
- Moccasin-type tinea pedis affects the medial and lateral aspects of feet along with the sole. Because of the mild nature of this infection and its subtle presentation, it may be present for years before the patient seeks treatment.
- Vesicular-type tinea pedis often involves the medial foot. It presents as a vesicular, pruritic, and sometimes painful eruption. It may represent a secondary bacterial infection in someone with chronic interdigital tinea pedis and can manifest with interdigital ulcers and erosions.

Toenails are most often infected with dermatophytes, and there are three classic presentations:

- Distal lateral subungual onychomycosis (DLSO) is the most common subtype, which presents with onycholysis (the pulling away of the nail plate from the nailbed), hyperkeratosis, and yellow-brown discoloration.
- Superficial white onychomycosis (SWO), in which the dermatophyte invades the surface of the nail and the dorsal nail plate is chalky white. When lightly scraped it yields a chalky scale.
- Proximal subungual onychomycosis (PSO) is less common than other clinical subtypes that usually affect immunocompromised patients. It appears as a chalky, white color at the base of the nail and extends distally.

When a patient presents with a nail problem it is important to think broadly about the differential because only 50% of nail problems are onychomycosis (Lipner & Scher, 2019). Not every toenail with abnormal appearance is infected with fungus. Other common considerations should be trauma, frequent immersion in water, psoriasis, atopic dermatitis, or HIV infection.

Cutaneous candidiasis may exacerbate or initiate intertrigo. Areas of *Candida* infections include skinfolds, interdigital areas, and nails. Moist, red, macerated patches within skinfolds are hallmark findings of intertrigo. Inflamed satellite pustules and papules suggest *Candida* involvement. Intertriginous candidiasis is most common in bedridden older adults due to immobility. Additional risk factors include incontinence, poor hygiene, obesity, and immune deficiencies.

Tinea (pityriasis) versicolor appears as macules, round patches, and plaques with overlying fine scale. The color varies from light pink to light brown and the condition often manifests on the upper trunk, proximal upper extremities, neck, and face. The lesions vary in size and may become confluent and cover large areas of the body. It is rarely pruritic, and the appearance is the primary concern.

Diagnostic Tests: Although clinical findings raise suspicion of fungal infection, diagnosis should be confirmed with testing due to overlap of other skin disorders that are similar in appearance. Fungal lesions evolve and are typically asymptomatic. Fungal infections are often found coincidentally by the provider on physical examination or presented by the patient when self-treatments have failed.

For fungal skin involvement, the gold standard of diagnosis is direct microscopic examination of a KOH wet mount preparation of skin scrapings (Gupta et al., 2020). Scale is scraped from the affected areas using a surgical blade and placed on a slide. Add one drop of 20% KOH and then place cover glass on top. Examine for hyphae or yeast. It is best to start at 10× (low-power) magnification. Segmented hyphae

© F.A. Davis Publishing

confirm dermatophyte (tinea) infections, whereas pseudohyphae and budding yeasts confirm *Candida* (Kang et al., 2019). Fungal culture is an alternative method for diagnosis, but this may take several weeks to obtain results. Although fungal culture will identify the responsible organism, most antifungal treatments cover most infectious organisms. Only 50% to 60% of nail abnormalities are due to onychomycosis and treatment is lengthy. For these reasons, onychomycosis should be confirmed by laboratory testing (Gupta et al., 2000). Approximately 60% to 70% of nail infections are due to dermatophytes; 30% to 40% are caused by a mold, *Scopulariopsis;* and 10% to 20% are due to a yeast (Lipner & Scher, 2019). *Candida*, often associated with fingernail onychomycosis, may not respond to treatments useful in treating dermatophytes (Habif, 2016; Westerberg & Voyak, 2013). Garcia-Doval and colleagues (2010) present a clinical diagnostic rule for dermatophyte involvement. In their study, they found that if the patient with suspected onychomycosis had greater than 25% involvement of the sole of the foot with plantar desquamation and the presence of interdigital tinea pedis, the positive predictive value of the rule was 81%, which is higher than that of laboratory tests.

Differential Diagnosis:

Scalp Lesions:

- Seborrheic dermatitis – The scale of seborrheic dermatitis appears waxy and yellow compared to the fine, white scale of psoriasis. The patchy alopecia often seen with tinea capitis is not a clinical finding for seborrheic dermatitis.
- Psoriasis – Inflamed, well-defined plaques with coarse white scale. Check for involvement of elbows, knees, and intertriginous areas.
- Atopic dermatitis
- Alopecia areata – Smooth, well-defined, round areas of alopecia.
- Bacterial folliculitis – Gram stain or culture will result with causative bacteria.
- Neoplasia needs to be considered with presence of a kerion

Lesions on the Trunk:

- Allergic contact dermatitis – Tends to be more pruritic than fungal infections.
- Atopic dermatitis – Adults rarely have trunk involvement.
- Nummular eczema – Round plaques with scale, no central clearing.
- Psoriasis – Plaques are thick, appear more inflamed, and have more visible overlying scale.
- Pityriasis rosea – Look for herald patch which may range in size from 3 cm to 10 cm.
- Tinea (pityriasis) versicolor – Involvement usually seen on trunk and neck.
- Early presentation of herpes zoster

Lesions in the Groin:

- Intertrigo – More inflammatory in nature. Check for satellite papules and pustules.
- Psoriasis – Satellite papules and pustules are diagnostic for *Candida*.
- Seborrheic dermatitis
- Erythrasma – Lacks the scale often found with fungal infections.

Lesions on the Feet: Between the Toes:

- Bacterial infections: erythrasma, impetigo, *Pseudomonas*
- *Candida* intertrigo

Moccasin Type:

- Allergic contact dermatitis
- Atopic dermatitis
- Dyshidrotic eczema
- Psoriasis – Often symmetric and limited to soles and palms.

Vesicular:

- Allergic contact dermatitis
- Dyshidrotic eczema
- Bacterial infection
- Bullous disease

Nail Involvement. Distal and Lateral Subungual Onychomycosis (DLSO):

- Psoriatic nails – Randomly scattered deep pits on the nail plate and splinter hemorrhages.
- Onychogryphosis (thickening and hardening)
- Onychauxis (overgrowth or thickening)

Superficial White Onychomycosis (SWO):

- *Candida* onychomycosis – Subungual thickening, redness and swelling of nail folds, and nail plate damage.
- Contact or irritant dermatitis

Tinea Versicolor:

- Vitiligo
- Pityriasis alba – Involves face, often seen in patients with a history of eczema.
- Seborrheic dermatitis – Thicker scale and involvement of scalp, ears, and eyebrows.
- Secondary syphilis
- Pityriasis rosea – Lesions are more inflamed and herald patch is present.

Treatment: In older adults, response to treatment may be decreased due to slower cell turnover and comorbid conditions, particularly diabetes and peripheral vascular disease. Tables 8-5 and 8-6 offer topical and systemic treatment options, respectively (National Library of Medicine National Institutes of Health [NLM-NIH], n.d.). For topical agents, the treatment is once to twice a day for 2 to 6 weeks and should be continued for 1 week after the lesions clear. Application should extend beyond the leading edge of the lesion. Azoles are effective for dermatophytes, *Candida*, and yeasts (tinea versicolor) (Hay, 2018). Within a class of medication, the options are comparable and should be selected based on cost and the preferred base (lotion, cream, ointment). Topical treatments are not useful for tinea capitis, and failure is common in tinea manuum and onychomycosis (tinea unguium).

Newer agents are more likely to cure tinea pedis than the older generation of antifungals, including clotrimazole, which is fungistatic, whereas terbinafine is fungicidal. Terbinafine 1% cream applied twice daily for 1 week has a high cure rate for interdigital tinea pedis and butenafine twice a day for a week is also very effective (Habif, 2016). Econazole and ciclopirox also have antibacterial properties and may be the drugs of choice if bacterial involvement is suspected.

© F.A. Davis Publishing

TABLE 8-5 Topical Treatment for Superficial Fungal Infections

DRUG CLASS	PREPARATION	USE
Azoles	Clotrimazole	Dermatophytes, tinea versicolor, and *Candida*
	Miconazole	Dermatophytes, tinea versicolor, and *Candida*
	Ketoconazole	Dermatophytes, tinea versicolor, and *Candida*
	Econazole	Dermatophytes, tinea versicolor, and *Candida*
	Oxiconizole	Dermatophytes, tinea versicolor, and *Candida*. Other azoles may be more effective against *Candida*.
	Sulconizole	Dermatophytes, tinea versicolor, and *Candida*. Other azoles may be more effective against *Candida*.
Allylamines	Naftifine	Dermatophytes, tinea versicolor, and *Candida*. Less effective than azoles.
	Terbinafine	Dermatophytes, tinea versicolor, and *Candida*. Less effective than azoles.
Naphthionates	Tolnaftate	Dermatophytes, but less effective than other treatment options
Pyridone	Ciclopirox	Dermatophytes, tinea versicolor, onychomycosis SWO, and *Candida*
Polyene	Nystatin	*Candida*

TABLE 8-6 Systemic Treatment for Superficial Fungal Infections

DRUG CLASS	PREPARATION	USE
Allylamines	Terbinafine	Dermatophytes and onychomycosis. More effective than oral azoles for clinical cure.
Azoles	Itraconazole	Dermatophytes, tinea versicolor, onychomycosis, and *Candida*
	Fluconazole	Dermatophytes, tinea versicolor, onychomycosis, and *Candida*
Mitotic inhibitor	Griseofulvin	Dermatophytes and onychomycosis

When tinea pedis is vesicular or has signs of maceration, the use of 1% aluminum acetate solution (Burow solution) compresses applied for 20 minutes several times a day is a helpful drying agent and facilitates the penetration of the topical antifungal treatment. Oral antifungal drugs may be used to treat the acute infection (Bolognia et al., 2018). In hyperkeratotic, moccasin-type tinea, keratolytic agents, such as ammonium lactate lotion or topical urea, can reduce the hyperkeratosis and allow for improved penetration. Applying a plastic occlusive dressing over the keratolytic agents enhances their effectiveness. Oral terbinafine daily for 4 weeks may result in cure rates of 95% (Habif, 2016). For tinea pedis it is important to assess the condition of the nails and treat any reservoir that may be present.

Due to limited penetration of the nail plate, topical antifungals are rarely useful in the treatment of onychomycosis, except for SWO. In the United States, three topical treatments are approved by the Food and Drug Administration. Ciclopirox topical (Penlac Nail Lacquer) is the oldest; new agents include tavaborole (Kerydin) and efinaconazole (Jublia). An intriguing alternative was presented by Derby et al. (2011). In a small study (including only 18 subjects) of the effectiveness of the lay treatment of onychomycosis with Vicks VapoRub applied topically once a day for 48 weeks, 83% of the participants reported satisfactory results, with 27.8% experiencing a complete clinical and mycological cure; 56% had partial clearance, and 17% had no improvement.

An alternative treatment of tinea (pityriasis) versicolor is selenium sulfide 2.5% lotion or shampoo applied for 10 to 15 minutes followed by showering off for 2 weeks. Weekly application for several additional months may prevent recurrence. The skin color alterations may take 1 to 2 months to resolve completely.

Research supports a variety of dosing options for all of the oral antifungal treatments, from daily to once-a-month pulse therapy. The duration of therapy depends on the site of involvement as well as the response. Although oral terbinafine is least toxic of the antifungals, all of the agents have the potential of serious side effects and require lab monitoring (Kreijkamp-Kaspers et al., 2017). Before recommending any oral treatment, consultation is recommended. Mechanical treatments of nails infected with fungus offer another option for resolution of the infection. Partial or total surgical nail removal is an option, but this approach can lead to significant morbidity and is rarely used (Bolognia et al., 2018).

Follow-Up: Follow-up of the patient with superficial fungal infections needs to be addressed on a case-by-case basis. A follow-up in 4 weeks is a reasonable option, especially for those patients on oral therapy, where hepatitis may appear after 4 weeks of treatment (Bolognia et al., 2018). For oral antifungal therapy lasting greater than 4 weeks, a baseline CBC and liver function tests are recommended with retesting every 4 to 6 weeks (Habif, 2016). Infection of the toenails requires 6 weeks or longer to judge results, and in tinea versicolor 1 to 2 months are required before the lesions resolve. Patient education regarding expected outcomes and possible

© F.A. Davis Publishing

side effects can help in the assessment of when or even whether follow-up is necessary.

Sequelae: The superficial fungal infections for the most part do not present a serious health threat to older adults. Their lack of symptoms is one reason they are often chronic before they are addressed. In older adults, onychomycosis can result in cellulitis and foot ulcers. The risk of superinfection with bacteria and resulting severe consequences is greatest in those with diabetes, peripheral vascular disease, or immune compromise. The *Candida* species may have systemic consequences and are often painful; treatment and prevention are key. The side effects of the treatments may be more concerning than the disease, and these risks are important to weigh in decision making. Serious consequences include hepatic toxicity, CYP450 interactions, neutropenia, and agranulocytosis.

Prevention/Prophylaxis: All fungus grows best in warm, humid environments. The key to prevention of all types is to keep the skin cool and dry. Avoiding occlusive footwear, wearing absorbent materials, and practicing good hygiene offer the best primary prevention. Tinea pedis, tinea manuum, and onychomycosis are difficult to completely eradicate; recurrence is common, and the diseases may become chronic in nature. The interdependence of these infections requires the complete resolution of all three in order to prevent recurrence. Tinea versicolor is the result of the conversion of the normal *Malassezia* skin flora to a mycelial form that is pathological and causes the scaly lesions. Older age actually decreases the risk of this disease because sebaceous activity declines with age. Prophylactic therapy with topical or oral antifungals has been effective in preventing recurrence which is common.

The *Candida* species are part of the normal flora in the mouth, gut, and vaginal tract. The key to prevention of recurrence is keeping the skinfolds dry. Use of a hairdryer to thoroughly dry the area after bathing, the use of aluminum acetate solution (Burow solution), and the application of antifungal or absorbent powder have all been shown to prevent recurrence (Habif, 2016; Wolff et al., 2017).

Referral: When definitive diagnosis is needed for suspected fungal infections of the skin, hair, or nails, referral is often necessary to confirm infection based on fungal culture, direct microscopy, PCR, and/or histopathology. This is particularly important for nail involvement given the extensive differential diagnosis of nail infections and adverse effects of oral antifungal treatment.

Education: Patient education should center on the cause of the infection and the risk of reinfection/recurrence. Prevention requires avoidance of situations that cause occlusive, warm, moist environments. This can be accomplished by wearing absorbent materials, loose clothing, and open-toe shoes in the summer, and wearing protective footwear in showers and around pools. Patients can be reassured that tinea versicolor is the result of a change in the normal body flora and not contagious, and that coloration changes will resolve with treatment. Prophylactic antifungal therapy may be required, especially for tinea pedis, tinea manuum, or onychomycosis.

Clinical Recommendation	Evidence Rating	References
A rule for the clinical diagnosis of onychomycosis was developed. Data supported that the rule was at least as accurate as laboratory tests. When dermatologists considered onychomycosis was the most likely diagnosis and plantar desquamation affected >25% of the sole of the foot, treatment could be started without further confirmation. The rule needs to be validated with primary care practitioners.	B	Garcia-Doval et al., 2010
A potassium hydroxide (KOH) preparation with skin scrapings from the affected areas is the primary diagnostic method of confirming epidermal dermatophyte infections.	A	Gupta et al., 2020
Oral ketoconazole is not a recommended treatment for dermatophyte infections. Newer antifungals are more effective, and oral ketoconazole carries a life-threatening risk of hepatotoxicity, drug-drug interactions, and adrenal insufficiency.	A	van Zuuren et al., 2015
A small study of topical Vicks VapoRub applied to nails affected with fungus confirmed by microscopy and culture was found to be as effective as topical ciclopirox 8%, the only FDA-approved treatment for onychomycosis. Participants were followed for 48 weeks, and the outcome measure was clinical and mycological cure. Patient satisfaction was also measured. The cost of treatment is less than one-fourth that of the prescription treatment.	B	Derby et al., 2011
Terbinafine and azoles are effective therapies compared to placebo for resolution of onychomycosis. Cure rates are higher for terbinafine when compared to azoles with equal risk of adverse events.	A	Kreijkamp-Kaspers et al., 2017
Imidazole (azole) topical medications, such as miconazole, econazole, ketoconazole, and clotrimazole are well established as effective treatments for ringworm (tinea) infections with low risk of adverse reactions.	A	Hay, 2018

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. CASE STUDY

Mrs. Jones is a 70-year-old woman you are admitting to the skilled nursing facility after a total hip replacement. When you obtain her past medical history, she reports a problem with a chronic rash under her breasts and in her supragluteal fold. She has tried a number of topical antifungal treatments without success. She has never seen a dermatologist. While she finds the rash a nuisance and experiences an occasional increase in itchiness, it is something she can live with. Her primary care provider diagnosed the rash as *Candida* and encouraged her to keep the area clean and dry and to use antifungals. Recently, her 42-year-old daughter was diagnosed with psoriasis and asked about a family history of the disease. Mrs. Jones was unaware of anyone in her or her husband's family with that diagnosis.

On physical examination, you note a shiny, erythematous lesion with symmetrical distribution under both breasts. It is well demarcated without drainage and without the presence of any satellite lesions. Examination of the gluteal fold reveals a similar well-demarcated, shiny, erythematous lesion without drainage. On close inspection of the rest of the body around the umbilicus, you note an erythematous patch with silvery scale. You ask Mrs. Jones about the lesion, and she states that it has been there for years. The lesion is worse in the winter, but she attributes this to the closures on her skirts and pants causing irritation. She reports some improvement when applying OTC hydrocortisone cream, although when she stops using the cream, the lesion returns. For this case, the answers and rationale for your decision making need to be provided.

1. What clues in Mrs. Jones' history can help you determine her diagnosis?
2. What signs on physical examination are most helpful to defend or refute the differential?
3. How would you classify the severity of Mrs. Jones' disease? Be specific in your explanation.
4. What would be the treatment(s) of choice in her case?
5. What are some important points to include in patient education?
6. What would require a referral to a dermatologist?

CHAPTER 9

Head, Neck, and Face Disorders

Laurie Kennedy-Malone

ASSESSMENT

When approaching the assessment of the head, begin by asking the patient if they have any headaches. If so, are they similar in presentation? Any history of head trauma or stroke? A systematic and thorough examination of the head and neck begins with the inspection of the face, head, and scalp. Assess the shape, size, and symmetry of the patient's features. Examine the shape of the skull, palpating the bones of the head for any anatomical irregularities, masses, or areas of tenderness. Inspect the hair for distribution, quantity, and any balding patterns, noting any uniform alopecia, nits, or seborrhea. Note any changes in the eyebrows, lateral loss of hair can be a sign of thyroid disease (Suchonwanit & Thammarucha, 2020). The scalp should be carefully inspected for any skin lesions on sun-exposed areas, noting pigment changes, tenderness, scales, or lumps. Assess for scars or bruising patterns. Note the symmetry of the patient's features, facial expressions, the presence of involuntary tics or tremors, periorbital edema, or facial drooping; palpate over the temples for any abnormality or tenderness in the temporal arteries. The presence of pain and nodules on palpation is not a normal finding even in very old individuals. Cranial nerve VII (facial nerve) should also be assessed at this time, noting any facial asymmetry, weakness, drooping of the lower eyelid, and unilateral paralysis (Suneja et al., 2020). The temporomandibular joint should be evaluated for degeneration; note if there is any crepitus as the patient lowers and raises their jaw or pain with chewing. Inquire if the patient hears any popping or grating when chewing or opening their mouth (Gauer & Semidey, 2015).

Eyes

Visual impairment is common in older adults, so it is important to review with patients any changes in vision and how they are adjusting to those changes. One will need to distinguish between normal age-related changes (accommodation, color perception, presbyopia, pseudoptosis, enophthalmos, arcus senilis, ectropion, and entropion) from common visual conditions (Besdine, 2019). Ask the patient about any visual changes that impair function and impact quality of life. Has the patient (or a family member) noted any change in cognition as the visual impairment progresses (Swenor et al., 2020)? Does the patient report having floaters, scotomas, diplopia, blurred vision, or glare? If the patient still drives, are they still driving at night? When was the patient's last eye examination, including screening for glaucoma?

Begin the inspection of the eyes by noting the position and symmetry of the surrounding skin and tissue, as well as the presence and position of the eyebrows and eyelashes. Screen visual acuity before proceeding with any other examination of the eye. Using a Snellen chart from 20 feet, or a handheld chart approximately 12 inches from the patient, assess visual acuity in each eye separately, then together; if the patient wears corrective lenses, they should have those lenses on for this test (Tatum III et al., 2018). Note the condition of the skin around the eyes, check the sclera, and note the color of the conjunctiva. Assess the presence of exophthalmos, xanthelasma, pinguecula, ptosis, edema, and skin lesions. The lids should be carefully examined for the presence of hordeolum, chalazion, ectropion, and entropion, which is most common among older adults (Besdine, 2019). Be careful to note any abnormalities in blinking (Parkinson's disease), dull or blank staring (hypothyroidism), residual facial paralysis (Bell's palsy or cerebrovascular accident), and skin changes. Decreased elasticity and turgor is a normal aging pattern; the skin around the eyes becomes thin and wrinkles appear. This is a normal change in older adults and makes skin turgor a poor determinant of hydration status (Suneja et al., 2020).

Note that basal and squamous cell carcinomas are common around the eye. Palpate for any tenderness over the lacrimal gland and assess the patency of the lacrimal duct. Examine the extraocular motions of the eye (cranial nerves III, IV, and VI). Check the visual fields (cranial nerve II), corneal reflexes (cranial nerve V), and pupillary reactions (cranial nerves II and III) with direct and consensual reactions. Examine the cornea for any scarring, presence of pterygium, corneal arcus, and opacities. Carefully perform a funduscopic examination; most older adults need dilation for accurate assessment of the fundus. If you see the fundus, note the narrow, pale appearance of the arterioles common in older adults.

© F.A. Davis Publishing

Sinuses

Inquire about any recent episodes of sinus congestion. Inspect and palpate over the frontal and maxillary sinus areas. Note any gross tenderness or inflammation in the sinus area or around the eyes.

Nose

Disorders of the sense of smell are common in older adults related to the atrophy of the olfactory bulb, history of allergic rhinitis, chronic rhinosinusitis, neurodegenerative conditions such as Parkinson's disease and dementias and certain medications (Malaty & Malaty, 2013). Patients should be questioned about the severity and persistence of hyperosmia or anosmia and how changes in the sense of smell affects their quality of life. Review allergies, history of sinonasal conditions, head trauma, polyps, and any familial history of neurogenerative conditions known to affect the sense of smell (Malaty & Malaty, 2013). Review any recent history of rhinitis, detecting from the patient any indefinable triggers and treatments. Inquire whether the patient has had any episodes of epistaxis especially for patients on anticoagulants medications (Womack et al., 2018).

Inspect the external nose for any asymmetry, inflammation, gross septal deviation, or deformities. Assess the function of the olfactory nerve (cranial nerve I) by having the patient identify familiar-smelling items such as coffee with the eyes closed. Assess for patency of each nostril. Examine the internal nose, noting any discharge, bleeding, or edema. Check the status of the turbinates and position of the septum using a large otoscope speculum. The color and consistency of the inferior and middle turbinates as well as the presence of any polyps should be noted (Suneja et al., 2020).

Ears

While hearing loss is attributed to aging, patients often do not report concerns. Question the patient or, if appropriate, a family member about concerns of decreased hearing and how the patient is compensating for the hearing loss (adaptive equipment, amplifier). Ask whether any auditory testing has been ordered and if hearing aids were recommended or used (Michels et al., 2019). Ask the patient if they are experiencing any tinnitus (buzzing, chirping). If so, when did it begin? Is it interfering with function? How are they compensating? Determine whether the patient is taking any ototoxic medications. Inquire about drainage, itching, and ear hygiene practices.

Carefully examine the external ears, noting their position and symmetry on the head, as well as any abnormal lesions, deformities, and the presence of tophi, keloids, cysts, or skin cancer lesions on the posterior ear and helix. Palpate the tragus for any tenderness, as well as for any preauricular or postauricular adenopathy.

Estimate auditory acuity (cranial nerve VIII) by using the whisper test or finger rub test, testing each ear separately. Use the Weber and Rinne tests to assess for any conductive or sensorineural hearing loss (Michels et al., 2019). If the patient wears an external hearing aid, it should be removed before examining the external canal. When examining the middle ear, note any inflammation, discharge, or erythema. Carefully examine for cerumen in the external auditory canal; if noted, ask the patient about ear hygiene and prior cerumen removal (Croke, 2017). If visible, inspect the tympanic membranes and surrounding landmarks for abnormalities. Note any foreign bodies, dull membranes, alterations in the cone of light reflex, and presence of fluid or scarring.

Oral Cavity

When approaching the examination of the mouth, begin by asking the patient if they have any loose or sensitive teeth. Do they notice any bleeding after mouth care? Explore if the patient wears dentures; ask whether they fit properly. Any noted changes in eating due to mouth pain or discomfort with chewing or swallowing? Does the patient see a dentist? If the patient is dependent for feeding, is oral care regularly performed? Has the patient noted any changes to the sense of taste (Malaty & Malaty, 2013)?

Perform a complete assessment of the lips, mouth, oral mucosa, and pharynx, noting the color, moisture, and presence of any abnormal lesions on and around the lips. Assess for any herpes simplex I, chancres, angular stomatitis, mucous retention cysts, angioedema, xerostomia, and fissures. Check oral mucosa for color, nodules, ulcers, or white patches (Besdine, 2019). If the patient has dentures, these should be removed to do a complete oral examination. Examine the fit of the dentures and assess the consistency of the gums under the dentures. If natural teeth are present, note any loose or broken teeth as well as caries. Because periodontal disease is the primary cause of tooth loss in the adult, do a careful oral and gum examination. Examine the gums for bleeding, discoloration, swelling, and retractions. Note the attrition of the teeth (exposed dentin) and enamel loss from years of chewing (Besdine, 2019).

Note the condition of the hard palate and the presence of torus palatinus, thrush, or other lesions. Assess the gag reflex and rise of the palate (cranial nerves IX and X). Carefully examine the tongue for symmetry, enlargement (hypothyroidism), growths, protrusions, or abnormal movements (cranial nerve XII) and the dorsum for any papillary atrophy. A swollen, red, painful tongue may indicate vitamin B or riboflavin deficiency. Note any inflammation or obstruction in the parotid (Stensen) or submaxillary (Warton) ducts. Thoroughly examine the area underneath the tongue, the floor of the mouth, and the tonsils, soft palate, uvula, and posterior pharynx, noting any lesions, inflammation, or exudate and the color. Examine the strength and movement of the temporal and masseter muscles (cranial nerve V), as well as any crepitus in the mandible junction. Complete assessment should also include evaluation of the voice (cranial nerve X) and speech (cranial nerves V, VII, X, and XII) (Suneja et al., 2020).

Neck

Inspect the neck for symmetry, masses, scars, tracheal position, and deviation. Look for the presence of thyroid inflammation or goiters. Carefully palpate for any lymphadenopathy, noting that loss of lean muscle makes it easier to feel nodes in the cervical region of older adults. Assess supraclavicular, tonsillar, superficial, deep, and posterior cervical chains and submaxillary, submental, occipital, preauricular, and postauricular nodes, noting any inflammation, tenderness, or change in size, position, or shape

© F.A. Davis Publishing

(Besdine, 2019). Hard, fixed nodes imply malignancy; tender nodes are typical of inflammation (Gaddey & Riegel, 2016). Gently palpate and auscultate the carotid arteries one side at a time for any nodularity or bruits. Note any jugular vein distention that occurs when the patient is seated. Check to see whether the patient uses any neck muscles to breathe. Carefully inspect and palpate the thyroid gland, noting any inflammation or nodules (unilateral). Examination of the range of motion of the neck should include flexion, extension, rotation, and lateral bending. Check the strength of the trapezius and sternomastoid muscles (cranial nerve XI) (Besdine, 2019).

A complete and thorough detailed examination of the head and neck has the potential to allow the examiner to discover multiple variants from the normal. Develop a clear and concise pattern of examination to ensure appropriate evaluation of these areas. Keep in mind the normal variants of the older person and how these differ from pathological or abnormal findings.

AGE-RELATED MACULAR DEGENERATION

Signal Symptoms. Age-related macular degeneration (AMD) is the leading cause of blindness in adults. It is a disease that results in a loss of central vision, which is most crucial for activities of daily living (ADLs) and instrumental activities of daily living (IADLs). The severity of central vision loss varies depending on the type of macular degeneration. Most recently, efforts have been made to standardize the terminology and classification of AMD by defining it as one disease with three stages: early, intermediate, and late. Late AMD is characterized by significant vision loss, which may occur with gradual loss due to "dry" macular geographic atrophy, or with rapid onset as a result of the neovascularization of "wet" macular degeneration (Wenick et al., 2018).

Dry, Nonexudative, or Atrophic Macular Degeneration. Gradual loss of central vision in one or both eyes, with complaints of difficulty reading or driving, blurred or fuzzy vision (late), and the concern that straight lines appear wavy. In early dry AMD there is the presence of drusen, yellow deposits under the retina. In the intermediate stage, pigmentary disturbances in the retinal pigment epithelium (RPE) occur, and in the late stage there is geographic atrophy (GA) with severe central vision loss.

Wet, Exudative, or Neovascular Macular Degeneration (NVAMD). This characterizes one form of late AMD with accelerated central vision loss in a period of weeks to a couple of months. The fragility of the neovasculature results in subretinal hemorrhage or fluid accumulation that destroys the visual center. The disease usually presents in one eye initially, but there is a greater than 40% risk of development in the other eye within 5 years.

Description: The macula in the center of the retina comprises millions of photoreceptor cells containing visual pigments for central vision. These are nourished by the RPE, part of a complex basement membrane that becomes sclerotic with age. AMD is defined as early, intermediate, and late, depending on the severity of vision loss and pathological findings. Dry AMD is most common, accounting for 90% of cases. Onset of visual loss is gradual and may not be noticed if only one eye is affected. The cause is unknown, but there is the presence of drusen and disintegration of the RPE and light-sensing cells. Late AMD with neovasculature occurs in 10% of cases of AMD but accounts for 90% of all AMD blindness. Patients with early and intermediate forms of AMD may develop neovascularization of the choroid area with leakage of new blood vessels and fluid into the retinal pigment epithelium, which causes scarring and additional damage to the macula. The risk ranges from 2% to 20% depending on the size of drusen present. The presence of GA does not protect against the development of NVAMD, with an incidence of 16%, which increases to 36% if NVAMD is present in the other eye (Wenick et al., 2018).

Etiology: A challenge in identifying the cause of dry AMD is the difficulty in distinguishing the early form from normal changes with aging and the lack of symptoms at this stage. As the macula ages, the RPE, Bruch membrane, and choroidal vessels are all affected. Hard drusen may be noted in almost all older eyes. It is the increase in size and number of drusen that is one indication of early AMD. Genetic predisposition and risk factors certainly contribute to the development of AMD. The role of inflammation in the development of AMD is the focus of research on the role of the complement pathway (Campbell & Doyle, 2019). NVAMD has been more aggressively studied in attempts to understand the origin of the angiogenesis. As a result of these studies, several pro-angiogenic factors have been identified. The vascular endothelial growth factor (VEGF) is the most important in intraocular angiogenesis, and its role has resulted in new treatment options for NVAMD. The use of anti-VEGF medications has been shown to stabilize visual function and stop progressive loss of vision (Arrigo, 2021). Research on targeted gene expression for both wet and dry AMD may lead to early diagnosis and treatment (Ammar, 2020; Cinici et al., 2021).

Occurrence: Common; macular degeneration is the leading cause of legal blindness in adults older than 55 years. Risk rises with age; occurrence is 30% in adults older than 75 years. In North America, 15 million people have nonexudative AMD, and 1.7 million have NVAMD. These numbers may be an underestimate because those with early AMD may have no visual changes and may not have been diagnosed. Those with early AMD and NVAMD are at low risk for increasing visual loss, with only one-third progressing to intermediate AMD in the next 5 years (Wenick et al., 2018).

Ethnicity: Individuals who are White are more likely to experience visual loss from AMD than individuals who are Black.

Contributing Factors: The primary risk factor for AMD is advancing age. Other risk factors include family history, smoking, exposure to sunlight, nutritional deficits, hyperlipidemia, and cardiovascular disease. History of AMD in one eye is a risk factor for developing it in the other eye (Brady et al., 2018; Thomas et al., 2021).

Signs and Symptoms: In early AMD there may be no symptoms, particularly if it is monocular. Later, patients may note a decrease in visual acuity or blurred vision that improves in bright light. In late NVAMD, straight lines appear wavy, and there may be a hole in central vision. White-yellow drusen spots are seen on funduscopic examination. Until recently, the primary screening device for NVAMD was the Amsler grid

© F.A. Davis Publishing

test, which, when administered, may reveal wavy lines or missing lines in central vision; however, it has low sensitivity (a high number of false negatives). New perimetry devices are now available for both clinical and home monitoring with better sensitivity and specificity for identifying NVAMD (Wenick et al., 2018). On funduscopic examination of those with NVAMD, choroidal neovascular membranes (CNVMs), subretinal fluid, hemorrhage, and subretinal lipid deposits may be present.

Diagnostic Tests: All patients should have a comprehensive eye examination by an ophthalmologist, including visual acuity with best correction, funduscopic examination, Amsler grid or perimetry assessment, fluorescein angiography, and fundus photos, including optical coherence tomography (Brady et al., 2018; Wenick et al., 2018).

Differential Diagnosis:

- Unexplained loss of visual acuity
- Diabetic retinopathy
- Ocular histoplasmosis
- Trauma with scar
- Hypertension

Treatment: The Age-Related Eye Disease Study (AREDS) found that patients at high risk for late AMD lowered their risk by 25% when treated with high doses of vitamin C, vitamin E, beta carotene, zinc oxide, and cupric oxide. This effect was confirmed through 10 years of follow-up. The efficacy of this was demonstrated for those with intermediate AMD or late monocular AMD to prevent further loss or involvement of the other eye. It is not recommended for those without AMD or those with early AMD who have a low 5-year risk of worsening vision. The risk versus benefits of this high-dose vitamin treatment needs to be evaluated for each patient. The AREDS2 evaluated the effect of substituting the carotinoids, lutein and zeaxanthin, as well as omega-3 (DHA) and eicosapentaenoic acid (EPA) for beta carotene and a lower zinc dose on progression of AMD (AREDS2 Research Group, 2013). The conclusion after 5 years was that eliminating beta carotene and lowering zinc did not make a difference in progression to advanced AMD, and the addition of lutein and zeaxanthin, DHA, and EPA did not further reduce progression. However, they concluded that there may be value in substituting lutein and zeaxanthin for beta carotene because beta carotene increased the risk of developing lung cancer, especially in smokers. Two new eye injections for dry AMD that target the complement cascade are in the last clinical trial phases. The use of stem cells to replace damaged retinal cells is also under investigation (Medieros & Mukamal, 2021). Low-vision enhancement aids are available to help patients with dry AMD. For patients with bilateral advanced and end stage untreatable AMD, a visual prosthetic implant may be considered.

First-line therapy for NVAMD includes monoclonal antibodies that have anti-VEGF abilities. These drugs are injected directly into the vitreous area of the eye and bind with the angiogenic VEGF or receptor and interrupt the neovascularization. They are not able to repair the basic defect or attack the source of VEGF, so they must be used repeatedly to suppress the angiogenic process (Brady et al., 2018). Ranibizumab and bevacizumab (off label) are two humanized monoclonal antibodies that are used to treat NVAMD successfully (Brady et al., 2018). They are injected intravitreally at monthly intervals; current focus is on determining optimal spacing and length of treatment for best results. Local side effects include eye pain, uveitis, and endophthalmitis. There are also potential systemic cardiovascular and thrombotic effects from these drugs, although these have proved minimal. Aflibercept is a newer agent that improves visual outcomes with less frequent injections; preliminary studies show it to be as effective as ranibizumab, with better outcomes in visual acuity and less frequent dosing or maintenance; (Arroyo, 2017).

Laser photocoagulation therapy is no longer first-line treatment since the advent of anti-VEGF therapies. Photodynamic therapy is now being studied as a possible combination therapy with anti-VEGF treatment (Arroyo, 2017). Research into surgical options has yielded disappointing results; likewise, use of statins for AMD has not shown positive results, but recent studies with a small number of participants showed some promise (Arroyo, 2017; Leung et al., 2018). Research is currently underway to find safe, effective treatments for both dry and wet AMD.

Follow-Up: All patients with AMD should be seen periodically by an ophthalmologist for reevaluation of disease progression and, where applicable, further treatment. Patients may be given an Amsler grid or the newest option of an at-home perimetry monitor to use weekly or monthly to check for visual changes.

Sequelae: Loss of central vision limits functional capacity and ability to read. Most AMD patients cannot drive. Environmental safety also is compromised; falls and hip fractures can occur in patients with AMD. Patients using high-dose vitamin and mineral therapy may have yellowing of skin. Smokers are at increased risk for lung cancer from beta carotene included in the first AREDS vitamin supplement formula.

Prevention/Prophylaxis: There is no specific prevention. The U.S. Preventive Services Tax Force (USPSTF) has determined that there is not enough evidence to support routine visual screening of older adults for AMD (USPSTF, 2016). Annual eye examinations in persons over 65 years old can facilitate early detection and, in the case of wet AMD, early intervention to limit visual loss. Smokers should be encouraged to quit.

Referral: All patients older than 65 years should be referred to an ophthalmologist for an annual eye examination. Patients younger than 65 years with visual symptoms also should be referred. Patients with AMD should be referred to the local chapter of the Blind Association for services, vision enhancement devices, and support groups.

Education: Teach patients the importance of seeking evaluation for visual symptoms as soon as they occur. Explain disease process and community support services. Educate the family about the need for environmental safety. Caution patients to avoid unproven remedies. Enforce the role of smoking as an independent risk factor in AMD.

BLEPHARITIS

Signal Symptoms: Redness, itching, burning, scaling of the eyelid margin

Description: Anterior blepharitis affects the eyelids, eyelashes, and follicles. It is chronic, bilateral, with two main types: staphylococcal and seborrheic. Posterior blepharitis is a chronic, bilateral, condition associated with meibomian gland dysfunction (MGD). It is common to see all types of blepharitis occur together (American Academy of Ophthalmology [AAO], 2018; Vagefi, 2017).

Etiology: Anterior blepharitis is associated with a staphylococcal infection or seborrheic dermatitis. Posterior blepharitis is caused by inflammation or infection of the meibomian glands resulting in plugging of the orifices and decreased meibum to the tear film and lid margins. The result can be atrophy and fibrosis of the glands (AAO, 2018; Vagefi, 2018; Watkinson & Seewoodhary, 2017)

Occurrence: Approximately 5% of all ophthalmological conditions in primary care and occurs equally among sexes.

Age: Increased incidence with age.

Ethnicity: No specific association.

Contributing Factors: Other factors include rosacea, dry eye, *Demodex* (mite) infection; viral infections (such as zoster), immunologic conditions (such as lupus or pemphigus), trauma, eyelid tumors, dermatoses, or medication side effects (AAO, 2018; Watkinson & Seewoodhary, 2017).

Signs and Symptoms: Blepharitis due to staphylococcal infection can be associated with scales, dry eye, erythema, ulceration, and loss of eyelashes. Seborrheic blepharitis has greasy scaling on the eyelids and is frequently associated with seborrheic dermatitis of the scalp and eyebrows. Signs of posterior blepharitis include excessive tearing, production of thick "cheese-like" material expressed with pressure on the glands, and hyperemia and telangiectasia of the lid margins, which can roll inward (AAO, 2018; Vagefi, 2018).

Diagnostic Tests: Diagnosis is usually based on patient history. Depending on the chronicity and severity, patients may need a comprehensive eye examination including visual acuity, slit-lamp examination, cultures, or meibomian gland imaging (AAO, 2018).

Differential Diagnosis:

- Discoid lupus erythematosus
- Postoperative endophthalmitis
- Conjunctivitis
- Hordeolum
- Chalazion
- Rosacea
- *Demodex* infection
- Carcinoma (should be considered if unilateral, chronic, and unresponsive to therapy; loss of normal eyelid margin; or focal eyelash loss [AAO, 2018]).

Treatment: Blepharitis is a chronic condition with no cure. The goals of therapy are to provide symptomatic relief and improve quality of life while controlling out-of-pocket costs. Management should be tailored to the patient and include an evaluation of comorbid conditions as well as a review of current medications for potential effects on the eye (AAO, 2018; Charters, 2019; Watkinson & Seewoodhary, 2017). Eyelid hygiene includes warm compresses for several minutes at least once a day. Eyelids can be cleansed once per day with diluted baby shampoo or a commercial eyelid cleaner, which can be applied with a pad, cotton ball, swab, or clean fingertip. Brief, gentle massage can be applied to the meibomian glands but avoid excessive pressure. Artificial tears may help dry eye, but if they are used more than 4 times per day, recommend a product with no preservatives (AAO, 2018; Bitton et al., 2019).

© F.A. Davis Publishing

Topical ophthalmic antibacterial ointments can be applied as directed, usually 1 to 2 times per day for a few weeks if needed. Treatment should be intermittent to avoid microbial resistance. Oral tetracyclines and macrolides may be needed, particularly for MGD. Topical corticosteroid drops or ointment may also be used for severe inflammation. Loteprednol or fluorometholone are preferred. Combination topical antibiotics and corticosteroids are available. Use minimal effective dose and avoid long term use. Topical cyclosporine may be effective in posterior blepharitis (AAO, 2018; Malhotra, 2020; Zhao et al., 2021). If treating possible Demodex (mite infestation), topical or systemic Ivermectin can be prescribed. Studies have shown that products with 50% tea tree oil have also been beneficial (Ergun et al., 2020; Mandal et al., 2017; Periman, 2020). Other treatment modalities for blepharitis, such as intense pulse light therapy, are also available (AAO, 2018; Mandal et al., 2017; Ruan et al., 2019).

Follow-Up: Based on severity, treatment choice, and comorbid conditions.

Sequelae: This is a chronic condition requiring long-term maintenance (AAO, 2018).

Prevention/Prophylaxis: Perform eyelid hygiene on a regular basis. Medications or other treatments are based on response to therapy.

Referral: Refer to ophthalmology with prolonged corticosteroid use to evaluate intraocular pressure. Prompt referral is needed with vision loss, eye pain, recurrent symptoms, or if the patient is unresponsive to therapy.

Education: Emphasize the chronicity of the problem. Develop a plan of care with the patient considering social determinants of health and quality of life with an emphasis on improving symptoms.

CATARACT

Signal Symptoms: Diminished vision in one or both eyes, poor night vision, sensitivity to glare. Because progression is gradual, changes may go unnoticed until visual loss is advanced.

Description: A cataract is an opacification of the lens that interferes with the passage of light through the lens, decreasing visual acuity. The location, size, and density of this opacity influence the degree of visual impairment (Harper, 2017; Yoo & Zein, 2021). Nuclear sclerotic cataracts affect contrast sensitivity, progress slowly, and tend to preserve functional reading vision while frequently causing nearsightedness. In contrast, posterior subcapsular cataracts progress more rapidly and interfere with reading vision.

Etiology: Most cataracts are related to the aging process. The gradual thickening or hardening in the lens is believed to be caused by oxidative damage to the lens protein.

Occurrence: The rate of visually significant cataracts in persons age 50 to 59 years old is 6.8%. Of persons older than 80 years, 68.3% have cataracts (Harper, 2017). Cataracts tend to be bilateral, although the rate of progression varies between the eyes.

Age: Although subtle changes in visual acuity related to cataract formation occur by age 50, people older than 75 years old experience most visually significant cataracts.

Ethnicity: Not significant.

Contributing Factors: Diabetes mellitus, hypertension, poor nutrition, cigarette smoking, high alcohol intake, trauma to the eye, long-term exposure to ultraviolet (UV) B radiation (sunlight), and a strong family history of cataracts are risk factors. Use of certain substances, including oral glucocorticoids, also contributes to cataracts. An association between cataracts and glaucoma and intraocular inflammation exists (Yoo & Zein, 2021).

Signs and Symptoms: The patient with a cataract initially may present with an improvement in near vision, requiring a new prescription for corrective lenses; distance vision will worsen (Harper, 2017). Patients also may experience blurred vision or sensitivity to glare from bright light or from automobile headlights during night driving. Complaints of having difficulty reading and distinguishing contrast sensitivities and of seeing a yellow tint or washed-out colors are common. Some patients may not seek evaluation of their symptoms by a

© F.A. Davis Publishing

health-care provider owing to denial or fear of loss of independence (driver's license being revoked), whereas other patients seek prompt assessment in the hope of early intervention. A recent history of falls, accidents, or injury is suspicious. On physical examination, visual acuity test results are abnormal for one or both eyes (evaluate near and distance vision). Examine the eye using an opaque light for opacification of the lens. The cataract may be visible to the naked eye. The red reflex may be absent, or the cataract may appear as a black area.

Diagnostic Tests: No diagnostic testing is required other than that for visual acuity and examination of the eye unless other visual problems are suspected. Refer the patient to an ophthalmologist for complete evaluation after initial screening. Pupillary dilation and slit-lamp examination will reveal white, gray, or brownish opacities if the cataract is developed. Dark areas on the red reflex in a dilated eye indicate small cataracts; the red reflex may not be visible if the cataract is large (Harper, 2017).

Differential Diagnosis:

- Corneal scarring
- Retinal detachment
- Macular degeneration
- Chronic glaucoma
- Diabetic retinopathy

Treatment: Treatment is determined after full evaluation by the ophthalmologist. Ultimately, surgical intervention is required with extraction of the cataract and immediate implantation of a plastic intraocular lens (IOL), unless contraindicated by other disease conditions. Phacoemulsification is the most common procedure for removal of cataracts. Laser surgery may also be used particularly for astigmatism with the main disadvantage of higher costs. A variety of types of implantable lenses are used depending on patient vision assessment and lifestyle. These include lenses that adjust for astigmatism and refractive errors. The main IOL used is the monofocal lens, with multifocal used for presbyopia and toric lens and laser for astigmatism (Yoo & Zein, 2021). Patients with posterior capsular opacification may require neodymium:yttrium-aluminum-garnet (Nd:YAG) laser capsulotomy. This should not be performed at the same time as other cataract surgery. Collaboration with the ophthalmologist is indicated for patients with severe cardiac, respiratory, or neuromuscular conditions that may prevent the patient from lying still or supine as required during the surgery. Patients with diabetes and hypertension should be instructed in medication use preoperatively. Patients receiving anticoagulant and antiplatelet therapy also should be managed collaboratively and individually. These medications are not usually discontinued preoperatively since cataract surgery is generally low risk for bleeding. Appropriate laboratory tests should be within therapeutic range within 24 hours of surgery (Yoo & Zein,2021). Patients who are or have been on alpha receptor therapy, such as tamsulosin for prostatic enlargement, may experience intraoperative floppy iris syndrome (IFIS). Discontinuing alpha blockers before surgery has minimal or no effect on preventing IFIS, but surgeons should be aware of their use in case modifications are needed during surgery (Yoo & Zein, 2021). Although still considered an alternate practice pattern, intracameral antibiotic injection during surgery has been shown to reduce rates of the rare complication of endophthalmitis (Durand, 2017; Gower et al., 2017; Hashemian et al., 2017).

The degree of visual impairment and its influence on the patient's activities of daily living determine the need and timing of the surgery (American Academy of Ophthalmology [AAO], 2020; Yoo & Zein, 2021). Initially, a conservative treatment plan may include a prescription for glasses and periodic reevaluation by the ophthalmologist, coupled with a plan for environmental safety and optimization of the patient's functional abilities within his or her visual limitations. Surgery is performed in an outpatient or short procedure unit, with the patient returning home immediately after discharge. With the advent of multifocal implantable lenses and toric lenses for astigmatism, glasses may not be required after surgery, however, insurers currently only support monofocal lenses. Advancements in technology continue for cataract refractive surgery (Alio et al., 2017; de Silva et al., 2016; Harper, 2017; Lawless, et al., 2017; Yoo & Zein, 2021).

Follow-Up: Immediate postsurgical care includes eye protection and application of topical agents prescribed by the ophthalmologist. The patient may be cautioned to avoid straining, lifting, or bending. Postoperative follow-up is usually within 24 to 48 hours. The family or health-care team should heighten precautions for environmental safety to avoid injury. Intensive supervision of mentally compromised patients is required to prevent damage to the operative site. Future follow-up includes a reevaluation of visual acuity, prescription of corrective lenses if indicated, and monitoring of the unaffected eye for cataract development.

Sequelae: Possible sequelae to cataract surgery include faulty wound closure with aqueous humor leakage, blindness secondary to choroidal hemorrhage, endophthalmitis, toxic anterior segment syndrome (TASS), inflammation, retinal detachment, prolapse of the iris into the corneal wound, and secondary glaucoma (AAO, 2016; Williams & Khandelwal, 2019; Yeu, 2021).

Prevention/Prophylaxis: The patient should be protected from exposure to UVB radiation by wearing sunglasses designed for this and by wearing a hat with a wide brim.

Referral: After the initial visual screening, refer the patient to an ophthalmologist for complete examination and treatment, including post-surgery follow-up.

Education: Provide the patient with information on age-related visual changes and the importance of protecting the eyes from sunlight with UV-blocking sunglass lenses; maintaining a nutritionally balanced diet including colorful fruits and vegetables; avoiding tobacco and high alcohol intake; and having regular eye examinations based on the recommendations of the eye specialist. Instruct the patient to seek prompt evaluation of any vision changes (Mayo Clinic, 2018).

EPISTAXIS

Signal Symptoms: Bleeding from the nose or into the posterior nasopharynx.

Etiology: More than 90% of the time the bleeding is the result of a spontaneous rupture of a blood vessel in the anterior septum in the Kiesselbach plexus (Nguyen, 2020; Sowerby et al., 2021; Womack et al., 2018). Local causes of epistaxis include trauma due to digital manipulation, irritation or inflammation of the nasal mucosa, foreign bodies, septal defect, or paranasal tumors. Systemic causes include hematologic, hepatic, renal, genetic, cardiovascular, or hereditary hemorrhagic telangiectasias (Beck et al., 2018; Nguyen, 2020; Tunkel et al., 2020).

Occurrence: Most people have at least one episode of minor, nonrecurring epistaxis (Beck et al., 2018; Sowerby et al., 2021; Tunkel et al., 2020). Several sources indicate a lifetime incidence of 60% with about 6% requiring medical intervention (Nguyen, 2020; Tunkel et al., 2020; Womack et al., 2018). Epistaxis occurs more frequently in males than in females (Tunkel et al., 2020). Patients older than age 65 have an increased risk for emergency department visits due to epistaxis (Tunkel et al., 2020).

Age: Epistaxis occurs most frequently in children under age 10 and in older adults (Tunkel et al., 2020).

Ethnicity: Not significant.

Contributing Factors: Local trauma to the anterior portions of the nose (digital, as in nose picking, and facial trauma) is usually the cause of epistaxis. Low humidity or cold weather, foreign bodies, intranasal neoplasms, septal abnormalities, inflammation from rhinosinusitis, intranasal steroids, and systemic medications, such as NSAIDs, anticoagulants, and antiplatelet therapies, may contribute secondarily to the occurrence of epistaxis. Systemic diseases that contribute include hypertension, hematologic malignancy, coagulopathy, or hereditary hemorrhagic telangiectasia. (Gudis & Soler, 2021; Nguyen, 2020; Tunkel et al., 2020; Womack et al., 2018).

Signs and Symptoms: Usually no signs or symptoms are associated with epistaxis other than external bleeding or an awareness of blood dripping down the posterior nasopharynx (Nguyen, 2020).

Diagnostic Tests: No laboratory studies are indicated for minor and nonrecurring epistaxis. For more substantial or recurrent epistaxis, a complete blood count (CBC), bleeding time, prothrombin time (PT), and partial thromboplastin time may be useful. In a patient who is on warfarin therapy, an international normalized ratio (INR) should be drawn if epistaxis occurs. If bleeding is severe and the need for blood replacement is anticipated, type and crossmatch also should be done (Nguyen, 2020; Tunkel et al., 2020).

Differential Diagnosis:

- Trauma
- Inflammation due to rhinitis or infection
- Vascular disorders
- Clotting disorders and blood dyscrasias
- Intranasal foreign bodies
- Hereditary telangiectasia
- Tumors (Tunkel et al., 2020)

Treatment: Most episodes of epistaxis are mild and self-limited, resolving spontaneously. Epistaxis may be controlled by pinching the nostrils together for 10 to 15 minutes, keeping the patient in an erect sitting position with head tilted forward to prevent blood from going down the posterior nasopharynx to protect the airway (Sowerby et al., 2021; Womack et al., 2018). Anterior bleeding that does not stop with manual pressure alone may be controlled with two sprays of oxymetazoline 0.05% applied directly to the bleeding site followed by 10 to 15 minutes of manual pressure.

© F.A. Davis Publishing

Silver nitrate may also be used for control of bleeding once the site of origin is located. Other devices include nasal tampons, such as Merocel or balloons for packing. If packing is needed, adequate pain management must be prescribed, and it should be removed within 2 to 3 days (Gudis & Soler, 2021; Nguyen, 2020; Tunkel et al., 2020; Womack et al., 2018).

Follow-Up: For recurrent episodes, follow-up visits are recommended as needed. Posterior epistaxis, comorbidities, or recurrent bleeding may necessitate admission or referral to an ear, nose, and throat (ENT) specialist for management (Beck et al., 2018; Gudis & Soler, 2021; Tunkel et al., 2020).

Sequelae: Anemia can be a complication of excessive or frequent bouts of epistaxis. Scarring, infection, or eustachian tube dysfunction can result from nasal packing. Severe blood loss can exacerbate existing diseases. Scarring or septal injury may occur from cauterization (Nguyen, 2020; Tunkel et al., 2020).

Prevention/Prophylaxis: Discourage patients from nose picking and rubbing, and excessive sneezing and forceful blowing of the nose; advise them to increase the humidity in the home, especially in winter months. Some patients may be prescribed bacitracin, saline gel, or petrolatum to apply in the Kiesselbach plexus area. Patients may also need to avoid spicy foods and strenuous activities (Nguyen, 2020; Tunkel et al., 2020).

Referral: Consultation with an ENT specialist is indicated for severe or recurrent epistaxis:

- Bleeding that is not controlled after 15 minutes of compression
- Evidence of massive bleeding
- Recurrent bleeding within the first hour
- Second episode of epistaxis within 1 week
- Uncontrolled bleeding from the posterior nasopharynx

The consulting physician may initiate interventions, such as the insertion of nasal tampons or an intranasal balloon to control bleeding. Intractable epistaxis may require transantral arterial ligation or embolization (Beck et al., 2018; Nguyen, 2020; Tunkel et al., 2020; Womack et al., 2018).

Education: Discourage picking of the nose and advise patients to increase the humidity in the home, especially in winter months, by means of a humidifier. Petrolatum or saline gel may be rubbed over the nasal septum to decrease dryness of mucosa or after treatment for acute epistaxis. Teach the patient how to manage simple epistaxis at home by leaning forward while pinching the soft part of the nose for up to 15 minutes, using oxymetazoline if necessary. Seek medical attention for excessive, persistent, or recurrent epistaxis. Prolonged hot showers and hot, spicy foods should be avoided. Instruct the patient to avoid nose blowing and to open the mouth when sneezing (Gudis & Soler, 2021; Nguyen, 2020; Tunkel et al., 2020).

Clinical Recommendation	Evidence Rating	References
Simple measures are helpful in stopping most nosebleeds: nose blowing to clear clots, pinching the nose for up to 15 minutes, and topical decongestants.	C	Ruhl, 2021
Cauterizing visible bleeding vessels with silver nitrate or electrocautery are equally effective.	B	Ruhl, 2021
Anterior packing with different nasal tampons appears to be equally effective.	B	Ruhl, 2021
Patients with resistant or posterior bleeds are likely to need posterior packing, surgery, or embolization.	C	Ruhl, 2021
Routine coagulation tests for epistaxis are not useful unless the patient is taking an anticoagulant.	B	Ruhl, 2021

GLAUCOMA, ACUTE AND CHRONIC

Glaucoma is the leading cause of blindness in the world (Kang & Tanna, 2021). Glaucoma encompasses several different eye diseases characterized by progressive neuropathy of the optic disc, leading to loss of vision. The optic disc is composed of vascular, neural, and connective tissue. The axons of the retinal ganglion cells form a rim around a shallow cup in the optic disc. Apoptosis of the ganglion cells of the retina leads to a thinning of the nerve fibers in the inner layer and axons, with atrophy of the disc and the appearance of cupping or expansion of the cup/disc ratio (Kang & Tanna, 2021; Salmon, 2017). The two most common are primary angle closure with acute or chronic closure glaucoma and primary open-angle glaucoma (POAG).

Signal Symptoms: Unilateral eye pain, visual blurring with halos around lights, conjunctival injection, and photophobia; nausea and vomiting may also occur. Approximately two-thirds of patients with angle-closure glaucoma will have vision loss without experiencing an acute episode.

Description: Acute glaucoma, also known as *angle-closure* or *narrow-angle glaucoma,* is an obstruction to the outflow of aqueous humor from the posterior to the anterior

© F.A. Davis Publishing

chamber through the trabecular meshwork, canal of Schlemm, and associated structures. It typically results in an elevation of intraocular pressure, damaging the optic nerve and causing loss of peripheral vision, eye pain, and redness. This type of glaucoma is uncommon but may occur as a primary disease or secondary to other conditions, and constitutes an ophthalmic emergency (Hoffman, 2018; Kang & Tanna, 2021; Salmon, 2017). Associated presenting symptoms may complicate diagnosis or result in misdiagnosis.

Etiology: The precise pathophysiology of angle-closure glaucoma is unknown. It is a disorder of the lens, iris, and retrolenticular system. In the acute form, pupillary blockage limits the progress of the aqueous humor through the trabecular network. The peripheral iris, which blocks the trabecular meshwork, is displaced forward (Kang & Tanna, 2021; Salmon, 2017).

Occurrence: Uncommon; accounts for 10% of all glaucoma. This disorder is more common in families with prior history and occurs more often in women.

Age: The predominant age range for acute glaucoma is 60 to 70 years old.

Ethnicity: Acute and primary angle-closure glaucoma are more common in Inuit and Asian populations.

Contributing Factors: Contributing factors include an anatomically narrow anterior chamber angle, requiring identification with the use of a special examination technique called *gonioscopy*. This examination technique is beyond the scope of the primary care practitioner, but the condition can be evaluated during the comprehensive eye examination. Other risk factors include hyperopia; small cornea; shallow anterior chamber; Asian ancestry; female sex; family history of glaucoma (first-degree relatives have a 2% to 5% risk over a lifetime); and use of antihistamines, adrenergic agonists, tricyclic antidepressants, selective serotonin reuptake inhibitors and serotonin and norepinephrine reuptake inhibitors, anticholinergics, and cholinergic agents—these drugs may precipitate an acute episode (Kang & Tanna, 2021; Salmon, 2017).

Signs and Symptoms: The presentation is often dramatic, but the diagnosis can be missed because of the associated symptoms. The history reveals severe, unilateral eye pain; blurred vision; lacrimation; reports of seeing colored halos around lights; and a red eye. Headache, nausea, and vomiting frequently accompany eye pain, causing eye pain to be overlooked. Emotional stress also is common. Examination reveals circumcorneal, conjunctival injection, tearing, and a fixed mid-dilated pupil that is nonreactive to light; the cornea is steamy or cloudy. Visual acuity, if evaluated, shows a loss in the affected eye.

Diagnostic Tests: Immediately refer patients for a complete ophthalmological examination (Salmon, 2017).

Differential Diagnosis:

- Conjunctivitis
- Hyphema
- Uveitis
- Corneal trauma or infection

Treatment: The patient with acute glaucoma needs an immediate consultation with and referral to an ophthalmologist. Permanent visual loss occurs within 2 to 5 days if this condition is untreated. Surgical treatment includes peripheral iridectomy or laser iridotomy. Intraocular pressure must be lowered preoperatively, which may require the use of an osmotic diuretic intravenously or orally and miotic eye drops. As the primary health-care provider, you must communicate to the specialist any medical conditions that need monitoring with the use of these agents. Bilateral treatment is indicated because patients are at risk for developing the same problem in the other eye (Kang & Tanna, 2021).

Follow-Up: The ophthalmologist treating the patient determines follow-up treatment. Periodic eye examinations are recommended by preventive guidelines.

Sequelae: If treated promptly, acute glaucoma is not associated with sequelae. If untreated, permanent visual loss occurs.

Prevention/Prophylaxis: Knowing the risk factors for acute angle-closure glaucoma, the health-care provider should educate patients about those risk factors (see under Education). Periodic eye examinations are recommended for prevention.

Referral: Refer the patient immediately on presentation and evaluation of symptoms.

Education: Teach patients with known risk factors (see under Contributing Factors) the importance of regular eye examinations and reporting of symptoms.

Clinical Recommendation	Evidence Rating	References
Acute angle-closure glaucoma is an ocular emergency that requires immediate lowering of IOP with topical/oral/parenteral medications. Laser iridotomy or lens extraction is performed for pupillary block.	A	AAO, 2021 Kang & Tanna, 2021 Salmon, 2017
About half of the patients will develop an acute crisis in the opposite eye. Consider prophylactic iridotomy or lens extraction.	A	Kang & Tanna, 2021

GLAUCOMA, CHRONIC (PRIMARY OPEN-ANGLE)

Signal Symptoms: None initially: silent; blurred vision, tunnel vision, night blindness, halos around lights.

Description: Chronic open-angle or primary open-angle glaucoma is an insidious optic neuropathy characterized by increased intraocular pressure (IOP) severe enough to damage the optic nerve. Progressive over time with a gradual visual field loss, chronic glaucoma is called the *silent blinder* because it often goes unnoticed until the later stages. Variants occur in which IOP does not increase, but the optic nerve still becomes damaged; this is termed *normal tension glaucoma* and is common in Asian populations (Kang & Tanna, 2021; Salmon, 2017). Conversely, some patients have increased IOP but show no optic nerve changes or visual defects; these are referred to as glaucoma suspects (American Academy of Ophthalmology [AAO], 2020a) or those with ocular hypertension (Kass, et al., 2021). Secondary glaucomas are the result of prior or concurrent ocular disease or trauma; they may have open angles caused by steroid-induced pressure increases (Kang & Tanna, 2021).

Etiology: The etiology of chronic glaucoma is unknown, but the disease is associated with increased IOP, optic nerve degeneration, and visual field loss. Because IOP is the one factor that can be measured, most reevaluation and treatment decisions are influenced by this measurement (Sihota et al., 2018).

Occurrence: In 2020, an estimated 76 million people worldwide had glaucoma and by 2040 that number will be 111.8 million (Tham et al., 2014). Prevalence of chronic glaucoma increases in persons older than 40 years, approaching 15% by age 75; 80% of cases are the open-angle type. Primary open-angle glaucoma causes 15% to 20% of all blindness in the United States and is the primary cause of blindness in African Americans (Salmon, 2017). Chronic glaucoma occurs equally in both men and women.

Age: The incidence increases in persons older than 40 years, with another increase in incidence in persons between ages 60 and 75 years. Onset is earlier in African Americans.

Ethnicity: African Americans, Afro-Caribbeans, and Hispanics are at a higher risk than the general population for developing chronic glaucoma (AAO, 2017a; Kang & Tanna, 2021; Salmon, 2017).

Contributing Factors: Risk factors include older age, a positive family history, African American ancestry or Latino/Hispanic ethnicity, type 2 diabetes mellitus, hypertension, myopia, low ocular perfusion, thinner central cornea, and genetic mutations (Kang & Tanna, 2021; Salmon, 2017). Risk factors for secondary open-angle glaucoma include long-term use of topical or oral corticosteroids. It is important to note if the patient had prior LASIK surgery because this can alter corneal thickness. Cataract surgery can also lower IOP, so this history is essential (Salmon, 2017).

Signs and Symptoms: The disease is asymptomatic in the early stages. By the time symptoms develop, significant neural damage has occurred. Eye health specialists frequently discover chronic open-angle glaucoma during routine eye examinations. Patients may present with a complaint of blurred vision, a request for new corrective lenses, or occasionally a report that they see a halo around lights (Kang & Tanna, 2021; Salmon, 2017).

On routine vision screening, visual acuity may be normal or unchanged from previous screening; visual fields may be decreased, however. The skilled examiner may detect changes in the cup-to-disc ratio on funduscopic examination—a cup with a diameter of more than 50% of the vertical disc diameter is highly suspect for glaucoma. Because it is difficult to perform a funduscopic examination on older patients without the benefit of a mydriatic agent, referral for specialized ophthalmological examination is essential. The ophthalmological examination may reveal increased IOP or signs of optic nerve damage without increased pressure (Kang & Tanna, 2021).

Diagnostic Tests: Visual acuity should be measured and compared with prior measurements; pupillary assessment should be included. A dilated funduscopic examination and slit-lamp examination of the anterior segment is conducted, assessing cup-to-disc ratio, asymmetry between discs, or other abnormalities. The most sensitive field testing is done by computerized automated perimeters (Chang, 2017). IOP has a circadian rhythm and is highest in the morning. Time of day, method, and measurements in both eyes are noted and compared with any prior measurements. Target IOP should be individualized with periodic evaluations. Quality of life, comorbid conditions, and social determinants of health, such as costs and adherence, should be considered when setting a target IOP (Sihota et al., 2018).

Gonioscopy is done to rule out other causes of IOP increase, including angle-closure glaucoma. Various imaging modalities, including fundus photography, optical coherence tomography, and scanning laser polarimetry, are used to preserve a permanent visual picture of the optic disc and are to be repeated later for comparison or evidence of disease progression (AAO, 2020b; Salmon, 2017).

Differential Diagnosis:

- Cerebral neoplasia
- Other optic neuropathies
- Vascular occlusive disease
- Trauma

Treatment: Chronic open-angle glaucoma cannot be cured. The goal of treatment is to halt progression of the disease and preserve existing vision as follows:

- IOP control within an identified range
- Stable visual fields
- No further progression of optic nerve damage

Mainstay treatment modalities include:

- Topical eye drops that reduce aqueous production or encourage outflow
- Laser trabeculoplasty
- Trabeculectomy or filtering surgery

Medical treatment with eyedrops is usually first-line therapy unless there are contraindications. Consultation between

© F.A. Davis Publishing

primary care provider and ophthalmologist may be indicated for patient safety and accurate identification of comorbidities and current medications (Kang & Tanna).

If topical ophthalmic agents do not effectively lower IOP, systemic carbonic anhydrase inhibitors can be added. These also may be used before surgery to lower the IOP. If medical therapy is unsuccessful, selective laser trabeculoplasty or filtration surgery (trabeculectomy) to improve aqueous outflow is indicated. The laser treatment is considered for older adults who cannot tolerate surgery, although the outcome is not as desirable as with surgery. In either case, medication still may be required after surgery (AAO, 2017b)

The iStent (one stent) and newer iStent inject (two stents) are available as microinvasive surgery devices. At the conclusion of cataract surgery, this stent is inserted into the canal of Schlemm, allowing the aqueous humor to bypass trabecular obstruction and drain directly from the anterior chamber into Schlemm's canal, lowering IOP. The iStent inject provides superior outflow and increased efficacy.

Follow-Up: Monitor patients for compliance with the treatment regimen. If eyedrops are used, ensure that the patient can instill these, or teach a family member or neighbor to do it. Monitor medications for adverse effects; the range and frequency of side effects to glaucoma medications are significant. Ensure that patients have regular ophthalmological follow-up visits. If visual loss is severe, evaluate the environment for safety and risk of falls or injury. If the patient is still a licensed motor vehicle operator, driver's license retesting may be indicated in the interest of public safety.

Sequelae: If initial presentation is monocular, the other eye may become affected. Changes in the patient's overall health may have implications for the treatment plan.

Prevention/Prophylaxis: The U.S. Preventive Services Task Force (USPSTF) found insufficient evidence to recommend general screening for glaucoma (USPSTF, 2013). Primary care providers need to be aware of risk factors and discuss these with patients who have not been diagnosed but are at risk. Patients who are glaucoma suspects or have actual primary open-angle glaucoma must be reminded of the need for eye examinations, continued monitoring, and adherence to the prescribed regimen. According to the American Academy of Ophthalmology (2020a), patients with known risk factors for glaucoma ages 55 and older should have a comprehensive medical eye examination every 1 to 2 years; ages 40 to 54, every 1 to 3 years; younger than 40 years, every 2 to 5 years. More frequent examinations may be recommended by the eye specialist based on individual risk factors or findings on examination. All adults 65 and older with no risk factors should have an eye examination every 1 to 2 years.

Referral: Refer patients initially for ophthalmological examination and diagnosis. Collaborate on the management plan if the patient has significant medical conditions that affect treatment options, particularly pharmacological choices. Refer patients for periodic follow-up eye examinations or for treatment of complications if they arise.

Education: Educate the patient about the chronic and progressive nature of the disease, the need to follow the treatment regimen as prescribed, and the need for regular follow-up eye examinations and reporting of symptoms, if any. Reassure the patient that, although the disease is not curable, it can be managed. Educate patients with known risk factors about the need for eye examinations despite the absence of symptoms. Asymptomatic patients may question the need for regular treatment. Explain that treatment is preventing disease progression, which is why there are no symptoms. The frequency or complexity of the medication regimen may influence compliance. Reinforce the role of medication in controlling IOP and preventing visual loss.

Clinical Recommendation	Evidence Rating	References
Prostaglandin analogs are effective drugs at lowering IOP and can be considered as initial medical therapy. New medications, comparable to prostaglandins with a different mechanism of action, can overcome some of the limitations of existing medications and improve adherence.	A	Kang & Tanna, 2021 MacIver et al., 2021 Marshall et al., 2018
The goal is a target IOP, based on clinical staging, that would stabilize glaucoma, prevent further visual loss without affecting quality of life.	A	Sihota et al., 2018
The IOP can be lowered by medical treatment, laser therapy, or incisional glaucoma surgery (alone or in combination). The choice of initial therapy depends on numerous considerations, and discussion of treatment with the patient should include the relative risks and benefits of the three options.	A	AAO, 2017b

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. For information about the SORT evidence rating system, go to https://www.aafp.org/afp/2004/0201/p548.html.

HEARING LOSS

Signal Symptoms: Decreased ability to hear in one or both ears, especially in noisy environments. Because age-related hearing loss is gradual and insidious, hearing loss may go unnoticed until it has progressed. Sudden changes in hearing warrant urgent evaluation (Gross, 2021a, 2021b).

© F.A. Davis Publishing

Description: Hearing loss is the decreased ability or complete inability to hear. The unilateral or bilateral loss may involve the external, middle, or inner ear (Michels et al., 2019).

Etiology:

Sensorineural. Hearing loss that is caused by an abnormal function of the cochlea, auditory nerve, or higher aspects of central auditory perception or processing. Presbycusis, noise-induced hearing loss, and ototoxic drug-related hearing loss are all sensorineural. As there is no cure for this, amplification is usually required.

Conductive. Hearing loss that is caused by an issue with sound wave conduction from the outer ear, tympanic membrane, or middle ear. Structural abnormalities, cerumen impaction, tympanic membrane perforation, middle ear effusion, ossicular damage from trauma or infection, otosclerosis, tympanosclerosis, cholesteatoma, middle ear tumors, temporal bone fractures, injuries related to trauma, and congenital problems are some of the causes.

Mixed. Hearing loss within an ear with both sensorineural and conductive components (Chandrasekhar et al., 2019; Michels et al., 2019).

Occurrence: Occurs in almost 15% of adults of all ages. More than 50% of those older than 70 years old, and 80% of those older than 85 years old have hearing loss (Michels et al., 2019).

Age: Sensorineural hearing loss increases with age (Michels et al., 2019).

Ethnicity: Presbycusis is most common in White men, followed by White women, Black men, and Black women (Cheslock & De Jesus, 2021).

Contributing Factors: Increasing age is the highest risk factor for hearing loss. Exposure to loud noises; heredity; ototoxic drugs, such as aminoglycoside antibiotics, salicylates, loop diuretics, cisplatin, and quinine; eustachian tube obstruction; chronic middle ear infections; and chronic cerumen impaction are contributing factors. Most cases of sudden unilateral hearing loss in older adults are idiopathic (Chandrasekhar et al., 2019; Gross, 2021a; Michels et al., 2019; U.S. Preventive Services Task Force [USPSTF], 2021).

Signs and Symptoms: Decreased ability to hear in one or both ears, especially in noisy environments. There may also be tinnitus, fullness, pressure, vertigo, or loss of balance. A history of noise exposure, prior ear problems, or familial hearing problems is significant. Older adults with hearing loss should also be screened for dementia (Chandrasekhar et al., 2019; Di Stadio, 2021; Michels et al., 2019).

An otoscopic examination of the external auditory canal and middle ear should reveal a clear ear canal with minimal cerumen and an intact tympanic membrane in the case of sensorineural hearing loss. Signs that may indicate other pathology are redness, foreign objects, discharge, odor, scaling, lesions, fluid, or cerumen impaction. Changes in the tympanic membrane may indicate conductive hearing loss (Leedy et al., 2021; Michels et al., 2019; USPSTF, 2021).

Diagnostic Tests: The gold standard for diagnosis is a diagnostic audiogram. Primary care provider awareness requires asking about and screening for hearing loss in older adults. A screening questionnaire could be utilized or asking a single question—"Do you have a hearing problem now?"—can also be effective. Use of a portable pure-tone audiometer in the primary care setting is also a quick screening test. Refer anyone with a hearing threshold of 40 dB or greater to audiology. A history of trauma or sudden hearing loss warrant an urgent otolaryngology consultation, and a computed tomography (CT) scan or magnetic resonance imaging (MRI), respectively, may be ordered. The Weber and Rinne tests can help to differentiate between sensorineural or conductive hearing loss (Chandrasekhar et al., 2019; Cheslock & De Jesus, 2021; Michels et al., 2019; USPSTF, 2021).

Differential Diagnosis:

- Ménière disease
- Acoustic neuroma (unilateral, with tinnitus)
- Cholesteatoma (unilateral)
- Meningioma (unilateral)
- Trauma (often unilateral)
- Otitis media with effusion (retracted tympanic membrane, fluid behind tympanic membrane)
- Acute otitis media (unilateral, ear pain; building, immobile tympanic membrane)
- Central auditory processing disorder (Michels et al., 2019)

Treatment: Treat any reversible or modifiable causes, and refer to audiology and otolaryngology, as appropriate. Amplification, assistive listening devices, and audiological rehabilitation may be helpful. Encouragement, follow-up, and support are important (Chandrasekhar et al., 2019; Di Stadio et al., 2021).

Cerumen Impaction. Cerumen, or earwax, is a naturally occurring substance that cleans, protects, and lubricates the external auditory canals, but obstructs the canals when the self-cleaning mechanism fails. This is most common in older adults; surveillance is recommended for those living in long-term care facilities and in those with developmental delays or hearing aids. Cerumen impactions can cause conductive hearing loss, tinnitus, aural fullness, otalgia, and pruritus. Cerumen disimpaction is only indicated if necessary for otoscopic examination, in young children, or those cognitively impaired who may not be able to express symptoms. Treat patients with cerumenolytic agents, irrigation, or manual removal, and instruct those with hearing aids on proper ear hygiene. Cerumenolytics may be indicated for recurrent cerumen impaction. Patients should be examined for resolution after treatment of impaction, repeating treatment or referring to otolaryngology for persistent or concerning impactions. Ear candling is not recommended to treat or prevent cerumen impactions (Leedy et al., 2021; Schwartz et al., 2017).

Presbycusis. Age-related hearing loss is usually bilateral, symmetric, and slowly progressive with a normal otoscopic examination. It is typical in older adults with a family history. Refer to audiology for diagnosis and amplification, and to otolaryngology if amplification is ineffective (Gross, 2021b; Michels et al., 2019).

Sudden Hearing Loss. This is usually unilateral with an onset of 3 days or less. More than 90% of cases are idiopathic; acoustic neuroma, stroke, or malignancy are the most

© F.A. Davis Publishing

common identified causes. Treatment of choice is oral or intratympanic steroids within 14 days of symptoms onset for best chance of meaningful audiological recovery. Patients should have an MRI to rule out retrocochlear pathology, as well as a formal audiogram and a referral to otolaryngology (Chandrasekhar et al., 2019).

Follow-Up: See patients as indicated by the cause of the symptom (USPSTF, 2021).

Sequelae: Possible complications depend on the cause of the symptom but may include permanent hearing loss. Patients may need hearing aids or assistive listening devices. Middle ear problems may progress to chronic ear problems, such as perforations and cholesteatoma. Social isolation, depression, and dementia may result from inability to communicate (Di Stadio et al., 2021; Michels et al., 2019; USPSTF, 2021).

Prevention/Prophylaxis: Advise patients to use protective devices to limit occupational or recreational noise exposures. Patients should be aware of the potential for barotrauma. Avoid any ototoxic medications. Teach proper techniques for cerumen removal and avoidance of ear swabs or other foreign bodies in the ear. Hearing screening tests are recommended for persons older than 65 years and those reporting hearing difficulty. The USPSTF does not recommend periodic screening for hearing loss in asymptomatic adults (Leedy et al., 2021; Michels et al., 2019; Schwartz et al., 2017; USPSTF, 2021).

Referral: Consult with appropriate specialists as indicated by cause of symptom. Refer to an audiologist for hearing aid evaluation. All patients with hearing loss and tinnitus should be advised of the benefits of audiological rehabilitation. Amplification may prevent and treat cognitive decline in older patients. All patients with unexplained or asymmetric hearing loss should have an otoscopic and audiometric evaluation. Select patients may also be evaluated for bone-anchored hearing devices or cochlear implants (Chandrasekhar et al., 2019; Di Stadio et al., 2021; Michels et al., 2019; USPSTF, 2021).

Education: Explain cause of symptoms, measures taken to determine the cause, and symptomatic treatment, if any. Advise patients when to seek medical care. Teach the importance of using hearing aids, if indicated, because this can make a significant difference in quality of life. It is important for all providers to work together as part of a multidisciplinary team. Patients with hearing loss should directly face others when talking, use adequate lighting, and minimize background noise. There are also auditory, visual, and tactile alerting systems that may be beneficial. Monitor for falls, hospitalizations, social isolation, and cognitive decline, which are all more prevalent with hearing loss (Chandrasekhar et al., 2019; Michels et al., 2019; Schwartz et al., 2017; USPSTF, 2021).

Clinical Recommendation	Evidence Rating	References
The U.S. Preventive Service Task Force found insufficient evidence to assess the balance of benefits and harm of screening for hearing loss in asymptomatic adults ≥50 years.	C	USPSTF, 2021
Thoroughly evaluate clinically and audiometrically any patient who complains of hearing loss if no easily reversible cause is identified (i.e., cerumen or infection)	C	Gross, 2021a
Bedside hearing tests have a good specificity but poor sensitivity for detecting hearing loss; if hearing loss suspected or reported, refer for formal audiometry.	C	Gross, 2021a
Sudden hearing loss warrants urgent evaluation and treatment by a specialist.	C	Gross, 2021a
Patients who report hearing loss should be referred for full audiometry.	C	Gross, 2021b
Order imaging and/or otolaryngology referral if vertigo, sudden onset, neurological symptoms, unilateral loss, or primarily low-frequency loss.	C	Gross, 2021b
Patients with presbycusis may benefit from amplification or assistive listening devices.	C	Gross, 2021b

HORDEOLUM AND CHALAZION

Signal Symptoms: Increased lacrimation with lump on eyelid.

Description: A hordeolum (stye) is an acute, purulent area of inflammation in the meibomian gland or gland of Zeis, commonly referred to as a "stye." The hordeolum typically contains *Staphylococcus aureus* bacteria; it can occur internally (underside of the eyelid) or externally at the lid margin (Ghosh & Ghosh, 2017); and some styes are sterile. A chalazion is a sterile mass on the eyelid caused by an inflammation and obstruction of a meibomian (oil-secreting) gland of the upper or lower eyelid. Meibomian glands lubricate the lid

© F.A. Davis Publishing

margins. The chalazion is more chronic in nature, painless, and lipogranulomatosis without erythema. It can interfere with vision at times and develops a rubbery consistency (Vagefi, 2018).

Etiology: Blockage in a duct leading to the eyelid surface from the meibomian gland or obstruction of the gland of Zeis results in inflammation or infection (usually from *Staphylococcus*) called hordeolum. If the blockage becomes chronic, progressing to the formation of a hard, granulomatous mass, it is called a chalazion.

Occurrence: Common and occurs equally in men and women.

Age: Can occur at any age.

Ethnicity: Not significant.

Contributing Factors: Previously unresolved blepharitis, poor hygiene, immunosuppression, and skin conditions, such as acne rosacea or seborrheic dermatitis, all are contributing factors to development of hordeolum or chalazion (Fort, 2018; Vagefi, 2018).

Signs and Symptoms: A hordeolum is an acute, erythematous, painful lesion at the hair follicles of the eye lashes (external) or the meibomian glands (internal) (Horak, 2021). A chalazion is a slow-developing, painless nonfluctuant mass, with inflammation of the meibomian gland and possible involvement of the surrounding tissue. It tends to be deeper within the lid than hordeolum. Physical examination with inversion of the eyelid reveals a red, elevated mass that may become large and press against the cornea (Vagefi, 2018).

Diagnostic Tests: None unless recurrent or unusual signs, then biopsy of lesion to rule out malignancy.

Differential Diagnosis:

- Foreign body
- Contact dermatitis
- Rosacea
- Atopic dermatitis
- Blepharitis
- Orbital cellulitis
- Acute dacriocystitis
- Sebaceous cell, meibomian gland, or basal cell carcinoma (Ghosh & Ghosh, 2017; Vagefi, 2018)

Treatment: Warm compresses are applied to the affected eyelid for 10 minutes, four times daily, to facilitate opening and drainage. Allow purulent lesions to drain without squeezing them. Massage of the eyelid after warm compresses may help to soften secretions. Many lesions resolve spontaneously without treatment. In cases of secondary infection, antibiotic eyedrops, or ointment may be used; combination antibiotic and steroid should be used only by an ophthalmologist. If the hordeolum progresses to preseptal cellulitis, prescribe a systemic antibiotic, such as dicloxacillin (Fort, 2018). Treatment of chalazion includes warm compresses for 15 minutes four times a day. Incision and drainage by an ophthalmologist may be needed if there is no resolution after 2 months. Antibiotics are not indicated because it is granulomatous in nature (Ghosh & Ghosh, 2017). A large nondraining hordeolum or chalazion may require emergency treatment if cellulitis occurs (Vagefi, 2018). A Cochrane review on the use of nonsurgical interventions for acute internal hordeolum found no evidence for or against nonsurgical treatment (Lindsley et al., 2017). Most chalazia will resolve with use of conservative measures (Jordan & Beier, 2020).

Follow-Up: See patient in 2 to 4 weeks to evaluate treatment.

Sequelae: Complete resolution may take several weeks to months; frequent recurrence may indicate underlying malignancy (Ghosh & Ghosh, 2017).

Prevention/Prophylaxis: Prevention strategies include advising the patient to perform proper lid hygiene (helps prevent recurrence) by gently scrubbing lids with diluted baby shampoo daily or directly applying baby shampoo with cotton-tipped applicator, then rinsing. Frequent hand washing is advised. Warm compresses should be initiated at the first sign of eyelid irritation or if chalazion starts to return; a clean cloth should be used for each warm compress to eye (Ghosh & Ghosh, 2017).

Referral: Refer to or consult with an ophthalmologist if the patient has a visual change, eye pain, or impairment to the eye, or if the chalazion does not heal spontaneously in 6 weeks, because surgical removal may be necessary.

Education: Explain the problem and treatment. Discuss prevention strategies.

Clinical Recommendation	Evidence Rating	References
Initial treatment includes warm compresses 4 times daily and topical erythromycin ointment for hordeolum.	C	Bragg et al., 2021 Wolter, 2017
Lesions refractory to treatment should be referred for incision and drainage (both hordeolum and chalazion).	C	Jordan & Beier, 2020 Wolter, 2017
Sebaceous carcinoma should be suspected in patients who are middle-aged and older with persistent chalazia. Ulceration, irregular/pearly borders, loss of lashes or eyelid margin, telangiectasia or proximal adenopathy (preauricular nodes): Consider biopsy of lesion.	C	Horak, 2021 Wolter, 2017

ORAL CANCER

Signal Symptoms: A lesion in the mouth or on the lip that does not heal. A long-lasting sore throat, earaches, swelling in the neck, unintentional weight loss or difficulty chewing or swallowing. There are some patients that have no symptoms at all (Pfister et al., 2020).

Description: Oral cancer includes cancers of the mouth and the back of the throat. These cancers can also arise on or under the tongue, at the base of the tongue, on the lining of the mouth and gums, and the area in the back of the throat (National Institute of Dental and Craniofacial Research, n.d.). The oral cavity includes the lips, the labial and buccal mucosa, the front of the tongue, the retromolar pad, the base of the mouth, the gingiva, and the hard palate (Figure 9-1). The oropharynx includes the palatine and lingual tonsils, base of the tongue, the soft palate, and the posterior pharyngeal wall (CDC, 2020).

Etiology: Alcohol and tobacco are the most common factors in the development of oral cancers. Since the whole aerodigestive tract may be exposed to the carcinogens, patients with head and neck (H&N) cancers are at risk for developing second cancers of the H&N, lung, esophagus, and other sites that share these risk factors (Pfister et al., 2020).

Occurrence: The rate of new cases of oral cavity and pharynx cancer was 11.5 per 100,000 men and women per year (SEER, 2022; Siegel et al., 2022). In 2020, it is estimated that about 65,630 new cases of oral cavity, pharyngeal, and laryngeal cancers will occur, which account for about 3.6% of new cancer cases in the United States. Approximately 14,500 deaths from H&N cancers will occur during the same time period. Squamous cell carcinoma accounts for more than 90% of these tumors (Pfister et al., 2021). More men develop oral cancer then their female counterparts.

Age: Oral cancer rates increase with age, causing the older adult to be at increased risk. The increase becomes more rapid after age 50 and peaks between ages 60 and 70 (Pfister et al., 2020).

Ethnicity: Oral cancer rates are higher in Hispanics and Blacks than for White males (NIDCR, n.d.).

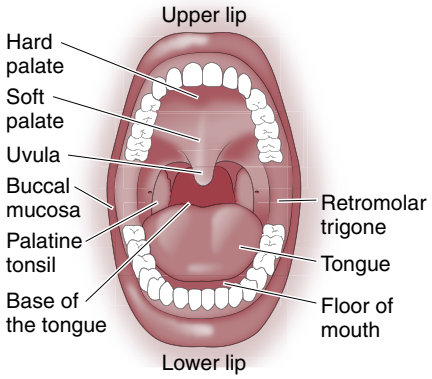

FIGURE 9-1 Oral anatomy.

Contributing Factors: There is an increased risk of oral cancers associated with tobacco use of any type (including smoking or chewing tobacco), and heavy alcohol intake. The combination of both smoking and drinking is synergistic in elevating risk of oral cancer (NIDCR, n.d.). Ultraviolet (UV) light exposure is a major factor in the development of lip cancer. Occupational exposures or being exposed to certain environmental substances, such as those associated with construction work, or working with textiles, ceramics, logging, and food processing industries can expose people to wood dust, formaldehyde, asbestos, nickel, and other chemicals, which can further increase risk. Epstein-Barr virus has been shown to increase the development of cancer in the nose, behind the nose, and cancers of the salivary glands. Human papillomavirus (HPV) has been discovered to have a close relationship to the development of head and neck cancers and is transmitted by oral sex. About 10% of men and 3.6% of women have oral HPV, and oral HPV infection is more common with older age (CDC, 2020).

Signs and Symptoms: A lesion in the mouth can cause a sore that does not heal on the gums, tongue, or lining of the mouth. Patients can also experience swelling of the jaw, unusual bleeding or pain in the mouth, a lump, or problems with ill-fitting dentures. A lesion at the back of the mouth (pharynx) or voice box (larynx) can lead to trouble breathing or speaking. Patients can also experience a lump in their mouth or throat, difficulty chewing or swallowing food, a globus sensation (a feeling that something is caught in the throat), ongoing pain in the throat, pain in the ear, difficulty hearing, or tinnitus (CDC, 2020).

Diagnostic Tests: Screening processes can warn patients about the possible development of the disease before any malignant progression has taken place. Most diagnostic modalities can detect lesions only after they have metastasized. Tissue biopsy followed by histological assessment is still considered as the gold standard for diagnosing oral cancer (Chakraborty et al., 2019). Appropriate selection and use of imaging studies is crucial for proper management of patients with head and neck cancers. CT and/or MRI are often the first diagnostic modalities used (Pfister et al., 2020). A dentist or medical practitioner may check the oral cavity during a routine checkup.

Differential Diagnosis: Differential diagnosis can include: traumatic ulceration, erythroleukoplakia (red or white-red plaques), median rhomboid glossitis (a fungal infection of the dorsal region of the tongue that resolves with treatment), eosinophilic granuloma (self-limiting chronic benign ulcerative lesion of the oral mucosa that it is similar to oral squamous cell carcinoma in its early stages), keratoacanthoma (tumor originating in the pilosebaceous glands and closely resembling oral cancer), or necrotizing sialometaplasia (characterized by salivary gland metaplasia, necrosis, and ulceration). Other differential diagnoses include benign tumors or infection (Bagan & Bagan-Debon, 2020).

Staging. The TNM Staging system is used to describe the amount and spread of cancer in a patient's body, using TNM.

© F.A. Davis Publishing

T describes the size of the tumor and any spread of cancer into nearby tissue (Figure 9-2); N describes spread of cancer to nearby lymph nodes; and M describes metastasis (spread of cancer to other parts of the body) (National Comprehensive Cancer Network [NCCN] 2021).

Treatment: There are three main treatments for oral cancer: surgery, chemotherapy, and/or radiation. The treatment for head and neck malignancies varies greatly based on the primary site and stage of disease. In general, surgery is the first treatment for cancers of the oral cavity and may be followed by radiation or combined chemotherapy and radiation (NCI, n.d.). There are several chemotherapeutic options for oral cancer. A chemotherapy drug may be used alone or combined with other drugs. Combining drugs can often shrink tumors better, but may cause more side effects (American Cancer Society [ACS], 2021). Radiation therapy might be used in a variety of ways. It can be used alone as the main treatment for small cancers or for those patients who are unable to have surgery. It can be used after surgery (adjuvant therapy), either alone or with chemotherapy (chemoradiation), to try to kill any cancer cells that might be lingering after surgery. It can also be used before surgery (neoadjuvant therapy) with chemotherapy (chemoradiation) or after chemotherapy to try to shrink some larger cancers. Radiation can also be used in combination with a targeted drug for larger cancers, if the patient is unable to receive chemotherapy (ACS, 2021). Clinical trials can also offer an alternative or additional treatment option for patients with H&N cancer. Recent, late-phase research clinical trials support the use of immunotherapy for patients with recurrent, unresectable, or metastatic H&N cancer (Pfister et al., 2020).

Sequelae: Patients with oral cancer are at risk of the cancer reoccurring and for developing new cancers in the head and neck area (ACS, 2021).

Prevention/Prophylaxis: People who have been treated for H&N cancers have an increased chance of developing a new cancer, usually in the head, neck, esophagus, or lungs. (NCCN, 2021). The primary intervention in preventing a reoccurrence targets decreasing or eliminating tobacco and alcohol intake. According to the National Cancer Institute (2021), another important intervention for preventing oral cancer includes not chewing betel quid. Chewing betel quid is common in many countries in South Asia and Southeast Asia, especially in China and India. It is a type of smokeless tobacco. Avoiding prolonged sun exposure can help decrease the chance of a sun-related malignancy. HPV has been proven to increase the incidence of oral cancer; therefore, eliminating oral sex or practicing safe sex can prevent HPV-related oral cancers (NCCN, 2021). Figure 9-3 show steps for oral cancer screening.

Referrals: The management of patients with head and neck cancers is challenging. To optimize treatment options and outcomes, oral cancer patients need access to the full range of support services and specialists with experience in managing head and neck cancers. Per the National Comprehensive Cancer Network ([NCCN], 2021), important members of the interdisciplinary team include:

- Head and neck surgery
- Radiation oncology
- Medical oncology
- Plastic and reconstructive surgery
- Specialized nursing care
- Dentistry/Prosthodontics
- Physical medicine and rehabilitation, including therapy for lymphoedema of the neck
- Speech and swallow therapy
- Clinical social work
- Clinical nutrition

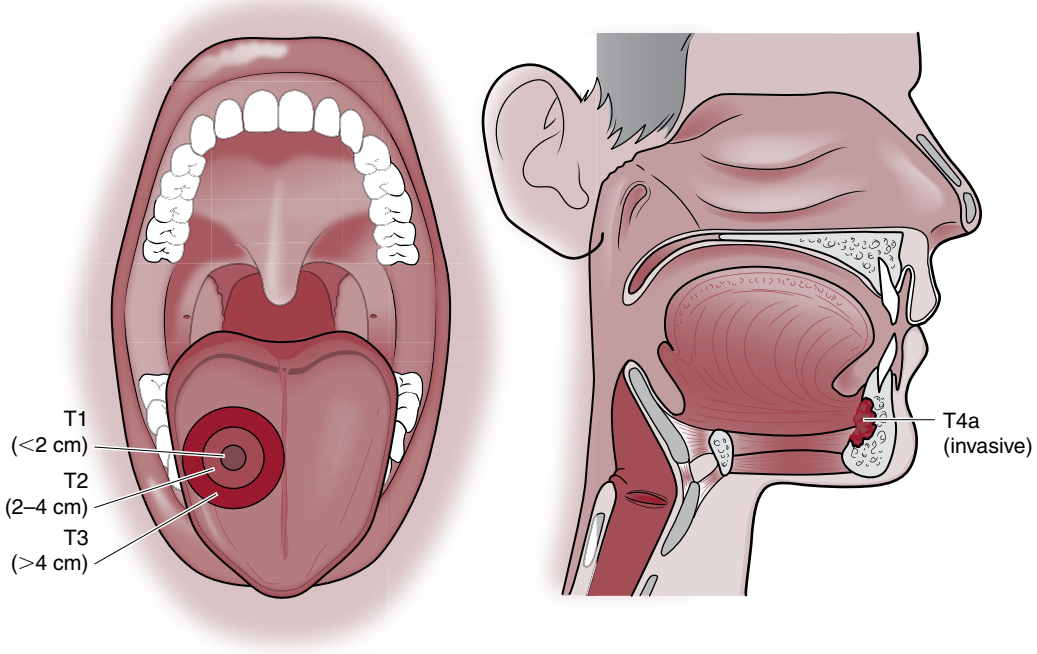

FIGURE 9-2 Oral cancer staging.

© F.A. Davis Publishing

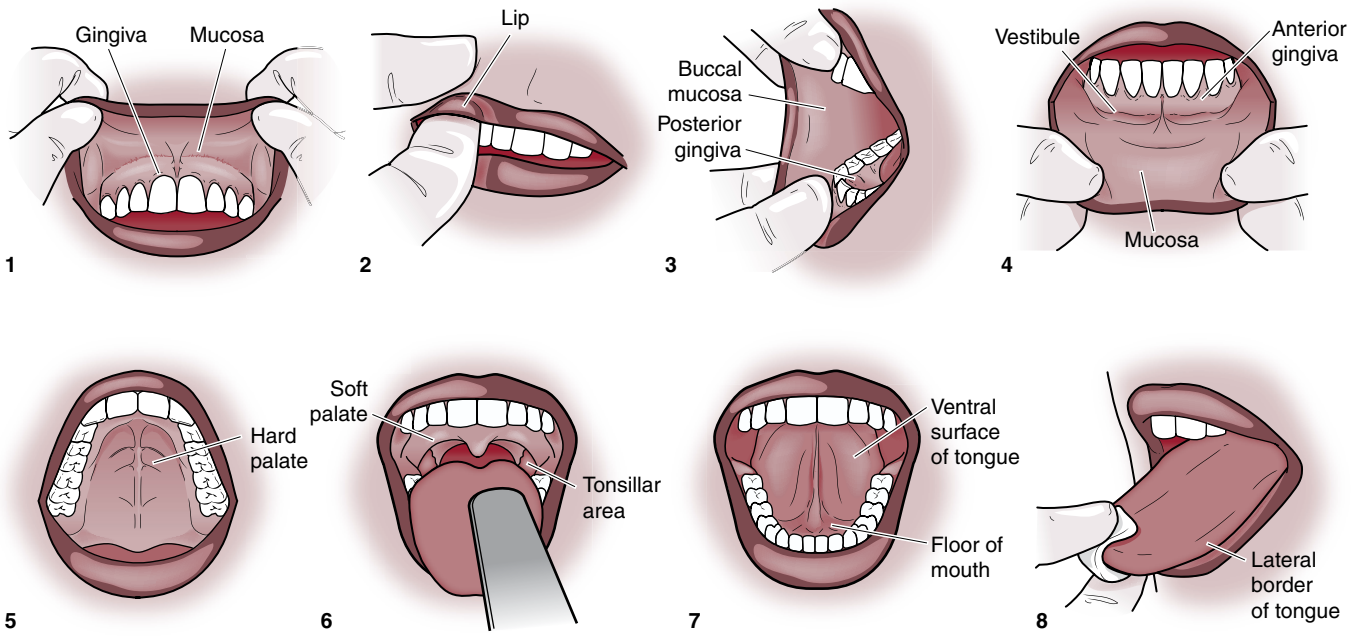

FIGURE 9-3 Oral cancer screening.

- Pathology (including cytopathology)
- Diagnostic and interventional radiology
- Adjunctive services such as neurosurgery, ophthalmology, psychiatry, addiction services, and audiology
- Palliative care

Education: Ongoing education about avoiding factors which increase the risk of oral cancer is critical. Teaching patients how to examination their oral cavity can help to detect reoccurrences. Regular visits to primary care providers, dentists, and specialists are essential.

Clinical Recommendation	Evidence Rating	References
Curative treatment for local oropharyngeal cancer typically consists of resection, which is preferred, or definitive radiation therapy. This surgical intervention consists of resection of primary tumor without neck dissection or resection of primary and ipsilateral or bilateral neck dissection or resection of primary tumor and lymph node biopsy.	A	National Comprehensive Cancer Network Guidelines (NCCN), 2021
Patients with metastatic oral cancer would benefit from either surgery or a clinical trial. For patients with positive margins detected in surgery, systemic therapy would be recommended. Following either surgery or clinical trials, radiation therapy should then be considered.	A	NCCN, 2021

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. RETINOPATHY

Signal Symptoms: Blurred vision, painless visual loss, poor night vision, poor color vision, floaters.

Description: Retinopathy, a disease of the retina, includes several types: hypertensive, diabetic, and, less commonly in older adults, sickle cell; polycythemia vera; and infectious causes such as toxoplasmosis or cytomegalovirus in HIV.

Etiology: The pathology of the retinopathy relates to the underlying cause. Systemic causes common to older adults include hypertension (arteriosclerotic retinopathy), diabetes (diabetic retinopathy), and AMD (see previous discussion). Hypertensive or arteriosclerotic retinopathy is related to the severity of the hypertension. Diabetic retinopathy is a highly specific microvascular complication of type 1 and 2 diabetes. It is related directly to the duration of diabetes, the patient's age at onset, and glycemic control. Diabetic retinopathy is either proliferative or nonproliferative. Nonproliferative retinopathy is most common in type 2 diabetics and is characterized by dilation of veins, microaneurysms, retinal edema and hemorrhages, and hard exudates. Proliferative retinopathy is common in type 1 diabetics and includes neovascularization, vitreous hemorrhage, and retinal detachment; secondary

© F.A. Davis Publishing

glaucoma also can occur because of blockage of outflow channels by new vessels. Diabetic retinopathy often coexists with hypertensive retinopathy.

Occurrence: Diabetic retinopathy is the leading cause of new blindness in people 20 to 74 years old. Up to 27% of people with type 1 diabetes have some retinopathy present in 5 to 10 years of diagnosis, and after 10 years the prevalence is 70% to 90% (Yanoff & Cameron, 2016). Nearly 80% people with type 2 diabetes develop retinopathy after 15 to 20 years and it is present in one-third at the time of diagnosis (Hammes et al., 2014). Diabetic retinopathy develops earlier in older patients, but proliferative retinopathy is less common. Proliferative retinopathy is more common with insulin use. According to the National Eye Institute (2020), diabetic retinopathy affects 7.7 million people ages 40 years and older. Hypertensive retinopathy is seen with poorly controlled hypertension.

Age: Older adult patients are more likely to have hypertensive or diabetic retinopathy because of the increase in chronic disease with age. Approximately one-half of all diabetes cases occur in persons older than 55 years. Men develop diabetic retinopathy sooner than women.

Ethnicity: Diabetes is more common in Native Americans, Asian Americans, African Americans, Hispanic Americans, and Pacific Islanders. Rates of diabetic retinopathy are highest among Hispanic Americans. Hypertension is more prevalent among African Americans.

Contributing Factors: Contributing factors in diabetic retinopathy include age at onset, type of diabetes, duration of disease, poor glycemic control (persistent elevated hemoglobin A1c), arterial hypertension, dyslipidemia, nephropathy, smoking, and stage at which retinopathy is detected (early detection of nonproliferative is preferred) (Thomas, et al., 2020). Duration of disease is the best predictive factor for retinopathy (American Academy of Ophthalmology [AAO], Retina/Vitreous Panel, 2020). Causes of other types of retinopathy include poorly controlled hypertension and AMD. Multiple sclerosis, sarcoidosis, and coagulopathies are also associated with proliferative retinopathy (Mathura et al., 2018).

Signs and Symptoms: Retinopathy usually develops without symptoms until advanced stages of the disease. If presenting with symptoms, they may be the insidious painless onset of decreased visual acuity. Patients may report blurred vision, poor night vision, poor color vision, or "floaters and flashers." The ophthalmoscopic examination may be the first point of detection in an asymptomatic patient. All patients with known diabetes or hypertension should have regular comprehensive eye examinations, including a funduscopic examination. The funduscopic changes seen in patients with hypertension include arteriolar narrowing, arteriovenous nicking, changes in arteriolar light reflex, and tortuosity of vessels. Classic nonproliferative changes in patients with diabetes are microaneurysms and hard and soft exudates. Clinical findings in patients with proliferative retinopathy are cotton-wool spots, deep hemorrhages, and neovascularization.

Diagnostic Tests: Dilated funduscopic examination and comprehensive eye examination, fundus photos, ocular coherence tomography (OCT), and fluorescein angiography are used to diagnose diabetic retinopathy (AAO, 2021; Janigian, 2018). Hypertensive retinopathy is a clinical diagnosis based on physical examination findings during slit-lamp examination. Although not specific for the diagnosis of retinopathy, regular monitoring of hypertension, lipids, and blood glucose is essential in disease management and prevention of complications.

Differential Diagnosis:

- Retinal detachment
- Cytomegalovirus retinitis (usually associated with HIV)
- Toxoplasmosis (associated with latent infection)
- Retinal vasculitis
- Retinal vein occlusion
- Hyperviscosity syndromes

Treatment: Prevention and early detection are fundamental to preserving vision. Annual ophthalmological examinations are required. For patients with diabetes, the goal is to optimize glucose control. Patients with hypertension or hypertension and diabetes should be treated to control blood pressure (goal is 130/80 mm Hg for those with diabetes, 140/90 mm Hg without diabetes). Blood pressure reduction should be slow and deliberate to minimize end-organ damage; treatment of the underlying pathology is essential. The parameters and goal of treatment in patients with hypertension and diabetes should be clear and concise.

For patients who have diabetes with nonproliferative retinopathy, macular edema is responsible for most vision loss. If macular edema is clinically significant, treatment with anti-VEGF is superior to laser therapy, but intravitreal steroid injection may also be used. For those with diabetes with severe nonproliferative disease, panretinal laser photocoagulation can lower the risk of progression to proliferative diabetic retinopathy (Crandall & Shamoon, 2016). For patients who have diabetes with vitreous hemorrhage and advanced neovascularization, vitrectomy can be of significant benefit (Mathew & Sivaprasad, 2018).

Follow-Up: Follow-up depends on the findings. A retinal specialist should follow up with patients with retinopathy. The primary care provider is responsible for regular disease management. The staging of retinopathy and the treatment plan require specialty follow-up.

Sequelae: Not all retinopathy is progressive. The condition and its outcome are related to the cause of the retinopathy and the degree of successful disease management. For hypertensive retinopathy, arteriovenous nicking and arteriolar narrowing are irreversible.

Prevention/Prophylaxis: Older adult patients should have an annual ophthalmological examination. During routine office visits, perform a funduscopic examination on the eyes of patients with diabetes and hypertension. Promptly refer the patient to a retinal specialist at the earliest report of vision change or abnormal examination findings. Patients with diabetes and hypertension should be aware of the goals of treatment and the need to control blood pressure and blood glucose. Home monitoring of blood glucose and blood pressure may be advised.

Referral: A retinal specialist should see all patients with retinopathy. All patients with diabetes and hypertension should see an ophthalmologist annually. Communication between

© F.A. Davis Publishing

the specialist and primary care provider is essential for optimal patient treatment.

Education: Patients should report any alteration in vision. Patients should know how the goals of blood pressure and blood glucose control relate to prevention of complications. Finally, patients should understand the importance of follow-up care. The goals of treatment should be a partnership between patient and health-care provider.

Clinical Recommendation	Evidence Rating	References
Refer patients with macular edema, severe nonproliferative retinopathy, or any degree of proliferative retinopathy to an ophthalmologist immediately for treatment.	A	AAO, Retina/Vitreous Panel, 2020

CASE STUDY

A 76-year-old woman presents today with complaints of nasal drainage, clearing of throat, and occasional nasal congestion, especially on waking in the morning. She has recently moved into an independent living center after living in her home for 40 years. She states that, although she has had these symptoms before, generally the symptoms appeared in the spring, and she associated the nasal drainage with pollination. Because it is winter, she could not identify the trigger of her symptoms.

Chief complaint: Persistent "runny nose" for 3-week duration, associated clearing of throat, and nasal congestion on awakening in the morning.

Objective data: Blood pressure (BP) 130/84, temperature 98.6, pulse 78, respiratory rate 20.

1. How will you use this information to prepare for today's visit?
2. What additional subjective data are you seeking, to include history of any allergies?
3. What additional objective data will you be assessing for?
4. What are the differential diagnoses that you are considering?
5. What laboratory tests will help you rule out some of the differential diagnoses?
6. What is your treatment, and what specific information about the prescription will you give to this patient?
7. What are the potential complications from the treatment ordered?
8. What additional specific laboratory tests will you consider ordering?
9. What additional patient teaching may be needed?
10. What type of specialist will you be consulting for this patient?

CHAPTER 10

Cardiovascular Disorders

Evelyn Duffy

ASSESSMENT OF THE CARDIOVASCULAR SYSTEM

Key symptoms for cardiovascular assessment include but are not limited to chest tightness or pressure, shortness of breath or difficulty catching breath, dizziness, syncope or near syncope, edema, abdominal pain, nausea and vomiting, and numbness and claudication of the extremities (Kane et al., 2018). Differentiating normal from abnormal cardiac function in an older adult can be a challenge because one in two older adults has cardiovascular disease (CVD). More specifically, almost one-half of all individuals older than age 60 years have severe coronary artery narrowing with a respective increase in myocardial demand. Of these, less than 50% have clinical signs and symptoms of this process. CVD is the most prominent cause of disability in this age-group and the leading cause of death, accounting for about one-half of all deaths among older adults. Coronary artery disease (CAD) is the most common type of CVD, but CVD also includes valvular disease, cerebrovascular disease that can result in strokes, and peripheral vasculature disease that can result in ischemia or blood clots. More than one in three adults has at least one type of CVD and nearly half of these are age 60 or older. Of those with CVD, nearly 18.2 million Americans have CAD, and the incidence increases with age (Virani et al., 2020).

ASSESSMENT OF RISK FACTORS FOR CARDIOVASCULAR DISEASE

Although some risk factors for CVD can be remedied, others cannot. The most important risk factors that cannot be remedied are advanced age, male sex, and genetic predisposition. The major remediable risk factors are control of hypertension (HTN), managing elevated lipid levels, increasing physical activity, and eliminating harmful habits such as abuse of alcohol or tobacco product. Smoking cigarettes is a dominant risk factor for cardiovascular and non-cardiovascular morbidity and mortality and is one of the most preventable risk factors with the greatest contributions to the development of CVD (Francula-Zaninovic & Nola, 2018). There has been a consistent decline in adult cigarette use between 2011 and 2018 (Virani et al., 2020). Since the 1970s, the mortality rate from CAD has shown a pronounced decline in the United States. Most of this decline can be attributed to changes in lifestyle and improved technologies such as thrombolytic drugs. The decline in CVD has occurred in older as well as younger age-groups, suggesting that the effects of risk factor modification persist well into later life (Virani et al., 2020).

Blood Pressure

The systolic blood pressure (SBP) rises with age; the diastolic blood pressure (DBP) remains the same or drops slightly over time. DPB tends to rise until the sixth decade of life and declines thereafter due to stiffer large arteries (Forman et al., 2019). Established HTN is a risk factor for CVD in older adults, with systolic elevations posing a greater risk than diastolic elevations. Overall, the risk of experiencing a cardiovascular event or death is two to three times higher in those with significant HTN than in those who are normotensive. Isolated systolic hypertension (ISH) is defined as an SBP greater than 160 mm Hg and a DBP of less than 90 mm Hg. Aggressive treatment of ISH has demonstrated a significant reduction in stroke, myocardial infarction (MI), and sudden cardiac death. Controlling HTN is important, but risk stratification should also be considered when treating the older person. The American College of Cardiology/American Heart Association (ACC/AHA) guidelines recommend an individualized cardiovascular risk assessment using the atherosclerotic CVD (ASCVD) risk calculator to direct treatment goals, the calculator is available on the Web at https://www.cvriskcalculator.com/ (Bakris et al., 2019). Control of HTN is the most potentially remediable risk factor, but control is challenging in those who are obese, continue to use tobacco, are physically inactive, and have poor glucose control.

Cholesterol

Serum cholesterol levels rise with age, up to age 60 years; thereafter, these levels begin to drop. The risk of the effects of an elevated cholesterol level persists from middle age to extreme old age. Aggressive efforts are often indicated to lower low-density lipoprotein (LDL) levels and raise high-density lipoprotein (HDL) levels for cardiac protection. Controversy exists about the role of statins in primary

© F.A. Davis Publishing

prevention of CVD in low-risk older adults, but a meta-analysis of the JUPITER and HOPE-3 trials demonstrated that in those 70 years of age and older, the use of statins offered a similar relative risk reduction of the incidence of CVD to those younger than the age of 70 (Grundy et al., 2019). The authors note, however, that the benefit needs to be weighed against the patient's life expectancy and the increased risk in this age-group of adverse events due to statin use.

Tobacco

Tobacco is an independent significant risk factor for CVD and the leading preventable cause of disease, disability, and death in the United States (Arnett et al., 2019). All tobacco cessation is strongly advised as both primary prevention and secondary prevention for those with known CVD, or in those who are at risk for developing CVD (Arnett et al., 2019).

Physical Inactivity, Impaired Glucose Control (Diabetes), and Obesity

Additional proven or postulated risk factors for CVD in older adults include lack of exercise, impaired glucose tolerance, and obesity. Older adults are most likely to have a combination of risk factors, which has a cumulative effect of increasing the risk of CVD. Evidence is compelling for improved exercise plans, control of blood glucose levels, and weight loss (Arnett et al., 2019).

Cardiac risk assessment tools, including the Global Framingham Risk Assessment, are available at https://www.nhlbi.nih.gov/health-pro/guidelines/in-develop/cardiovascular-risk-reduction/risk-assessment/. Assessment for metabolic syndrome and obesity, including body mass index (BMI) and waist circumference enhances risk assessment.

Age-Associated Changes in Cardiovascular Structure and Function

Aging is the main risk factor for CVD and the progression of CAD and cerebrovascular events. The progression of CAD and cerebrovascular disease is the leading cause of death for persons as they age. Vascular aging or arterial degeneration and hardening of the vasculature begins in the fifth and sixth decade of life and can accelerate incrementally depending on hereditary factors and cardiac risk factors (Hamczyk et al., 2020).

Aging is commonly seen as chronological years and a person's personal yearly milestone. Aging is more complex and is determined by the escalating toll of biological stresses. This includes oxidative stress and vascular inflammation that diminish one's capacity to overcome disease. Unless there is a break in the cycle of age-associated changes the renin-angiotensin-aldosterone signaling promotes a proinflammatory cycle that predisposes the person to CVD. Lifestyle health habits can either accelerate the disease process or slow it depending on one's willingness to adhere to healthy habits (Forman et al., 2019; Hamczyk et al., 2020). Aging causes structural and functional changes in the arterial system of the older adult. This occurs even if the person has no apparent CVD. With aging, the arterial wall media thickens due to smooth muscle cell hypertrophy, extracellular matrix accumulation, and calcium deposition. Intimal-medial thickness increases approximately threefold between the ages of 20 and 90 years in persons with normal SBP. This results in fraying of elastic fibers, reducing arterial flexibility, and an increase in vascular stiffness. Changes in vasodilating nitric oxide and vasoconstricting angiotensin II contribute to vascular aging (Forman et al., 2019). In the young, hearts are composed of approximately 25% cardiomyocytes and a complex structure of connective tissues. With aging, cardiomyocytes decrease due to apoptosis and hypertrophy occurs.

Left ventricular hypertrophy is usually due to increased cardiac demand caused by an increase in peripheral resistance. Peripherally, the vessels become atherosclerotic contributing to the increase in SBP with age. These structural and physiological changes in the aging cardiovascular system cause decreased capacity to endure stresses, decline in tolerance of physical activity, and limited functional reserve capacity. The left ventricle's (LV) diastolic performance is altered by aging, resulting in late LV filling facilitated by atrial contraction. The late filling is associated with modest left atrial size, thus increasing the risk for atrial arrhythmias. Fat deposits accumulate around the sinoatrial (SA) node, and the number of pacemaker cells usually decreases by age 75 years, contributing to chronotropic and arrythmia abnormalities. Baroreceptors become less sensitive with age, and the response to changes in BP and heart rate is often blunted.

These physiological changes have little functional impact on the aging heart at rest, but with exercise or stress, they render the aging heart less capable of increasing and sustaining an increase in cardiac output. Fast heart rates are commonly associated with diastolic filling abnormalities and higher LV diastolic pressure. This can result in higher pressures in the lungs, resulting in the development of heart failure with preserved ejection fraction (HF*p*EF). Maximal heart rate declines approximately 30% between ages 20 and 80 years. Cardiac dilation and increased stroke volume compensate somewhat for the diminished heart rate during exercise. (Forman et al., 2019).

Symptom Assessment

Using the Onset, Location, Duration, Characteristics, Aggravating factors, Relieving factors, Timing (OLDCART) mnemonic or Precipitating/Palliating factors, Quality, Radiation, Severity, Timing (PQRST) mnemonic, ask the patient about chest pain, shortness of breath, dizziness, palpitations, or edema. Establish the patient's usual baseline activities of daily living (ADLs) and activity level and ask how symptoms are affecting this. Some older adults experience palpitations as a nervous feeling, so include that in your questioning. Chest pain/pressure may present as heartburn or indigestion or as the patient's gastroesophageal reflux disease (GERD). Shortness of breath may be felt as anxiety but is a more common presentation of an acute coronary event than chest pain. Atypical presentation for MI includes vague symptoms such as nausea, decreased activities of daily living (ADL) status, and fatigue without chest pain/pressure, back pain. If the patient has known diabetes, the patient may present with a change in activity, general malaise, or with more heart failure symptoms, such as shortness of breath, dyspnea on exertion, paroxysmal nocturnal dyspnea, and orthopnea (Forman et al., 2019).

© F.A. Davis Publishing

CLINICAL EXAMINATION FEATURES

In the actual physical assessment of the older adult, the apical impulse is difficult to locate because the chest wall undergoes changes due to the intercostal muscles weakening, resulting in an increased anteroposterior diameter (Bickley, 2017).

Auscultation in the older adult frequently reveals changes in normal heart sounds, extra heart sounds, bruits, and murmurs. The S_1 is more easily heard, and splits of the first heart sound are more easily detected because of an ejection sound that occurs when the aortic valve cusp tissue fails to fold into the vessel wall during ejection. A change in the loudness of S_1, accompanied by a slow heart rate, may indicate heart block. The S_2 split on inspiration is narrower or absent because of decreased compliance of the pulmonary vasculature. An opening snap occurs when the mitral or tricuspid valve produces minor vibrations of increased intensity caused by more rapid cusp movement or a resistance to inflow caused by cusp fusion (Bickley, 2017). An audible opening snap is the best physical sign of mitral stenosis, but it becomes less obvious in the older adult whose valves are rigid and calcified.

Ventricular filling sounds, best heard with the stethoscope bell, are caused by the halting of the ventricle after ventricular filling. The physiological S_3, heard most clearly at the apex, disappears by the fourth decade as the ventricle stiffens and filling becomes less rapid. An S_3 in an individual more than 50 years old is usually pathological and reflects an increased filling rate, indicating heart failure (HF) or mitral regurgitation (Bickley, 2017). Early diastolic filling is reduced in healthy older adults resulting in an end-diastolic volume maintained by an increase in atrial contribution to left ventricular filling. This condition may cause an S_4, which in the absence of other findings, is considered normal in older adults.

The carotid arteries should be assessed routinely for the presence of bruit. Asymptomatic carotid bruit is a risk factor for stroke (Bickley, 2017). Studies demonstrate that a vessel is occluded more than 50% by the time a bruit can be heard. In older adults assess the top level of the internal jugular pulsation when evaluating jugular venous pressure. Do not use the external jugular veins because they may be sclerosed and appear to be falsely distended or may yield a falsely low pressure reading.

Prolonged extra heart sounds (murmurs), particularly systolic ones, are quite common in older adults. Systolic murmurs, which often indicate aortic valve disease, occur in more than 50% of individuals older than 70 years. The soft systolic ejection murmur is due to the dilation and the decrease in compliance of the aorta caused by stiffening of the aortic cusps without obstruction (aortic sclerosis). Loud murmurs, which usually indicate aortic stenosis, are often accompanied by a slow rising carotid pulse and left ventricular hypertrophy. An apical pansystolic or late systolic murmur also occurs frequently in older persons, resulting from floppy valves that become regurgitant over time. The two most common causes of mitral regurgitation are papillary muscle dysfunction (usually due to MI) and mitral annular calcification. Diastolic murmurs, which are always pathological, may be caused by heart block, aortic regurgitation, or mitral stenosis.

In the older adult, additional features of cardiac disease may be seen on physical examination of systems other than the heart. The eye examination may reveal the thick corneal arcus seen with lipid abnormalities or the funduscopic findings of atherosclerosis. The skin may demonstrate xanthomas or cholesterol nodules and changes in skin temperature, indicating a metabolic or peripheral vascular disease causing or contributing to cardiac disease. The presence of edema must be determined. The clinical cardiac examination features in the older adult include:

- Structural wall changes are common.
- S_1 is more easily heard.
- S_2 split is narrower.
- S_4 is common.
- Systolic murmurs are common.
- Bruits (carotid, abdominal) are common.

(Forman et al., 2019)

CARDIAC ARRHYTHMIAS

Signal Symptoms: No symptoms at times; feeling of heart "beating out of the chest."

Description: An arrhythmia is a disturbance of cardiac rhythm. Cardiac arrhythmias, which occur in either the presence or absence of underlying heart disease, may be life threatening or may be an incidental finding. Arrhythmias may be differentiated by type or mechanism (Khurshid et al., 2018; Prystowsky et al., 2020).

Atrial fibrillation (AF) is the most common sustained rhythm disorder. AF consists of numerous fibrillatory P waves that vary in shape, size, and timing. The ventricular response is often chaotic and rapid if the atrioventricular (AV) conduction is intact. AF can be clinically classified as follows:

- Paroxysmal: less than 7 days self-terminating or with intervention; episodes may occur with varied frequency
- Persistent: greater than 7 days and requires intervention to terminate
- Long-standing persistent: continuous AF more than 12 months
- Permanent: used when the patient and provider make a joint decision to stop further attempts to restore or maintain sinus rhythm
- Nonvalvular: in the absence of rheumatic mitral stenosis, a mechanical or bioprosthetic heart valve or mitral valve repair (Crawford et al., 2018)

Other prevalent forms of arrhythmias in the older adult population include:

Sick Sinus Syndrome: (1) Pathological bradyarrhythmia with an alternating supraventricular tachyarrhythmia (bradycardia-tachycardia syndrome); (2) There are three primary categories of supraventricular tachyarrhythmia: AF, atrial flutter, atrial tachycardia.

Arrhythmias Primarily of Atrial Origin. Atrial premature beats, ectopic atrial rhythms, multifocal atrial tachycardia, atrial flutter, and AF.

© F.A. Davis Publishing

Arrhythmias Arising Primarily Within the AV Node. AV nodal reentrant tachycardia, junctional premature beats, and nonparoxysmal junctional tachycardia.

Arrhythmias Partially Supraventricular in Origin. Pre-excitation syndromes.

Ventricular Arrhythmias. Ventricular ectopic beats are the most common variety.

Etiology: Most arrhythmias are thought to be caused by abnormalities either in impulse formation (disordered automaticity) or in impulse conduction (allowing reentry), or by a combination of the two. Increased automaticity is an accentuation of the inherent ability of many cardiac tissues to generate an independent rhythm. Reentry consists of a wave of excitation repeatedly circulating around a fixed anatomical obstacle. Triggered arrhythmias are caused by altered cellular depolarization (Prystowsky et al., 2020).

Occurrence: Studies show that asymptomatic older patients with no known structural heart disease have an incidence of up to 40% of sinus arrhythmia, supraventricular or ventricular premature beats, or supraventricular tachycardia (Khurshid et al., 2018).

Age: The prevalence of ventricular arrhythmia increases with age, occurring in 80% of healthy older adults ages 60 to 85 years. AF is diagnosed in 4.8% of women and 6.2% of men older than 65 years at baseline examination, and its prevalence is strongly associated with advanced age, particularly in women. Although no specific data are available, the incidence of junctional arrhythmias and tachycardias related to the accessory pathway may be lower in older adult individuals because of an age-related reduction in accessory pathway conduction.

Ethnicity: Not significant.

Contributing Factors: Pre-existing heart disease is a contributing factor to arrhythmias, with structural disease becoming more prevalent with age. The muscular response and contractility decrease as the patient ages. The patient experiences a reduction in cardiac function and contractility. This reduction is responsible for a decreased stroke volume and ejection fraction. The average older adult does not experience adverse symptoms with normal everyday activities. However, stressors (whether they are physical, psychological, environmental, or social) can increase the risk of illness in the patient. These illnesses are taxing to the patient's system, and the increased energy demands place an increased demand on the cardiac system. The aging process can also have an adverse effect on the cardiac valves. The valves tend to become thick and stiff secondary to arteriosclerosis and atherosclerotic plaques. Fibrosis or calcification in the vicinity of the AV node causes conduction disturbances. Atrial arrhythmias may be caused by a mechanical obstruction to atrial emptying with subsequent left atrial dilation, myocardial ischemia, and increased sympathetic activity.

An age-related factor associated with tachyarrhythmias is increased left atrial size. This enlargement may contribute to the increase in supraventricular ectopy. Increases in ventricular ectopic beats may be related to left ventricular enlargement. The overload of ionized calcium in the older myocardium may contribute to ectopy. Age-related factors associated with bradyarrhythmias include an age-related decline in the number of pacemaker cells and the presence of fat deposits around the SA node. His bundle cells are replaced with fibrous tissue, and adipose tissue and amyloid are deposited; this is also associated with conduction disturbance.

Systemic diseases (i.e., thyrotoxicosis, infection, hypoxemia, hypercapnea) can cause circulatory disturbances that may provoke an arrhythmia. Drugs that can cause an arrhythmia include digoxin and other antiarrhythmics, aminophylline, and alcohol. Electrolyte disturbances, particularly hyperkalemia, hypokalemia, hypercalcemia, and hypocalcemia, can precipitate ectopic beats. Family history of sudden cardiac death may indicate a predisposing factor for rhythm disorder, such as hypertrophic obstructive cardiomyopathy, congenital prolonged QT syndrome, or the presence of an aberrant conduction pathway (Khurshid et al., 2018).

Signs and Symptoms: The history, physical examination, and electrocardiogram (ECG) studies represent the cornerstone to evaluation of arrhythmias. Arrhythmias may cause symptoms due to a reduced blood flow or inadequate cardiac pump function. In the history, the patient may describe sensations that accompany abnormal cardiac rhythm such as pounding, racing, or skipped beats. Older adults are less likely to complain of palpitations and more likely to present with manifestations of heart failure (HF) or hypoperfusion (i.e., impaired mental function, dizziness, syncope). There appears to be a peak in syncopal episodes after age 65 years in both men and women. The Framingham study showed an increased incidence of syncope after age 70 years, from 5.7 events per 1,000 person-years in men ages 60 to 69 years, to 11.1 events in men ages 70 to 79 years (Grossman & Badireddy 2021). Along with the history of present illness, previous diagnosis and treatment for arrhythmia and cardiac disease should be elicited.

During physical examination, concentrate on the cardiac and peripheral vascular systems. Check the pulses for 1 full minute to determine rate and regularity (Prystowsky et al., 2020). Assess normal and extra heart sounds. S_1 intensity may provide information about the relation of atrial to ventricular contraction. The longer the PR interval, the softer the S_1. Note intermittent extra heart sounds (S_3 and S_4). The jugular vein must be assessed and in AV dissociation (when the atria and ventricles contract independently), giant A waves (cannon waves) may be observed. Provoking maneuvers should not be attempted by the advanced practice nurse but may be attempted by a cardiologist. These maneuvers include carotid massage (for atrial arrhythmias only), mild exercise, psychological stress, pharmacological stress, and electrical programmed stimulation (EPS).

Other indicators of hemodynamic response to an arrhythmia include level of consciousness and skin temperature and color. The history should guide the remainder of the episodic examination because it is also helpful in identifying the contributing factors that may precipitate or aggravate an arrhythmia.

Diagnostic Tests: Diagnostic testing includes a 12-lead ECG done with a rhythm strip, lasting at least 2 to 3 minutes. Include exercise testing for those with a clinical history suggesting exercise-induced arrhythmia. Ventricular arrhythmias can occur in individuals with or without cardiac disorders. The standard resting 12-lead ECG is indicated in all patients who are evaluated for ventricular arrhythmias (Prystowsky et al., 2020). An ambulatory 24-hour ECG (Holter monitoring) helps to quantify arrhythmias with reference to symptoms. Ambulatory ECG is indicated when there

© F.A. Davis Publishing

TEST	RESULTS INDICATING DISORDER
Rhythm strip	Rhythm disturbance may be present, or if transient, it may be absent
12-lead ECG	Acute MI or ischemia, prolonged QT intervals, and pre-excitation may be identified as precipitators of an arrhythmia
Ambulatory ECG monitoring	Quantifies arrhythmias with reference to symptoms
	Identifies patients at risk for sudden death by documenting ventricular arrhythmias and heart rate variability
Implantable loop recorder	In infrequent syncope this long-term device (14 months) may identify the precipitant
Echocardiogram	Identifies structural, functional, and hemodynamic abnormalities in the cardiovascular system
Cardiac electrophysiological study	Evaluates specific arrhythmias to distinguish these, determine location and characteristics, and guide therapy
Implantable cardioverter-defibrillator (ICD)	ICD firings may be due to recurrent arrhythmia
Electrolyte panel	Identify electrolyte disturbance (i.e., hypokalemia, hyperkalemia, hypomagnesemia, hypocalcemia) that may be causative or contributory
Coronary and LV angiography	Identifies CAD and LV function
Cardiac MRI	Especially useful in recognizing arrhythmogenic RV dysplasia, or infiltrative diseases

is a need to clarify the diagnosis by detecting arrhythmias, QT interval changes, T-wave alternans, or ST changes; to evaluate risk; or to judge therapy (Verrier & Ikeda, 2013). Event recorders are best suited for documenting less-frequent but more-prolonged bouts of arrhythmias, although not used with as much frequency. Patient-activated loop memory devices, which record the ECG before the symptomatic event, are most useful. His bundle electrograms involve the insertion of a transvenous electrode catheter into the right ventricle, to record depolarizations and the intervals. This method is most useful for distinguishing AV block from an ectopic focus.

Echocardiography is recommended in patients with ventricular arrhythmias who are suspected of having structural heart disease (Prystowsky et al., 2020). An echocardiogram is used more commonly than magnetic resonance imaging (MRI) or cardiac computed tomography (CT) scan because it is inexpensive in comparison. The echocardiogram is a useful tool in assessing for valvular disorders, left ventricular function and wall motion, and the ejection fraction. The electrophysiological (EP) testing is performed using intracardiac recordings, electrical stimulation, and drugs to assess and document ventricular tachycardia, guide ablations, and evaluate loss of consciousness in patients with arrhythmias as the suspected cause. EP testing is recommended for diagnostic evaluation of patients with remote myocardial infarction (MI) with symptoms suggestive of ventricular tachyarrhythmias, including palpitations, presyncope, and syncope. EP testing is recommended in patients with syncope of unknown cause with impaired left ventricular function or structural heart disease (Prystowsky et al., 2020).

In EPS, multipolar catheter electrodes are introduced into the venous or atrial circulation and advanced to various intracardiac positions to monitor the electrical activity or to induce an arrhythmia. EPS is most useful for determining sinus node dysfunction, AV block, intraventricular conduction disturbances, pre-excitation syndromes, supraventricular tachycardia, ventricular tachycardia, and unexplained syncope or palpitations. It is used also to monitor cardiac activity in survivors of sudden cardiac death.

Differential Diagnosis: Clarify the diagnosis with precision. Note reversible and precipitating causes of an arrhythmia and coexisting diseases.

Treatment: The incidence of asymptomatic arrhythmias of questionable clinical significance is high. Arrhythmias are never treated in isolation; some are benign, and some are lethal. Patients with hemodynamic compromise resulting from arrhythmia need to be hospitalized as soon as possible. Prehospital care for threatening hemodynamic instability secondary to tachyarrhythmia may include direct current cardioversion, and the nurse practitioner should be skilled in this intervention. After thorough investigation, the goals of arrhythmia treatment include the alleviation of bothersome symptoms, the prevention of complications from sustained arrhythmias, and the avoidance of sudden death associated with certain arrhythmias.

The risk of treatment is considerable. Aggressive therapeutic treatment is indicated when patients are symptomatic, and the urgency of therapy depends on the associated hemodynamic disturbance. A comprehensive treatment plan must address the three cornerstones of AF management: rate control, rhythm control, and prevention of thromboembolism. Goals of the therapy should be to obtain symptom control, stroke prevention, and a reduction in hospital recidivism (January et al., 2019; Khurshid et al., 2018). Three major factors determine how well a patient tolerates an arrhythmia: heart rate, duration of the arrhythmia, and presence and severity of associated underlying heart disease. Arrhythmias often cannot be controlled unless underlying cardiac problems are discovered and treated. No antiarrhythmic "wonder drug" exists, and the bothersome and potentially dangerous side effects necessitate determination of clear indications and use of the utmost caution. Pharmaceutical agent selection is based on the electrophysiology of the rhythm disturbance, the mechanism of action, and the side effects of the drug.

© F.A. Davis Publishing

Several new drugs are useful as an alternative to warfarin for the prevention of stroke and systemic thromboembolism in patients with paroxysmal to permanent AF and risk factors for stroke or systemic embolization who do not have a prosthetic heart valve or hemodynamically significant valve disease, severe renal failure, or advanced liver disease (Crawford et al., 2018; Prystowsky et al., 2020). Conditions common in older adults that can affect the choice, dosing, efficacy, and safety of antiarrhythmic therapy include decreased hepatic or renal function, decreased serum albumin levels, and electrolyte abnormalities.

The broad categories of arrhythmia treatment include medications, pacemakers, anti-tachycardia devices, implantable automatic cardioverter-defibrillators, catheter ablative procedure, and specific maneuvers. Defibrillation is the required intervention in ventricular fibrillation or pulseless ventricular tachycardia and is the most important determinant of survival in cardiac arrest. Patients defibrillated within 2 minutes have a 60% hospital discharge survival rate (Prystowsky et al., 2020). Vagal maneuvers (carotid massage or the Valsalva maneuver) may terminate or slow AV nodal reentry or AV reentry types. These maneuvers are associated with a high risk of emboli dislodgment. The carotid arteries should be assessed for bruit before administering massage. Because of the high mortality rate associated with antiarrhythmic surgery, it is not recommended in older adult individuals. The specifics of treatment are not detailed in this text because all assessment and management must be done in close collaboration with a physician specialist; much of the treatment is initiated by the specialist in the hospital setting.

Follow-Up: Because of their low therapeutic ratio, drug dosing and plasma concentrations of the antiarrhythmics are based on therapeutic monitoring. Side effects are significant and include the negative inotropic effect, which can precipitate HF or pro-arrhythmia in the presence of structural heart disease. Extracardiac side effects can also be significant, including anticholinergic effects, gastrointestinal effects, and neurological toxicity with some antiarrhythmic agents. Monitor patients after pacemaker insertion with regular follow-up appointments and ECG testing, specifically looking for pacemaker failure, infection, thromboembolism, perforation or dislodgment, and complicating arrhythmias.

Sequelae: Regardless of age, the nature and severity of underlying heart disease are of much greater prognostic significance than the arrhythmia alone. The following rhythm disturbances have been reported to carry a poor prognosis in patients with CAD: frequent ventricular premature contractions (VPCs) (greater than 10 per min), multiform VPCs, ventricular couplets, R-on-T phenomenon, and ventricular tachycardia.

Syncope can occur secondary to asystole. Syncope is an intermittent symptom that may be caused by an underlying arrhythmia with or without cardiac disease. Treatment goals are prevention of symptom recurrence, improvement of quality of life (QOL), and prolongation of survival. Permanent cardiac pacing may relieve the symptoms but may not affect the survival rate. Syncope recurs in approximately 20% of the patients (Grossman & Badireddy, 2021; Prystowsky et al., 2020). Bradycardia can contribute to complete heart block and to the development of HF in patients with associated ventricular dysfunction. Tachycardia can precipitate angina and circulatory arrest in patients with CAD. Bradyarrhythmias or tachyarrhythmias can cause systemic embolism and stroke. AF can result in HF and a low cardiac output state (Khurshid et al., 2018).

Prevention/Prophylaxis: All patients with AF should be considered for long-term anticoagulation with a direct-acting oral anticoagulant (DOAC) or warfarin. Aspirin, though less effective in preventing stroke, is an alternative for some patients in whom other anticoagulants are contraindicated. Electrolyte imbalances should be monitored, and metabolic disturbances treated. Patients receiving digoxin should be monitored for toxicity (Crawford et al., 2018).

Referral: All patients with treatable arrhythmias require collaborative management with a cardiologist. Clinically significant ventricular arrhythmias or any symptomatic arrhythmia is managed in the coronary critical care unit. A primary care provider may handle many atrial arrhythmias and low-grade ventricular arrhythmias; however, a cardiologist should be consulted for all clinically significant ventricular arrhythmias, arrhythmias resistant to routine therapy, or arrhythmias whose clinical significance is in doubt (Crawford et al., 2018; Khurshid et al., 2018).

Education: Carefully instruct all patients receiving antiarrhythmics about the therapeutic effects, side effects, and potentially adverse effects of these medications. Because patients with pacemakers are vulnerable to external electrical fields, they should be instructed to recognize this potential and avoid exposure. Patients with pacemakers must also be aware of signs and symptoms of pacemaker failure.

HEART FAILURE

Signal Symptoms: Dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, progressive activity intolerance, weakness, peripheral edema.

Description: As a clinical syndrome, heart failure (HF) is a secondary process associated with multisystem pathophysiology involving neurochemical regulation, abnormal cardiac muscle structure, and/or wall function. The older term *congestive heart failure* does not represent symptom presentation in all HF patients; therefore, the preferred term is *heart failure.*

Etiology: Cardiovascular disease (CVD) and hypertension (HTN) are the most common etiologies of HF; other causes are listed in Table 10-1 (McDonagh et al., 2021).

Universal definitions of HF include heart failure with reduced left ventricular ejection fraction (HF*r*EF)—previously referred to as *systolic heart failure*—with an ejection fraction ≤40% and heart failure with preserved left ventricular ejection factor (LVEF) (HF*p*EF)—previously referred to as *diastolic heart failure*—with an EF ≥50% (Bozkurt et al., 2021). Two new definitions are heart failure with mildly reduced ejection fraction (HF*mr*EF), with an EF 41% to 49%, and heart failure with improved EF (HF*imp*EF) in which initial EF is ≤40%, a ≥10-point increase from initial EF occurs, and subsequent EF is >40% (Bozkurt et al., 2021).

TABLE 10-1 Common Causes of Heart Failure

Cardiovascular	Coronary, myocardial, valvular, dysrhythmias (atrial fibrillation is the most common), pericardial
Toxic	Alcohol, cocaine, chemotherapy
Inflammatory/ Infection	Myocarditis, HIV
Metabolic	Anemia, thiamine deficiency, thyroid disorders
Infiltrative	Amyloid, sarcoid, hemochromatosis
Genetic	Family history
Situational	Sepsis, peripartum, Takotsubo cardiomyopathy

Occurrence: Approximately 6.2 million people in the United States older than the age of 20 years are affected by HF with 960,000 new cases annually (Benjamin et al., 2019). The annual incidence of HF in patients older than 65 years is 21 per 1,000 population (Dumitru & Baker, 2022) with a 5-year mortality rate in patients hospitalized with all types of HF approximately 75% (Shah et al., 2017). Hospital readmissions within the first 30 days are correlated with increased mortality risk (Kehra et al., 2018). HF is more common in men in the general population, but rates are higher in women within the long-term care setting.

Age: More common in older adults.

Ethnicity: African Americans have higher rates of HF (Pfeffer et al., 2019)

Contributing Factors: Nonmodifiable risk factors include sex and ethnicity. Advanced age is an independent risk factor for HF. Modifiable risk factors for HF are tobacco use, systolic blood pressure (SBP) of more than 140 mm Hg, fasting glucose of more than 125 mg/dL, elevated cholesterol, obesity, diet, and physical inactivity. Use of NSAIDs, COX-2 inhibitors, glucocorticoids, and thiazolidinediones are common precipitating factors for HF in older adults (McDonagh et al., 2021).

HF is caused by myocardial structural or functional damage that impacts left ventricular function; difficulty with ejecting blood (HF*r*EF) or effective ventricular relaxation (HF*p*EF). To maintain cardiac output, stroke volume, and vital organ perfusion, the sympathetic nervous system and renin-angiotensin-aldosterone system (RAAS) are activated to release neurohormones. Angiotensin II, a potent vasoconstrictor, leads to increased systemic vascular resistance, enhances the release of catecholamines from noradrenergic nerve endings, and directly stimulates the adrenal cortex to

© F.A. Davis Publishing

increase secretion of aldosterone. Vasopressin (antidiuretic hormone) and aldosterone secretion cause sodium and fluid retention with subsequent increase in blood volume. Increased systemic vascular resistance, decreased arterial pressure, increased venous pressure, increased blood volume, and decreased venous compliance further increase ventricular wall stress and myocardial oxygen demand. Ultimately, these normal physiological responses become maladaptive and result in damage to the heart, cardiopulmonary, renal, and systemic vasculature, and cause progression of HF.

Signs and Symptoms: Left ventricular heart failure leads to pulmonary venous congestion, subsequent right ventricular dysfunction, and portal and systemic venous congestion. Clinical symptoms of dyspnea on exertion or at rest, orthopnea, dry cough (worse in recumbent position), bendopnea (breathless when bending over), and/or paroxysmal nocturnal dyspnea indicate increased pulmonary venous congestion. Progressive lower extremity edema (not due to venous insufficiency or hypoalbuminemia) and abdominal symptoms (pain, distention, nausea, and early satiety) related to hepatic enlargement are symptoms suggestive of right ventricular failure or systemic venous congestion.

Signs that suggest HF include weight gain, tachycardia, S_3 or S_4 heart sound, laterally displaced point of maximum impulse (PMI), neck vein distention, rales in bilateral lower lobes that are not due to atelectasis, positive hepatojugular reflux, and ascites. Diminished mental acuity and reduced exercise tolerance are common in older adults with HF (Stefil et al., 2020).

HF classification is based on risk, cardiac structural changes, symptom presentation, and functional impairment. The New York Heart Association (NYHA) classifies HF based on functional limitation (Yancy et al., 2013).

- Class I: No symptoms and no limitation in ordinary physical activity (e.g., shortness of breath when walking, climbing stairs)
- Class II: Mild symptoms (mild shortness of breath and/or angina) and slight limitation during ordinary activity
- Class III: Marked limitation in activity due to symptoms, even during less-than-ordinary activity (e.g., walking short distances (20 to 100 m). Comfortable only at rest.
- Class IV: Severe limitations. Experiences symptoms even while at rest. Mostly bedbound patients.

This system may be difficult to apply to older adults with HF who may have functional decline related to comorbid conditions. A unique aspect of the NYHA system is that it is dynamic. As patient's symptoms improve, they can be reclassified.

The ACC/AHA system classifies HF in four stages as the syndrome progresses along the natural trajectory and is used in conjunction with, not as a replacement for, the NYHA functional classification system (Yancy et al., 2017). The ACC/AHA rating system is based on risk factors, structural changes, and history of HF symptoms. Stages A and B refer to risk factors and present opportunities for primary and secondary prevention measures.

- Stage A: Risk factors are present for HF without structural changes, history of signs or symptoms, or functional limitations.
- Stage B: Risk factors and structural changes in the heart are present without signs or symptoms of HF.
- Stage C: Risk factors, structural changes in the heart, and past or current signs or symptoms of HF are present. At this stage, the patient is diagnosed with HF that does not regress back to former stages.
- Stage D: HF is refractory despite maximum medical management. Patients are symptomatic at rest or with minimal exertion.

Diagnostic Tests:

Two-Dimensional Transthoracic Echocardiography Combined with Doppler Flow Studies. Two-dimensional echocardiogram is considered the most useful diagnostic tool for evaluation of ventricular ejection fraction and structural abnormalities for prognostic and interventional purposes (Yancy et al., 2017). Two-dimensional echocardiograms are essential to accurate diagnosis and treatment plan development. Echocardiogram is essential for those with unknown history of HF and clinical presentation to evaluate ventricular function, size, wall thickness, wall motion, and valve function criteria. Diagnosis of HF*p*EF is supported by (1) evidence of clinical HF symptoms, (2) normal or mildly abnormal LV systolic function, and (3) evidence of abnormal LV relaxation, filling, diastolic distensibility, or diastolic wall function (Bozkurt et al., 2021).

Electrocardiography. ECGs may indicate left atrial enlargement, left ventricular hypertrophy, arrhythmias, or ST-T wave changes associated with myocardial infarction (MI) or ischemia.

Cardiac Angiography. Cardiac catheterization may benefit older adults who are candidates for revascularization and may reveal hemodynamic abnormalities, the presence and severity of valvular heart disease, or CAD.

Chest X-Ray. Chest x-ray may reveal cardiomegaly, increased pulmonary vascularity, interstitial or pulmonary edema, and assists in evaluating alternative etiologies that may contribute or cause heart failure-like symptoms.

Brain Natriuretic Peptide (BNP) or N-Terminal proBNP (NT-proBNP). BNP and NT-proBNP are helpful in narrowing differential diagnoses or establishing prognosis. BNP elevation occurs slowly; therefore, levels are not helpful in acute HF episodes and better to evaluate trends over time. BNP levels of less than 100 pg/mL indicate that HF is unlikely. Levels between 100 and 500 pg/mL are indeterminate. Levels of more than 500 pg/mL may suggest HF but are not appropriate as "stand-alone" tests. Many factors influence BNP levels, including sex, age, obesity, chronic kidney disease, pericardial disease, AF and pulmonary embolism (PE) (Bozkurt et al., 2021).

Blood Chemistries and Complete Blood Count (CBC). CBC, comprehensive metabolic profile (CMP), magnesium and thyroid-stimulating hormone (TSH) levels should be obtained initially and periodically to evaluate renal, liver, metabolic, and hemodynamic status.

Serial Cardiac Enzymes. Cardiac enzymes (CK-MB, troponin) may reveal myocardial ischemia or infarction. Cardiac enzymes require time-sensitive processing; therefore, they have limited value in the long-term care setting. If the presentation is uncertain, transport via emergency medical services to an acute care facility.

© F.A. Davis Publishing

Differential Diagnosis: Atypical symptom presentation in older adults necessitates a thorough health history that includes evaluation of risk factors with correlation to physical examination findings and diagnostic test results. Dyspnea on exertion, the most common heart failure symptom, may be caused by numerous diseases, including asthma, chronic obstructive pulmonary disease, anemia, renal failure, dysrhythmias, cardiomyopathies, valvular heart disease, primary pulmonary HTN, PE, abdominal masses, deconditioning, and anxiety neurosis. Differentiation between HF*p*EF and HF*r*EF is crucial and best determined by two-dimensional echocardiography (McDonagh et al., 2021; Yancy et al., 2017).

Treatment: Treatment options for HF are targeted at symptom management, treatment of the causative disease process(es), and the resulting multisystem pathophysiology. Fragility, multiple comorbid disease processes, polypharmacy, age-related changes in pharmacokinetics and pharmacodynamics, and prevalence of geriatric syndromes require individualized treatment plans.

Angiotensin-Converting Enzyme Inhibitors. Unless contraindicated, angiotensin-converting enzyme inhibitors (ACEIs) should be used in the treatment of asymptomatic HF*r*EF or in patients with recent or remote history of MI regardless of LVEF. ACEI contraindications include unilateral or bilateral renal artery stenosis, hypersensitivity to ACEIs, angioedema, pregnancy, serum potassium more than 5.5 mEq/L that cannot be reduced, and hypotension in patients at risk for cardiogenic shock. ACEI therapy should be discontinued as a last resort in HF patients due to cardioprotective properties. All ACEIs should be started at low doses and gradually titrated over several weeks to achieve target doses daily based on renal function, potassium levels, BP, and tolerance. Obtain baseline serum potassium, serum creatinine, and blood urea nitrogen (BUN) levels before initiation and with dosage adjustments. Dosage adjustments should be made accordingly for symptoms of dizziness, light-headedness, or unsteadiness. ACEI cough is a common side effect and is characterized as a dry nonproductive cough which may be worse at night and can occur at any point in treatment. ACEI cough is a class-wide side effect and is not dose dependent.

Angiotensin II Receptor Blockers. Angiotensin II receptor blockers (ARBs) are an appropriate substitute for ACEIs because they do not inhibit kininase and are associated with lower incidence of cough and angioedema (Yancy et al., 2013). Isosorbide dinitrate and hydralazine combination therapy is an appropriate alternative in patients who experience hypotension, hyperkalemia, angioedema, or renal insufficiency with ACEI or ARB therapy, and those who do not respond to treatment with ACEIs and beta blockers. These medications have also shown benefit in African Americans with NYHA class III–IV HF*r*EF receiving guideline-directed medical therapy (McDonagh et al., 2021).

Angiotensin Receptor/Neprilysin Inhibitors. Angiotensin receptor/neprilysin inhibitors (ARNIs) are ARBs combined with an inhibitor of neprilysin, an enzyme that degrades natriuretic peptides, bradykinin, adrenomedullin, and other vasoactive peptides (McDonagh et al., 2021). ARNIs are approved as first-line treatment as a substitute for ACEIs or ARBs in those with symptomatic HF*r*EF and should not be used concomitantly with these agents; a 3-day washout period is needed (McDonagh et al., 2021). Clinical trials of ARNIs have shown a 20% reduction in cardiovascular death or HF hospitalization (McDonagh, 2021; Yancy et al., 2017).

Beta-Adrenergic Blockers. Carvedilol, metoprolol succinate, and bisoprolol are the only beta blockers indicated for treatment of HF and with evidence to support morbidity and mortality reductions in HF patients. Unless otherwise contraindicated (heart block, bradycardia, hypotension, severe respiratory disease), beta blockers are recommended for patients with recent or remote history of MI regardless of LVEF. Use of carvedilol or metoprolol succinate has been shown to decrease morbidity and mortality in HF patients and is recommended in patients with stage C HF and/or a history of MI regardless of LVEF.

Beta blockers are strongly associated with reduced risk of mortality and reduced rehospitalization during 30-, 60-, and 90-day follow-up periods. Carvedilol is the best option in those with advanced HF. Beta blockers should be used in combination with ACEIs, ARB, or ARNI if possible, for synergistic effect. Monitor older patients closely for volume status, emotional side effects, and functional decline. Contraindications include bronchospastic lung disease (e.g., asthma), symptomatic bradycardia, or advanced heart block without a pacemaker. Beta blocker initiation should be started only in a euvolemic patient. Initial dosages should be low and titrated slowly based on response to treatment and tolerance. Carvedilol may have a greater hypotensive effect in the older adult because of the vasodilatory effect of alpha-1 receptor blockade properties. Metoprolol succinate may be better tolerated in those with lower baseline BP levels and for rate control in concurrent atrial fibrilation. Consider carvedilol or bisoprolol in patients who require crushed medications.

Diuretic Therapy. Loop diuretics are used to reduce symptoms of peripheral or pulmonary congestion. Loop diuretics inhibit the Na+/K+/Cl- symporter in the ascending loop of Henle, whereas thiazide-type diuretics affect the Na+/Cl- in the distal convoluted tubules. Use of diuretics in the treatment of HF without ACEIs, ARBs, or beta blockers activates the RAAS and may hasten progression of HF. Most HF patients are resistant to the effects of hydrochlorothiazide; therefore, loop diuretics are preferred. When used in equipotent dosages, loop diuretics appear to have comparable diuretic effects (1 mg bumetanide = 40 mg furosemide = 10 to 20 mg torsemide). Furosemide should be initiated at 20 mg daily oral dosage in the older adult patient with mild symptoms, with dosage titration based on effect and tolerance. Bumetanide is 40 times more potent than furosemide and is less ototoxic, but it is associated with myalgias in some patients.

Fluid overload refractory to loop diuretics results from downregulation in renal response and sodium retention (Trullàs et al., 2016). The addition of a thiazide diuretic to a loop diuretic may be an indicated and efficacious option to reduce acute HF symptoms if a sub-therapeutic response to loop diuretic dosage increase is noted (Trullàs et al., 2016). Metolazone (2.5 to 5 mg daily), a thiazide-like agent, is a long-acting diuretic that is effective in increasing the effects of loop diuretics if given 30 minutes before the loop diuretic dosage. Combination therapy with metolazone requires close

© F.A. Davis Publishing

monitoring of potassium and magnesium levels. Torsemide may be advantageous because absorption is unimpaired and the response is less variable than the other loop diuretics. Amiloride, triamterene, and ethacrynic acid should only be considered if there is a life-threatening allergy to sulfa due to side effects and inability to protect against damaging neurohormonal activity. Spironolactone, a mineralocorticoid receptor antagonist (MRA), is an effective therapy in conjunction with ACEIs or ARBs to more completely block the deleterious effects of the RAAS in patients with stages C and D class III–IV HF*r*EF and in patients with LVEF of 40% or less who have adequate renal function without hyperkalemia. Providers should consider ability to monitor for renal dysfunction and hyperkalemia before initiation of therapy.

Mineralocorticoid Receptor Antagonists (MRAs). Spironolactone and eplerenone are recommended at low dosages once daily and should not be initiated in men with serum creatinine levels of 2.5 or more; in women with serum creatinine levels of 2.0 or more; or potassium levels of more than 5.0.

Sodium-Glucose Cotransporter-2 Inhibitors (SGLT2is). These drugs, originally introduced as treatments for diabetes mellitus are now recommended in HF*r*EF to reduce risk of hospitalization or major cardiology event in patients with or without diabetes mellitus. Empagliflozin and dapagliflozin have a diuretic and natriuretic effect resulting in reduced preload and afterload (Maddox et al., 2021).

Digoxin. Digoxin may be considered in the treatment of patients with HF without bradycardia who have persistent symptoms despite optimal therapy with ARNIs, ACEs, ARBs, beta blockers, SGLT2is, and MRAs. Digoxin may be helpful to control ventricular response due to AF in men with HF with LVEF of less than 50% (Yancy et al., 2013, 2016). To reduce morbidity and mortality, lower therapeutic range (0.5 to 0.9 ng/mL) is advised (Yancy et al., 2013). Evidence from several trials supports the use of digoxin to improve functional status and decrease HF hospitalization without improvement in mortality. Dosages for older adults should not exceed 0.125 mg daily (American Geriatrics Society, 2019). In older adults with renal dysfunction, every-other-day dosage may be appropriate.

Follow-Up: Fatigue and weakness without vital sign changes may occur with titration of any medication but are transient and should resolve within several days following dosage titration. Ask the patient about the presence of symptoms of HF as noted previously. Asking specific questions specific to triad symptoms (nocturnal dyspnea, orthopnea requiring two or more pillows, and dyspnea with exertion) is considered an optimal approach to symptom recognition. Ask general questions related to the patient's quality of life (QOL) such as sleep patterns, sexual difficulties, symptoms of depression, and coping behaviors. HF is a chronic illness with acute exacerbations, so assess caregiver burden. Immediate follow-up post-hospitalization and frequent follow-up may reduce readmission rates (Boxes 10-1 and 10-2).

Sequelae: Complications of HF involve hepatic and renal end organ disease. Fifty percent of patients with HF die from sudden cardiac death. All patients with HF should have an advance care plan and documented goals of care, including the Medical Orders for Scope of Treatment (MOST).

Prevention/Prophylaxis: Reducing cardiac risk factors is as effective in preventing coronary disease in older adults as it is in younger age-groups. Encourage risk factor reduction using age-specific guidelines to facilitate changes in lifestyle. Patients with HF are at risk for a vascular event, and there is no clear evidence regarding efficacy of prophylactic antithrombotic treatment (aspirin or warfarin) without other indications. Patients with HF should receive vaccination against influenza and pneumococcal disease.

Referral: Referral for interprofessional team and chronic care case management should be considered for all patients with HF. Warning signs for the need for hospitalization include increased dyspnea, weight gain that is resistant to diuresis, palpitations, persistent or recurrent dizziness, agitation or cognitive changes, inability to sleep because of paroxysmal-nocturnal dyspnea, abdominal pain, and a decline in activities of daily living (ADLs) and/or instrumental activities of daily living (IADLs).

Practice of best evidence involves shared decision making between an experienced, well-coordinated, primary care team in a patient-centered palliative care model. Referral to cardiology is indicated when the diagnosis is unclear, if the patient remains symptomatic despite appropriate therapy, and in those with significant cardiac disease. Hospice should

© F.A. Davis Publishing

be considered when a patient has stage D class IV HF, has an ejection fraction of 20% or less, is unable to tolerate optimal therapy due to hypotension or renal failure, or has symptoms that are not controlled with maximized medical management.

Education: Education and use of support groups are important for patients with HF, because adherence is a major cause of morbidity and unnecessary hospital admissions. Instruct patients and their families about the natural progressive trajectory of HF, necessary medications, dietary restrictions, HF symptoms that necessitate contact with provider, and prognosis. Discussions regarding advance directives should begin early in the trajectory. Explain typical symptoms of worsening HF and instruct patients to contact their health-care provider if these occur. Mild aerobic exercise increases functional capacity and improves the QOL for patients with HF but should be undertaken with provider supervision. Dietary sodium should be restricted to 2 or 3 g per day. Discourage alcohol use and tobacco use. Fluid restriction is not necessary unless there is hyponatremia, but patients with HF should avoid excessive fluid intake. Advise patients to contact the health-care provider if weight increases more than 2 pounds in a day or 5 pounds in a week.

HYPERTENSION

Worldwide, hypertension (HTN) is one of the five leading risk factors for disease burden, including cardiovascular disease (CVD) and death (Virani et al., 2021). Nearly one in every two adults in the United States has HTN (Virani et al., 2021). This high prevalence combined with population growth and an increased life expectancy of adults older than 60 years equates to providers treating more patients with HTN.

Signal Symptoms: Often referred to as the "silent killer," HTN is usually asymptomatic, presenting without overt symptoms (Kalehoff & Oparil, 2020). Only a portion of patients with hypertensive crisis present with nonspecific symptoms (headache, dizziness, palpitations, epistaxis, vomiting), cardiopulmonary symptoms (angina, arrhythmias, syncope, dyspnea), or focal neurological deficits (Ipek et al., 2017).

Description: HTN is the most common condition diagnosed in outpatient office visits in the United States (U.S. Preventive Services Task Force [USPSTF] et al., 2021). According to the latest American College of Cardiology/American Heart Association (ACC/AHA) guidelines for the detection, evaluation, and management of HTN in adults, blood pressure (BP) is categorized as normal, elevated, or HTN (stages 1 or 2) (Whelton et al., 2018). Normal BP is defined as less than 120/less than 80 mm Hg. Elevated BP is defined as 120 to 129/less than 80 mm Hg. Stage 1 HTN is defined as SBP 130 to 139 mm Hg or diastolic blood pressure (DBP) 80 to 89 mm Hg. Stage 2 HTN is defined as systolic blood pressure (SBP) greater than or equal to 140 mm Hg or DBP greater than or equal to 90 mm Hg (see Table 10-2). Notably, the 2018 guidelines of the European Society of Hypertension and the European Society of Cardiology (Williams et al., 2018) and the 2020 guidelines of the International Society of Hypertension (Unger et al., 2020) defined HTN as SBP 140 mm Hg and above or DBP 90 mm Hg and above.

Over a lifetime SBP and pulse pressure rise with age (Nuotio et al., 2020). However, DBP rises until about age 50 years and then slowly decreases as one ages (Nuotio et al., 2020). This explains why the most common type of HTN in older adults is isolated systolic HTN, defined as SBP of 130 mm Hg or greater and DBP of less than 80 mm Hg (Whelton et al., 2018).

HTN is a key risk factor for CVD (Virani et al., 2021). For every 20 mm Hg higher SBP and 10 mm Hg higher DBP, risk of death doubles from stroke, heart disease, and other vascular disease (Whelton et al., 2018). Higher SBP and DBP is also associated with an increased risk of angina, myocardial infarction (MI), heart failure (HF), stroke, peripheral arterial disease, and abdominal aortic aneurysm in adults ranging from 30 to 80+ years of age (Whelton et al., 2018). However, multiple, robust, randomized clinical trials, including studies in older adults, document effective treatment and management of HTN improves survival rates with cardiovascular benefits (Kalehoff & Oparil, 2020). More than one-half of patients with HTN have cardiovascular risk factors, so it is also important to screen for diabetes, dyslipidemia, overweight/obesity, metabolic syndrome, and unhealthy lifestyles (physical inactivity, tobacco use, and high alcohol use) (Unger et al., 2020).

TABLE 10-2 Classification of Hypertension

SYSTOLIC BLOOD PRESSURE	DIASTOLIC BLOOD PRESSURE	CLASSIFICATION
<120 mm Hg	and <80 mm Hg	Normal blood pressure
120–129 mm Hg	and <80 mm Hg	Elevated blood pressure
130–139 mm Hg	or 80–89 mm Hg	Stage 1 hypertension
≥140 mm Hg	or ≥90 mm Hg	Stage 2 hypertension

Adapted from Whelton et al., 2018.

Etiology: HTN develops in response to an increase in cardiac output or an increase in peripheral resistance. The exact etiology of primary HTN remains unclear but is thought to be a result of genetic and environmental factors that affect cardiovascular and kidney structure and function. Secondary HTN, accounting for about 5% of hypertensive cases, is caused from common conditions such as kidney disease (including renal artery stenosis), sleep apnea, prescription and over-the-counter (OTC) medications, excessive alcohol use, and primary aldosteronism (Whelton et al., 2018). Less common causes of secondary HTN include Cushing's syndrome, hypothyroidism, hyperthyroidism, primary hyperparathyroidism, and acromegaly (Whelton et al., 2018).

Occurrence: Approximately 47% of adults in the United States have HTN (Virani et al., 2021). Prevalence increases with age, especially in those age 65 and older who have a prevalence rate of 77% (Virani et al., 2021). With an aging population, the absolute number of older adults with HTN is expected to grow (Unger et al., 2020).

Age: Until age 64 years, prevalence of HTN is higher in men than women, yet women have a higher prevalence than men in those 65 years of age and older (Virani et al., 2021).

Ethnicity: HTN is more common and develops at a younger age in Black people in the United States as compared to Whites and Hispanics (Virani et al., 2021).

Contributing Factors: Contributing factors in the development of HTN include genetics, obesity, stress, lifestyle factors, and loss of elasticity in blood vessels. Aging is also a major contributing factor to HTN. As one ages, pulse pressure increases as changes in the arterial vessel structure and function occur (Pont & Alhawassi, 2017). Vascular resistance increases as vascular walls become stiff and less compliant. Structural changes within arterial endothelial also occur contributing to arterial stiffness. Older adults are also more salt sensitive due to reduced sodium excretion. This increased salt sensitivity is caused by a decline in kidney function and reduced generation of natriuretic substances (such as prostaglandin E2 and dopamine), resulting in elevated blood pressure (Pont & Alhawassi, 2017). An increased prevalence of comorbid conditions (such as declining heart and kidney function, diabetes, and glucose intolerance) are also contributing factors to

© F.A. Davis Publishing

vascular dysfunction and corresponding BP elevation in older adults (Pont & Alhawassi, 2017). Progressive kidney dysfunction and autonomic nervous system sensitivity that occur with aging also influence response to treatment.

Diagnostic Tests: All adults 18 years and older without known HTN should be screened for elevated BP (USPSTF et al., 2021). To diagnose HTN the provider should use an average of two or more readings obtained on two or more occasions (USPSTF et al., 2021; Whelton et al., 2018;). Out of office BP measurements (ambulatory or home BP monitoring) are recommended to confirm the diagnosis of HTN before starting treatment (USPSTF, 2021; Whelton et al., 2018). As part of the evaluation and work-up for primary HTN, the following studies should be considered:

- Comprehensive metabolic profile (CMP) (sodium, potassium, serum creatinine, estimated glomerular filtration rate, and fasting glucose are the priority)
- Complete blood count (CBC)
- Lipid panel
- Thyroid-stimulating hormone (TSH) levels with reflex to T4 if abnormal
- Urinalysis (dipstick urine test as a backup) to evaluate urinary albumin to creatinine ratio
- 12-lead electrocardiogram (ECG) (for detection of atrial fibrillation, left ventricular hypertrophy, ischemic heart disease)
- Echocardiogram and uric acid level (Unger et al., 2020; Whelton et al., 2018)

Differential Diagnosis: Differential diagnoses to consider are secondary causes of HTN such as substance/drug-induced HTN, advanced kidney disease, obstructive sleep apnea, hyperaldosteronism, hypothyroidism or hyperthyroidism, hyperparathyroidism, and Cushing's syndrome (Whelton et al., 2018). Because secondary causes of HTN are rare and less common in older adults, testing for secondary causes is generally not warranted unless the patient has resistant HTN, an acute rise in BP from previously controlled BP, hypertensive urgency and emergency, or strong clinical findings that suggest a secondary cause (Unger et al., 2020). The most common secondary causes in adults 65 years and older are renal artery stenosis (secondary to atherosclerosis) and kidney failure (Charles et al., 2017).

Accurate measurement of BP is important to the identification of patients who would benefit from better BP control. Providers should use an automated BP device (versus taking BPs manually) because results more closely align with BPs on a daily basis (Muntner et al., 2019). Using the correct size BP cuff is important. The most common cause of measurement error is using the wrong size BP cuff (Muntner et al., 2019). A BP cuff that is too small may falsely elevate BP; whereas a cuff that is too large may result in a falsely low BP measurement (Muntner et al., 2019).

Obtaining BP readings outside of the clinical setting is important to assess for white-coat effect, masked HTN, orthostatic hypotension, or postprandial hypotension, which provides an opportunity to improve BP control without overtreating. White-coat HTN in older adults is defined as having an elevated BP only in the office with a nonelevated ambulatory or home BP (Unger et al., 2020; USPSTF et al., 2021). White-coat HTN indicates an intermediate cardiovascular risk, somewhere between patients who are normotensive and those with sustained HTN (Unger et al., 2020). If the total cardiovascular risk is low and there is no evidence of end organ damage, lifestyle modifications are generally the mainstay of treatment (pharmacological treatment is not usually indicated) (Unger et al., 2020).

Alternatively, masked HTN occurs when office BPs are nonelevated, yet out-of-the-office (ambulatory or home) BPs are elevated (Unger et al., 2020). Patients with masked HTN have approximately the same risk of cardiovascular events as those with sustained HTN (Unger et al., 2020). In this situation repeated out-of-the-office readings are needed to confirm the diagnosis of HTN and pharmacological therapy (in addition to lifestyle modifications) is usually indicated to normalize out-of-the-office readings (Unger et al., 2020).

Orthostatic hypotension is defined as a significant fall in BP when moving from a supine or sitting to a standing position and may occur in up to 40% of older adults with cardiovascular risk factors (Setters & Holmes, 2017). Orthostatic hypotension may result from reduced baroreflex sensitivity with age and loss of artery compliance, hypovolemia, or polypharmacy (Oliveros et al., 2019; Shaw et al., 2019). Because orthostatic hypotension is a significant risk factor for falls and fractures in older adults, screening for orthostatic hypotension is an important part of the provider's work-up for HTN, especially for those with dizziness, light-headedness, or unsteadiness when standing up (Shaw et al., 2019). Orthostatic testing involves measuring BPs in two different body positions (most commonly sitting then standing). Orthostatic hypotension is present with a decrease in systolic pressure of 20 mm Hg or a decrease in diastolic pressure of 10 mm Hg within 3 minutes of standing when compared with BP from a sitting or supine position (Shaw et al., 2019).

Postprandial hypotension, an often underrecognized cause of syncope in older adults, is another important consideration in the work-up for HTN (Oliveros et al., 2019). Postprandial hypotension, defined as a drop in SBP by 20 mm Hg within 2 hours of a meal, increases the risk for falls in older adults (Trahair et al., 2017). Approximately 25% of healthy older adults experience postprandial hypotension, which increases to about 40% in those who live in aged care facilities (Trahair et al., 2017). Ambulatory BP monitoring can help diagnosis postprandial hypotension (Oliveros et al., 2019). Prevention can be addressed by recommending increased water intake before meals and eating six smaller meals as opposed to three larger meals (Oliveros et al., 2019).

Although a single, accurately measured BP may be a predictor of future cardiovascular risk, the International Society of Hypertension (Unger et al., 2020) and the USPSTF et al. (2021) recommend obtaining out-of-the-office BP readings in addition to those taken in the clinical setting for diagnostic confirmation before starting pharmacological treatment. Ambulatory or home BP monitoring are a better predictor of cardiovascular risk and/or target organ damage as compared to using one-time office readings (Whelton et al., 2018). In addition, home BP monitoring, along with office monitoring, optimizes patient engagement with shared decision making and treatment adherence. However, the provider should assess the patient or caregiver's capability of doing home BP monitoring and provide adequate instructions.

TABLE 10-3 2017 ACC/AHA Guidelines for the Treatment of Hypertension in Adults

Normal blood pressure	Evaluate yearly.
Elevated blood pressure or stage 1 hypertension with estimated cardiovascular risk less than 10%	Start treatment with nonpharmacological interventions and reevaluate in 3 to 6 months. Nonpharmacological interventions should include weight loss, heart healthy diet, sodium reduction, potassium supplement unless contraindicated due to chronic kidney disease or use of drugs that inhibit potassium excretion, increased activity, moderation in alcohol consumption, and smoking cessation. Goal of treatment <130/80 mm Hg.
Stage 1 hypertension with estimated cardiovascular risk 10% or greater	Initial treatment should include nonpharmacological interventions and antihypertensive drug therapy and reevaluate in 1 month. Goal of treatment <130/80 mm Hg.
Stage 2 hypertension	Initial treatment should include nonpharmacological interventions and antihypertensive drug therapy with two agents of different classes and reevaluate in 1 month. Goal of treatment <130/80 mm Hg.

Adapted from Whelton et al., 2018.

Treatment: The ACC/AHA guidelines incorporated new information regarding BP-related risk factors for cardiovascular disease and new BP thresholds for initiating antihypertensive drug therapy (Whelton et al., 2018). Based on these guidelines, BP targets for treatment should be SBP less than 130 mm Hg and DBP less than 80 mm Hg. These same targets are used for adults aged 65 or older who are noninstitutionalized, ambulatory, and community-dwelling (Whelton et al., 2018). However, for adults aged 65 years or older who have complex comorbid conditions and/or limited life expectancy (regardless of whether they are community-dwelling or residing in long-term care facilities) treatment should be based on clinical judgment, goals of care, and a team approach to determine risk/benefit for intensity of BP targets and choice of antihypertensive medications (Table 10-3) (Whelton et al., 2018).

The optimal BP target for older adults remains controversial in the literature, especially for those 70 years or older. Findings from a 2019 literature review of trials that tested various BP targets in adults aged 70 or older found benefits with a minimal SBP control of less than 150 mm Hg, with addition benefits being noted for those with SBP less than 120 mm Hg (Alsarah et al., 2019). Notably, the SPRINT study, which enrolled adults 70 years and older, found that intensive SBP control (<120 mm Hg) versus standard SBP control (<140 mm Hg) reduced cardiovascular disease by 33% and death by 32% without increasing the risk of falls, fractures, or kidney failure (Alsarah et al., 2019). A substudy of the SPRINT also found that intensive SBP reduction was associated with a significant reduction in the risk of mild cognitive impairment (Del Pinto et al., 2021). However, it is important to avoid hypotension (due to marked orthostasis or excessive BP variability) in older adults to prevent cerebral hypoperfusion resulting in negative cognitive effects (Del Pinto et al., 2021).

Guidelines from several American societies and the 2020 International Society of Hypertension guidelines (Unger et al., 2020) recommend that treatment goals in older adults be based on the patient's BP level and their overall cardiovascular risk. Because most older adults have a history of CVD or are determined to be high-risk based on risk calculators, a BP target of 130/80 mm Hg is reasonable. Regardless, management of HTN in older adults in the real world can be challenging and should be individualized.

Reaching and maintaining BP treatment goals in older patients also comes with challenges. Intensive BP lowering can result in dizziness or falls in older adults. Antihypertensive therapy in older adults may also result in polypharmacy, which increases the risk of side effects, adverse drug reactions (including drug-drug and drug-disease interactions), and cost (Reeve et al., 2020). Studies indicate that as the number of medications increase, patient adherence and quality of life (QOL) decrease, especially in older adults (Reeve et al., 2020). It is important to complete a medication reconciliation during each visit and specifically ask about how prescriptions are being filled and medications are being taken. Asking, "How do you take this medication?" will provide more information than asking, "Do you take this?" If possible, prescribing once-a-day treatments or single pill combinations to reduce the number of medications and the frequency of dosing supports medication adherence (Unger et al., 2020).

Hypertension in older adults is treated with the same medications as with younger patients, but the provider must consider age-related changes in metabolism and pharmacodynamics (Oliveros et al., 2019). Providers should first consider nonpharmacological interventions for BP reduction such as salt reduction, a healthy diet such as the DASH eating plan, weight loss (if overweight or obese), moderate consumption of alcohol, regular physical activity, smoking cessation, and reduction of stress (Unger et al., 2020).

When initiating antihypertensive drug therapy, first-line agents include thiazide diuretics, calcium channel blockers (CCBs), and angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin II receptor blockers (ARBs) (Unger et al., 2020; Whelton et al., 2018). Chlorthalidone is the preferred diuretic because of long half-life and proven reduction of CVD risk (Whelton et al., 2018). Loop diuretics and alpha blockers should be avoided because of their increased risk of falls with older patients (Oliveros et al., 2019). There is evidence that ACEIs and ARBs exert a protective effect on cognition for older adults (Del Pinto et al., 2021). However, simultaneous use of an ACEI and an ARB is contraindicated due to the increased risk of hyperkalemia or worsening kidney function (Whelton et al., 2018). Beta blockers are not considered first-line therapy for HTN because they do not have a strong antihypertensive effect. They may be considered in those with other comorbidities such as coronary artery disease (CAD) or HF. There is a risk that they may worsen cardiovascular outcomes in adults older than 60 years (Oliveros et al., 2019). The goal of the 2017 ACC/AHA guidelines is to facilitate evidence-based practice in the management of HTN in adults (Table 10-4).

TABLE 10-4 Evidence-Based Dosing for Antihypertensive Agents

MEDICATION	STARTING DAILY DOSE	TARGETED DOSE IN RANDOMIZED CONTROLLED TRIALS
Thiazide Diuretics		
Hydrochlorothiazide	12.5–25 mg	25–50 mg
Chlorthalidone	12.5–25 mg	12.5–25 mg
Chlorothiazide	12.5 mg	12.5–25 mg
Indapamide	1.25 mg	1.25–2.5 mg
ARBs (examples)		
Lorsartan	50 mg	100 mg
Valsartan	40–80 mg	160–320 mg
ACEIs (examples)		
Enalapril	5 mg	40 mg
Lisinopril	10 mg	40 mg
CCBs (examples)		
Amlodipine	2.5 mg	10 mg
Diltiazem ER	120–180 mg	360 mg
Beta Blockers (examples)		
Metoprolol	50 mg	100–200 mg
Atenolol	25–50 mg	100 mg

Source: *Whelton et al., 2018.*

Medications should be started at the lowest dose and an assessment of orthostatic hypotension should be obtained as doses are gradually increased to meet the targeted BP goal. In addition, kidney function should be assessed at baseline and periodically to detect possible increases in creatinine or estimated glomerular filtration rate (GFR), especially if the patient becomes hypovolemic, increasing the likelihood of renal hypoperfusion (Oliveros et al, 2019). Most older adults will require more than one medication along with lifestyle changes to reach the desired BP goal (Unger et al., 2020). Specific comorbid illnesses may guide the initial and subsequent choice of drug therapy. For example, ACEIs or ARBs are recommended for patients with kidney disease and/or diabetes (Unger et al., 2020).

Follow-Up: Follow-up is important, as the majority of patients with HTN are not adequately controlled. Per ACC/AHA guidelines, after HTN treatment has been started, low-risk adults with elevated BP or stage 1 HTN with low cardiovascular risks should be reevaluated in 3 to 6 months (Whelton et al., 2018). Adults with stage 1 and stage 2 HTN with high cardiovascular risks should be reevaluated within 1 month (Whelton et al., 2018). Comorbid conditions such as diabetes, HF, and chronic kidney disease will influence the frequency of follow-up visits.

Sequelae: Uncontrolled HTN is associated with serious long-term complications, such as left ventricular hypertrophy, HF, stroke, and kidney disease (Unger et al., 2020).

Prevention/Prophylaxis: One of the primary preventive measures for HTN is lifestyle modification. Excess weight, excess sodium intake, inadequate physical activity, smoking, inadequate intake of fruits and vegetables, and excessive alcohol consumption are all modifiable factors that can contribute to the onset of HTN (Unger et al., 2020).

Referral: Providers should consider referring to a HTN specialist when the BP goal cannot be attained within 6 months, if a secondary cause of HTN is suspected, or in the management of complicated patients who may benefit from consultation (Whelton et al., 2018).

Education: Patient education is important in preventing HTN and/or adhering to treatment once diagnosed. Lifestyle modifications and medication adherence must be reinforced with every patient. There are many patient-education resources available for health-care professionals. The AHA has disease-specific pocket guides available for health-care professionals to give to their patients, or patients can be referred to their Web site. Several online subscription services for health-care professionals also include patient education materials for HTN.

Providers should refer to evidence-based guidelines, such as those provided by ACC/AHA, when assessing and treating older adults with HTN, but recommendations are not a substitute for clinical judgment for individual patients. Older adults often have comorbid conditions or lifestyle practices that may impact treatment outcomes. Balancing competing risk factors for HTN-related risk of stroke, MI, and HF with treatment-related risks, such as fall-related fractures and adverse reactions to medications, is challenging and requires a patient-centered approach to treatment in older adults.

ISCHEMIC HEART DISEASE

Signal Symptoms: Angina pectoris and or anginal equivalent (shortness of breath/dyspnea, diaphoresis, extreme fatigue, or pain at site other than the chest) is the initial manifestation of ischemic heart disease (IHD). Typical angina is substernal chest discomfort associated with physical exertion or emotional stress and relieved with rest or nitroglycerin (Harber & Brenner, 2021). Women report epigastric discomfort; nausea; radiation of discomfort to the arms, neck, and interscapular areas; dyspnea; and fatigue (Antman & Loscalzo, 2018).

Description: IHD is also referred to as coronary artery disease (CAD) and occurs when there are one or more signs or symptoms of inadequate supply of blood to the myocardium. The most common problems resulting in IHD are related to obstruction of the epicardial coronary arteries due to atherosclerosis. Angina pectoris occurs when myocardial oxygen demand exceeds oxygen supply. Patients are considered stable when symptoms are manageable with either medical or revascularization therapy (Antman & Loscalzo, 2018). IHD is a chronic disorder that typically cycles through defined phases: asymptomatic, stable angina, accelerating angina, and acute coronary syndrome (ACS)/unstable angina/acute myocardial infarction (MI). The progression of the disease is not necessarily linear (Antman & Loscalzo, 2018).

Etiology: Atherosclerosis involving the coronary arteries is the common etiology of IHD. Evidence supports a multifactorial pathophysiology of coronary atherosclerosis that includes obstruction of the coronary arteries, reducing the quantity of oxygen-rich blood to the myocardium, and dysfunction of the coronary microvasculature and endothelium (Harber & Brunnell, 2021; Severino et al., 2020).

Occurrence: Cardiovascular disease (CVD) is the number one cause of death in both men and women. Among persons 55 to 85 years of age, approximately 21.5% of men and 15.3% of woman have IHD. Men have CVD at a younger age. Women lag behind men by 10 years. In those 40 to 59 years of age, men 6.3%, women 5.6%; in those 60 to 79 years of age, men 19.9%, women 9.7%; and in those 80 years of age and older, men 32.2%, women 18.8%. (Rodgers et al., 2019)

Deaths attributable to CVD steadily increased during the 1900s to the 1980s and declined into the 2010s, but they have increased over the last decade (Kahn et al., 2020; Virani et al., 2021). Recent studies (Arnett et al., 2019) state one in three deaths each year are caused by CVD. As of 2019, the annual incidence of new cases of MI and cerebrovascular accident (CVA) in the United States is 580,000 and 610,000, respectively (U.S. Preventative Services Task Force [USPSTF], 2019). Silent MIs are estimated to involve 160,000 additional persons (Gul & Markaryus, 2021). Mean predicted 10-year risk for CVD among adults aged 30 to 74 years has decreased from 7.2% during 1999 to 2000, to 6.5% during 2009 to 2010.

Age: The prevalence of CVD increases with age. The average age at first MI is 65.1 years for men and 72 years for women.

Ethnicity: In a meta-analysis involving 17 population-based cohorts worldwide, 60,211 participants without CVD at baseline were studied. The 10-year event rate for formation of carotid intima-media thickness was 6.7% in Asians, 7.8% in Hispanics, 8.1% in Whites, and 9.2% in Blacks. Ethnicity appears to significantly modify the association between risk factors and atherosclerotic disease (Willeit et al., 2020). The association between increase in age and atherosclerotic

© F.A. Davis Publishing

disease was weaker in Black and Hispanic populations. SBP elevations in Asians were strongly related to onset of disease. HDL cholesterol and smoking were associated less with disease onset in Black populations (Chi et al., 2020).

Contributing Factors: In the absence of an established model to predict outcome, consider the following risks:

1. Sociodemographic: Age is the single, strongest determinant of survival. Sex and ethnicity have fewer effects on risk. Lower socioeconomic status is associated with worse outcome.
2. Cardiovascular: Smoking, HTN, dyslipidemia, family history of premature CAD, obesity, and sedentary lifestyle have the greatest risk of complications.
3. Coexisting medical conditions: Diabetes, chronic kidney disease, chronic pulmonary disease, and malignancy influence the prognosis.
4. Cardiovascular comorbidities: Heart failure (HF), peripheral artery disease, and cerebrovascular disease are strong risk factors for mortality.
5. Psychosocial characteristics: Depression is strongly associated with worse survival rates. Poor social support, poverty, and stress are associated with poor outcome.
6. Health status: Patient's symptoms, functional capacity, and quality of life (QOL) are associated with poor survival and incidence of ACS.
7. Anginal frequency: The more frequent the angina, the stronger prediction of ACS and hospitalization.
8. Cardiac disease severity: The degree and distribution of stenosis are meaningful predictors of outcome (Nowbar et al., 2019).

Signs and Symptoms: A detailed assessment of chest pain includes the quality, location, severity, and duration of pain; radiation; associated symptoms; and provoking and alleviating factors. The quality of chest pain associated with IHD is most often described as squeezing, gripping, suffocating, or heavy. Women and older adults can present with atypical symptoms such as nausea, vomiting, mid-epigastric discomfort, or sharp pain. Anginal pain typically lasts minutes; is in the substernal area with pain that may radiate to the neck, jaw, epigastrium, or arms; often is aggravated by exertion or emotional stress; and relieved with rest or nitroglycerin. Patients with angina must be categorized as stable or unstable. Unstable angina is defined as new onset increasing in frequency, intensity, duration, or at rest.

Physical examination may be normal or nonspecific. The patient may present with HF, valvular disease, or cardiomyopathy. Bruits over vascular areas and/or diminished pulses might suggest vascular disease. Elevated blood pressure (BP) or xanthomas (lesions of the skin containing cholesterol and fat) may indicate risk factors for IHD (Antman & Loscalzo, 2018; Dababneh & Goldstein, 2021).

Diagnostic Tests: A resting electrocardiogram (ECG) is the initial test, followed by stress testing. See table below.

Differential Diagnosis: Aortic dissection, pericarditis, pulmonary embolism (PE), pneumothorax, pneumonia, pleuritic, esophagitis, spasm, reflux, biliary colic, cholecystitis, cholelithiasis, peptic ulcer, pancreatitis, costochondritis, fibrositis, rib fracture, herpes zoster, anxiety, panic disorder, affective disorders (anxiety/depression) (Antman & Loscalzo, 2018).

A resting ECG is recommended in patients when there is suspected cardiac cause of chest pain (Evidence Rating B). Those with evidence of prior MI, especially Q waves in multiple leads or an R wave in V1; persistent ST-T-wave inversions particularly in leads V1 to V3; left bundle-branch block or bifascicular block, second- or third-degree atrioventricular block, or ventricular tachycardias or hypertrophy have a worse prognosis than those with a normal ECG (Fihn et al., 2012).

When the evaluation is complete, the determination of the probability of IHD is sufficient to recommend further testing. The typical angina pain and the older age of the patient have a high likelihood of IHD. Diabetes has the greatest influence on increasing the probability of IHD (Antman & Loscalzo, 2018).

For those who have suspected IHD and a prior MI, Q waves or symptoms of HF, complex ventricular arrhythmias, or an undiagnosed heart murmur, an echocardiography to evaluate the left ventricular (LV) systolic and diastolic function and heart structures is recommended (Antman & Loscalzo, 2018).

TEST	RESULTS INDICATING DISORDER
ECG	ST-segment depression or elevation or T-wave inversion in the absence of left ventricular hypertrophy supports the diagnosis of ischemia
	Q waves may be evidence of an old MI
Exercise stress testing	Reproduces ischemic symptoms
	Defects in myocardial perfusion with exercise
	Cardiac risk identified in patients with a decrease in the BP, S_3, crackles, or prolonged down-sloping ST-segment depression after exercise
Myocardial perfusion imaging	Perfusion defects
	Left ventricular dysfunction
Echocardiogram	Assesses the severity of left ventricular dysfunction
Stress echocardiogram	Multiple reversible wall motion abnormalities
Cardiac catheterization	For patients who fail pharmacological therapy, have had an MI, or have unstable angina, to determine the severity of disease

© F.A. Davis Publishing

If there is a probability that IHD may be present, stress testing is the most common noninvasive test used to diagnose IHD. Stress testing is used to induce ischemia either by exercise or pharmacological stress agents. However, the production of ischemia is dependent on the stress imposed and submaximal exercise testing can fail to produce ischemia. Coronary artery stenosis under 70% may be undetectable. For those able to exercise, standard exercise ECG testing is recommended. The patient must have an interpretable ECG and a moderate physical ability to exercise. For those unable to exercise, pharmacological stress with nuclear myocardial perfusion imaging (MPI) or echocardiography is recommended.

Those patients who have survived sudden cardiac death, life-threatening ventricular arrhythmias, or HF should undergo coronary angiography (Antman & Loscalzo, 2018). Angiography is useful in patients with unacceptable ischemic symptoms despite guideline-directed medical therapy (Antman & Loscalzo, 2018). However, it should not be offered to those who are unwilling or are not candidates for revascularization.

Treatment: Details of treatment are noted in the following tables.

Follow-Up: See patient at regular intervals for chronic health management; instruct in emergency measures and lifestyle management.

Sequelae: IHD remains a major public health problem with more than 9 million people with angina worldwide. Survival rates of patient have been improving; however, it is still the number one cause of death in men and women. Patients

Medical Therapy to Prevent MI and Death		
Clinical Recommendation	**Evidence Rating**	**References**
Weight Management		
Body mass index (BMI) and/or waist circumference should be assessed at every visit, and encouragement for weight maintenance or reduction to maintain or achieve BMI 18.5 to 24.9 and a waist circumference less than 40 inches in men and less than 35 inches in women.	B	Fihn et al., 2012, 2014 Braun et al., 2018
Initial goal of weight loss should be to reduce body weight by approximately 5%–10% from baseline.	C	Fihn et al., 2012, 2014 Braun et al., 2018
Smoking Cessation		
Smoking cessation and avoidance of exposure to secondhand smoke.	B	Fihn et al., 2012, 2014 Braun et al., 2018
Management of Psychological Factors		
Screen for depression.	B	Fihn et al., 2012, 2014 Braun et al., 2018
Alcohol Consumption		
Limit alcohol to 1 drink (4 ounces of wine, 12 ounces of beer, or 1 ounce of spirits) a day.	C	Fihn et al., 2012, 2014 Braun et al., 2018
Antiplatelet Therapy		
Aspirin 75–162 mg daily in the absence of contraindication.	A	Fihn et al., 2012, 2014 Braun et al., 2018
Treatment with clopidogrel when ASA is contraindicated.	B	Fihn et al., 2012, 2014 Braun et al., 2018
Dipyridamole is not recommended.	B	Fihn et al., 2012, 2014 Braun et al., 2018
Beta Blocker		
Beta blocker therapy should be started and continued for 3 years in all patients with normal LV function after MI or ACS.	B	Fihn et al., 2012, 2014 Braun et al., 2018
Beta blocker therapy should be used in all patients with LV systolic dysfunction (EF ≤40%) with HF or prior MI (carvedilol, metoprolol succinate, or bisoprolol have been shown to reduce risk of death).	A	Fihn et al., 2012, 2014 Braun et al., 2018
Beta blockers considered for chronic therapy for all other patients with coronary or other vascular disease.	C	Fihn et al., 2012, 2014 Braun et al., 2018
Renin-Angiotensin-Aldosterone Blocker Therapy		
ACEIs for patients who have hypertension, diabetes, LVEF ≤40%, or chronic kidney disease.	A	Fihn et al., 2012, 2014 Braun et al., 2018
ARBS for patients with hypertension, diabetes, LV systolic dysfunction, or chronic kidney disease who are intolerant of ACEIs.	A	Fihn et al., 2012, 2014 Braun et al., 2018
Influenza vaccine is recommended.	B	Fihn et al., 2012, 2014 Braun et al., 2018
Estrogen therapy; vitamins C and E and beta-carotene, folate, or vitamin B_6 and B_{12}, chelation therapy, garlic, coenzyme Q10, selenium or chromium.	No benefit	Fihn et al., 2012, 2014 Braun et al., 2018

with symptoms of angina have MIs at a rate of 3% to 3.5% per year (Benjamin et al., 2019; Nowbar et al., 2019). Many people with IHD do not return to work after coronary revascularization and 15% to 20% rate their health as fair or poor. IHD continues to be associated with considerable morbidity despite the decrease in mortality rate. The costs of caring for patients with IHD are estimated at $156 billion in the United States for both direct and indirect costs.

Prevention/Prophylaxis: Healthy, active lifestyle; smoking cessation, weight control and control of HTN, diabetes, and cholesterol.

Referral: Patients with IHD will be comanaged with cardiology. There are other medical conditions, such as HIV and connective tissue disease, which may result in increased IHD. These patients will be comanaged with infectious disease and rheumatology to provide optimum care of these disorders. Ongoing reassessment of the patient's adherence to the therapy, adverse events, treatment goals, effectiveness of interventions, and risk factor reduction should be done. For those who have not met their goals, especially in the management of diabetes, depression, smoking cessation, and chronic kidney disease, referral to an appropriate specialist may be considered. If angina becomes unstable, the patient should know to seek emergency medical care (Braun et al., 2018; Fihn et al., 2014).

MYOCARDIAL INFARCTION

Signal Symptoms: Typical symptom is prolonged chest pain (more than 20 minutes' duration); atypical symptoms include shortness of breath, neurological symptoms (confusion, weakness), fatigue, gastrointestinal symptoms, and symptoms of or worsening heart failure (HF).

Description: Boyle (2017) defines myocardial infarction (MI) as a pathological clinical episode, triggered by myocardial ischemia, manifesting in myocardial injury or necrosis. MIs can be classified as acute ST elevation MI (STEMI) or non–ST elevation MI (NSTEMI). Essentials of diagnosis may include signal symptoms; chest "pressure" or "dull," "squeezing or aching" sensation; characteristic electrocardiographic changes; elevated biomarkers; troponins; and imaging that may show regional wall motion abnormality with normal wall thickness (Crawford et al., 2018). Thygensen and colleagues (2018) further expanded the definition of MI to include universal MI types (types 1 through 5). Each type has unique criteria, with types 4 and 5 being coronary procedure-related MI. Criteria to differentiate MI from myocardial injury was born out of the need to better define the occurrence of the myocardial event. The term *myocardial injury* should be used when there is evidence of elevated cardiac troponin values, and it is considered acute if it is at least one value above the 99th percentile upper reference limit (URL). The term *acute MI* (types 1, 2, and 3 MI) should be used when there is acute myocardial injury with clinical evidence of acute myocardial ischemia and detection of a rise and/or fall of the troponin values with at least one value above the 99th percentile URL and at least one of the following:

- Symptoms of myocardial ischemia
- New ischemic electrocardiogram (ECG) changes
- Development of pathological Q waves
- Imaging evidence of new loss of viable myocardium or regional wall motion abnormality
- Coronary thrombus found by angiography or on autopsy (autopsy does not apply to type 2 or 3 MIs)
  - Postmortem demonstrating acute atherothrombosis in the artery supplying the infarcted myocardium would meet type 1.

© F.A. Davis Publishing

- Evidence of imbalance of myocardial oxygen supply and demand not related to atherothrombosis meets type 2.
- Cardiac death in patients with symptoms suggestive of myocardial ischemia and presumed new ischemic ECG changes prior to troponin values are available or abnormal meets type 3 criteria.

Criteria for coronary procedure-related myocardial infarction (types 4 and 5) are as follows:

- MI related to percutaneous coronary intervention (4a)
  - MI related to stent thrombosis (4b) or restenosis (4c); both 4b and 4c meet the criteria for a type 1 MI
- MI related to coronary artery bypass grafting (CABG) is termed type 5 and is confirmed by elevation of troponin levels, new ECG changes, loss of viable myocardium, or angiographic flow limiting complications.

(Thygensen et al., 2018).

Etiology: The hallmark of acute coronary syndrome (ACS) is the sudden imbalance between myocardial oxygen consumption and demand, which is usually the result of coronary artery obstruction. This imbalance may also be caused by conditions such as excessive myocardial oxygen demand in the setting of a stable flow-limiting lesion and acute coronary insufficiency due to other causes (e.g., vasospastic angina, coronary embolism, and coronary arteritis). Noncoronary causes of myocardial oxygen supply-demand mismatch include hypotension, severe anemia, hypertension (HTN), tachycardia, hypertrophic cardiomyopathy, severe aortic stenosis, nonischemic myocardial injury, and multifactorial causes that are not mutually exclusive (Crawford et al., 2019; Thygensen et al., 2018).

Atherosclerotic plaque formation has been noted in persons younger than 20 years of age. Gradually, this atherogenic plaque builds up inside the intimal linings of the coronary artery(ies), resulting in both hardening of the arterial walls and narrowing of the coronary vessels. This atherosclerotic plaque contains lipid (cholesterol)–rich content, covered by a fibrous cap, which can ulcerate or fissure. Rupture of this vulnerable plaque can result in thrombosis, which partially or totally occludes the lumen of the affected artery(ies), either at the location where the thrombus formed or further downstream where a smaller artery could be blocked. The results are essentially the same—an abrupt decrease in coronary blood flow to the myocardium, termed *myocardial ischemia.* Prolonged myocardial ischemia can lead to tissue death and MI. Although there are other causes of MI due to reduced myocardial blood flow, including hypotension and prolonged coronary vasospasm, or severe hyperthyroidism (which can increase the heart's demand for oxygen), the most frequent cause of MI is due to atherosclerosis. Another factor that plays an important role in ACS is platelet activation and aggregation (Mechanic et al., 2021). Damaged blood vessels result in exposed collagen fiber in the basement membrane. Platelets subsequently adhere to this collagen fiber and become activated. On activation, platelets then release chemicals, including adenosine diphosphate and thromboxane (a vasoconstrictor), which causes additional platelet aggregation. A platelet plug (or clot) is formed, which decreases blood flow to the blood vessel (Maziar Zafari & Abdou, 2019).

Occurrence: When looking at all-cause mortality, coronary artery disease (CAD) is the most frequent cause of death in the United States. In persons aged 55 to 74 years in the United States, CAD occurs more frequently in men, with a median age of 64.9 years. Before menopause, due to estrogenic cardioprotective effect, women have a lower occurrence of MI than men; however, women of all ages have a greater risk of longer hospitalizations and complications. On average, women develop CAD 10 years later than men and suffer MIs and sudden death 20 years later than men. By age 75, postmenopausal women have an equal risk to men of CAD and MI (Rivera-Bou & Schrage, 2021).

In persons older than 75 years, CAD contributes to significant morbidities and mortality. In persons aged 75 years or older who present with MI, more than 60% have NSTEMI with associated in-hospital mortality, accounting for approximately 80% of all inpatient hospital deaths (Bradley et al., 2019). In addition, persons older than 65 years with MI are associated with higher post-discharge mortality, theoretically because of the higher incidence of diffuse CAD and existing poor myocardial perfusion. Data published by the Centers for Disease Control and Prevention (CDC, 2018, 2019) on coronary disease and MI found that males overall had a significantly higher MI rate than females; however, with successive age-groupings, the prevalence of MIs significantly increased. When identifying level of education with MI and CAD, persons who had less than a high school diploma experienced almost twice the occurrences of these conditions when compared with those who had college education.

Age: In 2010, the prevalence of cardiovascular disease (CVD) was greatest among persons aged 65 years and older (23.4%). Postmortem studies show that coronary atherosclerosis is widespread, even among asymptomatic adults. Aging itself may be a risk factor for MI in both men and women (CDC, 2019).

Ethnicity: The incidences and occurrences of patients having MIs and CVD by race and ethnicity have been reported by the CDC (2018, 2019). Specific groups were identified at increased risk, including those persons who are multiracial, Native Americans, and Alaskan natives, who have substantially higher prevalence of MI than non-Hispanic White or Black Americans (CDC, 2018, 2019). Overall, in patients with NSTEMI, Black patients (when compared to White patients) were younger, with comorbidities, including HTN, renal insufficiency, diabetes, and HF (CDC, 2018, 2019).

Contributing Factors: Risk factors for CAD and MI in older adults are essentially the same as in the younger population. Risk factors include HTN, hyperlipidemia, diabetes, insulin resistance, physical inactivity and sedentary lifestyle, overweight or obesity, family history of heart disease, poor diet, sleep apnea, alcohol, and stress. Cigarette smoking is associated with new coronary events for older adults. The risks of MI drop rapidly after smoking cessation and, at 5 years, the risk for new coronary events is similar to that of a nonsmoker (Virani et al., 2021).

Aging alters the cardiovascular system in ways that reduce cardiac reserve and efficiency, thus compromising the ability to respond to stress or illness. The cardiovascular system becomes less compliant as diastolic filling of the ventricles declines and afterload increases secondary to increased

© F.A. Davis Publishing

stiffness in the ascending aorta. The result is moderate left ventricular hypertrophy, which creates a more precarious balance between myocardial oxygen supply and demand. Other changes in the cardiovascular systems of older adults include decreased responsiveness to beta-adrenergic stimulation, decreased baroreceptor sensitivity, and an increased dependence on a higher end-diastolic volume to maintain cardiac output (Acharya et al., 2019; Walter et al., 2021).

Signs and Symptoms: With advancing age, the presentation of acute MI will be less likely to include the classic symptoms of crushing substernal chest pain, nausea, vomiting, and diaphoresis. Rather, atypical symptoms such as a vague ache or discomfort may be present. Older adults may not recognize that throat, shoulder, arm, jaw, or abdominal pain may be referred cardiac pain or angina equivalent. Dyspnea is the second most common symptom of MI in both younger and older populations. For patients 85 years and older, syncope, acute confusion, or stroke may be the only presenting symptom. Some older adults may present only with faintness, weakness, or restlessness (Acharya et al., 2019).

On physical examination, the patient may be anxious and weak and may appear cyanotic. Arrhythmias may be noted on the ECG. The skin may be diaphoretic, cold, and clammy. Thrills, heaves, and an abnormal point of maximal impulse (PMI) may be palpated. Peripheral pulses may be irregular, slow, fast, or thready. Auscultation may reveal an S_3 or S_4, pericardial friction rub, murmurs, or crackles. The physical examination must focus on ruling out diagnoses other than MI (Johnson & Ghassemzadeh, 2021).

Diagnostic Tests: Along with a chest x-ray examination, complete blood count (CBC), clotting profile, electrolytes, and cardiac biomarkers including troponin, evaluation for acute MI includes serial 12-lead ECGs (Boyle, 2017). Changes on the ECG indicative of STEMI include ST-segment elevation in leads facing the infarction. ST-segment depression is sometimes present. With the increased incidence of NSTEMI, the presence of a single normal ECG does not rule out MI; therefore, serial ECGs are necessary. However, ECG findings may be nondiagnostic or difficult to interpret in older adults because of possible abnormalities, such as left bundle branch block, left ventricular hypertrophy, and previously unrecognized MIs.

In older adults, the cardiac enzyme profile may be atypical. Creatine kinase (CK), an enzyme found in myocardial cells, is released into the bloodstream when cells are damaged, approximately 6 to 8 hours after the onset of pain. Because the baseline CK in older adults may be significantly lower than normal, even those with MI may not develop CK levels high enough to be interpreted as abnormal, owing to decreased muscle mass. CK-MB, an isoenzyme of CK, is released on the death of myocardial cells and not during ischemia. The presence of CK-MB is also found in skeletal muscle, which can result in false-positive results from noncardiac conditions such as renal failure, head or chest trauma, pulmonary embolism (PE), acute and chronic muscular disorders, hypothyroidism, or hyperventilation. Therefore, CK-MB measurements do not provide additional information to the algorithms of STEMI and are not preferred over cardiac troponins (Lan et al., 2019). Cardiac troponin T (cTnT) is a cardiac-specific marker for MI, with rises in concentration levels soon after chest symptoms begin (Lan et al., 2019). Although elevations may not occur for 6 to 12 hours after onset of symptoms, in approximately 80% of patients use of cTnT alone can result in a definitive diagnosis of STEMI. Lactate dehydrogenase levels are occasionally useful in patients with delayed presentation because this enzyme remains elevated for several days. Other tests for MI may include echocardiography or stress thallium scans (Gulati et al., 2021)

Differential Diagnosis: The pain from MI can be like that of acute pericarditis, PE, acute aortic dissection, or costochondritis. Many conditions can present as cardiac disease in older adults, including cor pulmonale, pneumonia, esophageal spasm, gastroesphageal reflux disease (GERD), hiatal hernia, gallbladder disease, osteoarthritis of the spine, inflammation at the chondrocostal junction, muscle injury, and panic disorder (Johnson & Ghassemzadeh, 2021; Kumar et al., 2020).

Treatment: The American College of Cardiology (ACC) and American Heart Association (AHA) have examined pharmacological and interventional treatments for acute MI and established guidelines for care. Nitrates, the cornerstone of therapy for ischemic pain, reduce preload and improve coronary perfusion. Chest pain should be treated with sublingual nitroglycerin, repeated three times, 5 minutes apart, unless the patient is hypotensive, has right ventricular infarction, or has aortic stenosis (Gulati et al., 2021). IV nitrates have been shown to limit infarct size and reduce pain, complications, and mortality. IV nitroglycerin is started at 5 mcg/min on an infusion pump and titrated to desired effect. Frequent monitoring is required because harmful effects can be seen if the systolic blood pressure (SBP) drops below 90 mm Hg. Morphine sulfate, 2 to 4 mg IV, repeated at 5- to 15-minute intervals, is also effective for pain relief and can be given with anxiolytics (Gulati et al., 2021). Supplemental oxygen (2 to 6 L/min nasal cannula) should be given if oxygen saturation is less than 94% or arterial oxygen saturations are low.

Thrombolytics. Reperfusion in patients who present to hospitals with percutaneous coronary angioplasty and intervention (PCI) capability has become the standard of care (Gulati et al., 2021). In hospitals without PCI capability and where patients cannot be transferred to a hospital with PCI capability within 90 minutes, treatment with fibrinolytic (thrombolytic) therapy initiated within 30 minutes of presentation should be performed unless contraindicated. The use of thrombolytics in STEMI patients has been shown to decrease mortality by up to 30% (Gulati et al., 2021; Ko et al., 2018). Thrombolytic agents include tissue-type plasminogen (tPA) and streptokinase (SK). Indications for thrombolysis are based on the existence of chest pain and specific ECG changes. Studies show that this therapy is frequently omitted for older adults. Reasons for this include frequent delay in seeking medical care, atypical presentation of MI, and a higher prevalence of NSTEMIs. Fear of hemorrhage following use of thrombolytics must be weighed against the proven gains in survival for all age-groups, especially for those presenting early with MI. A variety of studies suggest that SK may be as beneficial as tPA in treating the older MI patient, which is considerably less expensive (Rivera-Bou & Schrage, 2021).

Aspirin. Aspirin therapy in post-PCI STEMI patients without demonstrated aspirin resistance should be initiated at 162 to 325 mg daily and, depending on the type of stent implanted,

© F.A. Davis Publishing

the recommended maintenance dose to be used with ticagrelor is 81 mg (Gulati et al., 2021). In patients at risk for increased bleeding after stent implantation, lower-dose aspirin is reasonable. Aspirin (non–enteric-coated) should be given as soon as possible if there is no obvious contraindication. Patients taking nonselective NSAIDs (excluding aspirin) and cyclooxygenase-2 inhibitors should have these agents discontinued at the time of presentation with STEMI and not readministered during the course of hospitalization due to increased risk of mortality, reinfarction, myocardial rupture, HF, shock, or HTN (Boyle, 2017).

Thienopyridines. Concurrent use of dual antiplatelet therapy (aspirin and thienopyridines) in MI patients (STEMI or NSTEMI) following PCI with stent implantation is the gold standard for secondary prevention of subsequent cardiovascular events. Use of thienopyridines, including clopidogrel or prasugrel, is important to decrease the risk of death and stroke and to prevent reinfarction or in-stent thrombosis (Johnson & Ghassemzadeh, 2021). Thienopyridines should be initiated as a loading dose early, either before or at the time of primary or nonprimary PCI, and continued for a minimum of 12 months after bare metal stent placement in patients who are not at high risk for bleeding (Howard & Khot, 2021). In patients for whom nonemergent coronary artery bypass is planned, thienopyridine therapy should be discontinued for a minimum of 5 days for those patients receiving clopidogrel and 7 days for those patients receiving prasugrel (Howard & Khot, 2021).

Parenteral anticoagulants are recommended in all patients with ACS or in myocardial patients regardless of whether or not reperfusion therapy was received. Low molecular weight heparin (LMWH), unfractionated heparin, bivalirudin, enoxaparin, or fondaparinux is recommended in patients undergoing PCI (Howard & Khot, 2021). If a CABG is planned, anticoagulants should be withheld for 5 to 7 days before the procedure due to risks of excessive bleeding.

For patients not receiving thrombolytics, low-dose subcutaneous heparin or LMWH is indicated for prophylaxis of deep venous thrombosis. Older adult patients with large anterior MIs and HF, as well as those with documented left ventricular thrombus, should receive full heparin anticoagulation.

Angiotensin-Converting Enzyme Inhibitors (ACEIs). ACEIs reduce mortality in post-MI patients. ACEIs are recommended and should be continued indefinitely for every patient recovering from STEMI and for those with MI with a left ventricular ejection fraction (LVEF) less than 40% and no obvious contraindications to their use. For patients with preserved LVEF with HTN, chronic kidney diseases, or diabetes, ACEIs are recommended unless contraindicated (Bahit et al., 2018).

Angiotensin Receptor Blockers (ARBs). ARBs are recommended in those patients who are intolerant of ACEIs, who have HF with LVEF of 40% or less, or who have HTN.

Aldosterone Blockade. Aldosterone blockade is recommended for post-MI patients without severe renal dysfunction or hyperkalemia, with HF, with LVEF of 40% or less, or with diabetes who are already on a therapeutic dose of ACEI and beta blockade (Bahit et al., 2014).

Beta Blockers. Beta blockers have been shown to limit infarct size, decrease chest pain, improve prognosis, and reverse cardiovascular remodeling. They are generally well tolerated in patients ages 65 to 75 years. However, their use in this population "should be tailored based on other concomitant cardiovascular conditions and completeness of revascularization" (Motivala et al., 2016, p. 1647). Conditions that contraindicate the use of beta blockers in older adults include bronchospastic lung disease, marked bradycardia, hypotension, depression, acute heart failure, and diabetes. Beta blockers "have consistently been shown to improve outcomes in a variety of cardiovascular settings and therefore remain widely used" (Kumar et al., 2020; Motivala et al., 2016, p. 1647).

In acute MI, metoprolol or atenolol is given 2.5 to 5 mg IV every 5 minutes, for a total of 15 mg and 10 mg, respectively. Beta blockers should be initiated in the emergency department before PCI and within 24 hours in patients presenting with STEMI, MI, ACS, or left ventricular dysfunction with or without HF, unless contraindicated. Beta blocker use in this population has increased over time (Ko et al., 2018). Contraindications to beta blocker therapy include HF, evidence for a low cardiac output state, or risk for cardiogenic shock (Mechanic et al., 2021).

Statins and Lipid-Lowering Therapy. A lipid profile that includes total cholesterol, low-density lipoprotein (LDL), high-density lipoprotein (HDL), and triglycerides should be performed and assessed on all patients with ACS or MI within 24 hours of admission. Lipid-lowering therapy is recommended before discharge, with the LDL goal to be less than 100 mg/dL, preferably with further LDL reduction to less than 70 mg/dL (Wang et al., 2018). Dietary therapy is recommended for all patients, including consumption of omega-3 fatty acids, weight management, and physical activity.

Calcium channel blockers (CCBs) have limited use in STEMI and NSTEMI patients. Hypotension-induced tachycardia has been associated with the use of short-acting CCBs. Long-acting CCBs should be used sparingly, if needed, with additional precautions in those patients already taking digoxin or beta blockers (Zafari & Yang, 2019).

In terms of interventional management of older adults with MI, guidelines by both the AHA and ACC have established "door to needle" time of less than 30 minutes and "door to balloon" time within 90 minutes of initial presentation to the hospital for the best possible outcomes (Acharya et al., 2019). Percutaneous transluminal coronary angioplasty (PTCA) with PCI may be a valuable alternative in those for whom thrombolytics are contraindicated. CABG is preferred for patients with left main stenosis and those with moderately severe left ventricular depression. Emergency PTCA or CABG in older adult patients presenting with cardiogenic shock or HF is associated with high morbidity and mortality.

Glucose Control. Hyperglycemia (defined as blood sugar greater than 180 mg/dL) in patients with STEMI has been associated with adverse outcomes, including increased morbidity and mortality, as well as prolonged hospitalizations. Maintaining glucose control may decrease the inflammatory response and improve LVEF (Virani et al., 2021).

Follow-Up: Risk stratification for future cardiac events following stabilization from MI is necessary. Tests to evaluate for ischemia or myocardium at risk include low-level exercise test, nuclear perfusion scanning, and dobutamine echocardiography. Left ventricular function can be determined by

© F.A. Davis Publishing

echocardiography or radionuclide ventriculogram. Routine coronary angiography is not recommended for all patients with MI, but should be performed on patients with demonstrable ischemia. Patients at high risk for sudden death from arrhythmias should undergo electrophysiological (EP) evaluation.

Sequelae: Increasing age is associated with more complications after MI, including HF, arrhythmias, PE, cardiogenic shock, cardiac rupture, and death.

Prevention/Prophylaxis: Secondary prevention in the older adult patient includes use of aspirin, beta blockers, and ACEIs, unless there are absolute contraindications to these agents. Lipid-lowering therapy is also beneficial. Reduction of risk factors is necessary. Cardiac rehabilitation can be as beneficial in older MI patients as in younger ones. Emotional support remains important.

Referral: Suspicion of acute MI should prompt transfer of the patient to an environment equipped with cardiac monitoring and the ability to administer advanced cardiac life support. As hospitalization continues, consultation with a variety of disciplines, such as surgery, social work, and physical therapy, may be necessary.

Education: Individualized teaching following MI should be provided to the patient and family using age-specific teaching methods. Teach the basic definitions of CAD, angina, and MI. Patients need information on the healing process following MI, when to return to work or resume normal daily activities, and when to resume sexual relations. Give an exercise prescription. Involve patients and families in a discussion of the psychological adjustment following MI. Encourage risk factor reduction. Health-care practitioners should work with patients to set goals and design plans. Give patients information on community resources, such as the AHA or support groups in their area. Smoking cessation should be strongly encouraged, and pharmacological and nonpharmacological therapies should be discussed. Medication teaching and review are very important. Health-care providers should be aware of all medications prescribed for the patient and any over-the-counter (OTC) medications, including vitamins, minerals, and supplements. Patients should bring in all of their medications at each visit. Teach patients about the desired effects and common side effects of their medications. Emphasize the importance of taking aspirin and anticoagulants as directed to prevent in-stent thrombosis. Review what to do if medication cannot be taken or obtained. Discuss the use of nitrates for any chest pain, but avoid using nitrates in patients taking medications such as sildenafil, tadalafil, or vardenafil because of sudden drops in blood pressure (BP), resulting in hypotension.

Teach older adult patients about altered pain perception that can occur with age and with diseases such as diabetes. Teach patients and their families about warning signs such as chest pain or pressure, shortness of breath, indigestion, choking, sweating, dizziness, palpitations, severe weakness, and loss of consciousness. Establish a clear plan for obtaining prompt medical attention.

Clinical Recommendation	Evidence Rating (COR/LOE)	References
Oxygen		
Administer supplemental oxygen only if $SpaO_2$ is <90%, respiratory distress, or other high-risk features for hypoxia	C	Amsterdam et al., 2014
Nitrates		
Administer sublingual nitroglycerin (NTG) every 5 minutes × 3 for continuing ischemic pain and then assess need for IV NTG.	C	Amsterdam et al., 2014
Administer IV NTG for persistent ischemia, HF, or HTN	B	
Nitrates are contraindicated with recent use of a phosphodiesterase inhibitor.	B	
Analgesic Therapy		
IV morphine sulfate may be reasonable for ongoing ischemic chest pain.	B	Amsterdam et al., 2014
NSAIDs (except ASA) should not be started and should be stopped during hospitalization for non-ST elevation (NSTE)-ACS due to increased risk of MUSE	B	
Beta-Adrenergic Blockers (Beta Blockers [BBS])		
Oral BBs should be started within the first 24 hours if no HF is present or no low-output state, risk for cardiogenic shock, or other contraindications to BB.	A	Amsterdam et al., 2014
Use of long-acting metoprolol succinate, carvedilol, or bisoprolol is recommended for BB therapy with concomitant NSTE-ACS, stabilized HF, and reduced left ventricular (LV) function.	C	
Reevaluate to determine subsequent eligibility in patients with initial contraindication to BBs.	C	
It is reasonable to continue BBs in patients with normal LV function with NSTE-ACS.	C

Clinical Recommendation	Evidence Rating (COR/LOE)	References
Calcium Channel Blockers (CCBS)		
Administer initial therapy with nondihydropyridine CCBs with recurrent ischemia and contraindications to BBs in the absence of LV dysfunction, increased risk for cardiogenic shock, PR interval >0.24 sec, or second- or third-degree AV block without a cardiac pacemaker	B	Amsterdam et al., 2014
Administer oral nondihydropyridine calcium antagonists with recurrent ischemia after use of BBs and nitrates in the absence of contraindications.	C	
CCBs are recommended for ischemic symptoms when BBs are not successful, are contraindicated, or cause unacceptable side effects.	C	
Cholesterol Management		
Initiate or continue high-intensity statin therapy in patient with no contraindications.	A	Amsterdam et al., 2014
Obtain a fasting lipid profile within 24 hr.	C	
Aspirin		
Give non–enteric-coated aspirin to all patients promptly after presentation (162–325 mg).	A	Amsterdam et al., 2014
Aspirin maintenance dose is continued indefinitely (81 mg/day–325 mg/day).	A	
$P2Y_{12}$ Inhibitors		
Give a clopidogrel loading dose followed by daily maintenance dose in patients unable to take aspirin (75 mg/day).	B	Amsterdam et al., 2014
Prescribe clopidigrel or tricagrelor, in addition to aspirin, for up to 12 months for patients treated initially with either an early invasive or initial ischemia-guided strategy.	B	
Continue P2Y (clopidogrel or ticagrelor) for at least 12 months in post PCI with stents.	B	
Ticagrelor is preferred over clopidogrel for patients with early invasive or ischemia guided strategy.	B	
Cardiac Isoenzyme		
Troponin measurement should be done early (within 6 hours of arrival) ideally at presentation and at 3–6 hours after symptoms onset. Troponin T and I should be the only cardiac Isoenzyme to be measured.	A	Amsterdam et al., 2014 Jneid et al., 2017 American Society for Clinical Pathology, 2014–2017

VALVULAR HEART DISEASE

Signal Symptoms: Asymptomatic in early stage; fatigue and dyspnea are common, progressive valvular heart disease may present with accompanying chest pain, syncope, and heart failure (HF).

Description: Valvular heart disease (VHD) is damage to a valve or valves of the heart, causing cardiac dysfunction. Progressive, symptomatic VHD requires either a surgical or interventional procedure and is not able to be reversed via medical intervention. The most prevalent types of VHD in older adults result from calcific and degenerative valve disease. Valvular abnormalities can also occur secondary to dilated, restrictive, and infiltrative disease, which is often challenging to diagnosis (Falk & Hershberger, 2019). The most prevalent VHD disorders are aortic stenosis (AS), one of the most common valvular abnormalities seen in the aging heart, and mitral regurgitation (MR). Other types of VHD

© F.A. Davis Publishing

include aortic regurgitation (AR), mitral stenosis (MS), and (to a much lesser degree), tricuspid regurgitation (TR). AR can often be present with AS, complicating treatment options (Dewaswalal & Chait, 2021; Wang & O'Brien, 2018).

With the projection of the United States octogenarian population to triple to 32.4 million by 2050, the prevalence and the need for monitoring and treatment of VHD will increase (Kodali et al., 2018). Causes of VHD vary. Congenital conditions at birth can predispose someone to VHD as well as rheumatic heart disease due to strep infection, but incidence has decreased with rapid identification and treatment with antibiotics. Endocarditis can affect the valve leaflets causing VHD. Although IV drug abuse is not common in the older adult, screening for any history of IV drug use at any age is important in the face of VHD. HF, atherosclerosis, aortic aneurysm, hypertension (HTN), and myocardial infarction (MI) are all risk factors for developing VHD. Other causes for VHD include autoimmune disease, lupus, connective tissue disease, Marfan's syndrome, and restrictive heart disease. Amyloidosis must also be considered (Centers for Disease Control and Prevention [CDC], 2018; Falk & Hershberger, 2019).

Considerations for the Older Adult and Valvular Heart Disease

Management of VHD in the older adult requires careful and thoughtful decision making. VHD is complex and the decision to intervene and the choice of intervention should be through a shared decision between the patient and providers involved, including an integrated heart valve team. All risks, benefits, and alternatives as well as the patient's life expectancy and quality of life (QOL) need to be considered against the natural course of untreated disease when interventions for VHD are presented. It is important to evaluate whether they have a minimum of one-year good life expectancy and whether the perioperative risk of postoperative complications is low. A risk and frailty score should be calculated to assess for potential success of VHD intervention (Searle et al., 2008). The EuroSCORE and Society of Thoracic Surgeons (STS) score (http://riskcalc.sts.org/stswebriskcalc/#/) is used to calculate risk estimates of hospital mortality and postoperative complications (Kumar et al., 2018; Walter et al., 2021) Frailty score/index along with STS and other clinical variables such as major organ system dysfunction, and procedure-specific barriers, assist in deciding if the patient is low, intermediate, high, or prohibitive of surgical/procedural risk.

Surgical and/or transcutaneous approaches may be considered depending on specific parameters of left ventricular (LV) dimensions and ejection fraction (EF). In general, older patients have an increased risk of postoperative complications, often requiring longer lengths of hospital stay and convalescence (Pulok et al., 2020; Theou et al., 2021; Walter et al., 2021).

Aortic Stenosis: General Principles

In AS, there is a supravalvular or subvalvular obstruction of the left ventricular outflow tract. AS is graded using the valve hemodynamics that correlates with the A through D classification. In clinical practice, AS can generally be described as mild, moderate, severe, or critical but those descriptors are dependent on maximum aortic valve velocity, calculated aortic valve area as defined by aortic gradient and calculated aortic valve index (Table 10-5). It is more accurate to describe AS as the following: At risk, Progressive, Asymptomatic severe, Asymptomatic severe with LV systolic dysfunction, Symptomatic severe high-gradient AS, Symptomatic severe low-flow, low-gradient AS with reduced LVEF, Symptomatic severe low-gradient AS with normal LVEF or paradoxical low-flow severe AS (Otto et al., 2021).

Etiology: AS diagnosed before age 60 years is usually caused by a congenital bicuspid valve, whereas AS after age 60 years

TABLE 10-5 Stages of Valvular Heart Disease

AORTIC STENOSIS STAGE AND DEFINITION	VALVE HEMODYNAMICS
A: at risk	• Aortic V_{max} <2 m/s with normal leaflet motion
B: Progressive AS	• Mild AS: aortic V_{max} 2.0–2.9 m/s or mean ΔP <20 mm Hg • Moderate AS: aortic V_{max} 3.0–3.9 m/s or mean ΔP 20–30 mm Hg
C: Asymptomatic severe AS	
C1 Asymptomatic severe AS	Aortic V_{max} ≥4 m/s or mean ΔP ≥40 mm Hg AVA typically is ≤1.0 cm^2 Very Severe AS is an aortic V_{max} ≥5 m/s or mean P ≥60 mm Hg
C2 Asymptomatic severe AS with LV systolic dysfunction	• Aortic V_{max} ≥4 m/s or mean ΔP ≥40 mm Hg • AVA typically ≤1.0 cm^2
D: Symptomatic severe AS	
D1 Symptomatic severe high-gradient AS	• Aortic V_{max} ≥4 m/s or mean ΔP ≥40 mm Hg • AVA typically ≤1.0 cm^2 but may be larger with mixed AS/AR
D2 Symptomatic severe low-flow, low-gradient AS with reduced LVEF	• AVA ≤1.0 cm^2 with resting aortic V_{max} <4 m/s or mean ΔP <40 mm Hg • Dobutamine stress echocardiography shows AVA <1.0 cm^2 with V_{max} ≥4 m/s at any flow rate
D3 Symptomatic severe low-gradient AS with normal LVEF or paradoxical low-flow severe AS	• AVA ≤1.0 cm^2 with an aortic V_{max} <4 m/s or mean ΔP <40 mm Hg AND • Stroke volume index <35 m>/m^2 • Measured when patient is normotensive (systolic blood pressure <140 mm Hg)

AR, Aortic regurgitation; AS, Aortic stenosis; AVA, aortic valve area circulation; ΔP, pressure gradient between the LV and aorta; HF, Heart Failure; LV, Left Ventricular, LVEF, left ventricular ejection fraction; V_{max} maximum velocity.

© F.A. Davis Publishing

is usually caused by calcific degeneration of the valve. Occasionally, a patient after 60 years of age may present with a calcific bicuspid or rare, unicuspid aortic valve (Lewin & Otto, 2005). Other less common causes of AS include rheumatic fever, endocarditis, systemic lupus erythematous, and Fabry's disease (Otto et al., 2021; Slostad et al., 2019).

Occurrence: AS is the most common VHD in developed countries. It affects approximately 12.4% of the population older than 75 years of age with a predominance of 80% male in symptomatic AS (Akin & Nienaber, 2017). In the absence of a congenitally malformed valve, occurrence increases with age due to focal thickening or calcification of the valve. In terms of surgical prevalence, 40% of patients older than 70 years will be noted to have a bicuspid valve at time of intervention, but prevalence is much higher in those younger than 70 years. More than 50% of valve surgeries were performed in patients older than 70 years of age, with approximately 60% of these patients having trileaflet valve surgery and 40% having bicuspid aortic valve surgery (Otto & Bonow, 2014).

Age: Congenital valvular heart disease is present at birth; acquired valvular heart disease is found as chronological age progresses.

Ethnicity: Not significant.

Contributing Factors: Factors associated with degenerative aortic valve stenosis include age, male sex, current tobacco use, dyslipidemia, HTN, diabetes, and chronic obstructive pulmonary artery disease (Yan et al., 2017).

Prevention/Prophylaxis: There are no effective strategies to prevent VHD, particularly AS. Clinical trials looking at high-dose HMG-CoA reductase inhibitor (statin) therapy failed to prove any decreased progression nor regression of AS (Akin & Nienaber, 2017). However, angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) have been found to be beneficial with patients who have mild, moderate AS and symptomatic severe AS. Patients who have HF, LV dysfunction, and low blood pressure were prone to hypotension with the use of ACEI/ARBs; they should be used with caution and monitoring in these patients. The PARTNER 2 trial and registries looking at clinical implications of treatment with both ACEI and ARBs with severe symptomatic AS independently showed a decreased 2-year risk of all-cause and cardiovascular mortality when used pre- and post-transcatheter aortic valve replacement (TAVR). Caution is necessary so as not to give vasodilators in the presence of significant AS because they can potentiate significant hypotension and increase outflow obstruction from AS, worsening outcomes (Chen et al., 2020)

Signs and Symptoms: Many of these patients are asymptomatic. Prognosis is poor for patients who exhibit symptoms. Symptoms that may be associated with worsening prognosis are syncope, chest pain/angina, dizziness, and dyspnea. The survival rate decreases to 2 to 3 years for the patients who exhibit symptoms and do not have appropriate intervention (Walter et al., 2021). Angina is an early and more common symptom and can occur in the presence or absence of coronary artery disease (CAD). Presyncope followed by effort syncope occurs in about one-third of the patients with symptoms and is related to a fixed cardiac output due to the obstruction of the left ventricle created by AS. Exertional dyspnea indicates left ventricular dysfunction and HF.

Physical Examination Findings. The classic crescendo-decrescendo systolic murmur is heard at the second right intercostal space and radiates to the carotids. The murmur in older adults may radiate to the apex (Walter et al., 2021). This murmur, which peaks in intensity in mid to late systole, may also be associated with a thrill if greater than grade IV. The murmur intensity does not correlate with the severity of AS; often in the setting of HF the AS murmur may become softer as the cardiac output falls. S_1 is often soft, and can be inaudible in severe or critical AS. The S_2 may also be paradoxically split due to the late closure of the aortic valve (A_2). An S_4 is common, representing forceful atrial contraction in the setting of left ventricular hypertrophy. Other findings may include delayed carotid upstroke, a carotid and apical pulse lag time, systemic HTN, prominent "A" waves in the jugular venous pulse, and a sustained and forceful apical impulse. Isometric handgrip increases systemic vascular resistance, decreasing the intensity of the murmur. Standing and the Valsalva maneuver decreases ventricular filling, reducing the intensity of the murmur; squatting increases ventricular filling, reducing the intensity of the murmur (Walter et al., 2021).

Diagnostic Tests: In AS, the electrocardiogram (ECG) may be abnormal, demonstrating QRS or T-wave changes consistent with left ventricular hypertrophy. Chest x-ray examination is not recommended in routine screening of asymptomatic patients, but may provide information on valve calcification, cardiac chamber sizes, enlarged cardiac silhouette, and pulmonary vasculature.

Echocardiography is the standard test for assessing aortic valve stenosis and may demonstrate thickening and calcification of the aortic valve with decreased mobility of the leaflets. Doppler measurement of intracardiac blood velocity can help determine hemodynamic severity. The echocardiogram is useful for providing detail on the valve morphology. The following questions which can be answered include, but are not limited to: Is there congenital absence of valve cusp, degree of valve calcification, valve cusp mobility, aortic valve area, aortic valve pressure gradient, size of aortic root, left ventricular size, ejection fraction, posterior and septal left ventricular wall thickness, and concomitant valvular dysfunction and estimation of pulmonary artery pressures?

The frequency of echocardiogram assessment of AS is dependent on the degree of severity and symptoms (Table 10-6) (Otto et al., 2021). Exercise testing has limited utility in the evaluation of patients with AS. Pharmacological echocardiogram may be done in patients with low-gradient AS and can help to risk stratify patients in this category. Cardiac catheterization measurement of the systolic pressure gradient across the aortic valve is the definitive method for assessing AS in patients being considered for surgery or when there is a discordance between the clinical findings and the diagnostic tests. In patients with congenital AS there may also be abnormalities noted in the coronary arteries, which can be evaluated with the left heart catheterization. Right heart catheterization will provide information on hemodynamics. Cardiac MRI may be used to stratify patients with AS and assess the effect of chronic left ventricle pressure overload, volume, and overall function.

© F.A. Davis Publishing

TABLE 10-6 Frequency of Echocardiograms in Asymptomatic Patients with VHD and Normal LV Function

	TYPE OF VALVE LESION			
Stage	Aortic Stenosis*	Aortic Regurgitation	Mitral Stenosis	Mitral Regurgitation
Progressive (Stage B)	Every 3–5 yr (mild severity V_{max} 2.0–2.9 m/s) Every 1–2 yr (moderate severity; V_{max} 3.0–3.9 m/s)	Every 3–5 yr (mild severity) Every 1–2 yr (moderate severity)	Every 3–5 yr (MV area >1.5 cm^2)	Every 3–5 yr (mild severity) Every 1–2 yr Moderate severity
Severe asymptomatic Stage C1	Every 6–12 mo (V_{max} >4 m/s)	Every 6–12 mo Dilating LV: More frequently	Every 1–2 yr (MV area 1.0–1.5 cm^2) Every year (MV area <1.0 cm^2)	Every 6–12 mo Dilating LV: More frequently

Patients with mixed valve disease may require serial evaluations at intervals earlier than recommended for single-valve lesions. These intervals apply to most patients with each valve lesion and do not take into consideration the etiology of the valve disease.

**With normal stroke volume.*

LV: Left ventricular; MV, mitral valve; VHD: valvular heart disease; V_{max} Maximum Velocity

Treatment: No medical therapies are available to delay the progression of AS. The patient with asymptomatic AS will need frequent monitoring for the development of symptoms and progression of disease. Symptoms of AS are associated with substantial valvular obstruction and a risk of sudden death; surgical/transcutaneous management must be considered. Aortic valve replacement is associated with a higher mortality rate in older adults than in younger individuals. Factors associated with greater operative risk include emergency surgery, left ventricular dysfunction, right-sided heart failure, female sex, significant coronary disease, cachexia, additional valve replacement, kidney disease, or concomitant coronary artery bypass graft (CABG). The proper selection of the type of valve replacement is important in older adult patients. The bioprosthetic valves have fewer structural failures and are advantageous in that their use obviates the need for long-term anticoagulation (which is associated with substantial morbidity and mortality in older adults). The disadvantage of this valve type is that the tissue degrades, and many patients may require reoperation in 10 years. Mechanical valves are more durable and have better hemodynamic profiles, but they require lifelong anticoagulation therapy with vitamin K antagonists such as warfarin.

Balloon aortic valvuloplasty (BAV) was developed more than 30 years ago as an alternative to conventional surgical aortic valve replacement in older and frail patients. BAV remains a consideration as a bridge to surgical aortic valve replacement (SAVR) or TAVR or transcutaneous aortic valve implantation (TAVI) in patients with severe symptomatic AS (Dawkins & Makkar, 2017). Common bridge indications for BAV found in the literature include cardiogenic shock, poor LV function, patients at extreme-risk, and patients undergoing concomitant coronary interventions (Alkhouli et al., 2017). BAV is an alternative method of treatment; however, because it is associated with rapid restenosis and significant residual outflow obstruction, it is reserved as a palliative procedure for the symptomatic patient who is not a surgical candidate or as a bridge to surgery.

In the past, patients with advanced age and symptomatic severe AS who were not able to undergo surgery were often referred for palliation. The first successful percutaneous aortic valve replacement performed on an inoperable patient was in 2002. The first approval for the indication of severe AS came in 2011. The U.S. Food and Drug Administration (FDA) approved the TAVR procedure for high-risk surgical patients in 2012, and an indication for "valve-in-valve" procedure for failed surgical bioprosthetic valves was approved in 2015. In 2016, the FDA approved TAVR valves for patients with severe AS at intermediate risk. Following the results of the PARTNER-3 trial in 2019, the FDA further approved the indication for TAVR in low-risk patients. With the advent of new procedures, more options are available to patients with severe symptomatic AS, including high-risk, frail, older adults (Mahmaljy et al., 2021). Trials regarding the types of TAVR devices to use for specific patient types are ongoing.

Recent results of the CHOICE Trial (Randomized Comparison of Transcatheter Heart Valves in High Risk patients with Severe Aortic Stenosis: Medtronic CoreValve Versus Edwards SAPIENT XT) that spanned over a 5-year period and compared self-expanding versus balloon-expanding heart valves found no statistical significant difference between balloon-expandable (BE) valves and self-expanding (SE) valves in death from any cause, death by cardiovascular cause, stroke, or repeat hospitalization due to HF. Ongoing randomized clinical trials need to take place to ensure TAVR is appropriate for those patients with a longer life expectancy (Abdel-Wahab et al., 2020).

© F.A. Davis Publishing

Contraindications for TAVR/TAVI include:

- Life expectancy less than 12 months secondary to a non-cardiac cause
- MI within 30 days
- Congenital unicuspid, bicuspid, noncalcified valve
- Hypertrophic cardiomyopathy
- Short distance between annulus and coronary ostium
- Emergency need for surgery
- LVEF greater than 20%
- Severe pulmonary HTN with right ventricular dysfunction
- Echocardiographic evidence of intracardiac mass
- Thrombus or vegetation
- Native aortic annulus smaller than 18 or larger than 25 mm
- Severe MR
- Magnetic resonance imaging (MRI)-confirmed cerebrovascular accident (CVA) or transient ischemic attack (TIA) within 6 months
- End-stage renal disease
- Mixed aortic valve disease (AS and AR)
- Significant aortic disease

(Mahmaljy et al., 2021)

Indication for Aortic Replacement (Surgical or Transcatheter) for Aortic Stenosis

Aortic Stenosis (AS)	Class Indication	Level of Evidence
	I	Level B
Asymptomatic patients with severe AS and LVEF <50	I	Level B
Asymptomatic, severe AS and low surgical risk	IIa	Level B
Symptomatic with low-flow/low-gradient severe AS	IIa	Level B
Moderate AS and undergoing other cardiac surgery	IIa	Level C
TAVR is approved for the following: ■ Low to prohibitive surgical risk patients with severe AS ■ Valve-in-valve procedures for failed prior bioprosthetic valves

The AHA and ACC 2020 guideline recommendation for AS intervention can be found at https://doi.org/10.1161/CIR.0000000000000932

Mitral Regurgitation

Description: Mitral regurgitation (MR) is retrograde blood flow during systole from the left ventricle into the left atrium through an incompetent mitral valve. The mitral valve apparatus consists of mitral valve annulus, chordae tendineae, and papillary. Distortion of any of these structures may lead to an incompetent mitral valve and thus mitral regurgitation. MR is categorized by grades A to D. Grade A is patients at risk for MR, grade B is progressive MR, grade C is asymptomatic severe MR, and grade D is symptomatic severe MR. The progression of untreated disease may lead to pulmonary HTN and a failing left ventricle.

Etiology: Some of the common causes of MR are rheumatic heart disease, mitral valve prolapse, and ischemic heart disease (Crawford, 2017). In the older adult population, the most common causes of significant MR are myxomatous degeneration and ischemic heart disease. Congenital MR is rare but may be seen with cleft mitral valve in persons with Down's syndrome. MR may be further delineated as acute or chronic. Common causes of acute MR include chordal rupture, papillary muscle rupture, leaflet perforation, and trauma. Common causes of chronic MR include rheumatic fever, mitral leaflet prolapse, CAD, papillary muscle dysfunction, congenital heart disease, left ventricular dilation, myxomatous degeneration, and HTN.

Signs and Symptoms: The symptoms associated with MR can be quite variable from a state of asymptomatic to symptoms of left ventricular dysfunction, shortness of breath, paroxysmal nocturnal dyspnea, fatigue, as well as concomitant right-sided heart failure.

Physical Examination Findings. The murmur of MR is a holosystolic murmur heard best at the apex and may radiate to the axillae or back and may be associated with an S_3 gallop. In more acute mitral regurgitation, often from acute MI, an S_4 may be present secondary to a chordal rupture. Patients often will present in pulmonary edema if the acute MR is due to an acute MI. Chronic MR can cause dilation of the left atrium and may led to AF. Other examination findings may include edema, displaced apical impulse, and crackles on lung examination (Crawford, 2017).

Diagnostic Tests: In MR, the ECG shows left atrial enlargement or AF and the chest x-ray examination shows left ventricular dilation; in nonrheumatic forms of MG these are less distinctive. Echocardiography delineates overall ventricular function and Doppler studies show the jet and severity of the regurgitation, as well as the mechanism. Transesophageal echocardiography is a more precise way of visualizing the regurgitant jet.

Treatment: Medical management of MR includes use of ACEIs, digoxin, diuretics, and vasodilators to reduce the

© F.A. Davis Publishing

symptoms of HF and reduce the regurgitant volume. Anticoagulation may be needed if the patient has AF. Mitral valve surgery is considered in asymptomatic and symptomatic patients with progressive disease before signs of irreversible left ventricular dysfunction are present. The mortality rate associated with mitral valve replacement could be as high as 14% in the older adult. Mitral valve repair is associated with a lower operative mortality than mitral valve replacement and is preferred, as preservation of the existing valve architecture allows synchrony of left ventricular contraction. When mitral annular calcification is the cause, medical therapy is prudent because the operative risk is substantially higher in patients with this disease process. Acute MR from papillary muscle rupture or chordal rupture requires patient stabilization followed by surgery, which still carries a high mortality rate. Other therapeutic options for repair of the mitral valve may include mitral transcatheter edge to edge repair or MitralClip (Otto et al., 2021).

The American Heart Association (AHA) and American College of Cardiology (ACC) 2020 guideline (Otto et al., 2021) recommendations for MR intervention include:

Clinical Recommendation	Recommendation	References
MV surgery is recommended for symptomatic patients with severe primary MR (stage D) and ejection fraction greater than 30%.	B	Otto et al., 2021
Medical therapy is recommended for symptomatic or asymptomatic patients with severe primary MR and left ventricular dysfunction (stages C2 and D) in whom surgery is not possible or must be delayed and guideline-directed medical therapy should be initiated	A	Otto et al., 2021
MV repair is recommended when procedure is limited to posterior leaflet in the setting of chronic severe primary MR.	B	Otto et al., 2021
MV repair is recommended over MV replacement in patients with chronic MR involving anterior or posterior leaflets.	B	Otto et al., 2021
If patient undergoing other cardiac surgery and has chronic primary MR, they should also have MV repair or replacement surgery at the same setting.	B	Otto et al., 2021

VALVULAR HEART DISORDER	MURMUR	OTHER CARDIAC FINDINGS
Aortic stenosis	Systolic murmur heard at second right intercostal space and may radiate to carotids	Decreased cardiac upstroke. Best heard with patient sitting up and exhaling.
Aortic regurgitation	Diastolic blowing murmur at left sternal border	Rapidly collapsing pulse (Corrigan's pulse), preservation of A2 component of second heart sound, widened pulse pressure.
Mitral stenosis	Diastolic rumble	May be associated with signs of right heart failure including edema, ascites, elevated jugular venous pressure.
Mitral regurgitation	Holosystolic murmur heard at apex and may radiate to axilla	AF, ventricular gallop (S_3), displaced apical impulse laterally, crackles on lung examination.
Mitral valve prolapse	Mid-systolic click heard at apex	May be associated with mitral regurgitation.
Tricuspid stenosis	Mid-diastolic rumble heard at left sternal border; may increase with inspiration	Very rare finding but may be associated with right atrial myxomas or carcinoid syndrome.
Tricuspid regurgitation	Holosystolic murmur heard at right sternal border and increase with inspiration	May be associated with signs of right heart failure including edema, ascites, elevated jugular venous pressure.
Pulmonic stenosis	Harsh mid-systolic murmur heard at the 2nd left interspace and may radiate to the left carotid	May be associated with a palpable thrill. The second heart sound is widely split.
Pulmonic regurgitation	High-pitched diastolic murmur	Accentuated P2 of the second heart sound. May be louder in setting of pulmonary hypertension.

General Principles

Diagnosis: Often the first indication of VHD may be the auscultation of a cardiac murmur. It is important for advanced practice nurses to have good cardiovascular assessment skills. Auscultatory and other associated findings are listed in the table that follows and can be a useful guide in approaching the cardiovascular examination of all patients (Otto et al., 2021).

Follow-Up: For patients treated medically for valvular disease, close follow-up to monitor the effectiveness of treatment, adverse effects of medication, and progressiveness of the disease process is indicated. Medication therapy, particularly the use of anticoagulation therapy, requires meticulous attention. Surgically treated patients are monitored for valve function, fluid balance, and anticoagulation. Periodic echocardiographic (see Table 10-6), electrocardiographic, and chest x-ray monitoring may be indicated.

Sequelae: Untreated VHD may lead to progressive HF, dysrhythmias, and death. Valve replacement risks include thrombus formation, infection, or rupture at the attachment points to the valve ring. Infective endocarditis, which may occur with artificial valves, has a high risk of mortality, and requires reoperation. There is a high prevalence of gallstones in patients with prosthetic valves, thought to be due to low-grade intravascular hemolysis. In patients who are not surgical candidates, the symptoms of HF are progressive and disabling. Even in surgical patients, the symptoms of HF may recur or persist.

Prevention/Prophylaxis: In patients with prosthetic valves, the risk of thromboembolism decreases with an individualized antithrombotic regimen. The specific therapy is determined based on the comorbid state and the patient's overall status. Consider prophylactic antibiotic therapy (endocarditis prophylaxis) before any surgical or dental procedures in all patients with valvular disease, especially patients with valve replacement, rheumatic heart disease, aortic regurgitation, or mitral valve prolapse with significant MR murmurs.

Referral: All patients with symptoms of progressive valvular disease must be managed collaboratively with a cardiologist. Many require further collaboration with a cardiac surgeon. The Practice Guidelines for Cardiothoracic Surgery Concerning Valvular Heart Disease include the indications for surgery. In general, these include symptoms that cannot be controlled with medical therapy or indications of a threat to survival (i.e., angina, dyspnea, effort syncope or progressive impairment of ventricular contractility, and infective endocarditis).

Education: Older adults constitute 40% to 60% of all cases of endocarditis. Instruct all at-risk patients in the importance of good oral hygiene and antibiotic prophylaxis. Patients should be taught to monitor and report febrile illness.

Teach all patients with valve disease requiring medication therapy to report lack of therapeutic effect or any adverse effects of the drugs. Teach patients to be aware of drug-food interactions (e.g., green leafy vegetables and warfarin). Teach patients to have prothrombin time/INR checked on a regular basis if they are taking warfarin. Teach the patient with disabling HF about energy-conservation measures. Patients with hemodynamically significant valvular heart disease may need to limit vigorous physical activity. Deterioration may be rapid and symptoms insidious, so patients should be taught to report any changes in condition, even those they may feel are subtle.

CASE STUDY

Your 76-year-old patient has returned today for a focused visit. Her chief complaint is increasing fatigue and palpitations. She was discharged from the hospital 5 weeks ago after being treated for decompensated heart failure due to development of atrial fibrillation/flutter. She received an ablation and converted to normal sinus rhythm. When you saw her in follow-up within 1 week of discharge, she was euvolemic, remained in normal sinus rhythm, and reported feeling the best she had felt in 5 years. Her HF*r*EF was class C/II. She was able to walk in her neighborhood with minimal discomfort and manage her activities or daily living independently. Now she reports that starting about 4 days ago she noticed increasing fatigue. She was unable to do her daily walk without great distress so has discontinued those completely. She also reports feeling her heart in her throat several times a day.

PM: HF*r*EF 40%, obesity BMI 40, CKD stage 4, history of atrial fibrillation/flutter, s/p ablation 5 weeks ago, prediabetic diet managed.

Medications: Metformin XL 100 mg daily, lisinopril 10 mg daily, Bumex 4 mg daily, metolazone 2.5 mg every other day, spironolactone 25 mg daily, Eliquis 5 mg twice a day.

Vital signs Temp 36.8C BP 148/72 Pulse 110 R 18 Pulse Ox 98% on room air

1. What is your working diagnosis at this point?
2. Is there additional history you will need to obtain?
3. What physical examination elements will be most important?
4. What laboratory tests would be helpful?
5. What other tests will be necessary to refute or support your working diagnosis?
6. How would you classify her heart failure based on her current concerns?
7. What options would you consider for your next steps?

CHAPTER 11

Respiratory Disorders

Evelyn Duffy

ASSESSMENT

This chapter addresses problems of the lower respiratory tract, which includes the bronchi, bronchioles, alveolar ducts, and alveoli. Problems of the upper respiratory tract, nose, mouth, pharynx, larynx, and trachea are addressed in Chapter 9. Some problems of the upper respiratory tract can contribute to concerns that present as symptoms in the lower respiratory tract (e.g., postnasal drip), and should not be excluded from the broad initial differential diagnosis. Special considerations for assessing an older adult include changes in tissue and in the musculoskeletal and respiratory systems that are a result of the aging process.

Changes with Aging

The aging process is characterized by a loss of elasticity and flexibility in collagen and elastin that are components in lung tissue and can impede the normal expiratory recoil of the lung. The concurrent decrease in body water composition dries mucous membranes and interferes with the protective functions of the upper airway in expelling foreign material. Loss of elastin also affects the alveoli and the basement membrane of the capillary wall, where gas exchange occurs. A thickening occurs in both areas, limiting the amount of diffusion (Teall et al., 2021). Musculoskeletal changes, including calcification of costal cartilage and weakening of inspiratory muscles, result in a relaxation of the skeletal contours and an increased anteroposterior diameter, causing a barrel chest, although not as pronounced as that found in patients with chronic obstructive pulmonary disease (COPD). An exaggeration of the thoracic curvature may also occur, with some tracheal displacement. Expiratory muscles must work harder because expiration is no longer a passive act, resulting in use of accessory muscles (Teall et al., 2021). The residual capacity of the lungs is increased and inspiratory reserve capacity lessened. Air tends to fill the apices and not the bases. Because of decreased muscular strength, the cough reflex is not as forceful or as effective. All these changes occur gradually and are hardly noticeable unless a physiological challenge or stress arises. Even in such an event, exertional dyspnea may be the only observed change in the healthy older adult. Older adults who live an active lifestyle may not present with typical age-related changes. Healthy older adults or those with stable, chronic problems may first seek care when there is a change in functional capabilities. When presenting with a change in function, problems related to the respiratory system should be considered. Signs could include decreased exercise tolerance, shortness of breath with exertion, poor sleep quality, or easy fatigability.

Past Medical History

History questions should address each symptom using the OLDCART or PQRST symptom analysis. If there has been a history of respiratory issues, details regarding the extent of the problem need to be documented. Current or past tobacco use has been identified as the cause of many diseases of the respiratory system. To determine whether the patient should be screened for lung cancer requires documentation of how much the patient smoked, for how long, if they have quit smoking, and when that occurred (Wood et al., 2018). Exposure to vapors, gas, dust, and fumes in the workplace setting contributes to lung diseases including asthma, COPD, interstitial lung disease, sarcoidosis, pneumoconiosis (silicosis and asbestosis), and respiratory infections (Blanc et al., 2019). To further understand the patient's risk requires details about present or past occupational exposure. Medications should always be evaluated for those that might be contributing to symptoms. In addition to the well-known effect of dry cough associated with angiotensin-converting enzyme (ACE) inhibitors, cancer drugs, rheumatology drugs, amiodarone, and antibiotics all have been shown to contribute to the development of interstitial lung disease (Skeoch et al., 2018). If the patient is using inhalers, it is important to ask *how* they use them and have them demonstrate their use if possible. With the multiple inhalers on the market today and the constantly changing formularies of Medicare plan providers, it is also important to be sure the patient has not confused which inhaler is for rescue and which is for maintenance therapy. Inquire about a history of allergies, including seasonal, environmental, and food allergies. Include a review of immunizations for influenza, pneumococcal pneumonia, and pertussis. Family history of chronic lung diseases, tuberculosis (TB), or lung cancer may be elicited by asking if anyone in the family has had lung problems (Teall et al., 2021).

© F.A. Davis Publishing

Review of Systems

Key symptoms of lung disease should be assessed in the review of systems, including cough, dyspnea, and chest pain. If the concern is a cough, ask about onset and duration, timing, sputum production, or hemoptysis. If the patient describes coughing up blood, clarification of the amount and timing limits the differential. Coughing up sputum first thing in the morning that includes a few streaks of blood is more consistent with upper, rather than lower, respiratory concerns. Details regarding the cough should include whether there has been fever, chills, or night sweats (which may be present with TB). Cough that has been present for 3 to 8 weeks is considered subacute, and 8 weeks or more is considered chronic (Teall et al., 2021). This timing helps to define the list of possible differential diagnoses. Further details regarding associated symptoms are also important. Ask about the quality of the cough: Is it a deep cough, or does the patient hear themselves wheezing, barking, or whooping?

If there is dyspnea, ask if it is related to activity, or does it occur at rest or when lying down? Specific questions about changes in endurance, stair-climbing, or activities of daily living (ADLs) can quantify the extent that the dyspnea affects function. Knowing how many pillows are required to sleep comfortably at night defines orthopnea. If the patient reports waking up from sleep short of breath, they are describing paroxysmal nocturnal dyspnea (PND). If dyspnea interferes with eating, establishing if it occurs while eating or after the meal can help refine the diagnosis.

To assess any complaint of pain the initial questions need to address the possibility of life-threatening situations. Chest pain includes a broad list of possible causes including cardiac, gastrointestinal, musculoskeletal, and dermatological. Pain from pulmonary issues is usually a result of inflammation of the parietal pleura that occurs when the pleurae rub together. This can result from a number of conditions, including pneumonia, COPD, lung cancer, sarcoidosis, and pulmonary hypertension (Teall et al., 2021).

Physical Examination

Physical examination of the respiratory system begins with general observation of the patient: rate and ease of respirations at rest, conversational ability (limited by breathing problems), use of accessory muscles, posture, color, pursed lips, circumoral or nailbed cyanosis, and capillary refill. The chest and upper back should be exposed for full inspection and examination. Are both sides symmetrical, with equal respiratory effort and diaphragmatic movement? Is there any evidence of kyphosis, lordosis, or scoliosis? What is the anterior/posterior to lateral diameter?

Palpation of the posterior chest to confirm equal chest expansion is done by placing the thumbs on the chest wall near the vertebrae at T9 and T10 and spreading the hands. A small fold of skin should be between the thumbs. When the patient takes a deep breath per your instruction, the thumbs should move apart symmetrically. If pneumonia or consolidation is suspected, palpating for tactile fremitus may be helpful. Using the ball of the hand (metacarpophalangeal area of the palm) or the ulnar side of the hand, feel the vibrations in a side-to-side pattern while the patient says "ninety-nine." The vibrations should feel the same on both sides and should be stronger in the upper areas of the chest. Increased fremitus occurs with marked consolidation, such as lobar pneumonia.

Percussion of the posterior chest for resonance and symmetry is the next step, again using a side-to-side approach. Dullness is indicative of increased density, as found with pneumonia, tumor growth, or pleural effusion. Hyperresonance is found with air trapping in emphysema or with pneumothorax. Correlation should be made with the findings from the result of tactile fremitus.

Auscultation of posterior breath sounds for symmetry, presence or absence of adventitious sounds, and air movement is done with the patient seated and the arms resting on the knees or folded across the chest to retract the scapulae. Have the patient take a deep breath through the mouth, with the mouth open, inhaling and exhaling. The open mouth helps to amplify the breath sounds. Decreased breath sounds are common with a large body habitus or present in disease such as COPD, pleurisy, or pleural effusion. Wheezing is commonly heard with asthma or acute bronchitis, although it may also be part of the background of chronic bronchitis or COPD. Wheezing on inspiration is more indicative of large airway obstruction while wheezing on expiration occurs with obstruction of the small airways. If wheezing is heard on inspiration, have the patient cough, and wheezing that clears with cough is not pathological. Crackles are heard with heart failure, pulmonary edema, or pneumonia; basilar crackles that clear with coughing or deep breathing, as with wheezing that clears, are not pathological. Older patients may become lightheaded with deep breathing and may need this part of the examination to be spaced out over time. If pneumonia is suspected, vocal fremitus techniques such as bronchophony, egophony, or whispered pectoriloquy may be indicated. Examination of the lateral areas of the chest should be included with the posterior examination. The right middle lobe is best assessed on the right lateral area. Pneumonia is more common on the right because the right main bronchus is shorter, wider, and more vertical (Teall et al., 2021). The anterior examination is approached in the same way as the posterolateral examination.

After completion of the history and physical examination further assessment using laboratory studies and imaging may be considered. Pulse oximetry may have been done in the initial admission. Results can help to inform the need for more extensive testing such as pulmonary function tests (PFTs) or blood gasses. For older adults, PFTs may be difficult to complete. The patient's cooperation along with good coaching on the part of the technician improves reliability. When ordering a chest x-ray, consider whether the patient is able to stand for a posterior to anterior view (PA) or require an anterior to posterior view (AP). The AP view is less preferred because heart magnification is increased. (Teall et al., 2021). X-rays should be used judiciously and not in patients for whom the physical examination was without abnormal findings. Additional testing is described in detail in each of the disease sections in this chapter.

ASTHMA

Signal Symptoms: Wheezing, shortness of breath, cough (especially at night), chest tightness.

Description: The Global Initiative for Asthma (GINA) 2021 describes asthma as a heterogenous disease, usually characterized by chronic airway inflammation. It is defined by a history of respiratory symptoms such as wheezing, shortness of breath, chest tightness, and cough that vary overtime and in intensity, together with variable expiratory airflow limitation. Asthma is further classified by the several different phenotypes and categorized as intermittent, mild, moderate, or severe. The symptoms of asthma are often episodic, and a patient may be completely asymptomatic between attacks/exacerbations.

Etiology: Asthma represents a wide range of heterogeneous phenotypes. Each of these are different in the pathophysiology, etiology, and presentation. Risk factors include genetic, environmental, and host factors. Asthma is most prevalent in English-speaking countries.

The increase in asthma supports the theory that environmental changes are responsible. Genetics most likely play an important role in allergies in general and specifically in asthma. Multiple genes contribute to the development of asthma in different ethnic groups; research into genetic phenotypes is ongoing (GINA, 2021). Prenatal exposure to tobacco smoke is associated with asthma risk, which is increased when combined with postnatal exposure. Diet and stress in the prenatal period may affect the risk of atopic disease. Social determinants of health include family structure, socioeconomic status, and exposure to animals. When asthma is present in adults it may represent persistent childhood asthma, relapse of childhood asthma, or may be a true adult-onset asthma. Adult-onset asthma may be related to occupational exposure, but it is more often due to irritants, such as gastroesophageal reflux, or secondary to certain drug treatments.

Occurrence: Asthma affects 8% of adults older than 18 years. In the United States, it is responsible for 5.9% of clinic visits, and it has a mortality rate of 1.1/100,000 in the U.S. population (Centers for Disease Control and Prevention [CDC], 2021). Women are affected by asthma more often than men (CDC, 2021)

Age: Depends on the phenotype; allergic asthma is the most common form and most prevalent overall, but most often affects children. Late-onset asthma, also known as adult-onset, affects adults, as its name suggests. It is more difficult to differentiate late-onset asthma from other chronic lung conditions, such as chronic obstructive lung disease COPD or asthma-COPD overlap syndrome. Differentiation is important because it affects treatment choice and risk stratification (Enilari & Sinha, 2019)

Ethnicity: Moraes et al. (2018) acknowledge the challenge of identifying ethnic differences. They note the challenge of separating genes and environment and the increasing complexity of how we define ethnicity across studies. They found that Puerto Ricans had the highest prevalence of asthma with African Americans in second place.

Contributing Factors: Exposure to allergens, respiratory infections, family history/genetic predisposition, atopy, occupational irritants, tobacco smoke (smoking and passive smoke exposure), high levels of indoor and outdoor pollution, and obesity; rhinitis is a specific factor in older adults (GINA, 2021).

Signs and Symptoms: Patients may experience recurrent wheezing, cough (especially at night), chest tightness, breathing difficulty, and rhinorrhea/postnasal drip. Symptoms may occur in conjunction with a respiratory infection, weather changes, exposure to environmental allergens, strong emotional reactions, animal dander, mold, smoke, exercise, or other triggers. Medications, including aspirin, NSAIDs, and beta blockers can exacerbate symptoms. Older adults are less likely to sense dyspnea related to airway obstruction, even in the presence of cough, chest tightness, or wheezing (Seggev, 2019).

Differential Diagnosis:

- COPD
- Asthma-COPD overlap syndrome
- Heart failure
- Pneumonia
- Upper respiratory infection
- Cystic fibrosis/bronchiectasis
- Pulmonary embolism
- Obstructive sleep apnea
- Anxiety disorder
- Vocal cord dysfunction
- Cough secondary to drugs, most commonly ACE inhibitors
- Gastroesophageal reflux disease (GERD)
- Allergic bronchopulmonary aspergillosis

Diagnostic Tests: Spirometry is the gold standard for establishing a diagnosis of asthma. Ideally, this should be done prior to starting controller medications to best evaluate the severity of disease. Asthma is an obstructive lung disease, so the spirometry would show obstruction (reduced FEV_1/FVC ratio). Spirometry is generally repeated after the administration of a short-acting bronchodilator. On this post-bronchodilator study, an improvement of 12% and 200 mL in either the forced expiratory volume in 1 second (FEV_1) or forced vital capacity (FVC) indicates a reversible component. This may be helpful in differentiating asthma from COPD. If spirometry is normal, bronchoprovocation such as a methacholine challenge test may help to differentiate asthma from other conditions with a similar presentation (Urbankowski & Przybyłowsk, 2021); however, this test is extremely intensive and may be contraindicated in certain populations. Referral to pulmonology for further evaluation is recommended prior to ordering methacholine testing. Older adults tend to have increased hyperresponsiveness to bronchoprovocation even

© F.A. Davis Publishing

when adjusting for the baseline amount of airway obstruction, atopy, or smoking status, so the testing procedure itself may need to be adjusted.

The American Thoracic Society has endorsed the use of fractional nitrous oxide, measurement in exhaled breath, as a biomarker for eosinophilic inflammation and a complimentary tool to assess airway disease, including asthma (Duong-Quy, 2019). A history of atopy or allergen testing may establish an allergic component. In a patient with dyspnea, measurement of brain natriuretic peptide (BNP) and chest x-ray may be needed to rule out other conditions.

Laboratory testing, including absolute eosinophil count and immunoglobulin E (IgE) may be helpful in distinguishing allergic asthma from other types, especially when considering some of the newer biologic treatment options.

Despite the many available options diagnostic for testing, a thorough history and physical are an essential part of the work-up and should not be underemphasized. Ultimately the nurse practitioner needs to focus on the patient and their unique presentation.

Treatment: Long-term goals of asthma management include controlling symptoms to allow normal activity levels and minimize the risk of asthma-related morbidity and mortality. A partnership between provider and patient is an indispensable element of asthma management, which empowers the patient and allows for education, ongoing assessment, and early intervention. Asthma care paths that facilitate open communication and incorporate the patient's beliefs, goals, and values will improve health outcomes.

Identifying and avoiding potential triggers and treating modifiable risk factors are the first steps in managing asthma. It is critical to encourage patients to adhere to prescribed medication regimens, and all patients who can read and comprehend should have an asthma action plan that is updated whenever changes in treatment are made. A printable asthma action plan, including information on controlling environmental triggers is available at: www.nhlbi.nih.gov/health/public/lung/asthma/asthma_actplan.pdf. The plan may need to be adapted to older adults who cannot or will not perform peak expiratory flow rate (PEFR) monitoring. It is recommended that patients with moderate to severe asthma use a diary every day to record the PEFR and their symptoms (Dobra & Equi, 2018).

Beta-2-agonists, both long-acting (LABA) and short-acting (SABA), inhaled corticosteroids (ICSs), leukotriene antagonists (LTRAs), and long-acting muscarinic antagonists (LAMAs) are all medications used in the treatment of asthma, mainly in a stepwise approach. These steps are fluid, moving up or down along with the patient's symptoms.

When GINA updated recommendations for treatment of asthma in 2019 (Boulet et al., 2019) the primary change was a suggestion of the use of a combination ICS/LABA inhaler as a reliever medication instead of a SABA alone to reduce the risk of an exacerbation. Formoterol was the LABA chosen because the onset of action is more rapid than others in the same category.

The 2021 GINA updated guidelines now have two tracks, each with a 1 to 5 stepwise approach for the management of asthma for adults and adolescents (Fig. 11-1) The current guidelines no longer distinguish between mild intermittent and persistent asthma, noting that the distinction was arbitrary and both groups would benefit from an ICS to prevent exacerbations.

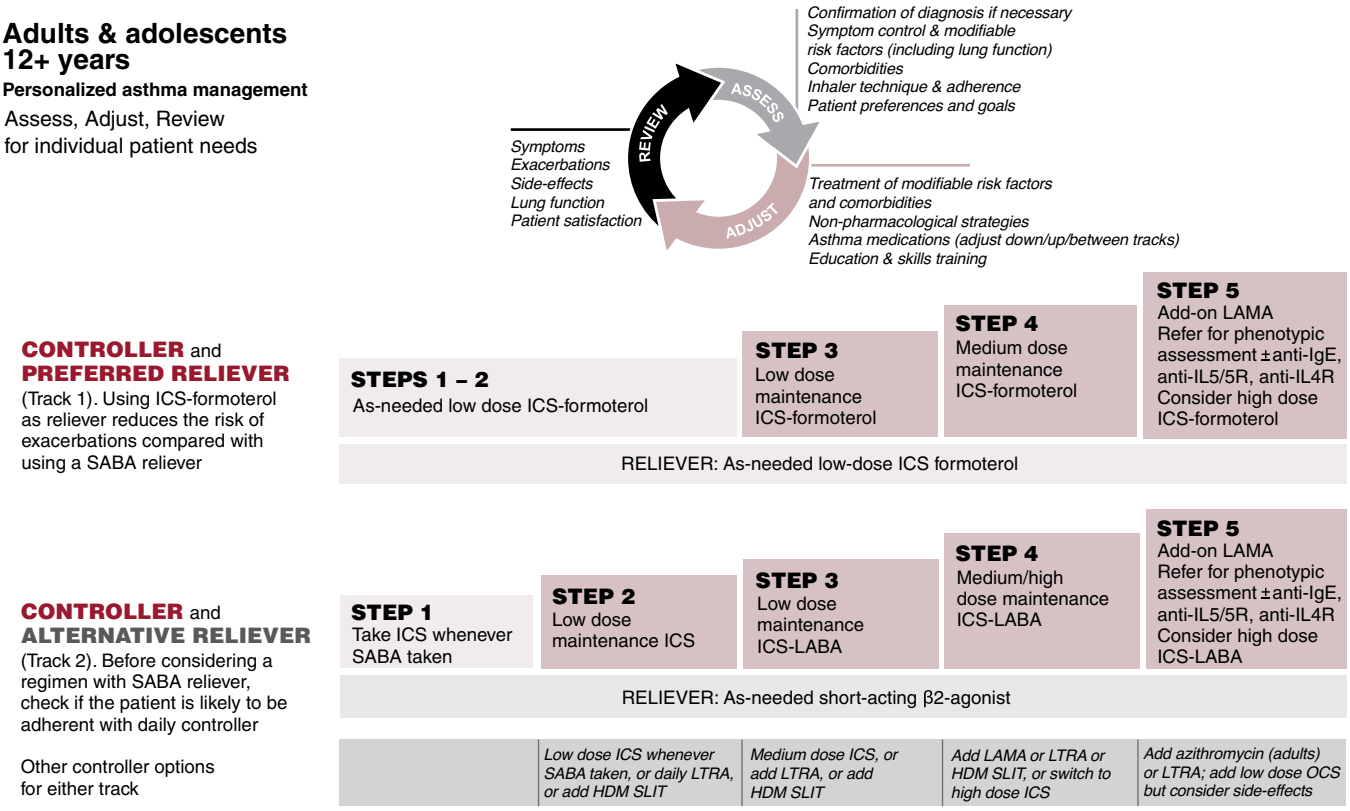

FIGURE 11-1. Global Initiative for Asthma stepwise approach for the management of asthma.

© F.A. Davis Publishing

Track one uses a combination ICS/formoterol as a reliever medication.

- Steps 1–2: Patients who have symptoms fewer than 4 to 5 days in the week can use a low dose ICS/formoterol inhaler as needed. Due to its more rapid onset, only formoterol is acceptable as the LABA in this approach.
- Step 3: Patients who have symptoms most days, or who wake with asthma symptoms once a week or more should be on a maintenance low dose ICS/formoterol inhaler with prn SABA.
- Step 4: Patients who have daily symptoms or wake with symptoms once a week or more and have low lung function should use medium dose ICS/formoterol inhaler with prn SABA.
- Step 5: Consider high dose ICS/formoterol inhaler, consider adding on LAMA, consider assessing for allergic contribution, consider assessing for/adding biologic.

Track two uses SABA for reliever, but the patient is either on an ICS controller or uses the ICS every time they use the SABA.

- Step 1: Symptoms less than twice monthly: take a dose of ICS whenever they use the SABA.
- Step 2: Symptoms twice monthly or more but less than 4 to 5 days per week: low dose maintenance ICS inhaler with prn SABA.
- Step 3: Symptoms most days or waking with asthma once a week or more: low dose maintenance ICS/LABA inhaler with prn SABA.
- Step 4: Symptoms daily, or waking with asthma once weekly or more and low lung function should be on medium to high dose ICS/LABA with prn SABA.
- Step 5: Symptoms still not controlled consider adding LAMA, consider assessing for allergic contribution, consider assessing for/adding biologic.

For steps 2 to 4 of either track, consider adding an LTRA, such as montelukast, either alone (step 2) or in combination with ICS (steps 3 to 4). A 2014 Cochrane review (Chauhan & Ducharme, 2014) found that LTRAs were safe but not as effective as monotherapy ICS for asthma. Because the response to LTRAs is both difficult to predict, with some patients dramatically improved and others minimally, a therapeutic trial is indicated with close monitoring for response. The use of theophylline is discouraged, especially in older adults, because of toxicity, drug interactions, and adverse effects.

Therapy may need to be customized in older adults or patients with comorbidities. For example, increasing the dose of an ICS and avoiding a LABA is prudent in a patient with heart disease, and in a patient with glaucoma or osteopenia, adding a LABA or LTRA instead of increasing the dose of ICS may be preferable. In short, guidelines are not meant to be absolute and do not preclude the use of clinical judgment.

Stepping down therapy is a gradual process compared to stepping up treatment. If a patient has been stable and well controlled for 3 months or more, it is generally safe to decrease the dose of ICS by 25% to 50% (GINA, 2021).

Patients experiencing an acute asthma exacerbation that is not responding to reliever medication should seek immediate emergency medical care. Aggressive treatment with nebulized SABAs and systemic (IV or oral) glucocorticoids for exacerbations remains the standard of care in the acute care setting. Patients who do not respond well within 4 to 6 hours should be hospitalized.

The long-term goals of treating asthma include assessing frequently, making adjustments to optimize symptom control to allow normal activity levels, minimizing side effects, and decreasing risks associated with exacerbations, including airway remodeling/fixed obstruction and death.

Prevention/Prophylaxis: There is no known strategy to prevent asthma. Patients with asthma should be given an influenza vaccine annually, pneumococcal pneumonia vaccine per schedule, and a COVID vaccine unless patient-specific contraindications exist. Partnership with the patient/family in education to recognize triggers, identify changes in status, and seek prompt medical assistance to avoid complications is key to success. Avoidance of environmental factors is also critical.

Education: Patient/family education is an important component of asthma management. In addition to educating patients on the disease and the need for frequent monitoring and immediate reporting of increased symptoms, a written asthma action plan should be initiated, detailing how to identify and deal with environmental triggers, medications dosage and frequency, and when to seek emergent care. Instruction in use and care of inhalers and spacers, if used, is also important. If the patient is on an ICS, instruct on the need for daily use and oral hygiene to prevent a fungal infection. Clarification of the action and role of quick relief inhaler versus daily controller therapy is important for medication adherence. The role of patient as partner in asthma management should be emphasized.

Gearing education to the health literacy level of the patient is crucial to gaining patient understanding and partnership. Patients who are still smoking should receive brief motivational counseling at each visit and referral to a Quitline or community-based smoking cessation program when ready to quit.

Referral: Consultation with an asthma specialist in pulmonology is advised at step 4, with a suggestion to consider a consultation at step 3. Older adults who have multiple comorbidities, have been treated in the emergency department (ED), or have been hospitalized due to an asthma exacerbation within the past year should also be managed in collaboration with an asthma specialist. Patients who require ongoing oral corticosteroids or more than two courses of oral corticosteroids in a year should be referred to an asthma specialist. Biologics such as an anti-IgE agent (omalizumab), IL-5/5R and IL-4 blockers (mepolizumab, benralizumab, dupilumab) may be a consideration for patients with poorly controlled allergic asthma, but they should be prescribed either by or in collaboration with an asthma specialist. Patients having any complications that affect asthma or those who require further testing should also be referred (GINA, 2021). Patients with characteristics of both asthma and COPD fall into this category. Patients and their families may also be referred to a community-based asthma education program, although many of these initiatives are more focused on childhood asthma. Referral to case management through local Area Agency on Aging services can be helpful if the patient has unmet care needs or financial problems with obtaining medications.

© F.A. Davis Publishing

Follow-Up: Regular monitoring should be done 1 to 3 months after initiation of treatment, and then every 3 to 12 months, depending on the level of control and severity. Patients should be seen within 1 week after an asthma exacerbation, and within 2 to 6 weeks when changes are made in stepwise management (GINA, 2021). Treatment step-down can be considered if the patient has had good control for 3 months; follow-up should be scheduled every 1 to 3 months after treatment step-down has been initiated (GINA, 2021).

Sequelae: Older adults with asthma may have increased bronchial hyperresponsiveness and a more rapid decline in lung function than in older adults without asthma. Older adults also may have increased treatment-related adverse events. Comorbidities such as COPD, cardiovascular disease, osteoporosis, glaucoma, diabetes mellitus, and other health problems complicate management and may limit treatment options. Older adults have the highest rate of asthma-associated mortality.

Clinical Recommendation	Evidence Rating	References
Inhaled corticosteroids (ICSs) are the preferred controller medication for all asthma.	A	GINA, 2021
Long-acting beta agonists (LABAs) are the preferred add-on agent due to lack of control, but they should never be used as monotherapy without ICSs.	A	GINA, 2021
It is important to educate patients on the proper technique for inhaled medications and trigger avoidance.	A	Maricoto et al., 2019
In severe or life-threatening exacerbation, the initial treatment should include oxygen, short-acting beta agonists, and systemic corticosteroids for most patients while arranging for transfer to an acute facility with monitoring.	A	GINA, 2021

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Signal Symptoms: Dyspnea, chronic cough with or without sputum production, decreased activity tolerance, wheezing.

Description: Chronic obstructive pulmonary disease (COPD) is defined by the Global Initiative for Chronic Obstructive Lung Disease (GOLD) as "a common, preventable and treatable disease that is characterized by persistent respiratory symptoms and airflow limitation that is due to airway and/or alveolar abnormalities usually caused by significant exposure to noxious particles or gases and influenced by host factors including abnormal lung development" (GOLD, 2022, p. 4). Airflow limitation in COPD results from parenchymal destruction (such as emphysema) and small airway disease that vary among individuals and evolve at different intervals over time (GOLD, 2022). Chronic inflammation is responsible for structural changes, narrowed passages of the small airways, and lung parenchyma destruction, leading to loss of alveolar attachments to the small airways and a reduction in lung elastic recoil (GOLD, 2022). As a result of the structural changes, the ability of the airways to remain open is diminished during expiration as a result. Characteristics of COPD are airflow limitation and mucociliary dysfunction, both of which are likely attributed to loss of small airways (GOLD, 2022). Emphysema is a pathological diagnosis, not a clinical one, although it is possible to see evidence of emphysema on chest imaging.

Patients with symptoms and/or exposure to risk factors for COPD should be considered for further assessment (GOLD, 2022). The most widely available test of airway obstruction is spirometry; however, it is possible for people to have evidence of structural lung disease (such as emphysema) without showing airflow limitation on spirometry. Both structural lung disease and airway obstruction in varying combinations can be seen in COPD (GOLD, 2022).

Etiology: The most significant etiological factor in the development of COPD and the progression of the disease is cigarette smoking (GOLD, 2022). However, individuals who are non-tobacco users may also develop airflow limitations and COPD (GOLD, 2022). Long-term asthma, especially if poorly controlled, has been attributed to some cases of COPD, and advancing age is a factor with symptoms presenting often after the ages of 40 to 50 years old (World Health Organization [WHO], 2017). Long-term cumulative exposure to noxious particles and gases, in combination with various other host factors such as airway hyperresponsiveness, inadequate lung growth and development during childhood, genetics, occupational/industrial gases or fumes, and indoor/outdoor air pollution are all contributing risk factors for COPD (GOLD, 2022; WHO, 2017).

Occurrence: COPD is a chronic disease with substantial morbidity and mortality worldwide, lending to social and economic burdens, long-term disability, and premature death (GOLD, 2022). Chronic lower respiratory disease, the predominant one being COPD, was the fourth leading cause of death in the United States in 2018 (Centers for Disease Control and Prevention [CDC], 2021). Globally, it is estimated that there are over 3 million deaths attributed to COPD (CDC, 2021; GOLD, 2022). An approximate 15.7 million Americans or 6.4% have been diagnosed with COPD (CDC, 2021). Over one-half of adults with abnormally low PFTs were unaware they had COPD and as a result the prevalence

© F.A. Davis Publishing

of COPD may be underrepresented (CDC, 2021). Low socioeconomic status is associated with an increased risk of developing COPD (Grahn et al., 2021).

The prevalence of COPD has been increasing more rapidly in women than in men (Grabicki M., et al., 2018). Some studies have suggested women are more susceptible to the detrimental effects of smoking than men, leading to greater severity of disease and burden of small airway disease despite a similar history of tobacco exposure (GOLD, 2022; Jenkins, 2017). Women who have COPD and have fewer pack-years of smoking than men, experience earlier onset, greater dyspnea, and progress to severe COPD more rapidly than men. Additionally, women with comparable smoking history have shown more loss of lung function, airflow obstruction, and exercise intolerance than men (GOLD, 2022; Jenkins, 2017). Grabicki et al. (2018) conclude that different gender phenotypes exist, which may indicate a need for more targeted assessment and management.

Age: Individuals aged 65 and older have the highest incidence of COPD (CDC, 2021). COPD development occurs gradually over time and most commonly becomes apparent after 40 to 50 years of age (WHO, 2017). Advancing age is a risk factor for COPD, although the evidence is unclear if it is the normal aging of the lungs that lead to COPD or if it is a result of cumulative exposures throughout life (GOLD, 2022).

Ethnicity: Incidence of COPD is lower in Black and south Asian people than in Whites (Gilkes et al., 2017).

Contributing Factors: Cigarette smoking is the most important risk factor for COPD (CDC, 2021; GOLD, 2022). Inhaling other pollutants and exposure to particles (e.g., second-hand smoke, pipe, water pipe, or cigar use), environmental and occupational exposures (e.g., biomass fuel exposure, chemicals, dust, fumes), and genetic determinants (e.g., alpha-1 antitrypsin deficiency) are other causative factors in COPD (GOLD, 2022; WHO, 2017). Chronic bronchitis and frequent respiratory infections have been associated with a greater risk of COPD (GOLD, 2022).

Signs and Symptoms: COPD is a complex, chronic disease that requires a comprehensive symptom assessment. A thorough history to include pattern of symptom development, past medical history, family history, exposure to risk factors, history of exacerbations, and/or hospitalizations for respiratory conditions aid in establishing the diagnosis of COPD (GOLD, 2022).

The most common symptom is chronic and worsening dyspnea. Other symptoms vary among individuals and depend on the severity of the airflow obstruction. In mild COPD, there may be dyspnea, cough (either productive or non-productive), wheezing, and chest tightness. As the disease progresses, dyspnea and cough will likely worsen, and other symptoms may emerge, including nocturnal waking with cough and or dyspnea. These patients may also experience more frequent episodes of temporary, sometimes severe, exacerbations and have increased oxygen requirements. In its more severe stages, symptoms will worsen, exacerbation rates may increase, and patients may feel increasing fatigue. They are also more likely to experience a decreased quality of life including anxiety and depression (GOLD 2022). In most people, symptoms vary from day to day and season to season. (GOLD, 2022).

Physical examination is not typically diagnostic in early COPD and may be normal (GOLD, 2022). In the early to middle stages, chest auscultation may reveal longer expirations with wheezing on forced expiration. Wheezes can sometimes be heard (most frequently with chronic bronchitis); the presence of crackles suggests possible pneumonia, pulmonary edema, or interstitial lung disease.

As the severity of the disease progresses, signs of airway limitations are more apparent on physical examination (GOLD, 2022). In advanced COPD, the examination may reveal decreased breath sounds, hyperinflation with resonance to percussion, use of accessory muscles of respiration, wheezes, crackles in the lung bases, pursed-lip breathing, and/or distant heart sounds (Bickley, 2017; Han et al., 2013). Hyperinflation restricts diaphragmatic movement, and the chest takes on a barrel-like appearance (Bickley, 2017). As the cardiovascular system attempts to compensate, tachycardia or a gallop rhythm commonly occurs. Right-sided heart failure and cor pulmonale seen in the later stages may present as jugular venous distension, hepatomegaly, or peripheral edema (Bickley, 2017). Patients frequently present for treatment due to health-related issues, such as upper or lower respiratory infections. In these instances, the clinician should assess for COPD as the underlying cause.

The impact of activity limitation, socioeconomic loss (e.g., missed workdays), and comorbid conditions (cardiovascular disease, heart failure, or osteoporosis) can help establish the diagnosis of COPD. The severity of symptoms and airflow limitation associated with COPD affect both quality of life and activities of daily living (ADLs). Functional limitation to activities, such as socializing, doing chores, sleeping, and work performance may vary daily (GOLD 2022).

Diagnostic Tests: Spirometry is the gold standard for measuring airflow limitation (GOLD, 2022; Guirguis-Blake et al., 2016). Airflow limitation that is not fully reversible is evident if post-bronchodilator first second of forced expiration/forced vital capacity (FEV_1/FVC) is <0.70 and FEV_1 is less than 80% predicted (Table 11-1) (GOLD, 2022). The U.S. Preventive Services Task Force (USPSTF) recommends spirometry only in symptomatic patients because there was no direct evidence to support screening asymptomatic individuals (Guirguis-Blake et al., 2016). Symptoms for considering a diagnosis and performing spirometry include dyspnea, cough, chronic sputum production, and recurrent lower respiratory tract infections, especially in the presence of risk factors, including

TABLE 11-1 Global Initiative for Chronic Obstructive Lung Disease: Post-Bronchodilator FEV_1 Classification of Severity of Airflow Limitation

PATIENT CRITERIA: FEV_1/FVC <0.70	
FEV_1 ≥80% predicted	GOLD 1: Mild
50% ≤FEV_1 <80% predicted	GOLD 2: Moderate
30% ≤FEV_1 <50% predicted	GOLD 3: Severe
FEV_1 <30% predicted	GOLD 4:Very Severe

© F.A. Davis Publishing

family history of COPD and/or childhood factors (GOLD, 2022). Because airflow usually decreases with age, spirometry predicted values are age adjusted. Spirometry has good sensitivity, but a peak expiratory flow measurement alone is unreliable when used as the only diagnostic tool because of weak specificity (GOLD, 2022). Because there is a weak correlation between FEV_1, symptoms, and impairment impacting an individual's health status, a more formal assessment of symptoms is indicated.

The 2017 GOLD guidelines added important multidimensional recommendations regarding COPD assessment, management, and treatment. In addition to results of spirometry, assessing the impact of COPD, the burden of disease, the risk of disease progression, and COPD exacerbation risk are integral components. The most comprehensive disease-specific questionnaires with reliability and validity focused on health status include the Chronic Respiratory Questionnaire (CRQ) and the St. George's Respiratory Questionnaire (SGRQ) (GOLD, 2022). Although comprehensive, these questionnaires are lengthy, and have very complex scoring, making them impractical for clinical use (GOLD, 2022). The brief and simple COPD Assessment Test (CAT) and COPD Control Questionnaire (CCQ) are both valid and reliable assessment tools and are the best for use in clinical practice (GOLD, 2022). The CAT is the more widely used clinically, and it is applicable worldwide because it is available in multiple languages (GOLD, 2022). The modified Medical Research Council (mMRC) questionnaire measures dyspnea on a scale from 0 to 4; this is also very useful clinically (GOLD 2022).

The most accurate staging of COPD now includes both spirometry and symptom burden. First introduced in the 2011 GOLD guidelines, the ABCD assessment tool considers the number and severity of exacerbations in addition to patient self-assessment using mMRC or CAT. High symptom burden and rate/severity of exacerbations combined with severity of airflow limitation allows for a more accurate assessment and therefore customized treatment plan.

Radiographic imaging with a chest x-ray alone is not diagnostic of COPD but can provide value in excluding differential diagnoses, detecting the presence of concomitant pulmonary disease (bronchiectasis, pleural diseases, pulmonary fibrosis), pneumonia, or cardiac diseases (e.g., cardiomegaly) (GOLD, 2022). Chest radiography in early COPD appears normal (Martini & Frauenfelder, 2018). Radiographic abnormalities associated with COPD such as lung hyperinflation, hyperlucency of the lungs, or tapering of vascular markings may be seen (GOLD, 2022; Martini & Frauenfelder, 2018). Structural lung disease (e.g., emphysema, gas trapping, or airway wall thickening) consistent with COPD findings may also be shown. Radiographic signs of advanced COPD with emphysema include hyperinflation, bullae/blebs, and a flattened hemidiaphragm. A chest x-ray is not recommended for screening of lung cancer, instead, the USPSTF (2017) recommends annual screening with low-dose computed tomography (CT) in adults aged 55 to 80 years with a 30 pack-year smoking history and who currently smoke or have smoked in the past 15 years.

Pulse oximetry is a noninvasive way to assess a patient's arterial oxygen saturation and need for supplementation oxygen therapy. If pulse oximetry is less than 92%, arterial or capillary blood gases are recommended (GOLD, 2022).

Laboratory tests are not routinely used in the assessment of COPD, but because it is common for those patients to have other chronic diseases, such tests can be useful to assess the overall health of the patient. Some consideration could be given to a complete blood count (CBC) with differential to rule out anemia, polycythemia which can occur in advanced COPD with hypoxemia, infection (elevated white blood cell count), or concomitant allergy/asthma (eosinophilia). Serum alpha-1-antitrypsin levels are not recommended for routine screening but should be considered for individuals presenting with COPD at early ages (less than 45 years of age), in non-tobacco users with clinical emphysema, and individuals with a family history of COPD or alpha-1-antitrypsin deficiency at a young onset (Carreto et al., 2020).

To evaluate for the comorbidity of coronary artery disease, an electrocardiogram (ECG) is recommended because patients with COPD and older adults often have atrial arrythmias. Peaked P waves in leads II, III, and aVF may be apparent in patients with pulmonary disease. If cardiac involvement is severe, an ECG in advanced COPD may demonstrate evidence of right-axis deviation, sinus tachycardia, and pulmonary hypertension with the presence of ongoing S waves in the lateral precordial leads.

Differential Diagnosis: Aside from asthma, COPD is fairly easy to distinguish from other potential differential diagnoses when appropriate testing, history taking, and examination are completed (GOLD 2022). Other differential diagnoses may include interstitial lung disease, heart failure, pneumonia, bronchiectasis, tuberculosis (TB), obliterative bronchiolitis, and diffuse panbronchiolitis.

Treatment: Individualize treatment goals according to the stage of disease, symptom assessment, patient goals, comorbidities, and risk of a COPD exacerbation. Treatment is targeted toward improvement of health/functional status and quality of life, prevention of disease progression, avoidance of exacerbations or complications, prevention of treatment side effects, and management of exacerbations (GOLD, 2022). The GOLD Report identifies four segments of a COPD management program: (1) diagnosis and assessment, (2) prevention and maintenance therapy, (3) management of stable COPD, and (4) management of COPD exacerbations.

Prevention and Prophylaxis:

- COPD is almost 100% preventable by avoidance of smoking. Early detection of COPD may alter the course and progression (CDC, 2020).
- All COPD patients should have annual influenza vaccine, and both the pneumococcal polysaccharide vaccine (PPSV23) and the Previnar 13 (PCV 13) are recommended for all patients at age 65 years (CDC, 2021). Prior to age 65, adults 19 to 64 years of age at high risk (e.g., cigarette smoking, chronic conditions, COPD) are recommended to have the PPSV23 and for individuals who receive a PPSV23 prior to age 65 years, revaccination is recommended with PPSV23 at age 65 years (CDC, 2022).

Risk Factor Reduction:

- Identification and reduction of exposure to risk factors is key in the prevention and treatment of COPD (GOLD, 2022).

© F.A. Davis Publishing

- Smoking cessation is the most effective and cost-effective intervention and should be promoted at every visit (CDC, 2021; GOLD, 2022). Counseling (brief or intensive), educational, and community resources are helpful. Pharmacotherapy (e.g., nicotine replacement therapy, bupropion, varenicline, or combination therapy) should be offered as a component of a supportive intervention program but not alone (CDC, 2021; GOLD, 2022).
- Identify and reduce personal exposure to occupational or environmental risk factors (fumes, gases, dust, indoor/outdoor air pollutants).
- Vaccination for influenza and pneumococcal pneumonia (PCV13 and PPSV23) are recommended unless contraindicated.
- Adequate hydration and nutrition are important.

Management of Stable COPD:

- Individualize assessment and treatment to reduce current symptoms and risk of exacerbations.
- Establish an active care-partnership with patients using shared decision making. Educate patients on the disease process, reasonable functional goals, pharmacological therapies, and risk factors for progression. Education must include recognition of instability and when to seek medical assistance. Adherence to treatment regimen should be included in education provided.
- Discussion of healthy living, nutrition, and physical activity is essential.
- Pulmonary rehabilitation is recommended in patients with high symptom burden to reduce symptomatology and risk of exacerbations (GOLD, 2022). Pulmonary rehabilitation has been shown to be a highly effective therapeutic intervention to improve dyspnea, health status, and exercise intolerance (GOLD, 2022).
- Long-term supplemental oxygen therapy in patients with severe resting hypoxia has been shown to improve survival (GOLD, 2022). Additional benefits include reduction in nocturnal hypoxemia, arrhythmias, polycythemia, and dyspnea. Increased exercise tolerance and improved cognition have also been observed. Criteria for oxygen therapy include resting PaO_2 ≤55 mm Hg or SaO_2 ≤88% with or without hypercapnia. Qualification criteria may be broader if there is evidence of pulmonary hypertension, polycythemia, or peripheral edema suggesting heart failure (GOLD, 2022).
- Anxiety and depression are comorbidities associated with COPD and attributed to poor health outcomes (Paine et al., 2019). Assess for symptoms and provide psychological interventions as indicated.

Pharmacological management is the cornerstone of COPD treatment and is directed at symptom improvement, exacerbation severity and risk reduction, and exercise tolerance and health status improvement (GOLD, 2022). The GOLD report recommends initiation therapy along with subsequent escalation and/or de-escalation of pharmacological management.

In select patients, surgical options such as lung volume reduction surgery (LVRS), bullectomy, and lung transplant may be considered. Bronchoscopic endobronchial valve placement, a less invasive alternative to LVRS, is now more broadly available (GOLD, 2022).

Open communication between the patient and provider is a vital part of comprehensive care. When COPD progresses, discussion of philosophy of care, including resuscitation and mechanical ventilation, becomes increasingly important, allowing patients to make their own decisions. Ideally, goals of care discussions should take place during periods of disease stability. In advanced or end-stage COPD, palliative care may be useful, and hospice is a reasonable consideration.

Management of COPD Exacerbations: COPD exacerbations are defined as "an acute worsening of respiratory symptoms that result in additional therapy." They are most often precipitated by respiratory tract infections (GOLD, 2022). Exacerbations are attributed to progression of disease, worsening health status, and increased mortality. COPD exacerbations are classified as mild, moderate, or severe (GOLD, 2022). Interventions aligned with severity include short-acting bronchodilators (SABDs) for mild exacerbations and SABDs and/or or oral corticosteroids for moderate exacerbations. For severe exacerbations, patients should seek care in an ED because hospitalization may be required (GOLD, 2022). Severe exacerbations may be associated with acute respiratory failure, which can be life-threatening (GOLD, 2022). When hospitalization for a COPD exacerbation is required, it is associated with a poor long-term prognosis.

Treatments for exacerbations include SABAs with or without anticholinergics, long-acting bronchodilators, systemic corticosteroids, antibiotics, oxygen therapy, noninvasive mechanical ventilation, and/or invasive mechanical ventilation (GOLD, 2022). Individualized action plans for management of COPD exacerbations, along with patient education, have been found to significantly reduce the risk of hospitalization (Schrijver et al., 2021). Goals for treatment include minimizing the negative impact of the current exacerbation and preventing future events (GOLD, 2022).

Pharmacological Management for Stable COPD: Pharmacological therapy for COPD has a significant role in reducing symptoms and minimizing exacerbations. It can also lead to improved exercise tolerance, health status, and quality of life (GOLD, 2022). Individualized treatment regimens should be based on severity of symptoms, degree of airflow limitation, and exacerbation history. A stepwise approach to therapy is utilized in the treatment of COPD. No current drug therapy has been proved to influence the long-term, progressive decline in lung function (GOLD, 2022). Classes of medications in the treatment of COPD are shown in Table 11-2.

Follow-Up: A newly diagnosed patient should be seen frequently until an optimal treatment plan is in place and disease education has been completed. For stable patients, routine reassessment every 3 to 6 months is advisable, with instructions to the patient or caregiver to schedule an interim visit if there is a change in status, increased symptoms, or an infectious process. For stable patients with other significant comorbidities, visits every 3 months are advisable. A team model for chronic care is optimal for COPD management. Periodic reassessment of pulmonary function and assessment of patient report of breathing status can guide therapy. Patients who are unstable or have had an acute exacerbation will need more frequent follow-up visits initially. Collaborative management with these patients is strongly advised. During the immediate

TABLE 11-2 Medications for Chronic Obstructive Pulmonary Disease

Inhaled $Beta_2$-Agonist Bronchodilators	*Short-acting (SABAs)* • Albuterol, levalbuterol • Reverse bronchoconstriction by relaxing smooth muscles in the airways • Rapid onset (about 15–30 minutes) • Duration of action: 4–6 hours • Are not recommended as scheduled monotherapy in patients with ongoing or frequent symptoms; stepping up therapy would be indicated in those instances *Long-acting (LABAs):* • Formoterol and salmeterol (12-hour duration) • Olodaterol, vilanterol, and indicaterol (24-hour duration) • Used for maintenance therapy to prevent acute bronchospasms • Not for relief of acute symptoms
Inhaled Anticholinergic/ Antimuscarinic Bronchodilators	• Block the bronchoconstricting effects of acetylcholine on muscarinic cholinergic receptors in the smooth muscle of the airways • Have anticholinergic properties and should be used cautiously in patients with narrow-angle glaucoma, significant prostatic hypertrophy, or bladder neck obstruction, and are contraindicated in patients who are allergic to atropine *Short-acting* • Ipratropium • 6- to 8-hour duration • Used in long-term and acute COPD management *Long-acting* • Tiotropium • Used for maintenance treatment • 24-hour duration • Shown to decrease symptoms of dyspnea and reduce the frequency of COPD exacerbations and hospitalizations
Glucocorticoids	• Have anti-inflammatory effects on COPD-associated inflammation *Inhaled corticosteroids:* • Monotherapy with ICSs is not recommended unless they are used in combination with inhaled bronchodilators. • Instruct the patient to rinse the mouth after using any ICS to reduce the risk of oral thrush. *Systemic corticosteroids:* • Have nonspecific anti-inflammatory properties and are used for short-term treatment in the management of an acute COPD exacerbation. • Are associated with numerous side effects and, therefore, have no role in long-term management of COPD.
Combination Bronchodilator Therapy	• Bronchodilators with different mechanisms of action may improve the degree of bronchodilation with a lower risk than that associated with increasing the dose of a monotherapy agent. • Combination inhaled therapy with LABAs, ICSs, or LAMAs are used for stable COPD patients with symptoms and may be more effective than the individual agents. • ICS/LABA combinations have been shown to be more effective than either component alone in terms of symptom improvement and exacerbation reduction. • Fluticasone/salmeterol and budesonide/formoterol are examples of combination ICS/LABAs. • In patients with stable, moderate to very severe COPD, a maintenance combination of an ICS/LABA or ICS/LAMA should be considered. • For patients with severe or very-severe COPD and persistent symptoms, triple therapy is recommended with a combination ICS/LABA/LAMA. • There are now single inhalers which offer this triple combination. • It is challenging to keep up with all the options available in inhaled format. The use of charts that include pictures can be useful in communicating with patients about what it is they are using for inhaled therapy.
Methylxanthines	*Theophylline* • A nonspecific phosphodiesterase inhibitor/oral bronchodilator • The most common methylxanthine, but use has decreased significantly • Has been found to be modestly effective with a narrow therapeutic index, potential for toxicity, many drug-to-drug interactions, and wide range of toxic adverse effects
Phosphodiesterase-4 (PDE4) Inhibitors	• Inhibit the breakdown of cyclic AMP, thus reducing inflammation. *Roflumilast:* • Once daily oral PDE4 inhibitor indicated in patients with severe or worse disease and frequent exacerbations • Has a high rate of side effects, including nausea, diarrhea, weight loss, headaches, and sleep disturbances • Using lower doses to start may be helpful • Avoid use in underweight patients or those with depression

Sources: *Anzueto & Miravitlles, 2020; Brightling & Greening, 2019; GOLD, 2022*

© F.A. Davis Publishing

post-acute period, a pulmonary specialist should manage the patient. Pulmonary rehabilitation is helpful in moderate to severe disease (GOLD, 2022).

Sequelae: COPD is a multisystem disease and can lead to respiratory infections, cor pulmonale, pulmonary hypertension, malnutrition, acute or chronic respiratory failure, steroid-induced myopathy, or Cushing's syndrome, bullous lung disease, polycythemia, and sleep-related hypoxemia. Depression is frequently associated with COPD (Paine et al., 2019).

Prevention/Prophylaxis: Avoidance of tobacco, smoking cessation, and avoidance of second-hand smoke are encouraged.

Referral: Collaborative management is advised in all patients. Refer patients to a pulmonary specialist during instability, for hospital and post-acute care, to evaluate for the appropriateness of surgical options, and for oxygen therapy evaluation. Refer patients to pulmonary rehabilitation for reconditioning and education on breathing techniques and energy-conserving measures. Consult with a dietary health professional when applicable. Post-acute COPD patients in the community should be referred for home care. Refer all patients to community resources and support groups. Palliative care and hospice options are considerations.

Education: Teach the patient, family, and/or caregivers about the disease process and its management, the association of risk factors such as smoking and importance of cessation, pharmacological therapy, oxygen therapy and precautions, and the importance of seeking early care for symptoms of exacerbation or infectious processes (GOLD, 2022). Self-management education and coaching are integral components of a chronic care model approach (GOLD, 2022). Self-management skills include monitoring and managing signs and symptoms of COPD, treatment adherence, and maintaining regular follow-up with health-care providers.

Clinical Recommendation	Evidence Rating	References
Smoking cessation is the most effective and cost-effective intervention and should be promoted at every visit.	A	GOLD, 2022 CDC, 2021
In patients with respiratory symptoms, particularly dyspnea, spirometry should be performed to diagnose airflow obstruction. Spirometry should not be used to screen for airflow obstruction in asymptomatic individuals.	B	GOLD, 2022
Pulmonary rehabilitation consisting of exercise training, muscle strengthening, nutritional counseling, energy conservation, ADLs, breathing modifications, medication education (including use of inhaler devices), and oxygen use is beneficial, particularly in moderate-to-severe COPD.	A	GOLD, 2022
Supplemental oxygen therapy in patients with resting hypoxia improves survival.	A	GOLD, 2022
Bronchodilators are the foundation of symptomatic management	A	GOLD, 2022
ACP, ACCP, ATS, and ERS recommend that clinicians prescribe either long-acting inhaled anticholinergics or long-acting inhaled beta agonists for symptomatic patients with COPD and FEV_1 <60% predicted. INFLUENZA

Signal Symptoms: Acute onset of fever, headache, myalgia, and malaise. These symptoms usually coexist with other respiratory complaints such as cough, dyspnea, sore throat, coryza, and rhinorrhea. Fevers generally range between 37.8°C to 40.0°C (100°F to 104°F). Older adults may present with more subtle symptoms such as confusion, appetite loss, fatigue or malaise, weakness, and dizziness along with exacerbations of other chronic conditions such as COPD or heart failure (Dolin, 2020a; Talbot, 2017).

Description: Seasonal influenza is an acute viral infection that affects the entire respiratory tract (nose, mouth, throat, and lungs). Several modes of influenza transmission have been identified, including inhalation of airborne particles or

© F.A. Davis Publishing

respiratory droplets (exhalation or talking within six feet, coughing and/or sneezing), fomites, and contact with contaminated surfaces. Seasonal outbreaks generally occur during colder months in temperate climates (U.S. Department of Health and Human Services [HHS], 2021a; Dolin, 2020a; Gaitonde et al., 2019).

The incubation period for influenza is between 1 and 4 days. The infectious period occurs 1 or 2 days before symptom onset and lasts 5 days on average but up to 10 days in some cases. Viral shedding may be even more prolonged in patients who are immunocompromised. Magnitude of shedding is variable and associated with disease severity (Dolin, 2020a; Gaitonde et al., 2019).

Etiology: Influenza infection is caused by a strain of A, B, or C viruses of the Orthomyxoviridae family. Influenza A infects both humans and animals and can rapidly mutate, resulting in novel virus variations. Lack of immunity to new viral strains resulting from these antigenic shifts has triggered numerous seasonal pandemics and epidemics over the last century. Influenza B viruses have two separate lineages and a lower propensity for mutation. Influenza B only infects humans and carries lower risk of causing seasonal epidemics than type A. Influenza C only infects humans and results in mild illness. Influenza C outbreaks tend to be sporadic and localized. Different strains of the virus may cocirculate during the influenza season (HHS, 2021a; Dolin, 2020b; Keilman, 2019).

Influenza A viruses carry greater transmissibility and disease burden than B or C type viruses. Subtypes of the influenza A virus vary in their degree of transmissibility and severity of disease burden. This group of viruses are responsible for the pandemics in 2018 (H1N1), 2009 (H1N1), 1957 (H2N2), and 1968 (H3N2). Although risk of human infection from Avian Influenza A (H5N1) is low, this strain has a much higher mortality rate compared to H1N1—50% and less than 15%, respectively (HHS, 2021a; Park & Ryu, 2018).

Occurrence: Pneumonia and influenza together are the eighth leading causes of death in the United States. The World Health Organization (WHO) (2017) reports lower respiratory infections as the fourth leading cause of death worldwide and the leading cause of death due to infectious disease. The 2019–2020 seasonal influenza caused approximately 35 million cases of symptomatic illness and more than 300,000 hospitalizations in the United States alone. The CDC also estimates flu burden of 16 million medical visits and 20,000 deaths during the 2019–2020 season. Visit rates to the ED for patients with influenza are 4.4 per 1,000 persons (HHS2021b; Herron, 2021; Reid & Fingar, 2020; WHO, 2021).

Older adults (65 years and older) carry the greatest risk of severe influenza disease. Hospitalization rates for older adults with influenza are estimated at 316.4 per 100,000 persons, compared to 191 per 100,000 adults aged 18 to 64. Influenza related mortality among older adults is more than twice that of adults under age 65. It is estimated that this vulnerable population accounts for up to 70% of influenza-related hospitalizations and more than 70% of flu-related deaths (HHS, 2021b). The number of deaths due to pneumonia and influenza is greater for women compared to men (Herron, 2021).

Age: Older adult patients are at increased risk for severe influenza and related complications (HHS, 2021c).

Ethnicity: Cause of death due to pneumonia and influenza is highest among Americans of Asian and Pacific Islander descent and lowest among non-Hispanic Black and White persons. Non-Hispanic Black, Hispanic or Latino, and American Indian or Alaskan Native persons are at increased risk for hospitalization from influenza (HHS, 2021b; Herron, 2021).

Contributing Factors: Modifiable risk factors related to flu-related complications include tobacco and alcohol use. Main factors associated with influenza morbidity and mortality in older adults are advanced age, presence of any medical comorbidity, immune-compromised states, and genetic predisposition. Older adults are much more likely to require hospitalization and develop serious complications secondary to influenza infection (HHS, 2021c; Keilman, 2019; Paules & Subbarao, 2017).

Chronic comorbidities commonly associated with severe flu-related illness and secondary complications include asthma, chronic lung disease, heart failure, diabetes mellitus, morbid obesity, renal disease, liver disorders, and those with history of stroke. Patients who are immunocompromised, such as those with cancer undergoing chemotherapy or those who require chronic use of corticosteroids and immune-suppressing drugs, are at increased vulnerability (Keilman, 2019; Walker et al., 2020; Zachary, 2021).

Immune senescence, genes, and genetic polymorphisms can influence susceptibility to influenza A infection by modulating risk for severe disease and mortality. Certain alleles operate along protective pathways by inhibiting viral replication and/or cellular entry by influenza viruses. Alternatively, other alleles, or lack thereof, result in defective complement system and impaired immune response (Clohisey & Baillie, 2019; Paules & Subbarao, 2017).

Residents of long-term care (LTC) facilities are particularly vulnerable, with influenza being a leading cause of communicable disease outbreaks. The prevention and control of seasonal influenza outbreaks in LTC has proven to be challenging. Older adults' atypical presentation of influenza often leads to delayed recognition and treatment, contributing to mortality rates as high as 55% due to outbreaks in LTC facilities (Richards & Stuart, 2020; Talbot, 2017).

Signs and Symptoms: Textbook clinical presentation includes subjective complaints of sudden onset fever, chills, cough, myalgia, arthralgia, and headache. Patients may also have complaints of fatigue, malaise, sore throat, nasal congestion, dyspnea and/or pleuritic chest pain. Older adults typically do not present with classic symptomatology. Fever is often absent, especially in patients who have received seasonal influenza vaccines. Gastrointestinal complaints such as nausea, vomiting, and diarrhea are not common. Older adults may present with anorexia, delirium, fatigue and/or low-grade fever (temperature greater than 37.3°C or 99.0°F). Older adults often present with signs of chronic illness exacerbations such as COPD or heart failure. (Dolin, 2020a; Keilman, 2019; Talbot, 2017).

Physical examination in uncomplicated influenza is often unremarkable, but when present, findings most commonly include skin flushing or oropharyngeal hyperemia. Ocular

© F.A. Davis Publishing

findings including conjunctivitis or excessive lacrimation may be present but are uncommon. Cervical lymphadenopathy generally is not present in the older adult presentation. Chest examination is often unremarkable, but diffuse rhonchi or rales are present in approximately 25% of cases (Dolin, 2020a; Paules & Subbarao, 2017).

Diagnostic Tests: Selection of diagnostic test for seasonal influenza should be determined by test availability and how quickly results are needed.

Molecular Assays: These tests preferred over antigen detection tests because they have the highest sensitivity, but they may not always be readily available. Molecular assays remain the gold standard for influenza testing of outpatient and hospitalized patients (Dolin, 2021; Uyeki et al., 2019). Rapid molecular assays, or nucleic acid amplification tests, are recommended for use in outpatient setting because of their high sensitivity and specificity and can be used at point of care, taking less than 20 minutes to result. These tests are also able to differentiate between type A and B influenza. They are not able to distinguish between variant influenza subtypes (Dolin, 2021; Uyeki et al., 2019).

Reverse-Transcription Polymerase Chain Reaction (RT-PCR) Tests: These tests are preferred for patients who are hospitalized and have high sensitivity. RT-PCR can differentiate between influenza types and subtypes. Multiplex RT-PCR tests should be used for hospitalized patients who are immunocompromised or mechanically ventilated, or cases in which such testing may alter treatment course. Multiplex assays can identify multiple etiologies of acute respiratory infections. The U.S. Food and Drug Administration (FDA) has approved several multiplex assays that can distinguish between strains of influenza A or B, and SARS-CoV-2. These assays are particularly useful during peak periods of influenza activity where these three viruses cocirculate (Dolin, 2021; Uyeki et al., 2019; Uyeki et al., 2020).

Antigen Detection Assays: These tests have poor sensitivity and are only recommended for use in hospitalized patients when molecular assays are not available. These tests should not be considered diagnostic and follow up testing with a molecular assay is needed to confirm or rule out diagnosis of influenza. Digital immunoassays are a newer option showing promise with sensitivity near that of molecular assays, but further experience with these tests is needed. They are not currently recommended because stronger evidence supporting test validity is needed (Dolin, 2021; Uyeki et al., 2019).

Viral Culture and Serological Testing: Viral cultures, formerly the gold standard for diagnosis, are no longer recommended for primary influenza diagnosis. These tests are still used in public health surveillance and institutional outbreaks to confirm negative rapid influenza diagnostic tests and antigen detection assays. Viral cultures typically take 48 to 72 hours or longer to be processed (Dolin, 2021; Uyeki et al., 2019).

Serological testing is not recommended for influenza diagnosis. Clinically, this test's only utility is in retrospective influenza diagnosis and is therefore generally reserved for research purposes only (Dolin, 2021; Uyeki et al., 2019).

Diagnostic Imaging: Chest x-ray or CT scan are appropriate if primary influenza pneumonia and/or secondary bacterial pneumonia are suspected. Chest x-ray findings in primary influenza pneumonia typically include bilateral opacities without consolidation. CT scan may demonstrate multifocal consolidation and/or ground glass opacities. Patients with concomitant viral and bacterial influenza pneumonia often have evidence of frank consolidation and bilateral pulmonary infiltrates on chest radiograph (Dolin, 2020a; File, 2020).

Outpatient Testing: Although uncomplicated influenza generally does not require hospitalization, high-risk populations benefit from prompt diagnosis and treatment to reduce risk of deterioration in condition. Accurate detection of influenza provides clinicians an opportunity to prescribe the appropriate treatment course, promoting antibiotic stewardship and reduces number of unnecessary tests to rule out alternate symptom etiologies (Uyeki et al., 2019).

The Infectious Disease Society of America (IDSA) recommends diagnostic testing during peak influenza activity periods for high-risk populations or for cases in which testing will alter the patient's treatment course. Testing is warranted if it will influence decision making regarding antibiotic versus antiviral medication, appropriate treatment setting, or reduce need for additional diagnostic testing (Uyeki et al., 2019).

Nasopharyngeal specimens collected within 4 days of symptom onset are preferred for diagnostic testing of influenza in the outpatient setting. Collection of nasal and throat swab specimens combined is acceptable when nasopharyngeal specimens are unavailable. Collection of nasal or throat swab specimens alone is not recommended. Flocked-swab specimen collection is preferred over non-flocked swab specimens (Uyeki et al., 2019).

During periods of low influenza activity, testing is not routinely recommended, except in patients presenting with acute onset of respiratory symptoms, with or without fever. Clinicians should also consider testing patients who present with non-specific respiratory illness, especially those who are immunocompromised or at high-risk of influenza-related complications (Uyeki et al., 2019).

Hospitalized Patients: During peak periods of influenza activity, the IDSA recommends diagnostic testing of patients with an acute respiratory illness or acute exacerbation of COPD, asthma, heart failure, or coronary artery disease upon hospital admission. During periods of low influenza activity, the IDSA recommends testing patients with known exposure to influenza or recent travel to an area of known outbreak who present with acute respiratory illness. Testing should be considered for hospitalized patients who are immunocompromised or at high risk of complications secondary to influenza (Uyeki et al., 2019).

Nasopharyngeal specimen collection is preferred for hospitalized patients without severe lower respiratory tract disease. Testing should be completed upon hospital admission or as soon as able. Endotracheal aspirate or bronchoalveolar lavage fluid specimens should be collected from all mechanically ventilated patients, even if upper respiratory tract specimens tested negative for influenza (Chow et al., 2019; Uyeki et al., 2019).

Differential Diagnosis:

- Common cold
- Allergic or seasonal rhinitis
- Coronavirus disease 2019 (COVID-19)
- Acute bronchitis

© F.A. Davis Publishing

- Asthma exacerbation
- Respiratory syncytial virus
- Rhinovirus
- Bacterial pharyngitis or tonsillitis
- Acute bacterial rhinosinusitis
- Pertussis
- COPD exacerbation
- Heart failure

Treatment: The IDSA recommends initiation of antiviral therapy for the following patients with suspected or confirmed influenza, regardless of immunization status or illness duration:

- All hospitalized patients with influenza
- All outpatients with severe or progressive illness
- All outpatients who are at high risk of influenza-related complications

Antiviral therapy should be considered for the following patients with suspected or confirmed influenza, who are not considered high risk for influenza-related complications, regardless of immunization status or illness duration:

- Outpatients presenting with symptom onset within the past 48 hours
- Symptomatic outpatients with household contacts who are immunocompromised or considered high risk of influenza-related complications
- Symptomatic health-care providers who regularly care for patients who are immunocompromised or considered high risk of influenza-related complications

Treatment with antiviral therapy should be initiated as early as possible, ideally within 48 hours of symptom onset, which is associated with reduction in illness severity and duration. It is recommended to initiate antiviral treatment while awaiting results of diagnostic tests. Patients with negative rapid antigen tests should still be treated with antiviral therapy if clinical presentation is highly suspicious for influenza because of the low sensitivity of these tests. Administration of antiviral therapy to hospitalized patients within 48 hours of symptom onset is also associated with shorter hospital length of stay (Dou et al., 2020; Gaitonde et al., 2019; Uyeki et al., 2019; Zachary, 2021).

Medication Management: IDSA recommends treatment of confirmed or suspected influenza with a single neuraminidase inhibitor (NAI) or cap-dependent endonuclease inhibitor. Oseltamivir is the preferred choice for uncomplicated and severe influenza; however, treatment selection should be individually based on patient needs and characteristics. Other acceptable antiviral treatment options include zanamivir, peramivir, or baloxavir marboxil. Treatment with combination NAI therapy is not recommended (Uyeki et al., 2019; Zachary, 2021).

Treatment with oseltamivir or peramivir is recommended for severely ill patients with influenza. Both drugs are subject to renal dose adjustments in older adults. The dose of antiviral medication should not be increased for treatment of patients with severe influenza. Initiation of antiviral treatment within 48 hours of symptom onset is associated with decreased length of hospital stays. No significant reduction in mortality rates, complications, or illness duration has been identified in patients treated with antiviral medication doses that exceed standard of care (Chow et al., 2019; Dou et al., 2020; Uyeki et al., 2019; Zachary, 2021).

Duration of treatment of uncomplicated influenza with oral oseltamivir or inhaled zanamivir is 5 days, while peramivir or baloxavir marboxil can be administered in a single dose. Clinicians should consider an extended course of antiviral treatment for patients who are immunocompromised, have influenza pneumonia, or acute respiratory distress syndrome (ARDS). Refer to Table 11-3 for comparison of antiviral medication options (Uyeki et al., 2019; Zachary, 2021).

Adjunct Therapies: Treatment of influenza with adamantanes (amantadine and rimantadine) is not recommended. These drugs are only effective against influenza A viruses and the rate of viral resistance to these medications is high. Adjunct therapy with corticosteroids is not recommended for adults with confirmed or suspected influenza unless there are other medical indications. Treatment with intravenous immunoglobulin therapy is not recommended for adults with confirmed or suspected influenza (Uyeki et al., 2019; Zachary, 2021).

Various herbal and homeopathic treatments are marketed for influenza treatment, none of which have strong evidence to support their use. These treatments pose additional risks for older adults. There is positive correlation between number of medications used, risk of adverse medication reactions, and drug-related hospitalizations. Older adults should be instructed to avoid over-the-counter (OTC) treatments for influenza without consulting their primary care provider (Halli-Tierney et al., 2019).

Symptom Management: Acetaminophen is the drug of choice for relief of fever, headache, myalgias, and arthralgias in older adults. NSAIDs should be used with extreme caution in the older adult population because of the increased risk of acute kidney injury, bleeding, and cardiovascular side effects. Symptom management with NSAIDs should be reserved for use in older adult patients when acetaminophen is contraindicated. NSAID therapy should be prescribed for the shortest duration possible and at the lowest effective dose. (American Geriatrics Society Beers Criteria® Update Expert Panel, 2019; Zachary, 2021).

Oral suspension guaifenesin or menthol lozenges are reasonable options for older adult patients who find cough associated with influenza particularly bothersome. Older adult patients should be cautioned to avoid OTC antihistamines and decongestants for symptom management. Patients should be instructed to maintain adequate fluid intake to avoid dehydration. Physical activity should be encouraged as tolerated to minimize deconditioning (Zachary, 2021).

Follow-Up: Follow-up is dependent on individual patient characteristics, comorbidities, and treatment response. Patients diagnosed with influenza in the outpatient setting should be counseled that recovery can take 1 to 2 weeks without antiviral treatment. Older adults who are at high risk of complications should schedule a follow-up office visit within a few days after completion of antiviral treatment. Patients should be instructed to call if symptoms worsen, if no response occurs after 3 to 5 days of treatment, or if symptoms recur. Patients hospitalized with influenza should follow up with their primary care provider within 1 week of hospital discharge.

TABLE 11-3 Comparison of Antiviral Medications for Seasonal Influenza Treatment in Adults

ANTIVIRAL AGENT	INDICATION	ROUTE/ FORMULA	DOSING WITH RENAL ADJUSTMENTS				SPECIAL CONSIDERATIONS
			CrCl >60	*CrCl 30 to 60*	*CrCl 10 to 30*	*CrCl <10*	
oseltamivir (Tamiflu)	Uncomplicated and severe influenza	Oral capsules	75 mg PO twice daily ×5 days	30 mg PO twice daily ×5 days	30 mg PO daily ×5 days	Avoid use	Preferred as first-line therapy over other neuraminidase inhibitors
zanamivir (Relenza)	Uncomplicated influenza	Inhalation	Two 5-mg inhalation (10 mg) twice daily ×5 days				N/A
			CrCl >50	*CrCl 30–49*	*CrCl 10–29*	*CrCl <10*	
peramivir (Rapivab)	Uncomplicated and severe influenza	IV infusion	600 mg IV ×1 dose over 15–30 minutes	200 mg IV ×1 dose	100 mg IV ×1 dose	Avoid use	Do not use if resistance to oseltamivir suspected.
			CrCl >50	*CrCl <50*			
baloxavir marboxil (Xofluza)	Uncomplicated influenza	Oral tablets	<80 kg: 40 mg PO ×1 dose; >80 kg: 80 mg PO ×1 dose	Undefined/not studied in this population.			Avoid administration with dairy products, calcium-fortified beverages, antacids, or other oral supplements.

CrCl = creatinine clearance

Sources: *Gaitonde et al., 2019; Hibberd, 2022; Uyeki et al., 2019*

Sequelae: The most common influenza-related complication is pneumonia, and older adults are disproportionately affected. Secondary bacterial pneumonia is most common, but primary influenza pneumonia is most severe. Patients predisposed to primary influenza pneumonia include those with valvular heart disease, chronic inflammatory lung disease, and pulmonary hypertension.

Secondary bacterial pneumonia should be considered in patients who have not improved following 3 to 5 days of antiviral therapy. Patients with deterioration in condition, respiratory failure, hypotension and/or fever should also be evaluated for presence of more extensive disease (Chow et al., 2019; Gaitonde et al., 2019; Uyeki et al., 2019).

The most common organisms associated with secondary bacterial pneumonia are *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Streptococcus pyogenes*. Sputum cultures should be obtained if able to aid decision making regarding antibiotic therapy. Empiric treatment should include a third generation cephalosporin such as ceftriaxone or respiratory fluoroquinolone such as levofloxacin or moxifloxacin. Treatment with vancomycin or linezolid should be considered in critically ill patients or those who do not improve with empiric treatment regimens, as these cases are suspicious for infection with multi-drug resistant organisms (MDRO) (File, 2020b; Khorramdelazad et al., 2021; Zachary, 2021).

Cases of H1N1 influenza A are associated with increased risk of clinical deterioration leading to rapidly progressive pneumonia, acute respiratory distress syndrome (ARDS), respiratory failure and multisystem organ failure. Combination of viral and bacterial pneumonia secondary to influenza infection is also common (Dolin, 2020a; Khorramdelazad et al., 2021; Malosh et al., 2018).

Older adults are at increased risk for secondary cardiac complications including acute myocardial infarction (MI), arrhythmia, myocarditis, and pericarditis. Other serious but less common complications include rhabdomyolysis, myositis, and toxic shock syndrome. Central nervous system complications are also rare but may include encephalopathy, encephalitis, transverse myelitis, aseptic meningitis, and Guillain-Barré syndrome (Dolin, 2020a; Khorramdelazad et al., 2021).

Older adults hospitalized with influenza are susceptible to complications that may be hospital- and/or geriatric-associated, including nosocomial infection, delirium, falls, medication-related problems, or exacerbation of chronic illness. These problems share multiple risk factors common to older adults, including functional impairment, cognitive impairment, gait instability, and frailty. These complications frequently occur together, prolonging hospitalization. Length of inpatient stay correlates with increased risk of morbidity and mortality during hospitalization and after discharge (Keilich et al., 2019; Mudge et al., 2019; Romero-Ortuno et al., 2017).

Functional decline resulting in slowed or a potentially incomplete recovery following influenza infection is common among older adults. Approximately 67% of older adults with influenza find themselves temporarily homebound, and 25% become temporarily bedbound, resulting in a tremendous impact on patients, families, and caregivers (Andrew et al., 2021; Talbot, 2017).

© F.A. Davis Publishing

Older adults hospitalized for influenza are particularly vulnerable to experiencing permanent decline in function. Approximately one-third of hospitalized adults aged 70 years and older will experience the loss of one basic activity of daily living (ADL). Only 30% of these older adults will fully recover this loss within 1 year of discharge. Skilled nursing care following hospital discharge is required for approximately 70% of adults aged 65 years and older. Risk of functional loss is associated with the number of pre-existing comorbidities, frailty, and disability prior to hospitalization (Andrew et al., 2021; Mattison, 2021).

Prevention/Prophylaxis: The most effective strategy for influenza prevention is vaccination, and herd immunity is an essential component for protection of older adults from seasonal influenza. All household contacts, caregivers and health-care professionals caring for older adults should be administered seasonal influenza vaccination every year. Immune senescence in older adults increases their risk for severe illness and mortality. This risk multiplies among institutionalized older adults with pre-existing functional impairments, frailty, and comorbidities, making presence of herd immunity imperative where institutional outbreaks are common and potentially devastating (Keilich et al., 2019).

All adults should be administered seasonal influenza vaccine each year. Older adults who become infected with seasonal influenza despite vaccination experience milder symptoms, shorter illness duration and are less likely to require hospitalization. Risk of influenza-related complications and mortality is also decreased among vaccinated older adults with influenza compared to those who are not (Andrew et al., 2019; Arriola et al., 2017). The American College on Immunization Practices (ACIP) and CDC recommend administration of influenza vaccine to all adults annually. Ideally, vaccination should occur before the end of October each year, but administration can be completed at any point during the influenza season (CDC, 2021; Hibberd, 2022).

The unique ability of the influenza virus to periodically mutate poses challenges to development of immunizations for upcoming influenza seasons. Quadrivalent influenza vaccines containing four strain antigens, two influenza A strains and both influenza B lineages, have shown greater efficacy in disease prevention than past trivalent formulas. These vaccines have also proven beneficial in reducing illness severity and hospital admissions due to influenza. Despite chance of mismatch between vaccine strains and seasonal circulating strains, vaccination is still the most efficacious strategy to reduce serious influenza outcomes (Andrew et al., 2019; Hibberd, 2022). Table 11-4 compares FDA-approved influenza vaccines.

Vaccine Contraindications and Precautions: Patients with history of anaphylaxis, angioedema, respiratory distress, lightheadedness, or recurrent vomiting secondary to egg exposure should not receive egg-based vaccine formulations. These individuals should be offered an alternative licensed formulation such as RIV4 or cell-cultured IIV4. Egg allergy should not be considered a contraindication to vaccination if the patient only experiences urticaria following exposure (Grohskopf et al., 2021). Egg-based formulations are contraindicated for all patients with history of anaphylaxis following any influenza vaccine. Administration of alternative formulations should be supervised by a healthcare provider capable of managing a severe allergic response in an in- or outpatient medical setting (Grohskopf et al., 2021).

Caution should be taken with patients who have a history of Guillain-Barré syndrome within 6 weeks following influenza vaccination. If the patient is considered low risk of secondary influenza complications, it is reasonable not to vaccinate. In adults or those who are at increased risk of influenza-related complications, a discussion of risk versus benefit of vaccination is essential. Antiviral chemoprophylaxis should be considered for any adult who has not received seasonal influenza vaccine (Grohskopf et al., 2021). Treatment with oral anticoagulants is not a contraindication for influenza vaccination, however a small gauge needle (23 gauge or smaller) should be used to reduce risk of hematoma (Hibberd, 2021).

Co-administration with Other Vaccines: Inactivated influenza vaccines can be administered at the same time as other inactivated or live virus vaccines, including the COVID-19 vaccine. When multiple injections are being given in a single visit, vaccines should not be administered in the same site. Deltoid muscle is the recommended site of administration for influenza vaccine (Hibberd, 2022).

Vaccination of Acutely Ill Patients: Influenza vaccination may be administered to patients with mild respiratory illness, with or without fever. Vaccination should be delayed for older adult patients with moderate or severe acute illness, with or without fever. The influenza vaccine should be administered as soon as possible, once patient symptoms have resolved (Hibberd, 2022).

Antiviral Chemoprophylaxis: IDSA recommends antiviral preexposure and postexposure chemoprophylaxis with oral oseltamivir or inhaled zanamivir in certain situations.

For outpatient exposures, IDSA recommends antiviral chemoprophylaxis for older adults in whom vaccination is contraindicated or unavailable and considered high risk of developing influenza-related complications for the duration of influenza season. Antiviral chemoprophylaxis of severely immunocompromised older adults regardless of vaccination status is recommended for the duration of influenza season. Antiviral chemoprophylaxis should be initiated as soon as possible after the first influenza case has been detected in the community (Uyeki et al., 2019).

IDSA recommends short-term antiviral chemoprophylaxis for unvaccinated adults who are at high risk of influenza-related complications and confirmed influenza outbreak in the community. These individuals should also be vaccinated as soon as possible. During peak periods of influenza activity, short-term antiviral chemoprophylaxis is recommended for health-care providers and close household contacts of older adults at high risk of secondary influenza complications in whom influenza vaccine is contraindicated or unavailable (Uyeki et al., 2019).

For institutional outbreaks, IDSA recommends outbreak control measures (active surveillance and antiviral chemoprophylaxis) be initiated when two cases of laboratory confirmed influenza are identified within 72 hours of one another in patients of the same ward or hospital unit. When results of molecular assays are not available on the same day of specimen collection, initiation of outbreak control measures should be considered if one or more patients are suspected to have healthcare-associated influenza. Active surveillance

TABLE 11-4 Comparison of FDA-approved Influenza Vaccine Formulations

TRADE NAME (MANUFACTURER)	FORMULATION	INDICATIONS (AGES)	DOSE/ MANUFACTURING	ADMINISTRATION ROUTE
Standard-dose, egg-based vaccines				
Fluarix (GlaxoSmithKline) Fluzone	Inactivated quadrivalent influenza vaccine (IIV4)	Healthy individuals ≥6 months	0.5 mL PFS or SDV	Intramuscular injection
FluLaval (GlaxoSmithKline)	Inactivated quadrivalent influenza vaccine (IIV4)	Healthy individuals 6 months to 64 years	0.5 mL PFS	Intramuscular injection
Afluria (Seqirus)	Inactivated quadrivalent influenza vaccine (IIV4)	Healthy adults 18–64 years	0.5 mL PFS or 5 mL MDV	Intramuscular injection or intramuscular jet injector device ("needle free")
Fluzone (Sanofi Pasteur)	Inactivated quadrivalent influenza vaccine (IIV4)	Adults ≥65 years	0.5 mL PFS or 5 mL MDV	Intramuscular injection
High-dose, egg-based vaccine				
Fluzone High-Dose (Sanofi Pasteur)	High-dose inactivated quadrivalent vaccine (HD-IIV4)	Adults ≥65 years	0.7 mL PFS	Intramuscular injection
Standard-dose, cell culture-based vaccine				
Flucelvax Quadrivalent (Seqirus)	Inactivated quadrivalent influenza vaccine (ccIIV4) non-egg based	Individuals ≥6 months	0.5 mL PFS or 5 mL MDV	Intramuscular injection
Standard-dose, egg-based adjuvanted vaccine				
Fluad (Seqirus)	Inactivated quadrivalent vaccine with MF59 adjuvant (aIIV4)	Adults ≥65 years	0.5 mL PFS	Intramuscular injection
Recombinant hemagglutinin vaccine				
Flublok (Sanofi Pasteur)	Recombinant quadrivalent HA vaccine (RIV4)	Adults ≥18 years	0.5 mL PFS	Intramuscular injection
Live attenuated egg-based vaccine				
FluMist (AstraZeneca)	Live attenuated quadrivalent vaccine (LAIV)	Healthy, non-pregnant individuals 2–49 years	0.2 mL prefilled single-use sprayer	Intranasal spray

HD-IIV4: high-dose influenza vaccine, quadrivalent; ccIIV4: inactivated adjuvanted influenza vaccine, quadrivalent; RIV4: recombinant hemagglutinin vaccine, quadrivalent; HA: hemagglutinin; PFS: pre-filled syringe; SDV: single dose vaccine; MDV: multidose vial.

Source: *Hibberd, 2022*

should begin immediately when one laboratory-confirmed case of hospital-associated influenza is confirmed (Uyeki et al., 2019).

In institutional settings with confirmed influenza outbreak, any patient presenting with acute onset of any respiratory symptom, with or without fever, or behavior change should be tested for influenza. Empiric antiviral treatment should be initiated as soon as possible for any patient suspected to have healthcare-associated influenza regardless of incomplete or pending diagnostic test results. All exposed patients should receive antiviral chemoprophylaxis as soon as possible, regardless of vaccination status or laboratory confirmed diagnosis (Uyeki et al., 2019). Also, antiviral chemoprophylaxis should be considered during the institutional outbreak for unvaccinated caregivers and staff and those who were administered an inactivated influenza vaccine during the institutional outbreak and for 14 days post-vaccination for the outbreak's duration (Uyeki et al., 2019).

Referral: Physical therapy for deconditioning due to influenza may be initiated during the acute recovery period and continued upon discharge with home health or skilled nursing services. Referral to an allergist should be considered for patients with history of allergic response to influenza vaccine.

Education: Patient education regarding appropriate prescribing of antibiotics is helpful in decreasing drug-resistant organisms. Teach groups of older adults (especially adults with comorbidities) about preventive measures, including care after discharge, follow-up, and possible vaccination. Educate patient and caregivers about the importance of nutrition, hydration, deep breathing exercises, and smoking cessation (Zachary, 2021).

LUNG CANCER

Signal Symptoms: Cough, dyspnea, weight loss, anorexia, hemoptysis.

Description: Lung cancer is a malignant neoplasm originating in the parenchyma of the lung or airways. Approximately 95% of all lung cancer is classified as non-small cell lung cancer (NSCLC) or small cell lung cancer (SCLC) (National Cancer Institute [NCI], 2020). NSCLC comprises 85% of cancer diagnoses and includes adenocarcinoma, squamous cell cancer, and large cell cancer (NCI, 2020).

Etiology: Research has shown conclusively that smoking is the number one risk factor for lung cancer (Centers for Disease Control and Prevention [CDC], 2020). Lung cancer can also be seen in patients who are never-smokers. The causative factors are not fully understood but are thought to be due to environmental factors, including exposure to second-hand smoke and chemicals such as radon, asbestos, arsenic, and diesel exhaust (CDC, 2020). Prior radiation therapy to the chest can increase the risk of a second primary lung cancer (CDC, 2020). Patients with pre-existing diseases that involve the lungs, such as chronic obstructive pulmonary disease (COPD), prior lung cancers, sarcoidosis, and scleroderma, are at increased risk for developing lung cancer. Studies have shown that patients with pulmonary fibrosis have an 8- to 14-fold increased risk for developing lung cancer (Mannino, 2021). Carriers of an alpha-1 antitrypsin deficiency have a twofold increased risk for lung cancer (Mannino, 2021). Genetic predisposition to carcinoma of the lung continues to be studied, but there is growing evidence that genetics can affect the risk of developing lung cancer and the prognosis (Mannino, 2021).

Occurrence: Lung cancer is the most common cause of cancer-associated deaths in the United States. It is the third most common cancer among men and women. Annually, more than 200,000 new cases of lung cancer are diagnosed and the disease accounts for 21.7% of all cancer deaths (NCI, 2021). More men (60.1 per 100,000 persons) have lung cancer than do women (47.9 per 100,000 persons) (NCI, 2021).

Age: Lung cancer can occur at any age, but there is a dramatic increase in new diagnosis after age 55 years. Most recent statistics show 34.4% diagnosed between 65 and 74 years, 26.6% between 75 and 84 years, and 9.7% among those more than 84 years old (NCI, 2021). More men (60.1 per 100,000 persons) have lung cancer than do women (47.9 per 100,000 persons) (NCI, 2021).

Ethnicity: Black men in the United States have a higher incidence of lung cancer than White men (55.4/100,000 persons vs. 47.1/100,000 persons [NCI, 2021]). No significant difference exists between Black and White women.

Contributing Factors: The cumulative dose or pack-years for cigarette smoking is related directly to the risk of developing lung cancer. The more cigarettes smoked per day and the longer the individual has smoked, the higher the risk of developing lung cancer. The risk of lung cancer is 10 to 30 times higher in smokers than in nonsmokers (Mannino, 2021).

© F.A. Davis Publishing

Cigar and pipe smokers and passive smokers have double the risk. The risks of developing NSCLC steadily decline for people who quit smoking and approach that of a nonsmoker after 15 years of abstinence. Individuals who have smoked for more than 20 years probably always will have a slightly increased risk of developing the disease, even after 15 years as a nonsmoker. Asbestos exposure alone increases the risk of developing pulmonary carcinoma, but when combined with interstitial lung disease, the risk increases. Other inhaled agents implicated in the development of the disease are radon, arsenic, nickel, chromates, halo ethers, alkylating compounds, and polycyclic aromatic hydrocarbons. Radon is a risk factor; air pollution also is thought to contribute to the development of lung cancer. Sarcoidosis carries a threefold increased risk; scleroderma increases risk of bronchoalveolar cancer.

Signs and Symptoms: Signs and symptoms of lung cancer are usually present only after the disease has progressed beyond the early stages. Routine screening for the disease with chest x-ray and/or sputum cytology is not recommended. The U.S. Preventive Services Task Force (USPSTF) (2021) updated lung cancer screening guidelines recommend annual low-dose computed tomography (CT) in adults aged 50 to 80 years with a 20 pack a year smoking history who currently smoke or have quit in the past 15 years. Screening should be discontinued once a person has not smoked for 15 years or develops a health problem that substantially limits life expectancy or ability to have curative lung surgery. Symptoms suggestive of lung cancer include a new or changing cough, hoarseness, hemoptysis, anorexia, cachexia, unexplained weight loss, dyspnea, hypoxia, wheezing, unresolving pneumonia, and chest wall pain (National Comprehensive Cancer Network [NCCN], 2021a). Patients initially may present with symptoms related to extra thoracic disease, including tracheal obstruction, esophageal obstruction with dysphagia, laryngeal nerve paralysis, phrenic nerve paralysis with elevated hemidiaphragm, sympathetic nerve paralysis or Horner's syndrome, pleural effusion owing to lymphatic obstruction, Pancoast's syndrome involving the eighth cervical and first and second thoracic nerves, or superior vena cava syndrome from vascular obstruction (NCCN, 2021a).

Patients with pericardial and cardiac extension of tumor may have symptoms of arrhythmia, tamponade, or failure. The presenting illness in patients with lung cancer may be paraneoplastic syndromes, including hypercalcemia, hypophosphatemia, hyponatremia with syndrome of inappropriate antidiuretic hormone, and hypercoagulable states.

Diagnostic Tests: After a history and physical examination suggestive of disease, the following tests are recommended (note that tissue biopsy results are required for diagnosis):

Noninvasive Testing:

- Chest x-ray: This may show nonspecific abnormalities, hilar masses, atelectasis, pleural effusions or masses, and infiltrates.
- CT scan, preferably with contrast: CT scan can assist in defining the characteristics, size, and location of the primary tumor, lymphadenopathy if present, and any abnormalities of the liver and adrenal glands (NCCN, 2021a,b).
- Fluorodeoxyglucose positron emission tomography (FDG-PET): This is a test that measures the metabolic uptake of glucose by cells; lung cancer cells have a higher cellular glucose uptake than normal cells. It is helpful in diagnosing metastatic disease (NCCN, 2021a,b).
- Magnetic resonance imaging (MRI) of the brain, with contrast: An MRI can assist in identification of brain metastases (NCCN, 2021a,b).

Invasive Testing:

- Transthoracic needle aspiration is usually reserved for specific circumstances.
- Fiberoptic bronchoscopy with biopsies has a very high sensitivity rating for diagnosis.
- Bronchoscopy with CT-guided transbronchial needle aspiration has an important role in diagnosis and staging of lung cancer.
- Endoscopic ultrasound, endobronchial ultrasound, and mediastinoscopy also contribute to staging; mediastinoscopy is considered the gold standard for identifying mediastinal involvement (NCCN, 2021a).
- If abnormalities suggest more extensive cancer, further testing will be conducted looking for extrathoracic, metastatic disease.

Staging: NSCLC staging was revised in 2017 and follows the tumor, node, metastasis (TNM) classification (Detterbeck et al., 2017). Correct staging is essential at diagnosis to identify treatment options, prognosis, and potential for recurrence.

SCLC staging also follows the TNM staging system, but delineates limited stage SCLC as any T, any N, M0, with the exception of T3–4. Extensive stage refers to any T, any N, M1a/b and T3-4 due to involvement of multiple lung nodules (Detterbeck et al., 2017).

Differential Diagnosis: TB, infectious granuloma, pneumonia, empyema, bronchiectasis, abscess, sarcoidosis, pneumonitis, and asbestosis all can mimic lung cancer.

Treatment: Surgical resection, radiation therapy, and chemotherapy are indicated for NSCLC; the stage of the disease, patient's functional status, and histology of the tumor determine the treatments. Recent advances in genotyping and targeting of altered signal mechanisms in lung cancer have allowed targeted treatment with immunotherapy, monoclonal antibodies, anti–vascular endothelial growth factor (anti-VEGF) agents, and other modalities (NCCN, 2021a). Multimodal chemotherapy and radiation are the treatment of choice for limited stage SCLC; cisplatin and etoposide are the preferred agents (NCCN, 2021b). Prophylactic cranial irradiation is done in select patients. In some patients with very limited disease, surgical resection may be done (NCCN, 2021b). Treatment of extensive stage SCLC is chemotherapy combined with immunotherapy for up to 6 cycles and then maintenance immunotherapy until intolerable toxicity or disease progression (NCCN, 2021b). Treatment after relapse is dependent on response to initial chemotherapy. If there is a positive response, the treatment is repeated. If nonresponsive to initial chemotherapy, "salvage chemotherapy" with a nonplatinum, single agent such as topotecan, gemcitabine, or taxane is attempted (NCCN, 2021b). Treatment for older adults should be individualized. A comprehensive geriatric assessment is

© F.A. Davis Publishing

often conducted and used in determining treatment options and the Karnofsky Performance Scale is also used by some specialists (McNair et al., 2022).

Follow-Up: Follow-up is individualized; generally, patients should be seen for follow-up every 3 to 4 months after treatment for lung cancer. During years 3 to 5, follow-up should be every 6 months. Yearly examinations are advised thereafter.

Sequelae: Disability and death are the chief sequelae of lung cancer.

Prevention/Prophylaxis: Prevention of lung cancer should focus on smoking cessation. Ask about and record the tobacco use status of every patient, advise patients who smoke to quit, and offer smoking cessation treatment at every office visit. Screening for lung cancer in asymptomatic patients is not advised. Screening in high-risk patients has not demonstrated any decrease in mortality; newer methodologies studying biomarkers have not been proved to date. The NCCN (2021a) and the USPSTF (2021) have issued guidelines endorsing screening with low-dose helical CT scan in high-risk patients. There is currently no recommended chemoprevention for lung cancer.

Referral: On suspecting lung cancer, refer the patient to a pulmonary specialist. At a later stage, referral to palliative care or hospice may be indicated. Give the patient information on the American Lung Association Information Line (1-800-LUNGUSA). Referral to a mental health specialist is indicated in severe depression unresponsive to treatment.

Education: Many smoking cessation programs are available. Examples include the National Cancer Institute Tobacco Quitline, the American Academy of Family Physicians Stop Smoking Kit, various pamphlets from the American Cancer Society, and A Healthy Beginning Counseling Kit from the American Lung Association; the Web site www.smokefree.gov is another resource. The primary health-care provider can assess the smoker's motivation to quit and offer brief motivational interventions at each visit. Provide information about support groups and community programs available to help with smoking cessation.

When a patient is diagnosed with lung cancer, education about type of cancer, treatment options, and prognosis is very important. This is typically done by the oncology team, but primary care providers can monitor for patient questions and communicate this to the specialty team.

PNEUMONIA

Signal Symptoms: Chills or hyperthermia, fever, sweating, chest discomfort or dyspnea, a new or worsening chronic cough with or without sputum. Nonspecific symptoms include fatigue, weakness, abdominal pain, nausea, appetite loss, headache, myalgia, and exacerbation of other chronic illnesses. In older adults, atypical presentations with confusion, increased falls, functional decline, or other nonrespiratory symptoms are more common, often leading to delayed treatment and increased mortality (Grief & Loza, 2018; Henig & Kaye, 2017; Lanks et al., 2019).

Description: Community-acquired pneumonia (CAP) is an acute lower respiratory tract infection of the lung parenchyma in which consolidation occurs as exudate fills the alveoli. CAP can be bacterial or viral. It begins outside of the hospital or is diagnosed within 48 hours of admission without recent (14 day) residence in a long-term care (LTC) facility. Hospital-acquired pneumonia (HAP) is defined as infection occurring 48 hours or more after hospital admission (Lanks et al., 2019).

© F.A. Davis Publishing

Ventilator-associated pneumonia (VAP), the most frequently acquired intensive care unit (ICU) infection, develops after 48 hours of endotracheal intubation. Cumulative risk increase corresponds with number of mechanical ventilation days, but identification of VAP most commonly occurs between days 5 and 9. Multiple factors contribute to VAP, including microaspiration, pathogenic colonization of the endotracheal tube and surrounding structures (oropharynx, sinuses, and stomach), secretions around the cuff, and impairment of secretion clearance within the airway (Modi & Kovacs, 2020b; Papazian et al., 2020).

Etiology:

Community-Acquired Pneumonia: The most common organism associated with CAP infection is *Streptococcus pneumoniae*. It is responsible for more than 25% of cases worldwide. Other common pathogens include *Mycoplasma pneumoniae, Chlamydophila pneumonia*, *Haemophilus influenzae, Legionella* species, and *Staphylococcus aureus.* Multi-drug resistant organisms (MDRO) such as methicillin-resistant *S. aureus* (MRSA) and *Pseudomonas aeruginosa* have also been identified as causative pathogens but are less common in patients with CAP. *S. aureus, S. pneumoniae,* and *H. influenza* are most commonly reported as causative organisms in LTC residents. Infection with MDROs is closely associated with disease severity and risk for hospitalization (Henig & Kaye, 2017; Lanks et al., 2019).

Hospital-Acquired and Ventilator-Associated Pneumonia: HAP in older patients can also be caused by *S. pneumonia and S. aureus;* however, other gram-negative bacilli, including *P. aeruginosa, Klebsiella pneumonia, Enterococcus coli,* and *Enterobacter species* account for a large number of cases. It is common to have a mixture of multiple organisms, including viruses such as influenza or SARS-CoV-2. The most common pathogens found in VAP are similar to those in HAP. Variations in microorganisms responsible for VAP are more likely related to ICU characteristics, the patient's underlying clinical condition, and length of mechanical ventilation (Lanks et al., 2019; Luyt et al., 2018).

Occurrence: Pneumonia and influenza together are the eighth leading causes of death in the United States. The World Health Organization (WHO) (2020) reports lower respiratory infections as the fourth leading cause of death worldwide and the leading cause of death due to infectious disease. Annual occurrence rates of CAP in adults younger than 65 years old in the United States are 24.8 cases per 10,000 persons. The incidence sharply increases with age to 63 cases per 10,000 persons aged 65 to 79 and 164 cases per 10,000 persons aged 80 and older (Herron, 2021; WHO, 2020).

Approximately 1 million adults seek hospital care each year due to pneumonia. Aside from childbirth, pneumonia is the leading cause of hospitalization for adults and causes 50,000 deaths each year. The emergency department (ED) visit rates for patients with pneumonia are 7.9 per 1,000 persons, and 12.2 per 1,000 persons for patients with both influenza and pneumonia. The ED visit rates also increase with age, from 7.1 per 1,000 adults aged 18 to 44 to 45.6 per 1,000 adults aged 85 and older (Arnold et al., 2020; Herron, 2021).

Approximately 30% of adults diagnosed with pneumonia require hospitalization on average. Hospitalization rates for older adults with pneumonia are 2 to 4 times higher than those of younger people. The mortality rate for intensive care unit (ICU) patients due to pneumonia is approximately 23%. Mortality risk increases with age and disease severity (Henig & Kaye, 2017; Herron, 2021; WHO, 2020). The number of deaths due to pneumonia and influenza is greater for women compared to men (Herron, 2021).

Age: Pneumonia is the most common cause of death from infectious disease in older adult patients (Herron, 2021).

Ethnicity: Cause of death due to pneumonia and influenza is highest among Americans of Asian and Pacific Islander descent and lowest among non-Hispanic Black and White persons (Herron, 2021).

Contributing Factors: Modifiable risk factors for acquiring pneumonia include tobacco use, alcohol use, protein-calorie malnutrition, and poor dental hygiene. Other contributing factors include age and comorbidities such as influenza, chronic obstructive pulmonary disease (COPD), structural lung disease, renal impairment, and cardiovascular disease. Other comorbidities that increase patient aspiration risk, such as dementia, stroke, and epilepsy, should also be considered (Lanks et al., 2019). Colonization of the oropharynx by gram-negative bacteria, an institutional setting, decline in immune function, hospitalization, use of sedating medications and proton-pump inhibitors, recent surgery or trauma, and diminished cough reflex also contribute to development of pneumonia. Presence of multiple risk factors are additive in weighing patient overall risk (Mandell & Niedermann, 2019; Modi & Kovacs, 2020b).

The greatest risk factor for HAP is mechanical ventilation. Other significant risk factors for include:

- Older age
- Reintubation or prolonged intubation
- Depressed consciousness
- Aspiration
- Trauma
- Chest or upper abdominal surgery
- Comorbidities
- Recent or current use of antibiotic therapy, especially broad-spectrum coverage
- Genetic polymorphisms
- Presence of an intracranial pressure monitor or nasogastric tube
- Agents that increase gastric pH (H_2 blockers, antacids, proton pump inhibitors)
- Paralysis
- Total opioid exposure
- Multiple surgeries and/or central venous catheter placements
- Frequent ventilator circuit changes
- Paralysis
- Underlying illness such as protein-calorie malnutrition, anemia, or chronic renal insufficiency
- Charlson Comorbidity Index (CCI) ≥ 3 (Klompas, 2022a).

The most significant risk factor associated with VAP is length of mechanical ventilation. Ten percent of patients ventilated for over 2 days will be diagnosed with VAP. Other risk factors include site-specific issues (poor compliance with VAP prevention bundle), immune system compromise, comorbidities, adult respiratory distress, patient positioning,

© F.A. Davis Publishing

and medications. Risk factors for VAP due to MDR pathogens include:

- Intravenous antibiotics treatment (within past 90 days)
- Septic shock
- Acute respiratory distress syndrome preceding VAP
- Acute renal replacement therapy preceding VAP
- Hospitalization of greater than or equal to 5 days before VAP diagnosis (Jean et al., 2020; Klompas, 2022b; Metersky & Kalil, 2018; Papazian et al., 2020).

Factors most associated with pneumonia-related deaths are age, disease severity, and number of chronic comorbidities. Chronic obstructive pulmonary disease, diabetes mellitus, cancer and dementia diagnoses are associated with pneumonia 1-year mortality risk. Rehospitalization within 30 days of discharge is another contributing factor (File, 2020a; Klompas, 2022a).

The CURB-65 score is used to stratify risk in patients with CAP. The five indicators that comprise the CURB score include the following:

- Confusion
- Blood urea nitrogen level greater than 19 mg/dL
- Systolic blood pressure <90 mm Hg or diastolic blood pressure ≤0 mm Hg
- Respiratory rate ≥30 per minute
- Age ≥65 years (Yealy & Fine, 2021)

There is a 21-fold increase in mortality among patients with two or more symptoms, specifically elevated BUN, decreased diastolic blood pressure, and/or tachypnea. A nine-fold increase in mortality is associated with presence of all three of these symptoms. The CURB-65 tool was designed to help guide provider decision making regarding need for hospitalization. With a score ≤1 the patient is considered low risk and can be treated at home, with a score of ≤2 it is recommended that the patient have a short inpatient hospitalization or be closely supervised in outpatient treatment. Providers should consider hospitalization and ICU care for a CURB score ≥3 (File, 2020a; Yealy & Fine, 2021). An interactive version of the score is available on the Web at https://www.mdcalc.com/curb-65-score-pneumonia-severity.

The pneumonia severity index (PSI) was designed to predict the 30-day mortality rate of patients with CAP and aid provider decision making related to need for home health support or inpatient hospitalization. The PSI score is calculated based upon patient demographic factors, comorbidities, physical examination findings, laboratory, and imaging studies with higher scores indicative of greater disease severity (Yealy & Fine, 2021). The PSI is most useful in the acute care setting where rapid laboratory results can be attained. An interactive PSI resource is available on the Web at https://www.mdcalc.com/psi-port-score-pneumonia-severity-index-cap.

Additional factors associated with pneumonia-related mortality include delirium, hypotension, hypothermia, multilobar disease, and laboratory abnormalities such as leukopenia, thrombocytopenia, thrombocytosis, and hyperglycemia. Increased mortality risk has been found with *S. aureus,* and gram-negative organisms including *P. aeruginosa* and *Klebsiella* species. Mortality risk is also increased for patients infected with drug resistant organisms and pneumonia due to multiple organisms (i.e., viral and bacterial disease) (File, 2020a).

Signs and Symptoms: The typical patient may present with subjective complaints of fever, chills, cough (with or without sputum), fatigue, malaise, dyspnea, decreased appetite and/or pleuritic chest pain. These symptoms however are commonly absent in individuals who are frail and in older adults, leading to a lag time before diagnosis. In the older patient, altered mental status (delirium), new onset or increased frequency of falls, increased respiratory rate, hypotension, anorexia, a marked functional decline, and new onset of urinary incontinence are typical symptoms. (Henig & Kaye, 2017; Ramirez, 2021).

Physical examination findings may include tachypnea, tachycardia, hypoxemia, accessory muscle use, tactile fremitus, dullness on percussion, and egophony. Adventitious lung sounds such as a wheeze and/or crackles that do not clear with cough or deep breathing are typical. Patients may also present with signs of dehydration and appear anxious, restless, or withdrawn (Henig & Kaye, 2017; Ramirez, 2021).

The most current guidelines for HAP/VAP diagnosis and management were released by the IDSA and American Thoracic Society (ATS) in 2016. These guidelines specify that diagnoses should be made based on clinical criteria alone and must include all the following:

- New or worsening pulmonary infiltrate on chest imaging
- Fever
- Increased oxygen requirement
- Productive cough

Fever and increased purulent secretions are common in HAP/VAP, and patients usually have diffuse rhonchi with an inability to mobilize secretions and may have either leukocytosis or leukopenia. Crackles, diminished breath sounds, tachypnea, wheezing, and hemoptysis, are common findings (Fernando et al., 2020; Metlay et al., 2019).

Diagnostic Tests: The diagnosis of CAP may be difficult in patients with underlying chronic comorbidities, especially those with pulmonary fibrosis, lung cancer or other chronic lung diseases, and heart failure. Recommendations for diagnostic testing continue to be controversial; however, the chest x-ray is considered the gold standard for the diagnosis of CAP. Other routine testing for patients treated on an outpatient basis is not recommended (Metlay et al., 2019; Modi & Kovacs, 2020a; Ramirez, 2021).

Laboratory Testing: Routine blood tests, including CBC with differential and basic metabolic panel, are helpful to determine disease severity and need for hospitalization. Leukocytosis with left shift is the most common abnormal finding. Measurement of C-reactive protein and/or procalcitonin can be helpful in distinguishing between bacterial or viral pneumonia. These tests should not be used to diagnose but can be helpful to prescribe appropriate treatment course and setting. (Klompas, 2022c; Modi & Kovacs, 2020a).

Diagnostic Imaging: CT scans of the chest are often ordered and are more accurate than chest x-ray, especially in the ED setting. CT scan should be considered for patients with negative chest x-ray and clinical presentation highly suspicious for pneumonia in addition to immunocompromised patients or those with structural lung disease (Ramirez, 2021). Studies have shown that ultrasound of the chest has better sensitivity and specificity than a chest x-ray and is comparable to that of a CT scan (Huggins & Mayo, 2021).

© F.A. Davis Publishing

Pulmonary infiltrate, lobular consolidation, or opacities found on chest x-ray, CT scan, or ultrasound confirm the diagnosis of pneumonia; however, chest x-rays have lower sensitivity and positive predictive rates compared to CT scan and thoracic ultrasonography. Validity of chest x-ray results are affected by interrater variability and patient-specific characteristics. (Klompas, 2022c; Modi & Kovacs, 2020a).

Microbiological Testing: Microbiological tests should be reserved for patients admitted to the hospital. Noninvasive respiratory cultures are preferred over invasive techniques and are recommended for patients with VAP, HAP (non-VAP), or severe CAP. Noninvasive cultures are more cost-effective, have faster turnaround, and offer a nonempiric approach to treatment. Treatment course for VAP, HAP, and hospitalized patients with CAP should be based upon clinical criteria and noninvasively obtained respiratory specimens or endotracheal aspirate (Kalil et al., 2016; Metlay et al., 2019).

Blood cultures are recommended for hospitalized adults with VAP, HAP, or severe CAP at time of diagnosis. Bacteremic pneumonia is indicative of disease severity and occurs in approximately 25% of cases. Urinary antigen test to detect pneumococcal disease is appropriate, and specificity for these assays exceeds 98% in adults. Urine antigen assay to identify *Legionella* pneumonia should be reserved for those patients with known exposure or recent travel (Doern, 2021; Metlay et al., 2019; Musher & Tuomanen, 2021).

Differential Diagnosis: The differential diagnoses of CAP are dependent on the results of the chest x-ray. Differentials for those with a positive chest x-ray include:

- Aspiration or chemical pneumonitis
- Pulmonary embolism
- Heart failure with pulmonary edema
- Exacerbation of pulmonary fibrosis or bronchiectasis
- Acute eosinophilic pneumonia
- Interstitial lung diseases
- Atelectasis
- Lung cancer
- Drug reactions
- Lung injury associated with e-cigarette, vaping products (EVALI) or cocaine use

For those without an abnormal chest x-ray the differentials are:

- COPD, asthma, or bronchiectasis exacerbations
- COVID-19
- Influenza
- Pertussis
- Acute bronchitis
- Upper respiratory tract infection (Klompas, 2022c; Ramirez, 2021).

Early stage VAP occurs within 48 hours of intubation, whereas later stage VAP emerges after the fourth day of intubation and is more likely to be associated with MDR bacteria. Differential diagnosis for VAP includes ventilator-associated respiratory infection and ventilator-associated tracheobronchitis (Jean, 2020).

Treatment: A crucial element in treatment is determining the severity of the illness and the setting, but other factors including oral intake, adherence, substance abuse, mental illness, cognitive impairment, patient function, and living situation. For community-dwelling older patients, the presence of a responsible caregiver and a supportive home environment is necessary. Temporary measures to increase support and monitor status of response may be introduced by ordering home health services. If the patient fails to recover or deteriorates despite these interventions, hospitalization should be contemplated. IDSA/ATS guidelines advocate the use of the PSI as a guide for determining outpatient treatment versus hospitalization (Metlay et al., 2019; Yealy & Fine, 2021).

Use of any prediction rule or tool should be tempered by clinical judgment. Objective criteria for hospital admission include (Ramirez, 2021; Yealy & Fine, 2021):

- Support at home
- Inability to take oral medications or fluids
- Delirium
- Severe acute metabolic, hematological, or electrolyte abnormalities
- Acute concomitant medical condition (e.g., malignancy, hepatic disease, renal insufficiency, cardiac disease)
- Hypoxemia on room air (PaO_2 less than 60 mm Hg)
- Multilobular involvement on chest x-ray
- Secondary suppurative infection
- Severe vital sign abnormality (systolic blood pressure less than 90 mm Hg, pulse greater than 125/min, respirations greater than 30/min)

CAP: The latest consensus guidelines from the IDSA/ATS for CAP (Metlay et al., 2019) support the following recommendations:

- Outpatient treatment for previously healthy adults with no risk factors for drug-resistant pathogens should consist of amoxicillin, a macrolide or doxycycline.
- Outpatient treatment for healthy adults who have been on an antibiotic in the previous 3 months should consist of a macrolide or respiratory fluoroquinolone (levofloxacin or moxifloxacin).
- Outpatient treatment for those with comorbidities, including diabetes mellitus, malignancies, alcoholism, chronic heart, lung, liver and or renal disease; recent hospitalization and receipt of oral antibiotics within the past 90 days; or history of MRSA or *P. aeruginosa,* monotherapy treatment should consist of a respiratory fluoroquinolone. Alternatively, combination therapy with a beta-lactam or cephalosporin and either macrolide or doxycycline may be considered based on patient characteristics.
- Outpatient treatment for those in an area with more than 25% macrolide-resistant *S. pneumoniae,* consider combination therapy with a beta-lactam or cephalosporin plus either macrolide or doxycycline or monotherapy with respiratory fluoroquinolone.
- Inpatient treatment of CAP (non-severe) should include a respiratory fluoroquinolone monotherapy or combination therapy with beta-lactam and macrolide; cefotaxime, ceftriaxone, ceftaroline, and ampicillin plus sulbactam are preferred.
- Inpatient treatment of severe CAP (requiring ICU management) with monotherapy is not recommended. Combination therapy should consist of beta-lactam antibiotic and either macrolide or respiratory fluoroquinolone.

© F.A. Davis Publishing

- Inpatient treatment of CAP with *Pseudomonas* risk factors should include a beta-lactam antibiotic (piperacillin/tazobactam, cefepime, ceftazidime, imipenem, meropenem, aztreonam) plus fluoroquinolone (levofloxacin or ciprofloxacin).
- Inpatient treatment of CAP with MRSA risk factors should include additional coverage with either vancomycin or linezolid.
- Doxycycline is an accepted substitution only when the patient has contraindications for both macrolide and fluoroquinolone treatment.
- Treatment should be instituted as soon as possible, and transition from IV to oral therapy should occur as soon as the patient is hemodynamically stable, shows clinical improvement, can ingest oral medications, and has no gastrointestinal tract problems. Duration of therapy is 5 to 7 days for those with mild infection and 7 to 10 days for those with severe infection or chronic comorbidities. Treatment should not be discontinued until the patient has been afebrile and clinically stable for a minimum of 48 hours (Metlay et al., 2019; Ramirez, 2021).

HAP and VAP: The most current guidelines for management of adults with HAP and VAP were published by the IDSA/ATS in 2016 (Kalil et al., 2016). After the potential for HAP/VAP is identified and specimens have been obtained, rapid empirical treatment with local antibiogram-driven choice of antimicrobial should be started. Knowledge of local resistance patterns, extent of MRSA, and other regional factors is essential. Treatment should be tailored to optimize antibiotic therapy and prevent resistance using pharmacokinetic and pharmacodynamic data (blood levels). The current guidelines recommend treatment for 7 days. Patients on IV antimicrobial therapy should be switched to oral therapy as soon as possible. Patients who are clinically stable and improving should be transitioned to oral antibiotics assuming they can tolerate oral medication (Kalil et al., 2016; Klompas, 2022b; Metersky & Kalil, 2018).

Routine treatment with adjunctive glucocorticoids is not recommended. The use of glucocorticoids in the treatment of HAP/VAP has had varying results and should be reserved for patients who may benefit from their anti-inflammatory effects. Glucocorticoid use is only recommended for critically ill ICU patients, defined by:

- Septic shock or respiratory failure with FiO_2 requirement of >50% plus or more of the following:
- Metabolic acidosis with arterial pH <7.3, lactate >4 mmol/L, or C-reactive protein >150 mg/L (File, 2021; Kalil et al., 2016).

Follow-Up: Follow-up depends on comorbidities and response to the prescribed treatment regimen. All patients diagnosed with CAP should schedule a follow-up office visit within a few days after the initial diagnosis and after completion of treatment, with future follow-up as needed. Patients should be instructed to call if symptoms worsen, if no response occurs after 3 to 5 days of treatment, or if symptoms recur. In most cases, follow-up chest x-ray is not necessary. In patients with comorbidities, smokers, and those older than 40 years old repeat chest x-ray after 7 to 12 weeks may be indicated (File, 2021).

Sequelae: The older patient with comorbidities is especially prone to complications and has a higher long-term mortality rate than those without comorbidities (Arnold et al., 2020; Henig & Kaye, 2017; Ramirez, 2021). Serious complications can occur with pneumonia, including respiratory failure and sepsis. Cardiovascular complications may occur and commonly include acute myocardial infarction (MI), heart failure, arrhythmias, pulmonary embolism, and stroke. Increased mortality is largely attributed to comorbidities and underlying illness, especially cardiovascular disease, COPD, diabetes, and renal disease (Arnold et al., 2020; Klompas, 2022a; Ramirez, 2021).

Prevention/Prophylaxis: Strategies for CAP prevention include smoking cessation and annual influenza vaccination and pneumococcal vaccination for at risk populations. Most current guidelines recommend that PPSV23 be administered to all patients 65 years and older. Those who have already received one dose of PPSV23 before age 65 should receive a booster 5 years after the first administered dose (Centers for Disease Control and Prevention [CDC], 2022; Ramirez, 2021).

In 2019, ACIP updated their recommendations regarding administration of PCV13 to all adults aged 65 and older. The current recommendation is to administer PCV13 to adults aged 65 and older with an immunocompromising condition, cerebrospinal fluid leak, or cochlear implant. Administration of PCV13 should be done first and at least one year apart from PPSV23. For immunocompetent adults, vaccination with both PCV13 and PPSV23 should be based on patient-provider shared clinical decision-making discussion. Healthy community-dwelling adults aged 65 or older are at low risk of exposure to pathogens covered by PCV13. This is due to the routine administration of this vaccine to children since 2010, reducing pneumococci transmission (Matanock et al., 2019).

Nursing home residents and adults residing in communities with low childhood vaccine uptake are at increased risk for pneumococcal disease. Adults with history of chronic heart, lung or liver disease, diabetes, alcoholism, and smoking are also at increased risk if they are exposed. PCV13 vaccine recommendation would be reasonable for these populations therefore, and a discussion regarding risk versus benefit of immunization should be prioritized. Patients hospitalized for pneumonia may be immunized before discharge (CDC, 2022; Matanock et al., 2019).

Best practices for VAP prevention include (Klompas, 2022a):

- Using noninvasive positive pressure ventilation
- Avoiding patient sedation whenever possible
- Instituting daily sedation vacations
- Assessing daily assessment extubation readiness
- Facilitating early mobility
- Changing ventilator circuits only if visibly soiled or malfunctioning
- Elevating the head of bed 30 to 45 degrees
- Using endotracheal tubes with subglottic secretion drainage ports (for patients expected to require mechanical ventilation 48 hours or longer)
- Using selective oral or digestive decontamination
- Performing routine oral care with chlorhexidine

Referral: Physical therapy measures for strengthening and ambulation may be initiated during the acute recovery period

© F.A. Davis Publishing

and continued during convalescence or replaced by restorative nursing measures. For those with chronic comorbidities, follow-up or referral to the appropriate specialist is indicated.

Education: Provider education regarding appropriate prescribing of antibiotics is helpful in decreasing drug-resistant organisms. Teach groups of older adults (especially adults with comorbidities) about preventive measures including care after discharge, follow-up, and possible vaccination. Educate patient and caregivers about the importance of nutrition, hydration, deep breathing exercises, and smoking cessation (Klompas, 2022a).

PULMONARY EMBOLISM

Signal Symptoms: Subjective: Acute onset chest discomfort, palpitations, dyspnea, dizziness, anxiety. Objective: often nonspecific findings, such as tachypnea, tachycardia, S_3, tricuspid regurgitation murmur, chest wall, back, or flank tenderness. Pulmonary embolism (PE) is difficult to diagnose due to variability in presentation (Rivera-Lebron et al., 2019). Some pulmonary emboli are asymptomatic and might be found incidentally on imaging. Clinical symptoms alone should not be used to confirm or exclude PE, instead probability scores and diagnostic algorithms should be utilized (Doherty, 2017; Kearon et al., 2016).

Description: PE is a life-threatening condition. It is the occlusion of the pulmonary artery or one of its branches by a thrombus originating from elsewhere in the body. A blood clot is the most common embolism, although fat, air, bone marrow, tumor cells, and foreign material also can occlude the pulmonary vasculature. A blood clot PE is one component of venous thromboembolism (VTE), which also encompasses deep venous thromboembolisms (Robertson & Jones, 2017).

Etiology: PE usually is caused by a dislodged thrombus from one of the veins of the legs or pelvis (deep vein thrombosis [DVT]). Most emboli are believed to arise from areas of decreased blood flow in the lower extremity proximal veins (iliac, femoral, popliteal). More than 50% of patients with proximal vein DVT also present with PE (Robertson & Jones, 2017).

Occurrence: The estimated incidence of PE is one to two per 1,000 (about 900,000 per year) in the United States. Both PE and DVT are VTE, and they often occur concurrently.

© F.A. Davis Publishing

PE is the third leading cause of vascular death after myocardial infarction (MI) and stroke, and 10% to 30% of patients will die of VTE within 1 month of diagnosis (Centers for Disease Control and Prevention [CDC], 2015).

Age: Risk of VTE increases with age, and more so in men than in women. However, many risk factors increase relative risk separate from age, such as oral contraceptive use or lifestyle choices such as smoking (Phillippe, 2017).

Ethnicity: Incidence varies by race; highest incidence is in those of African American descent, with Europeans in North America and Europe almost as prevalent. There is lower incidence in Hispanic, Asian, and Native American populations (Zakai & McClure, 2011).

Contributing Factors: PE may occur unprovoked or secondary to an environmental risk factor. Persistent risk factors include cancer, heart failure, obesity, and varicose veins. Transient risk factors include immobility such as bedrest of more than 3 days, presence of a central venous catheter, insertion of a pacemaker, or use of estrogen. Virchow triad of stasis or prolonged immobility, hypercoagulation, and venous trauma (endothelial injury with inflammation of the vessel lining) is a leading cause (Phillippe, 2017). Unprovoked PE is associated with nonenvironmental risk factors, such as age, male sex, and hereditary thrombophilias (e.g., deficiencies of natural coagulation inhibitors such as antithrombin, protein C and S, factor V Leiden, and prothrombin (Factor II) G20210A. Pregnancy, especially in the postpartum period, oral contraceptives, and hormone replacement therapy increase PE risk as well (Phillippe, 2017).

Signs and Symptoms: Signs and symptoms of PE tend to be nonspecific. Less than 20% of patients present with classic symptoms of chest pain, dyspnea, or hemoptysis. The Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED II) study showed that 97% of patients had more than one of the symptoms of dyspnea, pleuritic chest pain, and tachypnea; however, the great variability in presentation and multitude of potential causes for those symptoms make it difficult to diagnose PE without laboratory tests or imaging (Rivera-Lebron et al., 2019). A thorough history and review of system should reveal any subjective experiences such as acute onset chest discomfort, palpitations, dyspnea, dizziness, anxiety. This should be complemented by physical examination, which in case of PE may reveal tachypnea, tachycardia, S_3, tricuspid regurgitation murmur, chest wall, back, or flank tenderness. Auscultation of the lungs may be normal or may show localized wheezing, consolidation, or friction rub. Jugular venous distention and atrial arrhythmia may be present. Examination of the legs, especially of the iliofemoral and popliteal areas, may reveal signs of DVT. The arms, abdomen, and pelvic areas also should be examined for pain, erythema, or palpable vein cords. In the case of a massive PE, hypotension, circulatory instability, and cyanosis may be present (Rivera-Lebron et al., 2019). Some pulmonary emboli are asymptomatic and might be found incidentally on imaging. Clinical symptoms alone should not be used to confirm or exclude PE, instead probability scores and diagnostic algorithms should be utilized (Doherty, 2017; Kearon et al., 2016).

Diagnostic Tests: Clinical judgment in conjunction with clinical prediction scoring tools and diagnostic studies is recommended. The Wells Clinical Prediction Scoring Tool for Pulmonary Embolism considers clinical symptoms, tachycardia, recent immobility or surgery, hemoptysis, malignancy, and prior DVT/PE to help assign a pretest probability of PE (Table 11-5). A high Wells score does not require a d-dimer; instead, it should prompt imaging (Doherty, 2017).

TABLE 11-5 Wells Criteria

Clinical symptoms of DVT (minimum of leg swelling, pain with palpation of the deep veins)	3.0
An alternative diagnosis less likely than pulmonary embolism	3.0
Heart rate >100	1.5
Immobilization or surgery in the previous four weeks	1.5
Previous DVT/PE	1.5
Hemoptysis	1.0
Malignancy (on treatment, treated in the last six months or palliative)	1.0
Simplified clinical probability assessment	
PE likely	>4.0
PE unlikely	≤4.0

DVT: deep vein thrombosis.

From Wells, P. S., et al. (2000). Derivation of a simple clinical model to categorize patients probability of pulmonary embolism: Increasing the models utility with the SimpliRED D-dimer. Thromb Haemost; 83: 416-20. © Georg Thieme Verlag KG.

The chest x-ray is often abnormal, but usually nonspecific. It is used primarily to rule out other causes of symptoms such as pneumonia or heart failure. Electrocardiogram (ECG) changes that show signs of right ventricular strain, T-wave inversion in leads V1 to V4, QR pattern in V1, new-onset right bundle branch block, or S1Q3T3 complex can sometimes be seen in severe cases of PE. Mild PE cases may only reveal sinus tachycardia or atrial arrhythmias such as atrial fibrillation. PE patients may also have normal ECGs, which is why they are not normally considered diagnostic. In a patient deemed to be at low or intermediate risk of PE, a negative enzyme-linked immunosorbent assay (ELISA) d-dimer test can rule out the possibility of PE. The ELISA or ELISA-derived d-dimer assays have a sensitivity of 95% and can exclude PE in patients with a low to intermediate pretest probability (Doherty, 2017; Kearon et al., 2016; Konstantinides et al., 2019; Rivera-Lebron et al., 2019). The sensitivity of d-dimer testing varies; it increases with the extent of PE, and it decreases with age to only 10% in patients older than 80 years. D-dimer is nonspecific; it can also be elevated in the patient with cancer, during hospitalization, and in pregnant patients. Some studies suggest age-adjusted cutoffs to improve d-dimer testing in older adults (Konstantinides et al., 2019). Along with a high Wells score it may be found diagnostic, but in patients with low Wells scores, imaging should be pursued (Doherty, 2017).

Multidetector CTA (MDCTA) is widely available, and when used with IV contrast, the MDCTA can outline thrombi in the pulmonary arteries. MDCTA has almost replaced lung scanning and angiography as the standard for PE diagnosis (Doherty, 2017). Limitations for using MDCTA include patients

© F.A. Davis Publishing

with renal dysfunction, allergy to contrast media, possible pregnancy, critical illness, requiring ventilator support, or recent MI. In these cases, a ventilation/perfusion (V/Q) scan may be done. Additionally, if there is a high suspicion of PE but a negative MDCTA, a V/Q scan may be ordered. However, most clinicians feel more comfortable with MDCTA as a diagnostic tool because of its ability to provide anatomical demonstration of presence of a clot versus relying on the V/Q scans to assess the probability of embolism based on V/Q mismatch. V/Q scanning is done in the nuclear medicine department and may not be as readily available as MDCTA in many cases (Konstantinides et al., 2019; Rivera-Lebron et al., 2019).

Echocardiography is not recommended to diagnose PE, but it can help determine risk of mortality or adverse outcome. An echocardiogram can evaluate right ventricular function and detect a free-floating thrombus in the right heart, which can be associated with PE and increased mortality. In addition, if a massive PE is diagnosed, transesophageal echocardiography should be done to assess right ventricular function (Kearon et al., 2016; Konstantinides et al., 2019; Rivera-Lebron et al., 2019)

The myocardial markers, including cardiac troponin levels and BNP or NT-proBNP have no role in the diagnosis of PE but may serve to rule out other processes, reflect severity of PE, and have been associated with increased mortality (Rivera-Lebron et al., 2019).

Differential Diagnosis:

- Pneumonia
- MI
- Pericarditis
- Heart failure
- Pleural effusion
- Panic attacks
- Hyperventilation syndrome
- Pneumothorax
- Esophageal rupture
- Gastritis
- Gastric or duodenal ulcer
- Gastroesophageal reflux disease (GERD)
- Asthma
- Musculoskeletal pain
- Mediastinitis

Treatment: Treatment recommendation varies by PE severity, which is classified by hemodynamically stable or unstable patient status, by time of onset, and by location. Anticoagulation is the cornerstone of treatment. Goal of anticoagulation is to prevent early death, recurrence, or fatal VTE/PE. If no contraindications, anticoagulation should be initiated immediately in patients with high or moderate suspicion of PE while awaiting diagnostic test results. For acute PE, low molecular weight heparin (LWMH) is preferred over unfractionated heparin to reduce complications, but there is no difference in mortality (Robertson & Jones, 2017).

Severity of PE presentation may be determined by hemodynamic stability. In patients with a massive PE, acute right ventricular failure and low systemic output is the leading cause of death. Treatment should be individualized and supportive and may include the use of vasopressors. Oxygen administration and/or mechanical ventilation may be needed to reverse hypoxia (Konstantinides et al., 2019). If the patient is hemodynamically unstable (systolic blood pressure <90, heart rate <40) or is presenting with worsening respiratory insufficiency, severe right ventricular dysfunction, or major myocardial necrosis but has a low risk of bleeding complications, the patient should be treated in the inpatient setting with heparin and alteplase (Kearon et al., 2016). Catheter embolectomy or surgical embolectomy may be considered if absolute or severe contraindications to systemic thrombolysis or after failed thrombolysis (Rivera-Lebron et al., 2019).

Oral anticoagulation should be initiated simultaneously with or shortly after parenteral anticoagulation. Warfarin (Coumadin) has been the gold standard vitamin K antagonist (VKA) for more than 50 years and is monitored by measuring the international normalized ratio (INR). With warfarin therapy, an INR of 2.0 to 3.0 should be maintained. Long-term anticoagulation recommendations depend on existence of comorbidities such as cancer. If no cancer is present, direct oral anticoagulants (DOACs) and VKAs are preferred over LWMH; if cancer is present, LWMH is preferred. For anticoagulated patients, no IVC filter or compression stockings are recommended (Doherty, 2017; Robertson & Jones, 2017).

Follow-Up: Follow-up visits are on an individualized basis. Anticoagulation usually is continued for a minimum of 3 to 6 months after PE. Experts differ on optimal length of therapy and dosing adjustments in specific situations. CHEST 2016 guidelines recommend at least 3 months of anticoagulant therapy for provoked or unprovoked PE. The risk-benefit ratio should be evaluated after 3 months of therapy for the unprovoked PE. For the unprovoked first-time VTE with low to moderate bleeding risk, CHEST guidelines recommend extended anticoagulant therapy (no scheduled stop date). If bleeding risk is high, 3 months of anticoagulant therapy is recommended. In any case of extended anticoagulant therapy, risk–benefit for continued treatment should be reassessed at periodic intervals (i.e., annually). Extended therapy is recommended for the patient with active cancer and PE regardless of bleeding risk, keeping in mind the need to reassess risk–benefit periodically (Kearon et al., 2016).

Sequelae: Unrecognized PE can be fatal and is associated with overall mortality of up to 30% within the first month. Most deaths occur rapidly, and PE may only be diagnosed after death (CDC, 2015; Rivera-Lebron et al., 2019). Cardiac right ventricular function may become permanently affected leading to heart failure. Other complications include alveolar collapse, atelectasis, and pulmonary infarction. Complications from anticoagulation include uncontrolled bleeding and hematoma (Rivera-Lebron et al., 2019).

Prevention/Prophylaxis: PE is one of the most common preventable causes of hospital deaths in the United States. Patients should avoid controllable risk factors for PE such as sedentary lifestyle, obesity, and smoking. Encourage frequent ambulation, safety precautions to avoid injury to lower extremities, evaluation of possible hypercoagulation pathology, and prophylactic anticoagulation after orthopedic surgery of hip or knee. Prolonged sitting should be avoided. Consideration of prophylactic anticoagulation in any immobilized hospitalized patient and use of sequential compression devices may be helpful. Compression stockings and IVC filter

© F.A. Davis Publishing

are no longer recommended because of potential secondary complications (Doherty, 2017; Robertson & Jones, 2017).

Referral: Refer patients to internal medicine or emergency medicine for emergent evaluation and initial treatment plan when PE is suspected. When stable, patients can be managed on warfarin or DOAC therapy and therapy may be de-escalated after 3 to 6 months depending on risk factors. Warfarin requires regular monitoring of INR to maintain a therapeutic range. Although no regular monitoring of DOAC therapy is required for dosing, compliance is of utmost importance in order to achieve adequate therapeutic anticoagulant benefits (Doherty, 2017; Robertson & Jones, 2017).

Education: Provider education about awareness of PE in differential for chest pain or dyspnea is needed. Teach the patient, family, or caregiver about risk factors and preventive measures, disease pathology, monitoring for signs of recurrence, and need for compliance with anticoagulation therapy. Instruct the patient to use a soft toothbrush and an electric razor and to report bleeding gums, hemoptysis, and any blood in stool or urine. Advise patients to avoid aspirin, to consult with their health-care provider before taking any over-the-counter (OTC) medications, and to take precautions to avoid bumping or bruising.

Clinical Recommendation	Evidence Rating	References
Prevention of VTE should be considered according to the patient's baseline risk. Cancer, COVID-19, and other issues may contribute to needing prophylaxis. Acutely or critically ill patients with COVID-19 should receive anticoagulant thromboprophylaxis with low-molecular-weight heparin (LMWH) or fondaparinux over anticoagulant thromboprophylaxis with unfractionated heparin (UFH). Anticoagulant thromboprophylaxis with LMWH, fondaparinux, or UFH is recommended over anticoagulant thromboprophylaxis with a direct oral anticoagulant (DOAC).	A B A	Rivera-Lebron et al., 2019 Moores et al., 2020 Doherty, 2017
Clinical decision making: Estimate probability of PE based on a validated clinical decision tool such as Wells score and Pulmonary Embolism Rule-out Criteria (PERC), then use a validated diagnostic algorithm integrating findings from d-dimer and CTA (CT pulmonary angiography If CTA contraindicated may use ventilation/perfusion (V/Q) scan, or echocardiogram. After PE diagnosis is established: risk stratification is recommended using a composite of clinical appearance, systolic blood pressure, heart rate, respiratory rate, oxygen requirement, Pulmonary Embolism Severity Index (PESI) or sPESI, imaging for rigth ventricular dysfunction (CTA or echocardiography) and/or biomarkers (troponin, BNP or NT-pro-BNP).	A A A A	Doherty, 2017 Kearon et al., 2016 Rivera-Lebron et al., 2019 Konstantinides et al., 2019
Occurrence: 900,000 people could be affected (1 to 2 per 1,000) each year in the United States. 10%–30% of people will die within one month of diagnosis. Sudden death is the first symptom in about one-quarter (25%) of people who have a PE. 60% of all VTE events occur in those 70 years of age and older: The overall incidence of VTE is 1 to 2 per 1,000 person-years in the general population, which rises to 8 per 1,000 person-years in people older than 85 years. There are ethnic differences: highest incidence is in those of African American descent, with Europeans in North America and Europe almost as prevalent.	A A A	CDC, 2015 Phillippe, 2017 Zakai & McClure, 2011
Long-term anticoagulation recommendations depend on existence of comorbidities such as cancer. If no cancer is present, DOACs and vitamin K antagonists are preferred over LWMH, if cancer is present LWMH is preferred. With warfarin therapy an International Normalized Ratio of 2–3 should be maintained. For anticoagulated patients, no IVC filter or compression stockings are recommended.	A	Doherty, 2017 Robertson & Jones, 2017
Immediate anticoagulation is recommended for acute PE. LWMH is preferred over unfractionated heparin to reduce complications, but there is no change in mortality	A	Robertson & Jones, 2017
Thrombolysis: If hemodynamically unstable (systolic blood pressure <90, heart rate <40) or worsening respiratory insufficiency, severe right ventricular dysfunction, or major myocardial necrosis, and low risk of bleeding complications, treatment should be in the inpatient setting with heparin and alteplase. Catheter embolectomy or surgical embolectomy mostly only if contraindications to systemic thrombolysis (ST), after failed ST or catheter-directed thrombolysis (CDL).	A A	Kearon et al., 2016 Rivera-Lebron et al., 2019

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. PULMONARY TUBERCULOSIS

Signal Symptoms: Productive, prolonged cough; fatigue; low-grade fever; night sweats; poor appetite; weight loss.

Description: Pulmonary tuberculosis (TB) is a chronic necrotizing infection caused by a slow-growing acid-fast bacillus (AFB), *Mycobacterium tuberculosis* (Mtb). Airborne Mtb particles are called droplet nuclei which are 1 to 5 microns (use if symbol is fine) in diameter. These droplet nuclei remain suspended in the air for several hours when a person with active Mtb coughs, sneezes, or speaks (Churchyard, et al., 2017). The droplet nuclei multiply causing primary lesions in the lungs. Not all individuals exposed to Mtb become infected. The primary site for most cases of Mtb is the lungs. Extrapulmonary Mtb can affect any organ or tissue, such as the kidneys, spine, or brain. Most extrapulmonary disease is not contagious, except for laryngeal Mtb.

Etiology: The Mtb infection spreads by inhalation of airborne particles or droplets produced by persons with active pulmonary or laryngeal Mtb during coughing, sneezing, singing, and other expiratory efforts. The development of infection after exposure depends on the exposed person's ability to mount an effective immune response on the cellular level. In the initial 2 to 4 weeks before cellular immunity response occurs, direct pulmonary infection may develop, or lymphohematogenous circulation may lead to miliary, meningeal, or Mtb adenitis. When T cells recognize the specific antigen, they become sensitized, engaging the macrophages in destroying or containing the tubercle bacilli. This leads to healing, with no residual or calcified lymph nodes in the pulmonary or tracheobronchial areas. This latent stage is typical of 90% to 95% of infected persons, leaving them at lifelong risk for reactivation. Tuberculin skin testing documents exposure at 2 to 10 weeks after exposure.

Occurrence: In 2016, "a WHO endorsed estimate updated the global prevalence of LTBI to 23% corresponding to 1.7 billion people infected worldwide" (Cohen et al., 2019). Men have double the incidence of Mtb worldwide, but disparity may be explained partly by underreporting in women. Mtb was one of the top 10 causes of death worldwide in 2019, known as the disease of poverty. It is the leading cause of death in people with HIV and a major cause of death secondary to antimicrobial resistance. In 2019, of the 10 million people who fell ill with Mtb, 5.6 million were men, 3.2 million were woman and 1.2 million were children, and of all the combined TB cases, 8.2% have HIV (WHO, 2020). Eight countries accounted for two-thirds of the worldwide total: India, Indonesia, China, the Philippines, Pakistan, Nigeria, Bangladesh, and South Africa (WHO, 2020). In 2019, 1.4 million people died from Mtb. Worldwide the Mtb incidence rate fell by 9% between 2015 to 2019 (from 142 to 130 new cases per 100,000 population), including a reduction of 2.3% between 2018 and 2019 (WHO, 2020). Treating Mtb saved 63 million lives worldwide between 2000 and 2019 (WHO, 2020).

The WHO's 2021 *Global Tuberculosis Report* announced Mtb deaths rose for the first time in more than a decade due to the COVID-19 pandemic. In 2020, more people died from Mtb, with far fewer people being diagnosed and treated or provided with Mtb preventive treatment compared with 2019, and overall spending on essential Mtb services falling. The increase in the number of Mtb deaths occurred mainly in the 30 countries with the highest burden of Mtb. The WHO's modeling projections indicate the number of people developing Mtb and dying from the disease could increase in 2021 and 2022.

Age: Children and adolescents are more likely to have primary disease; adults and older adults are more likely to have recrudescent disease. Mtb disease in children under 15 years of age (also called pediatric Mtb) is a public health problem of special significance because it is a marker for recent transmission of Mtb. Also of special significance, infants and young children are more likely than older children and adults to develop life-threatening forms of Mtb disease (e.g., disseminated Mtb, Mtb meningitis). Among children, the greatest numbers of Mtb cases are seen in children younger than 5 years of age and in adolescents older than 10 years of age.

Ethnicity: As reported by the Centers for Disease Control and Prevention (CDC) (2020):

- Native Americans or Alaskan Natives: 3.2 Mtb cases per 100,000 persons
- Asians: 13.3 Mtb cases per 100,000 persons
- Blacks/African Americans: 3.4 Mtb cases per 100,000 persons
- Native Hawaiians and other Pacific Islanders: 18.7 Mtb cases per 100,000 persons
- Hispanics or Latinos: 3.5 Mtb cases per 100,000 persons
- White: 0.4 Mtb cases per 100,000 persons

Risk Factors: Overall, about 5% to 10% of infected persons who do not receive treatment for latent Mtb infection will develop Mtb disease at some time in their lives. For persons whose immune systems are weak, especially those with HIV infection, the risk of developing Mtb disease is much higher than for persons with normal immune systems. Persons who are at increased risk include those with:

- HIV infection
- Substance abuse issues (especially IV drug use)
- Recent infection with *M. tuberculosis* (less than 2 years ago)
- Chest x-ray findings suspicious of previous Mtb with no treatment or ineffective treatment
- Diabetes mellitus
- Silicosis
- Prolonged corticosteroid therapy
- Other immunosuppressive therapy
- Cancer of the head and neck
- Hematological and reticuloendothelial diseases
- End-stage renal disease
- Intestinal bypass or gastrectomy
- Chronic malabsorption syndromes
- Low body weight (less than 10% ideal body weight)

Other factors associated with increased risk include homelessness, residence in a congregate setting (e.g., nursing home, boarding home, prison, mental health facilities), low socioeconomic status, and health-care work in a high-risk area.

© F.A. Davis Publishing

Signs and Symptoms: Typical presentation includes cough, hemoptysis, weight loss, anorexia, adenopathy, fever, night sweats, decreased activity level, and pleuritic pain. In the average population, the onset is gradual and may go undetected for some time. In the older patient, these findings are not usually present, or they are so subtle and intermingled with other chronic illness symptoms as to be undistinguishable. Weight loss, dyspnea, or anorexia may be the only symptoms. Typical presentations include pneumonia, bronchitis, or heart failure with pleural effusion. Extrapulmonary Mtb may manifest with symptoms typical to the site involved (e.g., urinary incontinence or frequency and urgency for bladder Mtb).

Diagnostic Tests:

Tuberculin Skin Test (TST): The TST is used to determine whether a person is infected with Mtb. If a person is infected, a delayed-type hypersensitivity reaction is detectable 2 to 8 weeks after infection. The skin test is administered intradermally using the Mantoux technique by injecting 0.1 mL of 5 TU purified protein derivative (PPD) solution. The reading and interpretation of TST reactions should be conducted within 48 to 72 hours of administration.

TST Interpretation (CDC, 2020): Induration of 5 mm and more is considered positive in:

- Immunosuppressed individuals
- HIV infected individuals
- Recent contact with active TB patients
- Prior tuberculosis signs on chest radiograph such as fibrotic changes
- Organ transplant patients

An induration of 10 mm or more is considered positive in:

- Immigrants from endemic/high prevalence countries in the last 5 years
- High-risk area employees and residents
- Injection drug abusers
- Mycobacteriology laboratory professional
- Chronic medical conditions that increase the risk of tuberculosis include diabetes, kidney failure, malignancy

An induration of 15 mm or more is considered positive in:

- In any person, including healthy individuals without any risk factors for TB
- Patients who do not meet any of the above criteria

TST Conversion:

- According to the CDC (2020), the repeat TST is considered positive if there is ≥10 mm induration and the induration is increased by ≥6 mm compared to the previous test. This test interpretation is less sensitive but more specific. For more information about tuberculin skin testing, visit the CDC Web site.

The CDC in 2019 revised its guidelines that anyone working or volunteering in health-care settings should receive a TB risk assessment, TB symptoms screen, and a TST upon hire (Dobler et al., 2018; Sosa et al., 2019). A recent retrospective cohort study by Dobler et al. (2018) of about 40,000 health-care workers at a tertiary U.S. medical center in a low TB-incidence state found an extremely low rate of TST conversion (0.3%) during 1998 to 2014, with only a limited amount attributed to occupational exposure. Annual skin testing is not required unless there is a known exposure. It is recommended that you refer to your state and local TB screening and testing regulations which may be different that the current CDC guidelines.

Key Points:

- Training is essential for health-care providers to be proficient in the administration and interpretation of the TST.
- The TST should not be performed on a person who has written documentation of either a previous positive TST result or treatment for TB disease.
- Interpretation of the TST result is the same for persons who have had bacille Calmette-Guérin (BCG) vaccination because a majority of BCG cross-reactivity wanes over time.
- A TST that was not measured and recorded in millimeters (mm) of induration must be repeated.
- A TST cannot differentiate between a latent tuberculosis infection (LTBI) and active Mtb infection.

Interferon–Gamma Release Assays (IGRAs): IGRAs are used to determine whether a person is infected with Mtb by measuring the immune response to Mtb proteins in whole blood. Specimens are mixed with peptides that simulate antigens derived from Mtb and controls. In a person infected with Mtb, the white blood cells recognize the simulated antigens and release interferon-gamma (IFN-γ); results are based on the amount of IFN-γ released (CDC, 2011). As noted earlier, there are two U.S. Food and Drug Administration (FDA) approved IGRAs commercially available in the United States:

- QuantiFERON®-TB Gold-in-Tube test (QFT-GIT)
- T-SPOT® TB test

Key Points:

- Advantages of IGRAs include:
  - Requires a single patient visit to conduct the test.
  - Results can be available within 24 hours.
  - Does not boost responses measured by subsequent tests.
  - Prior BCG vaccination does not cause a false-positive IGRA test result.
- Limitations of IGRAs include:
  - Blood samples must be processed within 8 to 30 hours after collection.
  - Errors in collecting or transporting blood specimens or in running and interpreting the assay can decrease the accuracy of IGRAs.
  - Limited data on the use of IGRAs to predict who will progress to TB disease in the future.
  - Limited data on the use of IGRAs for:
    - Children younger than 5 years of age
    - Persons recently exposed to *M. tuberculosis*, persons who are immunocompromised, and serial testing.
  - Tests may be expensive.

© F.A. Davis Publishing

For more information, see *Latent Tuberculosis Infection: A Guide for Primary Health Care Providers* at https://www.cdc.gov/tb/publications/ltbi/.

Differential Diagnosis: Pneumonia, lymphoma, fungal infections, heart failure, pleural effusion, and lung cancer can mimic Mtb.

Treatment: Mtb treatment focuses on cure and reducing the transmission of Mtb to other people while ensuring safety and efficacy of treatment in the shortest time frame. Patients who are diagnosed with Mtb should be referred to a provider who specializes in treating Mtb (infectious disease, or pulmonary specialist). Before treatment, baseline laboratory tests, including liver function, bilirubin, complete blood count (CBC), blood urea nitrogen (BUN), creatinine, and serum uric acid, diabetes screen, HIV screen (if positive, CD4 lymphocyte count and HIV RNA load), and hepatitis B and C; chest x-ray; sputum smear and culture; drug susceptibility; visual assessment; color discrimination; weight; and symptom review are recommended. Once treatment begins, monthly liver function, bilirubin, CBC, BUN, creatinine, and serum uric acid, visual assessment, color discrimination, weight, and symptom review are recommended. Follow-up cultures should be done monthly, until two consecutive negative specimens are obtained, to determine response to treatment. If the culture is not negative after 3 months, suspect drug resistance or noncompliance and reevaluate. After culture is negative, obtain one additional culture at treatment completion.

- *Active Mtb:* In a patient who is not suspected of having drug-resistant Mtb treatment the preferred regimen consists of an intensive phase of 2 months of isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB) followed by a continuation phase of 4 months of INH and RIF (Sterling et al., 2020). If Mtb is susceptible to INH and RIF, EMB is not necessary, and the intensive phase consists of INH, RIF, and PZA only. Pyridoxine is given with INH to those at risk for neuropathy (e.g., persons infected with HIV; patients with diabetes, alcoholism, malnutrition, or chronic renal failure; or those of advanced age) (Sterling et al., 2020). It is preferred to have individuals take medication daily. Directly observed therapy (DOT) 5 days a week is considered the standard in most TB programs in the United States and Europe (Karumbi & Garner, 2015). DOT can be administered in the office, clinic, or any other place that is mutually agreed upon by trained personnel. This method is helpful in compliance and decreasing risk of developing resistant Mtb. There have been no large clinical trials that have compared 5-day administration versus 7-day administration, but experts agree that this is an acceptable alternative to meeting the definition of daily dosing (Karumbi & Garner, 2015; Sterling et al., 2020). *Note:* HIV-positive individuals require specific modifications in therapy. Refer to the CDC 2022 guidelines (https://www.cdc.gov/tb/publications/guidelines/hiv_aids.htm)
- *Latent Tuberculosis Bacillus Infection (LTBI):* The LTBI treatment guidelines were updated in 2020, comprising of three preferred rifamycin-based regimens and two alternative monotherapy regimens with daily INH. These treatments are for treating individuals who are infected with MtB that is presumed to be susceptible to INH or rifampin. (Sterling, 2020). These guidelines do not apply when the Mtb strain is resistant to INH and rifampin. There are specific guidelines that were published in 2019 for treating contacts who have been exposed to multidrug resistant MtB (Nahid et al., 2019).

The three preferred rifamycin-based regimens are:

- **3 months of once-weekly isoniazid plus rifapentine (3HP)**
  - Preferred regimen recommended for adults and children aged >2 years, including HIV-positive persons.
  - Administered through DOT.
  - Treatment completion rates were higher with the 3-month regimen (Nahid et al., 2019).
  - Possible disadvantages of this regimen include cost of medications that are greater than alternative treatments.
  - Systemic drug reaction or influenza-like syndrome that can include syncope and hypotension may occur (Nahid et al., 2019).
- **4 months of daily rifampin (4R)**
  - Preferred treatment of 4 months of daily rifampin is strongly recommended for HIV-negative adults and children of all ages.
  - Toxicity is less than 9 months of daily INH regimens.
  - Lower rates of discontinuation due to less adverse effects, lower hepatoxicity and a higher treatment completion rate.
  - The potential disadvantages of the rifamycin-based regimens are the many drug interactions, including warfarin, oral contraceptives, azole antifungals, and HIV antiretroviral therapy (Sterling et al., 2020).
  - Rifabutin may be used in place of rifampin when rifampin is contraindicated due to drug-drug interactions and INH cannot be used (Sterling et al., 2020).
- **3 months of daily isoniazid plus rifampin (3HR).**
  - Preferred treatment of 3 months of daily INH plus rifampin is conditionally recommended for adults and children of all ages and for HIV-positive persons as drug interactions allow.
  - Less hepatotoxicity occurs among those receiving the shorter course of therapy, although discontinuation of therapy because of adverse effects was more frequent (Sterling et al., 2020).
  - There is a higher risk of hepatotoxicity with the two drugs given together than with either drug given alone (Sterling et al., 2020).

Prescribing providers or pharmacists who are unfamiliar with rifampin and rifapentine might confuse the two drugs. They are not interchangeable. Careful attention should be taken to ensure that patients receive the correct medication. Preference for these rifamycin-based regimens is based on effectiveness, safety, and high treatment completion rates. Refer to the CDC for further information on treatment (https://www.cdc.gov/tb/topic/treatment/ltbi.htm).

- *Antibiotic resistant Mtb:* For drug-resistant Mtb, different culture guidelines apply. Several treatment options are available. Refer to the CDC for further information on treatment (https://www.cdc.gov/tb/publications/guidelines/mdr_tb.htm).

© F.A. Davis Publishing

Follow-Up: Monitor the patient closely during treatment for potential adverse events such as hepatotoxicity. (Refer to the section Treatment.) For the frail, older adult in a long-term care facility, more frequent monitoring for adverse effects of treatment, including anorexia, polyneuropathy, or development of medication-induced hepatitis, is warranted. DOT is normally used in these settings, so compliance is less of a concern. Refer community-dwelling older adults to the local or state health department for follow-up, monitoring of medication compliance and side effects, patient, and family education, and testing of close contacts.

Many agencies charged with monitoring and control have outreach services, such as home visits. Emphasize to patients that compliance is crucial to successful control. If no follow-up visitation is available through the monitoring agency, see the patient for monthly follow-up visits in the office.

Sequelae: Post-treatment complications include relapse, aspergilloma, bronchiectasis, carcinoma, chronic respiratory failure, cor pulmonale, chronic pulmonary inflammation. Development of drug-resistant organisms, particularly if a patient is noncompliant with the prescribed treatment.

Prevention/Prophylaxis: Individuals admitted to long-term care facilities must have a two-step PPD test unless there is documented proof of a positive test. PPD testing is also required if TB exposure is suspected. Any patient with a positive PPD must have a chest x-ray to evaluate for active or latent disease. When targeted testing reveals a positive tuberculin skin reaction but no evidence of active Mtb, it is referred to as latent Mtb. For those with a positive PPD test, it is recommended to screen annually for the presence of Mtb symptoms. The decision to institute chemoprophylaxis is a clinical judgment, based on a comparison of individual factors with the risk of developing Mtb (see Contributing Factors) versus the risk of toxicity. Refer to Treatment section for latent Mtb treatment.

Referral: Mtb is a mandated reportable disease. When a positive test is received, it is to be reported to your state or local jurisdiction. Refer to a TB clinic, infectious disease specialist, or pulmonary specialist for evaluation and management of Mtb treatment.

Education: Teach the patient, caregivers, close contacts, and paraprofessional providers about the nature of the disease, its mode of transmission, screening and control measures, and follow-up. Teach the patient or caregiver about medications, drug actions and possible side effects, length of treatment, and compliance in drug treatment regimens.

RESTRICTIVE LUNG DISEASE

Signal Symptoms: Rapid, shallow respirations; dyspnea; decreased activity tolerance; easy fatigability; nonproductive, irritating cough provoked by deep breathing or exertion.

Description: *Restrictive lung disease* refers to a heterogeneous group of disorders that share a common abnormal ventilatory function: a decrease in lung volumes, both in total lung capacity and vital capacity (Lutfi, 2017). This reduced capacity may be due to stiffness in the lungs themselves or stiffness of the chest wall, weak muscles of respiration, or obesity. Restricted breathing is characterized by small tidal volume and rapid respiratory rate. Unlike obstructive lung diseases the issue is not exhaling, it is inhaling that is the problem.

Etiology: Restrictive lung diseases, which have a variety of etiologies, are most easily divided into two subgroups: pulmonary parenchymal diseases (intrinsic causes) and extrapulmonary diseases (extrinsic causes).

Pulmonary parenchymal disease (intrinsic) includes (but not limited to):

- Idiopathic pulmonary fibrosis (IPF)
- Non-specific interstitial pneumonitis (NSIP)
- Cryptogenic organizing pneumonia (COP)
- Sarcoidosis
- Occupational exposures (silica, asbestos, talc, beryllium, coal)
- Organic dust exposures (farmer's lung, bird fancier's lung)
- Hypersensitivity pneumonitis
- Drug/radiation induced interstitial lung disease

Extrapulmonary (extrinsic causes)

- Kyphoscoliosis
- Pleural conditions (e.g., pleural effusion)
- Obesity

© F.A. Davis Publishing

- Neuromuscular disorders (amyotrophic lateral sclerosis, polio, muscular dystrophy)
- Diaphragm paralysis
- Cervical spine injuries
- Guillain-Barré syndrome

Occurrence: The overall incidence of restrictive lung disease is undeterminable because several distinct entities are involved; however, there are some statistics available for specific diseases. The prevalence of IPF was estimated in a systematic review as 2.8 to 9.3 per 100,000 in North America and Europe (Barratt et al., 2018). Occupational lung diseases are common in farmers and in people who work with silica, asbestos, beryllium, organic solvents, or cotton. The prevalence of sarcoidosis in the United States is 8 to 11 cases per 100,000 persons (Arkema & Cozier, 2020).

Age: Occupationally induced disease and IPF are seen predominantly in the older population; other restrictive lung diseases may occur at any age.

Ethnicity: The highest incidence and prevalence in the United States is in non-Hispanic Blacks, with Black women having the highest rate (Arkema & Cozier, 2020).

Contributing Factors: Risk factors vary with etiology, including smoking history, exposure to occupational dusts, abnormalities in skeletal structure, genetics, chemotherapy, certain antibiotics, amiodarone, neuromuscular, and autoimmune disorders (Kalchiem-Dekel et al., 2018).

Signs and Symptoms: Patients often present with complaints of dyspnea. The pattern and severity vary greatly according to the etiology. A nonproductive cough may be present. A careful, detailed history is essential, including prior systemic diseases, occupational or environmental exposures, family history, social history, and history of drug use (Kalchiem-Dekel, et al., 2018). Medications including amiodarone, nitrofurantoin, hydralazine, gold, chemotherapeutic agents, and procainamide can cause drug-induced pulmonary parenchymal disease (Kalchiem-Dekel et al., 2018). Prior radiation can result in fibrosis. Use of tobacco should also be ascertained; it is common for patients to have a mixed pattern of obstructive and restrictive disease. The initial presentation of breathing problems often occurs after an acute respiratory viral infection.

Physical findings may reveal skeletal abnormalities, such as kyphoscoliosis, limiting lung expansion. Physical assessment of the lung initially may be unremarkable. In intrinsic disease, with progression of the disease, inspiratory crackles ("Velcro") typically are heard at the bases. Cyanosis and clubbing of fingers and toes may occur in IPF. In the end stages, signs of right-sided heart failure, including cor pulmonale, appear.

Diagnostic Tests: Because of the diverse nature of the conditions leading to restrictive lung disease, it is challenging to address diagnostic testing and results. Many results are specific to the causative condition. Routine testing includes complete blood count (CBC), chemistry profile, and liver function tests. If more common lung diseases are ruled out the patient should be referred to a pulmonologist for further assessment.

Test	Results Indicating Disorder
Pulmonary function test	Normal FEV_1/FVC ratio but decreased FVC and FEV_1; decreased total lung capacity, residual volume, and functional residual capacity. Residual volume–to–total lung capacity ratio is normal to low. Most have a gas exchange problem with marked decrease in single breath diffusing lung capacity for carbon monoxide. Diagnosis of restriction and extent of restriction is based on total lung capacity.
Chest x-ray	Increased interstitial markings, especially in lower fields. Hilar and mediastinal lymphadenopathy in sarcoidosis, some lymphomas, and silicosis. Pleural effusion and thickening with collagen-vascular disease, lymphoma, and asbestosis. A scattered reticulonodular pattern and ground glass opacities are common.
High-resolution computed tomography scan	In idiopathic pulmonary fibrosis, patchy, peripheral bibasilar reticular abnormalities in the subpleural area; with advanced disease, subpleural fibrosis and honeycomb pattern are present.

Source: Kalchiem-Dekel et al., 2018

In the late stages, arterial blood gases help to identify the degree of hypoxemia and carbon dioxide retention. In select cases, bronchoscopy and biopsy may be indicated (Kalchiem-Dekel et al., 2018).

Differential Diagnosis:

- Infectious or neoplastic diseases
- Chronic obstructive pulmonary disease (COPD)
- Heart failure
- Wegener's granulomatosis
- Goodpasture's syndrome
- Bechet's disease
- Sjögren's syndrome
- Systemic sclerosis
- Pneumoconiosis
- Tuberous sclerosis
- Eosinophilic pneumonia

Treatment: Therapy depends on the specific diagnosis obtained from clinical evaluation, imaging, and lung biopsy, and the disease progression. If occupational exposure is suspected, the causative agent should be avoided. Any patient with suspected intrinsic/parenchymal restrictive lung disease should be referred to a pulmonologist for a formal evaluation and treatment planning. Therapy with corticosteroids and cytotoxic agents (e.g., azathioprine and cyclophosphamide) is the primary treatment for many interstitial diseases, although objective data to support their use are lacking (Kalchiem-Dekel, et al., 2018)

The American Thoracic Society (ATS) and other global organizations' official statement on the evidence-based treatment of IPF was issued in 2011 and updated in 2018 (Raghu et al., 2018), citing the weakness of the evidence for current

© F.A. Davis Publishing

treatments, including corticosteroids, cytotoxics, immunosuppressants, and other miscellaneous drugs, and encouraging individual patient and specialist discussion before implementing any drug therapy. The ATS statement recommends against treatment of IPF with corticosteroids alone or in combination with cytotoxics or immunosuppressants (Raghu et al., 2018). Pirfenidone and nintedanib are approved for IPF and have been shown to slow functional decline and disease progression, although they are not curative and have a side-effect profile that may preclude continued use (Spagnolo et al., 2021). Lung transplantation is the only treatment to prolong survival in IPF (Kalchiem-Dekel et al., 2018); post-transplant the patient will be on immunosuppression for life. In the end stage of restrictive lung diseases, administer supplemental oxygen for supportive care; consider palliative care and hospice.

Follow-Up: Follow-up visits are scheduled as indicated by symptoms and comorbidities. Periodic chest x-rays or pulmonary function tests (PFTs) may help to chart diseases course and evaluate response to treatment. For many of the restrictive lung diseases the patient will be comanaged with a pulmonologist.

Sequelae: Use of corticosteroids or immunosuppressives may result in increased risk of infection and should be started and managed by a pulmonologist. Pulmonary hypertension and right-sided heart failure may occur. Restrictive lung diseases are chronic and there is no known cure.

Prevention/Prophylaxis: Give patients the pneumococcal pneumonia and influenza vaccines. Advise patients to avoid known exposures, tobacco use, and persons with acute, infectious upper respiratory illness.

Referral: Any patient with interstitial lung disease should be referred to a pulmonologist who should manage their pulmonary disease.

Education: Teach the patient and family about chronic disease management, regular self-care habits, and early intervention in acute illness. Discuss prognosis and preferred choices for end-stage disease.

Clinical Recommendation	Evidence Rating	References
Interstitial lung disease diagnosis can be made with a chest x-ray, pulmonary function tests consistent with restrictive lung disease, and typical findings on high-resolution computed tomography. Lung biopsy is necessary in atypical cases.	C	Oliveira et al., 2018
No treatment has been shown to have consistent benefit in idiopathic pulmonary fibrosis (IPF).	C	Kalchiem-Dekel et al., 2018 Spagnolo et al., 2021
Corticosteroids, supplementary oxygen, and pulmonary rehabilitation may provide symptomatic relief.	C	Kalchiem-Dekel et al., 2018
At present, there is no evidence for an effect of corticosteroid treatment in patients with IPF. On the other hand, other fibrotic lung diseases, such as nonspecific interstitial pneumonia, are reported to show a better response to corticosteroids. Making a clear distinction between IPF and other entities grouped under the umbrella term interstitial lung disease is, therefore, essential, because this may have therapeutic and prognostic implications.	C	Kalchiem-Dekel et al., 2018

UPPER RESPIRATORY TRACT INFECTIONS (RHINITIS, RHINOSINUSITIS)

Signal Symptoms: Nasal congestion, rhinorrhea, purulent nasal discharge, sneezing, sore throat, cough, headache, facial pain, myalgias, malaise, low-grade fever.

Description:

Rhinitis: Can be either allergic, non-allergic, mixed, atrophic, or acute and chronic rhinosinusitis in origin. Allergic rhinitis (AR) is intermittent or persistent with symptoms of sneezing, rhinorrhea, nasal congestion, postnasal drainage, and nasal/ocular pruritis with immunoglobulin E (IgE)-dependent events. It can be either seasonal or perennial with different allergen triggers. Non-allergic rhinitis (NAR) has symptoms of sneezing, rhinorrhea, and conjunctivitis (Bozek, 2017) along with postnasal drainage without specific IgE-dependent events (Baptist & Nyenhuis, 2016). NAR can be intermittent, persistent, seasonal, and/or completely caused by triggers (Baptist & Nyenhuis, 2016). Mixed rhinitis symptoms can be variable with a mixture of symptoms from AR and NAR. Presence of symptoms are not explained completely by the IgE specific reaction (Baptist & Nyenhuis, 2016) and therefore may show IgE elevated levels in the serum at times, whereas other times these levels will not be elevated in the same person (Bozek, 2017). Symptom triggers help to determine whether the person has mixed rhinitis or not. Atrophic rhinitis manifests with symptoms of congestion, nasal crusting, and strong foul odor but can have symptoms of both AR and NAR (Baptist & Nyenhuis, 2016).

© F.A. Davis Publishing

Rhinosinusitis: Chronic rhinosinusitis (CRS) is the chronic inflammation of the nose and paranasal sinuses along with having two of the following symptoms for more than 12 weeks: nasal discharge, nasal congestion or obstructions, facial pain or pressure, purulent rhinorrhea, and reduction or loss of smell. Acute rhinosinusitis (ARS) can be viral or bacterial in nature and lasts less than 4 weeks (London & Ramanathan, 2018).

Etiology: Viruses that cause upper respiratory tract infections (URIs) are adenovirus, coronavirus, rhinovirus, human metapneumovirus, enterovirus, influenza, parainfluenza, and respiratory syncytial virus (Pelzman & Tung, 2021). Certain bacteria and other pathogens are also causes. Bacterial infections may occur after viral infections because of the immune system being activated so much that normal tissue is left open with little to no defense.

Differential Diagnosis: In the older adult, other causes of the rhinitis should be considered, including granulomatous diseases such as Wegener's granulomatosis and sarcoidosis along with nasal polyposis, hypothyroidism, cerebrospinal fluid leak and malignancy (Baptist & Nyenhuis, 2016). Medications that can cause drug-induced rhinitis in the older adult are antihypertensives, psychotropics, alpha-adrenergic antagonists, and phosphodiesterase-5 inhibitors (Baptist & Nyenhuis, 2016). There can also be an overlap of AR and NAR in atrophic rhinitis, which means there can be different triggers for the symptoms of someone with all three conditions (Baptist & Neynhuis, 2016).

Prevalence: Upper respiratory tract symptoms are in the top 10 reasons year-round that adult patients seek medical help (Pelzman & Tung, 2021). Rhinitis occurs in about 32% of adults aged 54 to 89 years of age, with AR occurring in about one out of every six Americans. Rhinosinusitis occurs in as many as one in every eight adults (London & Ramanathan, 2018), with CR occurring in 10% of adults (Baptist & Neynhuis, 2016).

Age: AR has an increasing occurrence in those older than 60 years of age (Bozek, 2017).

Ethnicity: No Specific data found.

Contributing Factors: The older adults have changes that occur with aging that increase their risk or symptomatology to viral and bacterial infections. Exposure to allergens can activate worsen the symptoms (Baptist & Nyenhuis, 2016).

Signs and Symptoms: See signal symptoms.

Diagnostic Tests: Diagnosing URIs and differentiating between the different types of URIs is done from signs, symptoms, and physical examination (Baptist & Nyenhuis, 2016; Pelzman & Tung, 2021). There are some tests that can be performed to help with diagnosis, and those are serum IgE, skin prick test, streptococcus A test (rapid or culture), imaging, complete blood count (CBC), and procalcitonin (Baptist & Nyenhuis, 2016; Pelzman & Tung, 2021). The severity of the symptoms and signs can help determine which diagnosis is most likely. Some types of URIs have the same symptoms, but the severity of the symptoms will help to determine which type is the most likely diagnosis (Pelzman & Tung, 2021).

Treatment: Many URIs are viral. Symptom management is the best treatment (Pelzman & Tung, 2021). Viral URIs will generally resolve within 2 weeks even without treatment (London & Ramanathan, 2018; Pelzman & Tung, 2021). One mainstream treatment for rhinitis and any URI is avoidance of triggers or exposures that will cause worsening of symptoms (Baptist & Nyenhuis, 2016; Valdes & Tewfik, 2018). Second generation antihistamines and topical antihistamines are preferred over first generation antihistamines because of their central nervous system effects and increased interaction with other medications. These medications help with ocular and nasal pruritis, rhinorrhea, and sneezing (Baptist & Nyenhuis, 2016). Intranasal corticosteroids help reduce nasal congestion, rhinorrhea, and nasal pruritis, but they can cause epistaxis, nasal dryness, and mucosal crusting. Decongestants and nasal saline irrigation can help with congestion and other symptoms (Baptist & Nyenhuis, 2016). Analgesics and antipyretics are used for headaches, myalgias, and malaise that may arise with URIs (Pelzman & Tung, 2021). The combination of a topical antihistamine and a topical steroid has shown to help control symptoms of NAR better than taking either as monotherapy (Baptist & Nyenhuis, 2016).

Antibiotics, such as amoxicillin with or without clavulanate, should be prescribed for uncomplicated bacterial rhinosinusitis for 5 to 10 days (London & Ramanathan, 2018). ARS can become bacterial when it lasts more than 7 to 10 days or when symptoms improve followed by a period of worsening symptoms (Franck & Zehtabchi, 2019; London & Ramanathan, 2018). It is recommended not to use antibiotics in those with CRS (Franck & Zehtabchi, 2019). Bacterial otitis media and pharyngitis can also be treated with amoxicillin with or without clavulanate (Pelzman & Tung, 2021).

Follow-Up: No specific time frame for follow-up has been established, but generally patients can be advised to return if symptoms worsen or do not resolve in an allotted amount of time (such as 2 weeks for ARS).

Sequelae: Symptoms of URI may get better followed by a period of worsening symptoms. At that time, this may indicate the URI has become bacterial in nature and treatment with the appropriate antibiotic is recommended (Franck & Zehtabchi, 2019; London & Ramanathan, 2018).

Referral: Referral to an ear, nose, and throat specialist might be needed with recurrent epistaxis to help determine the cause and when someone with CRS has not responded to empiric treatment. Refer to an allergist for those who appear to have an allergic component that fails to respond to empiric treatment and in cases where the diagnosis is uncertain (London & Ramanathan, 2018).

Prevention/Prophylaxis: Advise patients to avoid exposure allergens and triggers, touching their face, and contact with other people who are sick/infected. Advise patients to use good hygiene by washing their hands regularly.

Education: Provider Education: Providers should remember that most URIs are generally viral in nature and therefore symptom management is recommended. Only after the course of sickness has improved then becomes worse or has lasted more than 7 to 10 days should antibiotic treatment be considered (Franck & Zehtabchi, 2019; London & Ramanathan, 2018). Purulent nasal discharge does not necessarily indicate a bacterial infection (Valdes & Tewfik, 2018).

© F.A. Davis Publishing

Patient Education: Explain the diagnosis and nature of the diagnosis to the patients. Explanation as to why antibiotics are not being prescribed may be necessary. Make sure that patients follow the plan of care and inform them of what to do if they do not respond to treatment or, if during treatment, they become worse. If antibiotics are indicated and prescribed, explain the importance of the patient completing this course of treatment and not to stop taking the medication because symptoms have improved or resolved.

CASE STUDY

A 70-year-old patient comes to the clinic for their annual Medicare Wellness visit. The patient reports that over the past year they have noticed increased dyspnea with exertion and a cough productive of sputum that varies in color from thick white to thicker and more yellow. They have no history of an acute illness and no fever, chills, or GI symptoms. The patient does have a history of seasonal allergies with occasional wheezing and bronchitis. The patient uses an inhaler during those periods of exacerbation. The patient states that the albuterol inhaler has not helped the current symptoms. They continue to work on cutting back on smoking but currently smoke about a pack in 3 days. Medications include lisinopril for hypertension, metformin for diabetes, famotidine at bedtime for GERD, fluticasone 1 spray in each nostril twice a day, and cetirizine at bedtime as needed for seasonal allergies. Other findings include:

- Vitals: BP 140/70, P 80, R 18, T 37°C, pulse ox 95% on room air.
- PE: HEENT moist mucous membranes, TMs intact
- Chest AP:LAT diameter 1:1, lungs resonant to percussion, tactile fremitus symmetrical, breath sounds distant, but no crackles, rhonchi, or wheezes heard.
- Heart: RRR no murmurs or gallops
- Extremities: Nonpitting edema bilaterally
- Dermatological: Skin warm, intact, no lesions.

1. From the patient's chief concern, how would you classify the cough—acute, subacute, or chronic?
2. What differentials would you include based on that classification?
3. What can you rule out based on the history and physical examination?
4. What follow-up investigation, laboratory studies, or other tests would be helpful in confirming your presumptive diagnosis?
5. What is the #1 recommendation you can provide the patient today regardless of their final diagnosis?
6. Will you prescribe any additional medication or treatment? If so, what will you prescribe?
7. When would you have the patient return in follow-up?

CHAPTER 12

Peripheral Vascular Disorders

Catherine Ratliff and David Strider

ASSESSMENT

A comprehensive vascular assessment may be integrated into the general history and physical examination for the patient with vascular disease. A systematic head-to-toe examination, done consistently for each patient, will minimize the chance of missing subtle signs related to vascular deficits.

The clinician should begin with auscultation of the carotid arteries bilaterally. Cardiac murmurs will usually radiate into the carotid arteries, and an underlying bruit may not be discerned. The subclavian arteries should then be auscultated over the upper anteromedial chest area. During this phase of the examination, the jugular veins should be inspected for jugular vein distention. This can best be assessed when the patient is lying down with the head of the bed elevated 15 degrees.

The clinician should proceed to the palpation of the brachial, radial, and ulnar arteries. Such palpation should be scored on a scale of 0 to 4 (4 = pulsatile, bounding; 3 = easily palpable with full triphasic pulse; 2 = biphasic pulse that may be a bit harder to locate initially; 1 = monophasic pulse that may come and go depending on position of fingertips; and 0 = absent pulse by palpation, which may be detected by Doppler ultrasound). All palpable pulses should be graded in the assessment and documented.

The clinician should evaluate any pain, coolness, paresthesia, motor weakness, discoloration, or tissue loss in the hands. Careful inspection of the distal fingers and the nailbeds may reveal signs of tissue malperfusion. The finger joints should be inspected for cyanosis and/or petechiae. The fingernails should be checked for clubbing, which suggests chronic hypoxemia. For any patient confirmed or suspected to have vascular disease, blood pressure should be checked in both arms.

The heart should then be auscultated to detect rhythm regularity, S_1, S_2, and any extrasystolic sounds such as S_3, S_4, or pericardial rub. Murmurs should be noted and classified as per the cardiac assessment guidelines. The abdomen should be auscultated for celiac artery, superior mesenteric artery, and renal artery bruits, which are best heard 4 to 8 cm above the umbilicus and 1 to 2 cm to the right and left of midline abdomen. The clinician should listen to the femoral artery in each groin for the presence of bruits. Following this, the abdomen should be lightly palpated just to the left of midline, approximately 4 cm above the umbilicus, to evaluate for a pulsatile abdominal aorta. In slender individuals, the abdominal aorta is often fairly easy to palpate. A bounding, pulsatile abdominal aorta in an individual may suggest aneurysmal formation. The clinician should note and document any tenderness or guarding associated with the abdominal palpation. There are many other causes for abdominal tenderness that the clinician should be aware of, in addition to arterial and venous disease, including pancreatitis, liver contusions, cholecystitis, appendicitis, splenic infarction, pyelonephritis, cystitis, gastroenteritis, peptic ulcer, and small bowel obstruction.

Once the abdominal examination is complete, the clinician should progress to the vascular assessment of the lower extremities. The femoral arteries should be palpated over the groin area and documented on the scale of 0 to 4. Any pulse deficits should be followed up with a Doppler examination. The popliteal fossa should be inspected and palpated bilaterally in order to locate the popliteal artery and assess for the possibility of popliteal artery aneurysms. The clinician should inspect the calves and feet for edema, skin turgor, and skin pigmentation. Thick, hyperpigmented skin in the lower calves and feet may be an indication of chronic venous insufficiency, whereas thin, shiny, pale skin is more consistent with peripheral arterial insufficiency. The dorsalis pedis and posterior tibial pulses should be palpated. If those pulses are not palpable, Doppler ultrasound should be used. Any Doppler signals should be located and identified with an indelible marker pen. At this time, the heel, the medial and lateral malleoli, and the toes of each foot should be inspected for breakdown. As in the hands, any pedal pain, coolness, paresthesia, motor weakness, discoloration, or tissue loss should be documented. Dorsal and plantar flexion of the feet should be assessed and recorded with muscular strength graded on a scale of 1 to 5.

The vascular examination then turns to a careful evaluation of the cranial nerves (CNs), usually focusing on CN II to CN XII. Evaluation of pupillary light and accommodation

© F.A. Davis Publishing

response (CNs II and III); following the eyes in a lateral, medial, superior, and inferior gaze (CNs III, IV, and VI); and evaluation of facial smile, scowl, and opening eyes against pressure (CNs V and VII) should be completed. Gross hearing assessment, with follow-up by Weber and Rinne testing, may ascertain any CN VIII deficits. Evaluating the tongue protrusion, uvula rise, cough reflex, gag reflex, and shoulder shrug will provide information on the integrity of CNs IX, X, XI, and XII. Document the conformation of the uvula, which may be bifid or singular (some connective tissue disorders have associated bifid uvula).

Completion of the CN examination provides the healthcare team with an excellent neurological baseline before interventions for carotid artery disease. Assessment findings related to vertebrobasilar insufficiency may include balance problems, dizziness, and coordination deficits. Focal neurological deficits such as arm, leg, and/or facial weakness on one side of the body; loss of speech; difficulty speaking or swallowing; and unilateral or partial vision loss signify transient cerebral ischemia that may be related to severe carotid artery stenosis (Rasmussen et al., 2019).

Following the neurological examination, the clinician should ascertain any specific end organ perfusion deficits, as shown by the following signs and symptoms:

- Pain in the feet, calves, thighs, and or buttocks, either at rest or with ambulation (peripheral arterial disease [PAD])
- Any open wounds or blisters on the distal aspects of feet and/or hands (PAD)
- Abdominal pain, nausea, vomiting, and/or diarrhea after a meal (mesenteric ischemia)
- Persistent abdominal/back pain (abdominal aortic aneurysm or dissection)
- Unilateral CN deficits (carotid artery disease)
- Balance/coordination deficits (possible vertebrobasilar malperfusion)
- Chest and/or back pain (ruling out myocardial ischemia, pneumothorax, and pulmonary embolus)

Once the focused vascular assessment and history are completed, the clinician will have achieved a baseline to guide future interventions to delineate and treat vascular lesions.

ABDOMINAL AORTIC ANEURYSM

Symptoms: Persistent or intermittent pain in the middle or lower abdomen, often radiating to the lower back, which is characteristic of a rapidly expanding, leaking, or ruptured abdominal aortic aneurysm (AAA). Most AAAs are asymptomatic.

Description: The abdominal aorta is the large artery that provides blood to the digestive organs, liver, kidneys, spleen, spinal cord, and lower extremities. It extends inferiorly from the descending aorta to the iliac arteries. An AAA is a dilation of the abdominal aorta that is one and one-half to two times greater than the size of the nondilated proximal or distal aorta. The AAA involves all three layers of the arterial wall.

Etiology: Most AAAs are atherosclerotic in nature; other causes include trauma, infection, and inflammation. Connective tissue disorders, such as Ehlers-Danlos' syndrome and Marfan's syndrome, predispose the patient to AAA formation (DelloStritto et al., 2017) Most AAAs are infrarenal (65%), occurring below the renal arteries. Patients with AAAs are more likely to have arterial aneurysms in other locations such as the thoracic aorta, the common iliac arteries, the common femoral arteries, and the popliteal arteries.

Occurrence: Ruptured AAA is ranked as the 13th leading cause of mortality in the United States, which is approximately 15,000 deaths per year (Kohlman-Trigoboff et al., 2020) Mortality rates for ruptured aneurysms are 70% to 90%, compared with 5% operative mortality for elective open surgical repair and 2% to 3% for endovascular stent AAA exclusion.

Age: More frequent in adults older than 50 years old; prevalence rate is 2% to 4%.

Ethnicity: Occur more frequently among Whites than any other race, and there is a familial history associated with AAA development particularly among first-degree relatives.

Contributing Factors: Risk factors for developing AAA include arteriosclerotic heart disease and arteriosclerotic changes of other vessels, smoking history, hypertension, hyperlipidemia, chronic obstructive pulmonary disease, obesity, family history of AAA, diabetes mellitus, cystic medial necrosis, Marfan's syndrome, and previous spinal cord injury. Individuals with an aneurysm of other large blood vessels in the extremities and carotid arteries also have an increased risk for AAA (Ullery et al., 2018). Onset occurs around age 50 years for men and 60 years for women. Incidence steadily increases with age and peaks at age 80 years. AAA is five times more likely in men than in women. Aortic dissection involves a splitting apart of the aortic wall layers, such that two or more blood flow channels are created within the aorta. Acute aortic dissection may produce intimal flaps that occlude major take-off vessels, leading to end organ ischemia. Progressive dissection may lead to weakening of the entire aortic wall, resulting in aneurysm formation and possible rupture. Isolated celiac and/or superior mesenteric artery dissection may occur, although this is much less likely than the initial aortic dissection (Duraikannu et al., 2020).

Signs and Symptoms: Most patients with AAAs are asymptomatic (66% to 75%), except in the presence of dissection, rupture, or impending rupture. A pulsatile abdominal mass at or slightly above the umbilicus in the epigastrium palpated, on the abdomen, is consistent with but not conclusive for an AAA. Palpation is easier in thin individuals. If noted in an obese individual, they are usually quite large. AAA should be

© F.A. Davis Publishing

suspected in individuals with a femoral or popliteal aneurysm because 30% of individuals with a peripheral aneurysm also have an AAA. In patients with symptomatic AAAs, the complaints include mild-to-severe abdominal, flank, or lower back pain. Other symptoms may include nausea and vomiting, gastrointestinal bleeding, and lower extremity ischemia. Rupture is the most lethal clinical presentation, with symptoms including sudden onset of severe abdominal and back pain, hypotension, and the presence of a pulsatile, expanding mass. There is a high mortality rate associated with ruptured AAAs. The possibility of ruptured AAA should be considered in any adult with acute abdominal or flank pain (Ullery et al., 2018).

Diagnostic Tests: The best initial screening test is an ultrasound of the abdominal aorta. In cases where surgery is planned, angiography and computed tomography (CT) scan with IV contrast are indicated to size the aneurysm and diagnose any tears or perforations.

Differential Diagnosis: It is important to evaluate for and treat hypertension and heart disease, because early steps in AAA management include blood pressure control and recognition or enhancement of cardiac function. An ectatic abdominal aorta (aortic diameter of 2.5 to 2.9 cm) without aneurysm may be palpated and confused with AAA. Other acute causes of abdominal and back pain may mimic a ruptured AAA and must be ruled out. Major imaging modalities for a patient with suspected or known AAA include abdominal ultrasound, CT scan, magnetic resonance angiogram (MRA), and angiogram.

Treatment: The rate of AAA growth for an individual is unpredictable. Some aneurysms may remain stable for long periods, whereas others may enlarge quickly. Medical management of an asymptomatic, small AAA should include blood pressure control, regulation of heart rate, and smoking cessation. Beta blockers have been shown to slow the long-term growth of aortic aneurysms. Angiotensin receptor blockers (ARBs), such as losartan, may also have a major role in critical blood pressure and heart rate control for patients with aortic aneurysms or dissections.

Initial treatment for symptomatic AAA, whether ruptured or not, involves aggressive blood pressure control. Mean arterial pressure should be maintained between 60 and 70 mm Hg, and systolic blood pressure should be kept between 100 and 120 mm Hg. Arterial pressure monitoring is recommended, and parenteral antihypertensive agents, such as esmolol, nicardipine, nitroprusside, labetalol, or nitroglycerin, should be used to quickly and consistently maintain blood pressure in these ranges. Cardiology should be consulted, and a transthoracic echocardiogram should be done to assess heart function. If the patient is to be medically managed, transition to oral antihypertensive agents should begin, using beta blockers, calcium channel blockers, clonidine, ARBs, and labetalol to maintain blood pressure control.

The two invasive options for excluding an AAA when it becomes symptomatic or becomes greater than 5 cm in diameter in women or greater than 5.5 cm diameter in men include open surgical repair and endovascular repair (EVAR) (Krishna et al., 2020). Elective EVAR is associated with lower rates of perioperative (30-day) morbidity and mortality compared with elective open repair (<2% versus 5%); long-term outcomes are similar to open AAA repair (Chaikof et al., 2018).

Thirty to fifty percent of individuals with ruptured AAA die before reaching a hospital and 30% to 40% of those with ruptured AAA die after reaching the hospital (Kohlman-Trigoboff et al., 2020). Average postoperative length of stay for an elective AAA surgical repair is 5 days. The major cause of death after AAA repair is myocardial infarction. Other complications include renal failure, limb ischemia, ischemic colitis, hemorrhage, and pneumonia with prolonged ventilator dependence, and paraplegia (Chaikof et al., 2018).

EVARs are less invasive procedures used for AAA repair. Stent-graft selection is dependent upon physician preference and patient anatomic characteristics as determined by preprocedure imaging results. The graft is deployed through the femoral or the iliac artery. Not all AAAs are anatomically appropriate for stenting. Current success rates are higher than 90%, with a mortality rate of less than 2%. Most patients are discharged from the hospital in 1 to 2 days (Kohlman-Trigoboff et al., 2020). Complications after endovascular treatment may include arterial injury at access site, arterial embolization, endoleak (blood flow outside the lumen of the graft but within the original aneurysmal sac), postimplant syndrome (back pain and fever without elevated white blood cell count or other signs of infection), and graft limb distal thrombosis (Kohlman-Trigoboff et al., 2020).

Follow-Up: Surveillance of patients with an AAA, including imaging at 12-month intervals for patients with an AAA of 4.0 to 4.9 cm in diameter. Rescreening intervals to check for AAA expansion shorten as the AAA enlarges (Chaikof et al., 2018). When anatomically feasible, EVAR is recommended over open repair for ruptured AAA (Chaikof et al., 2018).

Sequelae: The most common complication of AAA is rupture. Infrequent complications are thrombi to the lower extremities and preexisting infection of the aneurysm (mycotic aneurysm), with *Salmonella* and *Staphylococcus aureus* being the most commonly identified organisms. Fungal infections of the aorta pose significant challenges and require long-term IV antimycotics, such as fluconazole after 6 weeks of an IV course of antifungal agents, until surgical repair is done.

Prevention/Prophylaxis: Because most AAAs are atherosclerotic in nature, the same long-term preventive measures for reducing coronary artery disease, cerebrovascular disease, hypertension, and hypercholesterolemia should be applied. Diabetes mellitus has been shown to be protective against AAA. These include lifestyle modifications with control of hypertension, prescribing statin therapy, and daily aspirin (Ullery et al., 2018). The Society for Vascular Surgery (SVS) recommends AAA screening in men and women aged 55 years with a family history of AAA. Patients with diabetes have a lower incidence of AAA, a lower growth rate, and a reduced risk of rupture, which could be from the excess of vascular matrix deposition and increased collagen synthesis (aortic wall stiffness) characteristically seen in diabetic arteriopathy (Sprynger et al., 2019). The prevalence of AAA in the first-degree relatives of affected families is reported to be associated with a two- to fivefold increase in the risk of AAA. Several inheritance patterns for AAA development have been proposed. Although genetic disorders associated with aneurysm formation, such as Marfan's syndrome, Ehlers-Danlos'

© F.A. Davis Publishing

syndrome, and Loeys-Dietz's syndrome, are more commonly associated with aneurysms of the ascending and thoracoabdominal aorta (Ullery et al., 2018).

Referral: Referral to a vascular surgeon is essential for all patients with symptomatic AAAs. Furthermore, any patient with a known AAA, even if not symptomatic, should be screened with serial ultrasound imaging at least once a year.

Education: Patients and their families should be taught the importance of follow-up; ways to manage hypertension, hypercholesterolemia, smoking, and other risk factors; and the signs and symptoms of rupture that should be reported to the physician immediately (sudden onset of abdominal or back pain, dizziness). The risks of operative versus nonoperative treatment should be explained thoroughly to the patient and family.

CHRONIC LYMPHEDEMA

Signal Symptoms: Swelling of the affected body part, usually the limb, because of impaired flow of lymph fluid.

Description: Lymphedema is a progressive condition of abnormal lymph accumulation in the interstitial tissues due to a disruption of lymph flow. The lymph system is a low-pressure system that includes capillaries and depends on muscle movement to advance the fluid to the vascular system. Most of the lymph drains into the thoracic duct on the left side of the body and into the brachiocephalic vein.

Etiology: Lymphedema is swelling caused by impaired lymph transport, which results in an accumulation or pooling of protein-rich fluid in the interstitial space. Lymphedema is most commonly caused by surgery, radiation, or infection that damages the lymphatic system.

Occurrence: Lymphedema affects about 250 million patients worldwide. Secondary causes of lymphedema vary according to geographic distribution. In developing countries, it is often a part of parasitic infections, with filariasis being the most common cause in the world. In developed countries, secondary lymphedema mainly occurs after cancer therapy (Schulze et al., 2018). Primary (vascular anomalies) lymphedema is rare, with an estimated prevalence of 1 in 100,000 individuals, and it usually occurs during childhood, but may present at any age. Approximately 99% of individuals with lymphedema have a secondary disease (such as systemic disease, trauma, or surgery) (Grada & Phillips, 2017).

Age: Not confirmed as a risk factor for lymphedema.

Ethnicity: Not significant.

Contributing Factors: The types of cancer associated with secondary lymphedema include breast cancer, gynecological cancer, lymphoma, melanoma, and urological cancers. Surgery, radiation, trauma, infection, malignancy, or scar tissue can cause secondary lymphedema by obstructing the lymphatic system. For example, patients with a history of breast cancer with axillary node dissection or radiation, groin node dissection or radiation, and a postoperative infection have an increased risk for developing lymphedema. With primary or congenital lymphedema, females are affected twice as often as males. With secondary lymphedema in the United States, females may be affected more often, but that is because a common cause of secondary lymphedema is breast cancer, which is primarily a woman's disease. Morbid obesity (body mass index >25) can also increase the rate of secondary lymphedema (Torgbenu et al., 2020).

Signs and Symptoms: Swelling or edema is the characteristic symptom of lymphedema. Additional symptoms may include heaviness or tightness, aching and fatigue in the affected limb, restricted range of motion, recurring cellulitis in the affected extremity, and hardening and thickening of the skin. The Stemmer sign (or Kaposi-Stemmer sign) is another clinical indication of lymphedema in which one is unable to pinch a fold of skin at the base of the second toe on the dorsal aspect of the foot or between the second and third finger. Skin that does not fold up into a pinch is considered a positive sign of lymphedema. False-positive Stemmer signs may be seen in individuals with obesity or spinal muscle atrophy. Because the test exhibits moderate specificity, lymphoscintigraphy may be considered for patients with a high suspicion of lymphedema that have a negative Stemmer sign (Goss & Greene, 2019).

Diagnostic Tests: Diagnosis of lymphedema is typically made through clinical presentation and medical history, such as a cancer diagnosis. Lymphoscintigraphy is a well-established radiological examination to evaluate and confirm the diagnosis, as well as to measure lymphatic function and effect of complex decongestive therapy (CDT) (Forte et al., 2019). Bioimpedance spectroscopy (BIS) measures the composition of tissues (e.g., fluid such as lymph) and may be used for early diagnosis as well as determining the effectiveness of therapy (Forte et al., 2019).

Differential Diagnosis: Knowing if the patient had a prior history of comorbid conditions that can cause swelling of the extremities, such as cardiac disease, venous ulcer disease, renal disease, hepatic disease, trauma, and infection, is also important. Patients with rheumatoid arthritis, obesity, lipedema (painful fat syndrome), and venous ulcer disease are at greater risk for lymphedema because these conditions add additional stress to the impaired lymphatics. Lymph nodes are located around most joints, so patients undergoing such surgical procedures as total knee replacements may be at greater risk for developing lymphedema because lymph nodes can become injured during the surgery. Procedures such as vein-stripping can exacerbate mild lymphedema (Grada & Phillips, 2017).

Treatment: Complete decongestive physiotherapy (CDP) is the gold standard for lymphedema management. CDP is a specialized massage technique designed to stimulate the lymph vessels, break up subcutaneous fibrous tissue, and redirect the lymph fluid to areas where lymph flow is normal.

© F.A. Davis Publishing

It involves four steps: manual lymph drainage (MLD), compression bandaging, exercises, and skin care.

Conservative Treatment: The use of multilayer compression bandages and/or compression stockings is an important component for all patients with lymphedema to prevent the reaccumulation of lymph fluid in the limb.

Pharmacological Treatment: Diuretics are not beneficial with lymphedema because they draw off excess water in the interstitial spaces but not the protein. Lymphedema is a high-protein edema, and the high osmotic pressure from the increased protein in the interstitial space causes rapid reaccumulation of edema. In addition, the higher concentration of protein in the edema fluid causes increased fibrosis and induration of the skin. Diuretics are not contraindicated for the treatment of other conditions in lymphedema patients, but they should not be used as primary treatment for lymphedema.

Surgical Treatment: Surgical intervention is indicated for those with persistent lymphedema with a positive lymphoscintigram who do not respond to more conservative methods such as CDP. These procedures can be broadly categorized as physiological, including lymphovenous bypass and using a vascularized lymph node transplant; or de bulking, by suction-assisted lipectomy or direct excisional procedures (Schaverien & Coroneos, 2019).

Follow-Up: Patients with lymphedema need regular follow-up by health-care providers to make sure that the CDP is effective and adequate and, if not, appropriate modifications can then be made to the care plan.

Sequelae: Lymphangitis and cellulitis are complications seen with lymphedema. Once patients develop these infections, they are at greater risk for developing them again.

Prevention/Prophylaxis: Lifelong CDP is essential to prevent worsening of the lymphedema and to avoid complications.

Referral: Patients with lymphedema should be referred to a lymphedema specialist or clinic.

Education: It is important to teach patients with lymphedema about the disease process, its lifelong treatment with compression bandaging, the importance of avoiding complications such as lymphangitis, and resources, such as the National Lymphedema Network, that are available to them.

PERIPHERAL VASCULAR DISEASE

Signal Symptoms: Pain, intermittent claudication of the feet, tissue loss in affected leg/arm.

Description: Peripheral vascular disease (PVD) refers to a disease or process that alters blood flow to or from the extremities and vital organs other than the heart. These processes may involve the arterial, venous, or lymphatic systems, but most often are due to enlarging atherosclerotic plaques in the distal aorta or in major bifurcations or areas of angulation in the iliac, femoral, and popliteal arteries. Peripheral arterial disease (PAD) is characterized by impaired circulation to the lower extremities. In its most severe stage, known as critical limb ischemia (CLI), patients are at an increased risk of cardiovascular events, amputation, and death.

Etiology: Atherosclerotic plaques may be fatty streaks, fibrous plaques, or complicated calcified lesions. Fatty streaks are early lesions that occur in the intima of arteries. Fibrous plaques and areas of intimal thickening are the most frequently occurring type of lesion. Complicated (heterogeneous) plaques, as well as calcified fibrous plaques with potential for necrosis and thrombosis, are associated most often with symptoms in PAD patients (Duff et al., 2019).

Occurrence: CLI prevalence in the United States is estimated to be approximately 2 million and is likely to increase with age, in individuals with diabetes, and in those who smoke. Prevalence estimates in studies of the U.S. Medicare population range from 0.3% to 2.0% (Duff et al., 2019). Symptomatic PAD is two to five times more prevalent in men than in women; particularly for more severe or symptomatic disease.

Age: The prevalence of PAD increases with age, affecting over 10% of individuals in their seventh and eighth decades of life and over 20% of those older than age 80 years (Krawisz et al., 2021).

Ethnicity: Black individuals have the highest rates of PAD (Krawisz et al., 2021).

Contributing Factors: Risk factors for PAD include type 2 diabetes mellitus, smoking, obesity, hypertension, dyslipidemia, family history of PAD, cerebrovascular disease, and stroke. The presence of three or more of these risk factors increases the risk of PAD ten times. The most significant risk factor for the development of PAD is smoking (Krawisz et al., 2021).

Signs and Symptoms: Intermittent claudication is the early symptom of PAD. It is described as a painful cramping of the muscles of the leg during walking. It goes away when the patient stops walking and resumes after the patient starts walking again. It also may be described as a sensation of tiredness or fatigue. Intermittent claudication is present in only 10% to 20% of PAD patients. Walking limitations in PAD patients are multifactorial (reduced limb perfusion, systemic inflammation, vascular dysfunction, impaired angiogenesis, reduced microcirculatory flow, and skeletal muscle dysfunction) reflected in the self-restriction of activity to reduce leg pain (Hamburg & Creager, 2017). Ischemic rest pain is described as a burning sensation and localizes to the metatarsal heads or to an ischemic ulcer. Pain is often worse at night when the leg is elevated. Relief may occur with dependency of the foot. Ischemic rest pain requires immediate attention. Ulceration or gangrene develops at an area of external pressure or at the site of a minor injury, with gangrene representing CLI. Acute arterial ischemia results from arterial thrombosis, embolism, or trauma, with symptoms that are sudden in onset. It often causes the five Ps: pain, pallor, pulselessness, paresthesia, and paralysis. Other symptoms may include decreased sensation and mottling of the extremity. Acute arterial ischemia may be due to thrombus from the left atrium, sudden onset of atrial fibrillation, dislodging of

© F.A. Davis Publishing

calcium plaque in the aorta, and/or intrinsic hypercoagulopathy. A thorough patient history and physical examination are essential to determine the stage and type of vascular disease. (Hamburg & Creager, 2017).

Diagnostic Tests: Ankle-brachial index and systolic arterial pressure measurement with continuous-wave Doppler are first-line tests. In cases where surgical intervention is being considered, angiography is indicated. Assessment of distal arterial system patency can be done by Doppler ultrasound, which can also detect and pinpoint occluded areas (Kieback et al., 2019).

Differential Diagnosis: Buerger's disease and Raynaud's phenomenon also should be considered when diagnosing PAD. Buerger's disease may occur in individuals less than 35 years old who are smokers, and it may affect the upper as well as the lower extremities. This rare disease causes inflammation of the blood vessels, which can result in clot formation. Raynaud's phenomenon affects the fingertips, the tips of the ears and nose, and the feet. Patients with Raynaud's phenomenon have symptom exacerbation with any cold temperatures. Other diagnoses that mimic the symptoms of PAD include gout, arthritis, diabetic neuropathy, sciatica, and severe venous insufficiency (Dua & Lee, 2016).

The hallmark signs and symptoms of venous ulcers include distal lower extremity edema; warmth of the foot; large, irregular, copiously draining ulcers in the distal calf or foot dorsum; and hyperpigmentation of the surrounding skin. Arterial insufficiency ulcers usually are found over the medial or lateral malleolus, heel, or distal aspect of the toes. Wounds associated with arterial ischemia are small and drain minimally but are extremely painful.

Treatment: The main goal of PAD treatment is to slow the progression of the disease. Treatment may be conservative, pharmacological, operative, or endovascular. Risk factor recognition and lifestyle modification are the central tenets for managing patients with long-term PAD.

Conservative Treatment: Conservative treatment involves modification of risk factors, including smoking, blood pressure control, and diet. Smoking is the number one modifiable risk factor, and there are numerous methods available to help individuals stop smoking (Ding et al., 2019). In addition, managing diabetes and hyperlipidemia are key measures. Exercise is an essential element of PAD management because collateral vessels are strengthened and stimulated to grow with the onset of an exercise program such as walking. Formalized vascular rehabilitation programs are becoming more common with better reimbursement by insurers. Home exercise programs should focus on exercising three or more times per week for at least 30 minutes per day. Patients should be instructed to walk until pain develops, walk a few steps more through the pain, rest until pain goes away, then resume walking. Over time, the patient should be able to walk farther with fewer rest breaks. Meticulous foot care is important to prevent complications of ulceration and gangrene. Patients should be instructed about wearing properly fitted footwear, daily inspection of feet and legs, avoidance of walking barefoot, application of lotion on feet and legs, and meticulous toenail trimming. Podiatrist consultation is recommended for patients with fungal overgrowth and/or ingrown toenails.

Pharmacological Treatment: Pharmacological treatment is provided with conservative treatment. Currently, aspirin (81to 325 mg daily) is one of the mainstays for such treatment. Aspirin has been shown to prevent progression of disease in patients with claudication. Cilostazol (Pletal) may be effective in relieving symptoms of claudication by improving walking distance through the promotion of vasodilation and antiplatelet activity. Vasodilators and anticoagulants have not proved effective in relieving pain symptoms. Clopidogrel (Plavix) 75 mg daily is an antiplatelet medication that helps reduce the risk of stroke, heart attack, and other atherosclerotic problems. Clopidogrel is frequently used for at least 3 months after peripheral arterial stents have been placed. Medications for the management of hypertension, diabetes, and hyperlipidemia should be used with the goals of euglycemia, normotension, and attainment of a healthy lipid profile (Rasmussen et al., 2019).

Surgical Treatment: Surgical treatment of PAD involves revascularization of the affected extremity. Surgical options should be considered when pain limits the patient's lifestyle or when ulceration or gangrene is present. Surgical options involve using vein graft or synthetic graft material. Long-term patency rate is dependent on smoking cessation, exercise, antiplatelet therapy, and diabetic control, as well as the location, length, and diameter of the graft (Rasmussen et al., 2019).

Endovascular Treatment: Endovascular options for the treatment of PAD include balloon angioplasty and endoluminal stents, which are minimally invasive for the patient. Angioplasty involves inflating a balloon across a stenotic lesion. Stents are devices that are deployed in a stenotic lesion to keep the vessel open. Other interventions include thrombolysis with fibrin-degrading infusions, mechanical thrombectomy, atherectomy, and subintimal recanalization (Rasmussen et al., 2019).

Follow-Up: Follow-up should include evaluating the patient's response to pharmacological intervention and the progression of risk factor modification. Ankle Brachial Indexes (ABIs) with pulse volume recordings (PVRs) should be done at least yearly to assess lower extremity perfusion (Rasmussen et al., 2019).

Sequelae: Patients with PAD have a 30% to 50% incidence of coronary artery disease and a 15% to 25% rate of carotid artery stenosis. The yearly cardiovascular rate including myocardial infarction, stroke, or death is approximately 5% to 7% in patients with PAD. Only 20% to 30% of patients with PAD die of noncardiovascular-related issues (Dua & Lee, 2016).

Prevention/Prophylaxis: Prevention of PAD focuses on slowing the progression of disease in patients with symptoms. This can be accomplished through risk factor modification, as discussed earlier. Good foot care, in conjunction with exercise, smoking cessation, glucose management if diabetic, and lipid management can prevent the development of tissue loss or gangrene.

Referral: Referral for surgical or endovascular treatment should occur when claudication becomes disabling to the patient, when ischemic rest pain or gangrene is present, or when nonhealing ulceration is present.

Education: Education needs to focus on proper follow-up and the modification of risk factors as discussed earlier; patients also need to be taught to report any new onset of symptoms, including nonhealing ulcers. There is a need for more research on the differences between the treatment for PAD in men and in women (Dua & Lee, 2016).

© F.A. Davis Publishing

VENOUS DISEASE (CHRONIC VENOUS INSUFFICIENCY)

Signal Symptoms: May be asymptomatic but could also present with swelling that subsides with elevation of lower extremities, eczematous skin changes, dull ache in lower extremities, and presence of varicosities.

Description: Venous leg ulcers (also known as chronic venous insufficiency ulcers, venous stasis ulcers, lower extremity venous ulcers, or varicose ulcers) are the most common leg ulceration. They typically occur over the medial malleolus, but they can also occur over the lateral malleolus. The ulcers are irregular and shallow with granulation tissue and fibrin present in the wound bed. Exudate is moderate to heavy, but if there is an arterial component, the amount of exudate may be decreased. These wounds often have a foul odor as well. The area around the wound often presents with dermatitis from the increased permeability of the venous capillaries causing protein to leak into the interstitial space, becoming irritating to the epidermis and dermis. The loss of protein and red blood cells into the subcutaneous tissue results in a brownish discoloration of the skin referred to as hemosiderin staining. Over time, the induration and hyperpigmentation is associated with fibrosis of the adipose tissue of the leg, which is called lipodermatosclerosis.

Etiology: Venous hypertension as a result of venous reflux (incompetence) or obstruction is thought to be the primary underlying mechanism for venous ulcer formation. Normally, blood flows from the superficial veins to the deep veins. Unidirectional valves and contraction of the calf muscles assist in blood flowing from the superficial to the deep veins. If there are any abnormalities (i.e., valvular incompetence, deep vein thrombosis, and/or failure of calf muscle pump), the deep and superficial veins become distended, increasing venous pressures.

Occurrence: Approximately 7 million individuals worldwide have venous disease, 2 million of which have venous leg ulcer. Venous leg ulcers account for 80% to 90% of all leg ulcers (Kelechi et al., 2020).

Age: As one ages (>50 years of age), the incidence of venous ulcers increases (Kelechi et al., 2020).

Ethnicity: There are no data to support an ethnic predisposition to venous disease.

Contributing Factors: Risk factors for venous leg ulcers include advanced age, obesity, pregnancy, thrombophilia, systemic inflammation, anticardiolipin antibody, venous thromboembolism (VTE)/phlebitis, varicose veins, pulmonary embolus, sedentary lifestyle or occupation, reduced mobility, simultaneous insufficiency of two out of three venous systems, trauma/surgeries/leg fractures, impaired calf muscle pump, restricted range of motion of the ankle, family history of venous disease, injection drug user, and previous leg wound (Kelechi et al., 2020). The presence of comorbid conditions such as cardiovascular disease, hypertension, lymphedema, and orthopedic procedures can also increase the risk of venous leg ulcers (Kelechi et al., 2020). Women are affected more than men, with multiple pregnancies or pregnancies close together increasing the risk.

Signs and Symptoms: Edema that worsens with standing and decreases with leg elevation is the classic sign of venous leg ulcers. The edema may be pitting or nonpitting. Other signs include hemosiderosis (hemosiderin staining), venous dermatitis (manifested as erythematous, scaly, pruritic skin), ankle flaring (cluster of spider veins), varicose veins, scarring from previous ulcers, and lipodermatosclerosis.

Diagnostic Tests: In many cases of venous ulcers, diagnosis may be made by clinical assessment alone, which includes skin changes in the leg, extent and location of edema, capillary refill less than 2 seconds, and palpation of pedal pulses. Duplex ultrasonography imaging with or without color has become the standard diagnostic tool for assessing venous disease. Duplex imaging produces images of blood flow and its direction through vessels, pinpointing the anatomical site of reflux or obstruction; thickened, abnormal vein walls; and the presence and age of a thrombus. Duplex scanning can be used to calculate the superficial venous pressures and allows for quantification of venous reflux and valve closure times. An ankle-brachial pressure index is also recommended to rule out significant arterial disease, especially before application of compression therapy.

Differential Diagnosis: Lower leg edema, which is one of the classic signs of venous disease, is also seen with other diseases as well. Deep vein thrombosis usually presents with pain and the presence of a thrombus on ultrasound. Patients with heart failure usually present with dyspnea, orthopnea, and a decreased ejection fraction. Patients with cirrhosis will have abnormal liver function studies, and those in renal failure will have proteinuria. The diagnosis of venous disease can be narrowed by categorizing the edema according to its duration (acute or chronic), distribution (unilateral or bilateral), and accompanying symptoms (e.g., pain, itching, skin changes).

Treatment: Treatment for venous ulcers includes management with compression therapy, leg elevation, medications, and surgery.

Conservative Treatment: Compression therapy is the gold standard for venous ulcers and is used by those with chronic venous disease to manage the edema and increase venous return. Compression has been shown to improve healing of venous ulcers when compared to no compression (Wound, Ostomy, and Continence Nurses Society, 2019) and reduce venous ulcer recurrence (Wound, Ostomy, and Continence Nurses Society, 2019). Compression is also effective in the improvement of symptoms of chronic venous disease, reduction of edema and pain, and improvement of quality of life (Kelechi et al., 2020).

Compression can be achieved with the use of a single layer wrap (bandage) or the use of multiple layer wraps (bandages) (Wound, Ostomy, and Continence Nurses Society, 2019). There are also compression garments, such as reusable Velcro wraps (e.g., CircAid®), sleeves (for example, the tube-shaped Tubigrip™), compression stockings, and intermittent pneumatic compression pumps (Wound, Ostomy, and Continence Nurses Society, 2019).

© F.A. Davis Publishing

Another feature of compression products is based on the type of material in the wrap (bandage). Elastic (which adapts to changes in limb size) should be prescribed for those who are sedentary. Inelastic (which will not change with limb size), should be prescribed for those who frequently ambulate. For patients with mixed venous and arterial disease (ankle-brachial index of greater than 0.5 to 0.8), a trial of supervised modified light compression up to 30 mm Hg may help decrease edema and promote ulcer healing (Wound, Ostomy, and Continence Nurses Society, 2019). Leg elevation above the heart for 30 minutes three or four times per day when used with compression can also help reduce edema (Wound, Ostomy, and Continence Nurses Society, 2019).

Pharmacological Treatment: Horse chestnut seed extract (HCSE) in a dose of 300 mg twice daily may reduce edema and pain in venous leg ulcers (Wound, Ostomy, and Continence Nurses Society, 2019). People with bleeding disorders, kidney disease, or liver disease should not take HSCE. There may also be interactions with certain medications, such as lithium, diabetic drugs, and anticoagulants, which might result in low blood sugars and slower blood clotting (Wound, Ostomy, and Continence Nurses Society, 2019). Pentoxifylline (Trental) 400 mg three times per day has been used to treat venous ulcers. It has been shown effective when used with compression and may be beneficial as monotherapy in those patients who cannot tolerate compression (Wound, Ostomy, and Continence Nurses Society, 2019). Topical steroids may provide short-term improvement of venous dermatitis. Oral antibiotics are only warranted in cases of suspected cellulitis (Wound, Ostomy, and Continence Nurses Society, 2019).

Surgical Treatment: Surgery should be considered when topical therapy and compression are not able to heal the venous ulcer. Surgical options to treat venous disease include interruption of the perforating veins with subfascial endoscopic perforator surgery (SEPS), laser ablation, radiofrequency ablation (RFA), and sclerotherapy (Wound, Ostomy, and Continence Nurses Society, 2019). Surgical procedures available for valvular incompetence include artificial valve insertion, direct valvuloplasty, and autogenous vein valve transplantation (Wound, Ostomy, and Continence Nurses Society, 2019). Skin grafts and bioengineered human skin equivalents may be used for those with large or refractory venous ulcers, but they must be used in conjunction with compression therapy to improve healing (Wound, Ostomy, and Continence Nurses Society, 2019).

Follow-Up: The goals of care are to reduce edema, promote ulcer healing, and prevent reoccurrence of the ulcer.

Sequelae: Compliance with compression, ulcer size, and duration of the ulcer affect ulcer healing. Ulcers larger than 5 cm^2 and present for more than 6 months are predictive for nonhealing, so early assessment and treatment with compression therapy is important to reduce complications such as infection from nonhealing ulcers (Wound, Ostomy, and Continence Nurses Society, 2019).

Prevention/Prophylaxis: The daily use of compression therapy for the rest of one's life is recommended to promote healing and reduce the chance of reoccurrence.

Referral: Patients with venous leg ulcer disease with impaired calf muscle pump function may benefit from physical therapy that includes flexion and extension exercises, as well as walking programs to improve calf muscle pump function (Wound, Ostomy, and Continence Nurses Society, 2019).

Education: Patients with venous ulcer disease should be instructed to use compression stockings every day for the rest of their lives and replace these compression stockings at least every 6 months. They should elevate the affected leg or legs above the heart several times a day. Physical activity is recommended to increase venous return and should be performed based on the patient's medical condition, but may include ankle flexion exercises, brisk walking, and sitting in a rocking chair and using the feet to push down to plantar flex the ankles.

CASE STUDY

M. J. is a 76-year-old woman who lives on the side of a very steep mountain. The home health nurse has visited her once a week for the last year. She has running water, electricity, and a coal stove with backup oil heat for very cold winter nights. She uses the telephone for communication. She has diabetes mellitus, hypertension, and hypothyroidism and is in atrial fibrillation. She has never been in the hospital before.

Her current medications include metformin (250 mg twice a day), losartan (50 mg/day), levothyroxine sodium (Synthroid) (50 mcg/day), digoxin (0.125 mg/day), furosemide (Lasix) (10 mg/day), aspirin (81 mg/day), simvastatin (20 mg/day), and warfarin (Coumadin) (4 mg/day, with 6 mg on Sundays). Allergies are to penicillin (hives) and to metoprolol (hypotension and dizziness). M. J. stopped smoking 5 years ago, but until then she smoked one-half pack a day.

Last laboratory test results (1 week ago) were: hemoglobin A1C (Hgb A1C) 8.3, international normalized ratio (INR) 1.7, sodium 129, potassium 5.8, chloride 102, CO_2 20, blood urea nitrogen (BUN) 45, creatinine 1.5, glucose 289, white blood cell (WBC) count 6.8, Hgb 10.1, hematocrit 30.2, platelets 215,000.

The home health nurse calls you from the patient's house, where she notes that the patient had a 5-minute spell of visual loss in her right eye. It has not recurred. During this period, M. J. noted that her left hand and left leg felt "funny," and her left foot and leg were so weak that she could not walk.

M. J. has a heart murmur, described by the home health nurse as loudest over the right sternal border and more prominent in the systolic phase. Furthermore, the home health nurse tells you that she hears bruits on both sides of the neck, with the right being louder than the left. The blood pressure in the right arm is 135/72 mm Hg and 110/66 mm Hg in the left arm. Heart rate is irregular at 75 to 90 beats per minute. The left hand and fingers have always been cooler than the right. Lungs are remarkable for wheezes. The patient has no fever. Oxygen saturations at room temperature are 90% to 92%, which has been her baseline.

1. What concerns do you have regarding M. J. at this point?
2. Do you need to see M. J. fairly soon, or can she come to see you at her regularly scheduled appointment in 3 weeks?
3. If you were to see M. J. in the next 24 hours, what additional tests would you perform?
4. Based on the laboratory results given, what changes would you make in her medication profile?
5. Which arm will you use for blood pressure recordings in the future?
6. What systolic blood pressure range would you order for M. J., as a general target?
7. If M. J. has a repeat episode of right eye blindness, lasting 30 minutes this time, what would you do?

CHAPTER 13

Gastrointestinal Disorders

Laurie Kennedy-Malone

ASSESSMENT

Accurate history taking of gastrointestinal (GI) complaints is essential for completing an assessment of the older adult. The physical examination is often unremarkable, and laboratory findings may not provide diagnostic information because the presentation of illness in an older adult is usually subdued (Vonnes & El-Rady, 2021). GI conditions common in older adults include esophageal, gastric, and motility disorders such as Barrett's esophagus, gastric cancer, GI bleeding, *Clostridioides difficile* colitis, inflammatory bowel disease, diverticular disease, constipation, and colon cancer (Dumic et al., 2019; Soumekh & Katz, 2021).

Gathering the Gastrointestinal History

Generally, the chief complaints of GI conditions can be categorized into symptom cluster areas for further exploration: abdominal pain/discomfort, gastroesophageal reflux disease (GERD)/regurgitation symptoms, nausea/vomiting, diarrhea/incontinence, and difficult defecation and constipation (Koloski et al., 2017). Explore with the patient any episodes of change in appetite, anorexia, involuntary weight loss, dyspepsia, dysphagia, heartburn, nausea, regurgitation, vomiting, painful or difficult defecation, diarrhea, tenesmus, or constipation. Inquire if there has been any associated trauma with the presenting symptom, any hematemesis, hematochezia, or melena (Malagelada et al., 2017; Mealie et al., 2020; Wilkinson et al., 2019). If the patient's chief complaint is abdominal pain, differentiate between organic and functional origins of pain (Dunlap & Patterson, 2020).

Determine the sequence of events that triggered each symptom. Inquire about precipitating factors, such as an introduction of new foods or beverages (intolerance), meal consumption, position of the body, use of caffeine, alcohol use, or smoking. Were any other symptoms present that can be clustered to form a differential diagnosis? It is important to discern from patients what therapeutic measures they have initiated to alleviate the symptoms (McGee, 2020; Mealie et al., 2020). Determine whether the treatment is a previously prescribed regimen, an over-the-counter (OTC) medication, an herbal product, or a home remedy. Ask the patient when the last time a fecal occult blood test was performed and whether they recently had a colonoscopy.

Abdominal Symptoms

Although abdominal pain is a common acute problem with which patients present to their health-care providers, older adults may not experience the typical symptoms of abdominal disorders that younger patients report. If patients present with abdominal pain, it is important to discern the characteristic of the pain. How quickly did the pain begin? Was the pain abrupt? Is the pain progressive or intermittent? Has the patient ever experienced this type of pain before and, if so, what was the diagnosis and treatment? Has the patient noted any improvements with self-treatment, positioning, vomiting, or defecation? What is the referral pattern? Is the pain worse at night or during the day? Is it relieved or aggravated by food? If the patient reports triggers to abdominal pain by food, ask more specific questions pertaining to food to discern if the patient is having a specific food intolerance(s) or possible food poisoning. Does the patient have any associated symptoms of regurgitation, reflux, cough, nausea, vomiting, constipation, or diarrhea? (McGee, 2020). Ask about the severity of pain by having the patient rate the pain on a scale from 1 to 10; however, realize that in older adults' pain may be blunted despite the underlying pathology (Dumic et al., 2019; Vonnes & El-Rady, 2021). Determine the patient's family history of GI disorders, including malignancies. Gather a history of previous abdominal surgeries. Inquire about alcohol use or drug abuse. Ask the patient if they are taking any medications to decrease or stimulate appetite depending on the chief complaint. Inquire about any history of jaundice, heart disease, or peripheral vascular disease. Review all current medications (Mealie et al., 2020).

Inspection

The physical examination of the abdomen begins with inspection, checking for overall symmetry while observing the patient lying down. The practitioner can consider the abdomen to be divided into four quadrants, visualizing an imaginary vertical line from the sternum to the pubis passing though the umbilicus and a horizontal line drawn through the umbilicus.

© F.A. Davis Publishing

In addition to being familiar with the underlying organ systems and referred pain in the four quadrants, the nurse practitioner should be familiar with other anatomical landmarks, such as epigastric, periumbilical, suprapubic, and McBurney's point, which is one-third of the distance from the right anterior superior iliac spine to the umbilicus (Mealie et al., 2020).

Carefully examine for scars, lesions, stomas, striae, discoloration, dilated veins, or other marks. If surgical scars are detected, review with the patient their surgical history if not documented. Determine whether the abdomen is concave or protuberant. Is an umbilical, abdominal wall, incisional, or inguinal hernia present? If a hernia is suspected, have the patient raise the head and note if there is presence of a bulge (Shakil et al., 2020). Is a lift noticeable? Is there abdominal distention? If so, is the distention local or generalized? Causes of generalized distention include abdominal fat, peritoneal fluid, or gaseous distention, whereas local distention often is indicative of obstruction or organ or structural enlargement. Examine the umbilicus. Signs of ascites include a flat or everted umbilicus (Williams, 2009). Check for any bulging in the flanks as a sign of ascites.

Examine the skin of the abdomen for color, noting if there is any jaundice (as found in liver disease) or biliary tract obstruction, bruising, or telangiectasias (Suneja et al., 2020). A bluish discoloration detected around the umbilicus is known as Cullen's sign, which is often found in patients with bleeding in the peritoneum. If the bluish discoloration is on the flanks, this is known as Grey Turner sign and is often indicative of retroperitoneal bleeding, as in pancreatitis (Mealie et al., 2020; Rastogi, 2019). Jaundice in the area of the umbilicus is known as Ransohoff's sign and is a result of a ruptured common bile duct (Rastogi et al., 2019). Note whether there are any pulsatile movements across the abdomen. If present, this sign may be indicative of a vascular aneurysm or a wide arterial pulse pressure. Visible intestinal peristalsis may be indicative of bowel obstruction (Shimizu & Tokuda, 2013). If pink or purple striae appear on a pendulous abdomen, consider underlying Cushing syndrome (Mealie et al., 2020). Examine for any evidence of a pulsatile mass, which may be present in an abdominal aortic aneurysm or in muscle diastasis (Dunlap & Patterson, 2020).

Auscultation

Auscultations follow inspection of the abdomen. Using the diaphragm, place the stethoscope lightly against the skin. Listen for bowel sounds, vascular bruits, and rubs. Bowel sounds are produced by peristalsis. A murmur heard in the abdomen may be an aortic aneurysm. A constant systolic-diastolic bruit may occur when the patient has an arteriovenous fistula in the renal vessels. Other sites to auscultate for bruits during abdominal examination include the iliac arteries and the femoral arteries (Mealie et al., 2020)

Take the time auscultate for presence or absence of bowel sounds. Generally, people who are hungry have active bowel sounds. Bowel sounds described as high pitched, rumbling, or tinkling are known as borborygmi. A rushing sound is associated with bowel obstruction. If bowel sounds are absent, listen for 5 minutes. Listen for a loud succussion splash over the abdomen of a patient in whom you suspect a gastric obstruction or dilations (Williams, 2009). Suspect peritonitis, mesenteric thrombosis, or advanced intestinal obstructions when bowel sounds are absent (Jackson & Cruz, 2018). Nurse practitioners should not, however, rely on auscultation alone for diagnostic purposes; studies have refuted the usefulness of auscultation when differentiating patients who have normal versus pathological bowel sounds (Felder et al., 2014).

Percussion

Percussion of the abdomen is performed to determine the density of tissue of the abdominal organs by the sounds emitted when tapped (Rastogi et al., 2020). It is normal to hear tympanic sounds over the stomach, whereas dullness is expected over a distended bladder, the liver, and the spleen (Suneja et al., 2020). Dullness noted over other areas of the abdomen is a deviation from the norm. Definitive percussion is used to ascertain the size and shape of the liver and spleen. Because the liver decreases in size starting at about age 50 years, the normal range of the liver size in an older person is 6 to 12 cm (Williams, 2009).

Palpation

Perform light palpation to discern abdominal masses; enlarged organs such as liver, spleen, and kidneys; and areas of tenderness. If a mass is detected, the nurse practitioner needs to determine whether the mass is intra-abdominal or within the abdominal wall. Using the palm and extended fingers of the right hand, press about 21 cm deep. If a patient has complained of abdominal pain, always palpate in a quadrant away from the identified location. (Suneja et al., 2020). If noted tenderness is elicited over the epigastrium, consider gastritis or early acute cholecystitis from visceral nerve irritation (Mealie et al., 2020).

Once you discover the tender area, maintain pressure over the area to determine the consistency of the pain. Try to note if there is any voluntary guarding by the patient during palpation. If the pain diminishes despite the applied pressure to the area, inflammation is unlikely. If you suspect intra-abdominal tenderness, proceed to deep palpation. Check for referred rebound tenderness by applying pressure with the tips of the fingers to a site distant from the areas of questionable tenderness, and then quickly remove them from the abdomen (Suneja et al., 2020). Assessment of the patient's facial expression is warranted, especially in older adults who have difficulty with communication (Williams, 2009). Specific maneuvers to detect tenderness can lead the examiner to making a differential diagnosis; for instance, tenderness medial to McBurney's point suggesting a Meckel diverticulum should be distinguished from typical appendicitis tenderness. If tenderness is elicited remote from the areas palpated after release of pressure, consider peritoneal irritation (Mealie et al., 2020); a positive Rovsing's sign suggests right-sided peritoneal irritation if pain is reported when the examiner has performed deep palpation on the lower left quadrant (Rastogi et al., 2018). Although it is known that older adults may present with a subdued presentation of appendicitis, two maneuvers may elicit signs of an inflamed appendix. Pain may be elicited when the patient lifts the right knee as the examiner presses on the knee at the same time (psoas sign) and or by internal rotation of the flexed right thigh (obturator sign) (Hirsch, 2017).

© F.A. Davis Publishing

BOWEL OBSTRUCTION

Signal Symptoms: Cramping abdominal pain, dehydration, nausea, vomiting, obstipation, restlessness.

Description: Bowel obstructions are classified as mechanical or nonmechanical and partial or complete and are located in either the small or large intestine (Jackson & Cruz, 2018).

Etiology: Normal flow of gastric and intestinal contents is interrupted (Jackson & Cruz, 2018). A mechanical bowel obstruction results when there is a complete or partial blockage of the lumen of the bowel by an adhesion, tumor, or hernia. Additionally, adynamic ileus and colonic pseudo-obstruction occur because of a lack of enteric propulsion resulting from trauma, medications, metabolic disturbance, and postoperatively (Catena et al., 2019). Postoperative adhesions cause approximately 60% to 70% of small bowel obstruction (SBO) (Ozturk et al., 2018).

Occurrence: The incidence of SBO annually in the United States is about 350,000 (Reddy & Cappell, 2017), and large bowel obstruction occurs approximately four to five times less frequently than SBO (Jaffe & Thompson, 2015). Bowel obstruction occurs equally in men and women.

Age: Bowel obstruction from all causes, except intussusception, is more prevalent in older adults (Panzera et al., 2021).

Ethnicity: Not significant.

Contributing Factors: Most common causes include adhesions from previous abdominal or pelvic surgery, neoplasms, and herniation (Jackson & Cruz, 2018). Additional causes for mechanical obstruction include diverticulitis, foreign bodies (including gallstones, although uncommon), volvulus (twisting bowel on its mesentery), and intussusception (telescoping of one segment of bowel into another), fecal impaction, endometriosis, inflammatory bowel disease stenosis (Catena et al., 2019; Jackson & Cruz, 2018; Ozturk et al., 2018).

Signs and Symptoms: Patients should be asked about last bowel movement, ability to pass gas, previous episodes of diverticulosis or chronic constipation, any evidence of rectal bleeding or unexpected weight loss. Question the patient about medications to include any taken to relieve symptoms of pain and bloating (Catena et al., 2019). Older adults often present for evaluation late in their illness and often have atypical or nonspecific complaints (Ozturk et al. 2018). Older patients may present restless, show dehydration, sepsis, dry mucous membranes (Reddy & Cappell, 2017); underlying signs of prefrailty or frailty may be evident (Ozturk et al., 2018). The most common symptoms reported are bloating, colicky cramping abdominal pain, nausea, vomiting, abdominal distention, cessation of flatulence, and obstipation (Jackson & Cruz, 2018). It is important to note in patients with incomplete obstruction, watery diarrhea may be present initially (Ten Broek et al., 2018).

Inspect the abdomen for evidence of surgical scars and external hernias; the level and the location of the obstruction determines the amount of abdominal distention (Jackson & Cruz, 2018). Observe for visible peristalsis, which is a sign of bowel obstruction (Shimizu & Tokuda, 2013). Auscultate bowel sounds. In acute mechanical bowel obstruction, the bowel sounds are hyperactive and are described as "high-pitched tinkling" (Jackson & Cruz, 2018). Bowel sounds may be absent with advanced obstruction in the intestinal tract (Jackson & Cruz, 2018). Palpation of the abdomen may reveal abdominal wall or groin hernias. In mechanical obstruction of the large bowel, symptoms are similar to an SBO, but they appear more gradually. Perform a digital rectal examination to determine whether fecal impaction or rectal mass is a source of the obstruction (Jackson & Cruz, 2018). Given the possibility of dehydration and/or sepsis, monitor the vital signs for evidence of tachycardia and hypotension (Jackson & Cruz, 2018).

Diagnostic Tests: Standard laboratory evaluation includes a complete blood count (CBC) with differential and a metabolic panel to assess the patient for presence and severity of hypovolemia, hypokalemia, hypochloremia, metabolic alkalosis (may be evident in patients with emesis). Leukocytosis may be evident in patients who have had intestinal bacterial transmission or bowel perforation (Jackson & Cruz, 2018). Presence of leukocytosis, especially in frail older adults, may be delayed (Ozturk et al., 2018). Obtaining a serum lactate and C-reactive protein (CRP) should be considered in patients with suspected mesenteric ischemia or peritonitis (Ten Broek et al., 2018).

The initial imaging of a patient with a suspected bowel obstruction is the plain abdominal x-ray with flat and upright views, although the results may be normal in patients early in the obstruction phase or in those with a proximal obstruction (Catena et al., 2019; Jackson & Cruz, 2018). Plain films can identify multiple air-fluid levels, distention of small bowel loops, and the absence of gas in the colonic section (Ten Broek et al., 2018). If x-rays do not show an obstruction and there is a high index of suspicion, a computed tomography (CT) scan should be used to further evaluate. CT scan is found to have as much as a 90% sensitivity in identifying the presence of bowel strangulation and can identify the etiology and the site of the obstruction (Ten Broek et al., 2018). A water-soluble contrast enema may be ordered if a bowel obstruction is suspected (Catena et al., 2019). Ultrasonography may be used in the evaluation of acute abdominal pain and can be used to identify obstruction along with its cause (Catena et al., 2019; Jackson & Cruz, 2018).

Differential Diagnosis:

- Cholecystitis
- Constipation
- Diverticulitis
- Gallstones
- Abdominal hernia
- Narcotic bowel
- Appendicitis (stump appendicitis)
- Pelvic inflammatory disease
- Mesenteric ischemia
- Pseudo-obstruction (Ogilvie's syndrome)
- Medication adverse effects
- Postoperative paralytic ileus
- Perforated viscus/intra-abdominal sepsis
- Renal colic (Catena et al., 2019, p. 2; Jackson & Cruz, 2018, p. 346, Reddy & Cappell, p. 28)

© F.A. Davis Publishing

Treatment: Acute intestinal obstruction is a common reason for older adults to be admitted for evaluation by a general surgery service and to be treated by nonoperative management (NOM) or surgery (Catena et al., 2019; Jackson & Cruz, 2018). Initial treatment of a bowel obstruction consists of hospitalization for nasogastric suctioning and IV fluid administration to correct fluid and electrolyte imbalance (Ozturk et al., 2018). Bladder catheterization may be considered to monitor urine output (Jackson & Cruz, 2018). In the absence of clinical sign of strangulation or peritonitis, the patient can be treated with NOM up to 72 hours. Systematic signs of tachycardia, fever, focal tenderness, and elevated lactate levels can indicate intestinal ischemia (Ten Broek et al., 2018). Immediate surgical intervention is indicated for suspected vascular insufficiency, perforation, or strangulation of the bowel or in patients whose condition deteriorates from the time of admission (Jackson & Cruz, 2018). Bowel obstruction caused by tumors is treated with surgical resection and anastomosis when the patient's condition permits (Catena et al., 2019).

Follow-Up: Ten Broek and colleagues (2018) recommend NOM should be attempted for 3 to 5 days, then surgical management used for unresolved obstructions.

Sequelae: Complications from bowel obstruction include wound dehiscence, aspiration, short bowel syndrome, pneumonia, bowel perforation, anastomotic leak, and renal failure (Smith et al., 2021). Delay in surgery may increase morbidity and mortality outcomes in older adults (Ozturk et al., 2018). Recurrence of adhesive small bowel obstruction is common with nonoperative treatment (Catena et al., 2019; Jackson & Cruz, 2018). In older adults with a diagnosed malignancy as the cause of the bowel obstruction, consideration of the patient's wishes and quality of life need to be forefront (Ozturk et al., 2018).

Prevention/Prophylaxis: Caregivers must understand the importance of avoiding fecal impactions in patients at risk for this condition.

Referral: Consider referring to surgical service upon admission to the hospital (Jackson & Cruz, 2018).

Education: Inform older adults with diagnosed untreated internal and external hernias of the possible complication of bowel obstruction.

CHOLECYSTITIS

Signal Symptoms: Acute onset of right upper quadrant and/or epigastric pain that is persistent, with radiation to back or shoulders, and usually related to history of fatty meal intake prior to onset (Vagholkar, 2020).

Description: May fall into one of three categories: acute gallbladder inflammation related to cystic duct obstruction by gallstones, acalculous cholecystitis without presence of stones or sludge, or chronic gallbladder inflammation (Mou et al., 2019; Vagholkar, 2020).

Etiology: Gallstones are mainly composed of cholesterol, and stone formation is associated with pregnancy, rapid weight loss, diabetes mellitus, dyslipidemia, obesity, genetics, female sex, medications, older age, and metabolic syndrome (Zhao et al., 2019). Cholecystitis usually occurs when a gallstone obstructs the cystic duct; however, acalculous cholecystitis may be found in approximately 10% of cases, specifically in critically ill states (Vagholkar, 2020). Trapped bile caused by the blockage of the cystic duct leads to inflammation, impaired circulatory flow, and ischemia. The risk of bacterial infection climbs, with increased complications after 72 hours of symptoms (Mou et al., 2019). Common culprit organisms are *Escherichia coli*, *Klebsiella pneumonia*, and *Bacteroides fragilis* (Pisano et al., 2020). *Enterococcus* species may be found in immunocompromised patients (Pisano et al., 2020). Acute acalculous cholecystitis (AAC) is precipitated by stagnant bile and ischemic states; the critically ill patient who has suffered trauma, recent surgery, shock, sepsis, cardiac complications,

© F.A. Davis Publishing

sickle cell disease, diabetes, and total parenteral nutrition is at risk for AAC (Alshargi et al., 2018; Vagholkar, 2020).

Occurrence: Gallstones' prevalence ranges between 10% and 15% among adults, and 10% to 15% of these individuals will develop acute symptoms (Mou et al., 2019; Pisano, et al., 2020). ACC comprises the majority of all cases, with only 10% AAC (Vagholkar, 2020). Gallstones may be an incidental finding via imaging, and 80% of those with gallstones are asymptomatic (Mou et al., 2019). In the older adult, cholecystitis can present with atypical features and likely a complicated disease course (Chhoda et al., 2021).

Age: During reproductive years, women are more prone to gallstones than men (Mou et al., 2020; Vagholkar, 2020). As age increases, the risk for gallstones increases regardless of gender (Chhoda, 2021; Vagholkar, 2020). The risk of biliary disease is from 14% to 23% for the older adult, with increasing prevalence to 80% if older than 90 years (Chhoda et al., 2021).

Ethnicity: A high prevalence for cholecystitis exists among Hispanics and Native Americans; in the United States, biliary disease is greater in Hispanics compared to all other ethnicities (Figueiredo et al., 2017).

Contributing Factors: Nonmodifiable risk factors for cholecystitis include advancing age, female sex, race, and family history of gallbladder disease (Vagholkar, 2020). Females less than age 50 have a threefold likelihood of developing ACC compared to men (Mou et al., 2019). Obesity is a known predisposing factor to cholecystitis (Vagholkar, 2020). Diabetes, alcoholic cirrhosis, inflammatory bowel disease, chronic hemolysis, pancreatic insufficiency, and hyperlipidemia predispose patients to gallstone development. Gallstone formation may be attributed to use of exogenous estrogens prescribed for postmenopausal hormone replacement and hormonal contraceptives (Figueiredo et al., 2017). Gallbladder stasis, a precursor to gallstone formation, occurs with extended total parenteral nutrition (Vagholkar, 2020). Patients who experience rapid weight loss are at high risk for the development of gallstones, placing those with history of bariatric surgery at greater risk for gallstones.

Signs and Symptoms: The most common type of presentation includes the acute onset of right upper quadrant and/or epigastric pain that is moderate to severe in nature, persistent, and without any relieving factors (Mou et al., 2019; Vagholkar, 2020). Associated symptoms may include nausea, vomiting, malaise, fever, and poor appetite. A change in mental status, incontinence, and falls in the older adult may be the only outward sign (Chhoda et al., 2021). Physical examination may reveal right upper quadrant subcostal tenderness, guarding, and pain on inspiration (Murphy's sign) (Pisano, 2020; Vagholkar, 2020). The absence of Murphy's sign does not exclude the acute illness; the older adult may not exhibit Murphy's sign (Chhoda et al., 2021). Biliary colic pain can initially start in the epigastric region, then radiate to the right upper quadrant (RUQ); thus, it is important to question the patient about generalized upper abdominal pain (Vagholkar, 2020). In a patient who reports experiencing symptoms for days, rebound tenderness may suggest perforation. Jaundice on examination would raise concern for possible complications including obstruction; however, 15% of presentations will have jaundice (Vagholkar, 2020).

Diagnostic Tests: Mild leukocytosis with increased band formation is the most common abnormality seen on laboratory studies; however, white blood cell (WBC) counts may not be elevated in the older adult (Vagholkar, 2020). Significant leukocytosis would raise concern for complicated cholecystitis secondary to perforation, gangrene, and sepsis (Vogholkar, 2020). Elevation in lipase, amylase, and elevated liver function tests would prompt further evaluation for gallstone pancreatitis (Chhoda et al., 2021). In chronic cholecystitis, however, laboratory values may be normal. Elevations in alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are common, and the total bilirubin and alkaline phosphatase can have a lag effect, increasing through the acute clinical course.

Real-time ultrasonography of the gallbladder and biliary tree is the diagnostic procedure of choice for both acute and chronic cholecystitis, showing gallstones, thickening of the gallbladder wall and, if the common bile duct is obstructed, dilation of the biliary tract (Pisano et al., 2020). An additional imaging modality called the hepatobiliary iminodiacetic acid scan (HIDA) is useful if there is concern for cystic duct obstruction or biliary dyskinesia. A computed tomography (CT) scan is often performed to evaluate acute abdominal pain when diagnosis is unclear; yet it is less sensitive at identifying gallstones than an ultrasound (Alshargi et al., 2018; Pisano et al., 2020). In situations where choledocholithiasis is questioned, a magnetic resonance cholangiopancreatography (MRCP) is highly sensitive and specific (93% and 96%, respectively) for biliary tree obstruction (Pisano et al., 2020). In cases with high suspicion for choledocholithiasis, MRCP can reduce the need for unnecessary endoscopic retrograde cholangiopancreatography (ERCP) (Pisano et al., 2020). Liver functions tests (LFTs), including bilirubin, may be elevated due to inflammatory gallbladder and biliary tree without any presence of choledocholithiasis; therefore, serologies are not sufficient to diagnosis choledocholithiasis, and further imaging is needed (Pisano et al., 2020). An endoscopic ultrasound (EUS) and MRCP are useful preoperatively if there is moderate concern for choledocholithiasis; an ERCP or intraoperative cholangiography (IOC) is necessary for patients with high risk for choledocholithiasis for both diagnostic and therapeutic purposes (Pisano et al., 2020).

Differential Diagnosis:

- Perforated peptic ulcer in older adults
- Appendicitis
- Liver abscess
- Diverticulitis
- Hepatitis
- Acute pyelonephritis
- Gastrointestinal (GI) carcinoma
- Acute pancreatitis
- Myocardial ischemia
- Herpes zoster
- Gastritis
- Peptic ulcer disease
- Mesenteric ischemia
- Cholangitis
- Irritable bowel syndrome
- Gastroesophageal reflux disease (GERD) (Jones et al., 2021)

Treatment: Acute episodes require hospital admission in preparation for cholecystectomy; at this time antibiotics are given intravenously and selected based on targeting enteric pathogens. Antibiotic resistance should be taken into consideration, with antibiotic therapy tailored according to identified pathogens. Antibiotic choices may include but not limited to piperacillin-tazobactam, ampicillin-sulbactam, meropenem, imipenem-cilastatin, and third generation cephalosporins combined with metronidazole (Vagholkar, 2020). Depending on surgical risk, laparoscopic cholecystectomy is the preferred method of surgical intervention and should be undertaken within 72 hours (Chhoda et al., 2020; Mou et al., 2019). Open cholecystectomy may be necessary if patients are morbidly obese, if they are at increased risk for adverse reactions to anesthesia, or if there is a concern for malignancy, or if the patient has peritonitis, advanced liver disease with cirrhosis and portal hypertension, sepsis with cholangitis, or pancreatitis (Vagholkar, 2020). Supportive measures include giving analgesics and antiemetics as needed. The risk of conversion to open cholecystectomy is linked with male sex, older age (greater than 60 years), and prior abdominal surgeries (Pisano et al., 2020).

A cholecystectomy for acalculous cholecystitis in the critically ill patient may be on hold and delayed until health improves, with a percutaneous cholecystostomy (PC) tube as an initial approach to treatment (Mou et al., 2019). PC should not be performed on patients with coagulopathy, with complications including biliary leak, peritonitis, vascular compromise, and dislodgement of catheter (Chhoda et al., 2021). The general surgeon may weigh risks and benefits of a PC versus interval cholecystectomy in a patient with multiple comorbidities; if PC is performed within 24 hours of symptoms, hospital length of stay may be reduced (Mou et al., 2019). The recurrence risk of events following conservative management of cholecystitis is high; therefore, surgical intervention should be undertaken if there are no contraindications. In the event of choledocholithiasis, an ERCP may be undertaken for stone extraction prior to cholecystectomy (Pisano et al., 2020). If the clinical status is unknown regarding choledocholithiasis, a cholecystectomy with intraoperative cholangiogram is indicated to ensure no occult stones remain. Cholangitis requires prompt recognition in order to provide IV antibiotics, biliary decompression via ERCP, and close monitoring for sepsis. Subsequent cholecystectomy is indicated after biliary decompression.

Although used less often now than in the past, oral ursodeoxycholic acid may be considered for dissolution of gallstones less than 10 mm for prophylactic purposes in higher risk patients; however, the gallbladder must be functioning and the cystic duct must be patent (Chhoda et al., 2021). Recurrence rate of stones is more than 50%, even with ursodeoxycholic acid. Extracorporeal shock wave lithotripsy is a possible alternative in nonsurgical candidates, yet potential complications, including biliary pancreatitis and hematomas, may raise concern for the procedure.

Follow-Up: Postoperative management of routine cholecystectomy includes monitoring for impending infection, adverse drug reactions and interactions, and changes in functional and mental status. For the frail older adult who has undergone percutaneous cholecystostomy, observation for complications is crucial. For older women, the dosages of estrogen preparations may need to be reduced, if applicable, due to the idea that estrogen may contribute to gallstone development (Figueiredo et al., 2017).

Sequelae: Complications of acute cholecystitis include gangrenous cholecystitis, perforation, emphysematous cholecystitis, cholecystoenteric fistula, gallstone ileus, choledocholithiasis leading to cholangitis, and acute biliary pancreatitis (Chhoda et al., 2021). Frail older adults, especially those who are diabetic, are at high risk for complications from cholecystitis (Pisano et al., 2020). Patients may develop diarrhea and/or bloating postprandially after ingesting higher fat and greasy foods postcholecystectomy, but symptoms may improve over time; however, symptoms may be long term.

Prevention/Prophylaxis: The importance of resting and avoiding risk factors after acute cholecystitis or an exacerbation of chronic cholecystitis needs to be emphasized.

Referral: A surgical consultation is necessary if acute cholecystitis is suspected. A gastroenterologist should be consulted for the frail older adult who is not a surgical candidate, or in the clinical scenario of choledocholithiasis. Biliary pain in patients with a prior history of a cholecystectomy should be evaluated for a retained common bile duct stone. Referral to a gastroenterologist for evaluation by ERCP, magnetic resonance imaging (MRI), or endoscopic ultrasonography is highly recommended (Pisano et al., 2020).

Education: To prevent complications, encourage patients with chronic cholecystitis and patients for whom surgery is contraindicated to report early signs and symptoms of an acute attack. Patients also should be educated that gallstones could recur in the common bile duct, despite prior cholecystectomy.

CIRRHOSIS OF THE LIVER

Signal Symptoms: Jaundice, fatigue, spider angiomas, palmar erythema, nodular liver, choluria, ascites, encephalopathy.

Description: Cirrhosis occurs when there is chronic insult to the liver, resulting in fibrous and nodular regeneration of the existing hepatocytes, resulting in significant scarring and impaired liver function. From 1999 to 2019, cirrhosis was the eleventh leading cause of death in the United States with an average annual death rate over 40,000 per year (Centers for Disease Control and Prevention National Center for Health Statistics, 2020). The annual health-care costs for cirrhosis and advanced liver disease in the United States are between $12 billion and $23 billion (Peery et al., 2019).

Etiology: The most common etiology for cirrhosis in the United States is viral hepatitis (mostly hepatitis C and hepatitis B), alcoholic liver disease, and nonalcoholic steatohepatitis (NASH, an advanced form of nonalcoholic fatty liver disease [NAFLD]) (Smith et al., 2019). Hepatitis C recently replaced alcoholic cirrhosis as the leading cause of cirrhosis in patients who are on the liver transplant list. However, with increasing prevalence of fatty liver disease, estimates suggests that NASH will replace hepatitis C as the leading cause of cirrhosis in transplant-listed patients between 2025 and 2035 (Smith et al., 2019). The cause of primary biliary cirrhosis, a chronic autoimmune inflammatory disease of the liver in which the intrahepatic bile duct is destroyed, is unknown. Other causes of cirrhosis include autoimmune diseases (such as autoimmune hepatitis and primary sclerosing cholangitis), abnormal storage diseases (such as hemochromatosis, Wilson's disease, and alpha-1 antitrypsin deficiency), cardiovascular diseases (such as right-sided heart failure, Budd-Chiari's syndrome, and Osler-Weber-Rendu's disease), medications, sarcoidosis, and schistosomiasis (Smith et al., 2019).

Occurrence: In the United States it is estimated that 630,000 Americans have cirrhosis, although many are asymptomatic. The asymptomatic nature of early cirrhosis is why true estimates are hard to derive and likely two-thirds of patients are unaware of their disease (Scaglione et al., 2015).

Age: Liver disease, including cirrhosis, is diagnosed most frequently between the ages of 65 and 74 and is the eleventh leading cause of death (Centers for Disease Control and Prevention, 2018; Centers for Disease Control and Prevention National Center for Health Statistics, 2020). Additionally, advancing age increases the risk of drug-induced liver injury, especially with medications such as nitrofurantoin, isoniazid, and amoxicillin-clavulanate; this is likely affected by a predisposing influence of polypharmacy (Chalasani et al., 2014).

Ethnicity: The overall prevalence of cirrhosis is higher in non-Hispanic African Americans and Mexican Americans (Scaglione et al., 2015).

Contributing Factors: Overall, being male is independently associated with cirrhosis (Scaglione et al., 2015). However, in individuals who consume alcohol and develop alcoholic liver disease, progression to cirrhosis occurs more frequently in women compared to men (Crabb et al., 2020; Singal & Mathurin, 2021). The most common cause of cirrhosis in the United States is viral hepatitis, most often chronic hepatitis C or hepatitis B infection (Scaglione et al., 2015; Smith et al., 2019). Chronic alcohol consumption, either by itself or with other cirrhosis risk factors, is the second leading cause of cirrhosis; however, only 10% to 20% of patients with alcohol-associated liver disease will progress to cirrhosis (Singal & Mathurin, 2021; Smith et al., 2019). Finally, NAFLD and NASH are the third leading cause of cirrhosis, although it is expected to surpass hepatitis C as the leading cause of liver transplant within the next 5 to 15 years (Smith et al., 2019). Risk factors associated with NAFLD and NASH include many of the components of metabolic syndrome such as obesity, type 2 diabetes mellitus, and dyslipidemia (Chalasani et al., 2018). Additionally, although liver disease is the eleventh leading cause of death in the general population, it is the second or third leading cause of death in patients with NAFLD (Younossi & Henry, 2016). It should be noted that in patients with these three leading causes of cirrhosis, approximately 10% to 20% will develop cirrhosis within 10 to 20 years (Smith et al., 2019).

Drug-induced liver injury (DILI), and subsequent cirrhosis, is affected by several variables including age, sex, malnutrition, comorbidities, alcohol consumption, metabolic profile, dose, class effect, polypharmacy, and duration (Chalasani et al., 2014). The most common medications implicated in DILI include amoxicillin/clavulanate, isoniazid, methotrexate, allopurinol, amiodarone, fluroquinolones, macrolides, and nitrofurantoin. Certain infectious diseases, including sarcoidosis and

© F.A. Davis Publishing

schistosomiasis, have predisposed patients to a risk of developing cirrhosis (Smith et al., 2019). Other common causes of cirrhosis include certain storage diseases (such as hemochromatosis, Wilson's disease, and alpha1-antitripsyn deficiency), immune-mediated diseases (such as autoimmune hepatitis, primary biliary cholangitis, primary sclerosing cholangitis), cardiovascular conditions (such as heart failure, veno-occlusive disease [Budd-Chiari's syndrome], hereditary hemorrhagic telangiectasia [Osler-Weber-Rendu's disease]), and chronic biliary disease (such as recurrent bacterial cholangitis and bile-duct stenosis) (Smith et al., 2019).

Signs and Symptoms: Many patients are asymptomatic until advanced disease and decompensated cirrhosis occurs. When patients do exhibit symptoms, they can include anorexia, fatigue, weakness, generalized pruritus, right upper quadrant discomfort, unexplained weight loss, jaundice, ascites, peripheral edema, and encephalopathy (confusion and altered sleep). When questioned, reports of weight loss, easy bruising, and gastrointestinal (GI) bleeding may be common (Butterworth, 2019; Martin et al., 2014; Smith et al., 2019).

There are several physical examination findings that may be present in patients with cirrhosis (Smith et al., 2019). These may include muscle wasting, asterixis, jaundice, scleral icterus, spider nevi, ascites, dilated abdominal veins (caput medusae), enlarged or shrunken liver, hemorrhoids, splenomegaly, edema, erythema, palmar erythema, Kayser-Fleischer's ring around the cornea of the eye (in Wilson's disease), xanthoma, spider angiomas, clubbing of fingers, changes in the nailbed (Terry's nails, with two-thirds of the nailbed appearing white), Dupuytren's contracture, and asterixis. In men there may be decreased body hair, gynecomastia, and testicular atrophy.

Diagnostic Tests: The U.S. Preventative Services Task Force (USPSTF) recommends screening all adults 18 years and older for unhealthy alcohol intake (USPSTF et al., 2018). All adults should be screened yearly with a single question to elicit even a single episode of binge-drinking (five or more drinks a day for men, four or more for women) in the past year (Crabb et al., 2020). For any who answer yes, an assessment tool, such as the AUDIT (Alcohol Use Disorders Identification Test) (Saunders et al., 1993), AUDIT-C (first three questions of the AUDIT tool), or CAGE Questionnaire (Ewing, 1984), is recommended to evaluate for and diagnose alcohol use disorder (AUD), which can lead to alcoholic liver disease and cirrhosis (Crabb et al., 2020). It allows the practitioner to explore the patient's history of chronic alcohol use and the status of functional impairment.

In early or compensated cirrhosis, laboratory results may be normal; suspicion of liver injury may be aroused by elevated liver transaminases (aspartate transaminase/alanine transaminase [AST/ALT]) or abnormal imaging results (Smith et al., 2019). Other serologies alluding to possible cirrhosis include thrombocytopenia (typically with portal hypertension), elevated transaminases with an AST:ALT ratio greater than 1, elevated serum bilirubin, prolonged prothrombin time/International Normalized Ratio (PT/INR), and low serum albumin. For patients with whom there is suspicion of cirrhosis, other pertinent laboratory tests may help elicit specific etiology including viral hepatitis serologies (primarily for hepatitis B and hepatitis C); ferritin and transferrin saturation (for hemochromatosis); fasting lipid panel and hemoglobin A1c (Hg A1c) (for metabolic syndrome and NAFLD/NASH cirrhosis); antinuclear antibody, antismooth muscle antibody, and antimitochondrial antibody (for autoimmune cirrhosis); and ceruloplasmin (for Wilson's disease) (Smith et al., 2019).

In cirrhosis patients, a complete blood count (CBC) with indices may reveal anemia, which depends on etiology but is often multifactorial in nature, and may include chronic GI bleeding, alcohol toxicity, folate deficiency, anemia of chronic disease, splenomegaly, suppression of bone marrow, and hemolysis. Serum ammonia level is elevated in patients with hepatic encephalopathy resulting in confusion, disturbed sleep, and asterixis. The alpha-fetoprotein (AFP) level is elevated in patients with hepatitis C and is also a tumor marker for hepatocellular carcinoma (Marrero et al., 2018). Finally, certain biomarkers have been developed to help discern the degree of fibrosis and presence of cirrhosis, including the Fibrosis 4 score, Fibrotest/Fibrosure, NAFLD fibrosis score, and AST to platelet ratio index score; however, these are mostly validated in hepatitis C, except for the NAFLD fibrosis score, although they may still be helpful (Smith et al., 2019).

Abdominal ultrasound, a cost-effective option, can be ordered initially when cirrhosis is suspected to evaluate for findings suggestive of cirrhosis including surface nodularity, coarseness, increased parenchymal echogenicity of the liver; it can also be used for screening of cirrhosis sequelae including ascites, splenomegaly, portal hypertension, hepatocellular carcinoma (in conjunction with serum alfa-fetoprotein [AFP]), and portal vein thrombosis (with the addition of Doppler scanning (Marrero et al., 2018; Smith et al., 2019)). However, it should be noted that while ultrasonography has high sensitivity and specificity for detection of steatosis (94% and 84%, respectively), it is less effective at detecting fibrosis and cirrhosis (40% to 57% sensitive) (Smith et al., 2019). This is why liver biopsy, either percutaneous or transjugular, remains the gold standard for diagnosing liver cirrhosis (Smith et al., 2019). However, biopsy may still have a 20% rate of error in staging level of fibrosis and may also be unnecessary if clinical assessment, laboratory findings, and imaging results significantly suggest cirrhosis and biopsy would not alter patient management (Afdhal, 2003; Smith et al., 2019).

Differential Diagnosis:

- Liver cancer
- Alcoholic hepatitis
- Acute viral hepatitis
- Congenital hepatic fibrosis
- Idiopathic portal hypertension
- Idiopathic thrombocytopenia purpura (ITP)
- Ischemic hepatitis
- Schistosomiasis (O'Shea et al., 2010)

Treatment: The overall goal of treatment in cirrhosis is based on preventing liver decompensation, preventing cirrhosis complications, and preventing death (Smith et al., 2019). To prevent further hepatic insult, all patients with cirrhosis, regardless of etiology, should be counseled on complete abstinence of alcohol (Crabb et al., 2020; European Association for the Study of the Liver, 2018; Singal & Mathurin, 2021; Smith et al., 2019). Additionally, patients should also avoid or

© F.A. Davis Publishing

have dose-reduction with certain medications either due to hepatotoxicity or adverse effects that can affect cirrhosis management. These can include acetaminophen, NSAIDs, angiotensin-converting enzyme inhibitors, and systemic antifungals; whereas statins can cause elevated transaminases, they may be safely used (Chalasani et al., 2014; Smith et al., 2019). Some herbal medications and supplements have also been shown to be hepatotoxic, including germander, mistletoe, green tea extracts, echinacea, kava kava, camphor oil, black cohosh, saw palmetto, skullcap, valerian, aloe vera, vitamin A supplements, Herbalife products, Hydroxycut, and others (Bunchorntavakul & Reddy, 2013; Pittler & Ernst, 2003). A review of the patient's immunizations should be completed regularly to determine the need for influenza, hepatitis A and B, and pneumococcal pneumonia vaccines (Smith et al., 2019).

Nutritional therapy is of the essence because it has been estimated that as high as 75% to 90% of cirrhosis patients have malnutrition, which is more prevalent in advanced and decompensated disease, and more likely in alcohol-associated cirrhosis (Palmer et al., 2019). Poor nutrition has also been associated with cirrhosis complications such as ascites, hepatic encephalopathy, poorer liver function, and mortality. Because of this, it is recommended that all patients undergo assessment of body composition utilizing body mass index (BMI) and assessment for sarcopenia, lipopenia, and volume overload (Palmer et al., 2019). In cirrhotic patients, BMI needs to be adjusted, typically due to ascites and volume overload, although there is no validated way to do this; calculation with post-paracentesis weight may help (Tandon et al., 2016). The liver is the primary organ for the production and storage of many essential nutrients including glycogen/glucose, iron, proteins, vitamin A, vitamin D, vitamin B_{12} coagulation factors, hormones, cholesterol, ammonia, and others (Palmer et al., 2019). Malnutrition in cirrhotic patients often presents with loss of skeletal muscle and decreased muscle strength (which can be easily assessed with handgrip strength) (Palmer et al., 2019). In addition to sarcopenia, poor protein intake and synthesis results in low serum protein levels, decreased colloid pressure, and subsequently peripheral edema and ascites. Nutritional support as an attempt to counter sarcopenia, ascites/edema, and malnutrition should be multifactorial. Patients with cirrhosis (who are not obese) should consume 35 kcal/kg body weight per day and 1.2 to 1.5 g protein/kg body weight per day (European Association for the Study of the Liver, 2019). Specifically branch-chain amino acids (BCAAs, including valine, leucine, and iso-leucine) are plant-based amino acids needed for protein synthesis. Data shows that supplanting with oral BCAAs can reduce hepatic encephalopathy (Gluud et al., 2017); limited data show they may also possibly improve the patient's nutritional profile, prevent hospitalizations, and improve quality of life (Petta et al., 2010). Finally, consumption of a protein-rich late evening snack can help prevent protein breakdown during fasting state and has been shown to improve serum albumin levels, reduce AST/ALT, PT/INR, and ammonia levels and subsequently reduce recurrence of hepatic encephalopathy and ascites; however, the best composition of late evening snacks has not yet been determined (Chen et al., 2019; Palmer et al., 2019). Cirrhosis patients with ascites should have a 2,000 mg daily sodium restriction to help prevent edema and ascites (Smith et al., 2019). Multiple vitamin and mineral supplements should be prescribed, including adequate intake of vitamins A, D, E, and K, as well as B vitamins (if deficient), zinc, copper, and magnesium; avoid supplements with manganese because manganese levels are often high in patients with cirrhosis, and manganese can subsequently accumulate in the brain (Palmer et al., 2019). It is recommended, however, that a multiple vitamin without iron be used, unless iron-deficiency anemia is present (O'Shea et al., 2010).

Treatment for complications of cirrhosis may include antibiotics for infections such as spontaneous bacterial peritonitis (and possibly prophylactic antibiotics for recurrent episodes), diuretics if the patient has ascites or edema, and nonselective beta blockers for portal hypertension and variceal prophylaxis (European Association for the Study of the Liver, 2018; Smith et al., 2019). For hepatic encephalopathy treatment or prevention, lactulose and/or rifaximin are commonly used (Smith et al., 2019). Therapeutic paracentesis with albumin infusion may be needed for recurrent, especially large volume, ascites and eventually a transcutaneous intrahepatic portosystemic shunt (TIPS) may be necessary (European Association for the Study of the Liver, 2018; Smith et al., 2019). Guideline-based esophagogastroduodenoscopy (EGD) should be performed to screen for esophageal varices, especially in patients who cannot undergo nonselective beta blocker prophylaxis (Smith et al., 2019). Variceal banding can be utilized to prevent or treat variceal hemorrhage, which has been associated with a mortality rate near 15% (Cabrera et al., 2017).

Finally, as 80% of patients with hepatocellular carcinoma (HCC) are found to have pre-existing cirrhosis, all patients with cirrhosis should undergo HCC screening with liver ultrasound (Marrero et al., 2018). Serum AFP tumor marker is often added because it increases ultrasound sensitivity for HCC detection from 78% to 97% and from 45% to 63% in detection of early HCC and has a lower cost than computed tomography (CT) or magnetic resonance imaging (MRI) (Colli et al., 2006; Tzartzeva et al., 2018). However, any suspicious findings should be followed with CT or MRI for definitive diagnosis (Marrero et al., 2018).

Follow-Up: Surveillance of the older adult with cirrhosis depends on the stability of the patient and the presence of complications. Patients should be seen at least every 6 months to assess for problematic or worrisome signs or symptoms. Stable older adults should have repeat CBCs, complete metabolic profile, PT/INR, and liver ultrasound/AFP 6 months to 1 year after initial diagnosis, and then every 6 months thereafter to identify cirrhosis complications such as anemia, thrombocytopenia, coagulopathy, metabolic derangements, HCC, and others. Additionally, model for end-stage liver disease (MELD) and Child-Pugh scores should be calculated every 6 months on all cirrhosis patients (Smith et al., 2019). Unstable patients may need to be monitored more frequently.

Sequelae: Complications from decompensated cirrhosis commonly includes ascites, spontaneous bacterial peritonitis resulting from uncontrolled ascites, abdominal hernia from uncontrolled ascites, malnutrition, esophageal variceal bleeding, hepatocellular carcinoma (incidence from 1% to 8% per year depending on cirrhotic etiology), hepatic encephalopathy, portal hypertension (Marrero et al., 2018; Smith et al., 2019). Less common complications include

© F.A. Davis Publishing

hepatopulmonary syndrome, portopulmonary hypertension, renal failure, hepatorenal syndrome, cirrhotic cardiomyopathy, and relative adrenal insufficiency (European Association for the Study of the Liver, 2018). It should again be stressed that any cirrhotic patients who develop decompensated cirrhosis or complications should be referred to a specialist such as gastroenterology or hepatology (if available).

Alcoholic hepatitis may occur with cirrhosis with continued alcohol consumption and is generally defined as alcohol-related acute onset of symptomatic hepatitis. Severity is measured with calculation of the Maddrey discriminant function (DF), which is a score based on PT and serum bilirubin and can assess for mortality risk and guide treatment (Crabb et al., 2020; Singal et al., 2018; Singal & Mathurin, 2021). General management of these patients includes alcohol abstinence, fluid management, nutritional support, ulcer prophylaxis with proton-pump inhibitors (PPIs), and possibly glucocorticoids (Crabb et al., 2020; Singal et al., 2018). Patients with moderate to severe alcoholic hepatitis have 1-month mortality rates as high as 50% (Crabb et al., 2020). In severe alcoholic hepatitis (DF greater than or equal to 32), the use of nonselective beta blockers has been associated with increased risk of acute kidney injury and should therefore be discontinued (Sersté et al., 2015). Additionally, patients with severe alcoholic hepatitis should be trialed on prednisolone (40 mg/day orally), unless steroids are contraindicated, followed by calculation of the Lile score on day 7; the Lile score determines whether the patient is responding to steroids, of which 60% do (Crabb et al., 2020; Singal & Mathurin, 2021). A Lile score of 0.45 or less indicates response and improved mortality risk, and the prednisolone is continued for 28 days followed by a 2-week taper; if greater than 0.45 the patient is nonresponsive to steroids, has a poor prognosis, and steroids are subsequently discontinued (Crabb et al., 2020; Singal & Mathurin, 2021).

Prevention/Prophylaxis: Cessation of alcohol consumption is crucial to the prognosis of cirrhosis. Avoidance of hepatotoxic medications, especially NSAIDs, is recommended for patients with cirrhosis. All patients with cirrhosis should be given the hepatitis A and B vaccines unless they are shown to be already immune based on serological testing. The polyvalent pneumococcal vaccine and annual influenza vaccines also are recommended for these patients. Preventive strategies for patients with cirrhosis need to focus on the prevention of complications by instituting measures such as routine follow-up with laboratory testing and abdominal imaging, as well as endoscopic screenings for varices and variceal prophylaxis, unless contraindicated.

Referral: A gastroenterologist should be consulted when varices are suspected, and variceal bleeding occurs. An EGD is performed to manage complicated patients. Patients presenting with a new onset of ascites need to be referred for consideration of diagnostic paracentesis (European Association for the Study of the Liver, 2018; Smith et al., 2019). Referral to a hepatologist for patients with cirrhosis should be considered early on to plan management for complications and formulate plans for end-stage liver disease. Cirrhotic patients with a MELD score of 15, or any complication of decompensated cirrhosis should be referred to a liver transplant center for transplant evaluation; in the absence of significant comorbidities, age alone is not a contraindication for transplant and should not prevent the primary care practitioner from referring elderly patients for transplant evaluation (Martin et al., 2014; Smith et al., 2019).

Education: Instruct patients to eliminate all alcohol consumption. Recommend an alcohol treatment program and provide the telephone number for the nearest chapter of Alcoholics Anonymous. Patients should be requested not to self-medicate with over-the-counter (OTC) medications, including herbal products to prevent drug-induced liver injury. Patients with cirrhosis should eat small, frequent meals of a balanced diet containing 1.2 to 1.5 mg protein/kg body weight per day. Three to four cups of coffee daily, unless contraindicated for other reasons, has been shown to help prevent fibrosis progression in patients with NAFLD and hepatitis C as well as reduce risk of HCC in cirrhosis (Smith et al., 2019). Additionally, because of risk of fatal *Vibrio vulnificus* infection, patients with cirrhosis should be educated to avoid brackish/salt water and consumption of raw seafood (such as found in sushi) (Smith et al., 2019). Patients with encephalopathy should not be driving or operating complex machinery. For patients with end-stage liver disease, palliative care measures should be initiated.

CLOSTRIDIOIDES DIFFICILE (FORMERLY KNOWN AS *CLOSTRIDIUM DIFFICILE*)

Signal Symptoms: Profuse, watery, malodorous diarrhea; abdominal discomfort; nausea; fever

Description: *Clostridioides difficile* infection (CDI) is a consequence of the colonization and subsequent infection of the colon by this organism following a disruption of the normal flora of the gut by antibiotic exposure (Solanki et al., 2021). Once established in the colon, *C. difficile* produces two potent toxins, Toxin A and Toxin B, that cause fluid secretion, inflammation, and injury to the colonic mucosa, resulting in diarrhea and/or colitis. Toxin A is responsible for increased intestinal permeability and fluid secretions, whereas Toxin B produces inflammation of the colon (Solanki et al., 2021). Due to increasing antibiotic usage, new and dangerous strains continue to emerge (Solanki et al., 2021). Intestinal colonization by *C. difficile* strains does not always result in infection or clinical symptoms, meaning some individuals may be asymptomatic carriers. An estimated 4% to 15% of adults who are otherwise healthy may be a carrier, with carriage also estimated to be 21% in those hospitalized and up to 30% in residents of long-term care (Kelly et al., 2021). Clinical presentation of *C. difficile* diarrhea varies from mild diarrhea as the only symptom to fulminant, life-threatening colitis.

Etiology: CDI is no longer only a hospital-acquired infection, with an estimated 51.9 episodes per 100,000 people in communities affected (Solanki et al., 2021). Risk factors include antibiotic exposure, older adults, and health-care facility exposure; however, the presence of inflammatory bowel disease, compromised immunity, liver and kidney disease, cardiac disease, chemotherapy, prolonged hospital stays, and prior gastrointestinal (GI) procedures also play a role in increasing the risk for CDI (Johnson et al., 2021; Kelly et al., 2021; Sams & Kennedy-Malone, 2017). Less-known risk factors include intensive care admission, prior hospitalization within several months, ventilatory support, enteral feedings, malnourished states, Caucasian race, and hypoalbuminemia (Kelly et al., 2021; Sams & Kennedy-Malone, 2017).

Bacterial spores are spread via the fecal-oral route and thrive on surfaces such as toilets, hospital equipment, and door handles (Sams & Kennedy-Malone, 2017). These spores have the potential to survive for months, even in harsh circumstances. Asymptomatic carriage of the organism by patients is not uncommon and may hinder adequate infection control measures. Patients who are admitted to the hospital and already asymptomatically colonized with this organism have six times risk of developing CDI (Kelly et al., 2021).

Occurrence: Data from 2011 reported an estimated 453,000 cases of CDI annually, with 14,000 deaths (Kelly et al., 2021). However, cases have decreased between 2011 and 2017, with long-term care facilities reporting 55% decrease in CDI incidences for years 2011 to 2015 (Kelly et al., 2021).

Recurrence is most commonly found in those older than 65, multiple and severe comorbidities, and exposure to antibiotic use following an infection (Dumic et al., 2019). Inflammatory bowel disease (IBD), prior organ transplants, end-stage renal and chronic kidney disease, and stem cell transplants have significantly increased risk of recurrent CDI (McDonald et al., 2018). PPI use has been associated with initial and recurrent CDI, but judicious use is appropriate if patients require proton-pump inhibitor (PPI) therapy according to appropriate indications (Kelly et al., 2021). Recurrence of CDI is defined by the presence of diarrhea and a positive stool test, usually occurring 2 to 8 weeks after treatment (McDonald et al., 2018). Different strains of the bacteria may be responsible for recurrent infection; however, recurrence more often is actually relapse of the recent infection (McDonald et al., 2018).

Age: Although the infection is difficult to manage in all ages, older adult patients can be particularly challenging to treat. Individuals aged 65 years and older have an increased risk for CDI along with severe disease manifestations (Dumic et al., 2019). Advancing age correlates with difficulty in successful treatment, while recurrence risk also increases with advancing age. The concern for decreased immunity in the older adult population is felt to contribute to complicated disease course (Dumic et al., 2019).

Gender: Females have been shown to have higher incidence rate of CDI than males (Solanki et al., 2021).

Ethnicity: CDI occurs in all ethnic groups, but Whites have been found to have higher incidence rates than other ethnicities (Kelly et al., 2021).

Contributing Factors: The main contributing factor to the development of CDI is antibiotic exposure. All antibiotics, including antibiotics used in treatment for CDI, have the potential to stimulate the development of CDI. Advancing

© F.A. Davis Publishing

age is a known risk factor. Due to age-related changes in the gut microbiota, older adults are at increased risk for severe presentation, and decreased functional status is independently known as a risk factor for poorer outcomes (Dumic et al., 2019).

Signs and Symptoms: The incubation period has been estimated anywhere from 2 to 3 days to approximately 1 week, but the exact incubation period is unknown (McDonald et al., 2018). Symptoms can appear immediately after beginning antibiotic therapy, or they may not develop until several weeks to months after completion of antibiotic therapy (McDonald et al., 2018). Older adults can present atypically, with lack of fever, and alteration in mental status or confusion can be an early sign (Sams & Kennedy-Malone, 2017).

CDI is classified as non-severe, severe, or fulminant. Non-severe CDI is characterized by white blood cell count 15 g/dL or less and creatinine less than 1.5 mg/dL (Johnson et al., 2021). Increasing leukocytosis or worsening renal function would be considered severe; fulminant process would include hypotension, shock, ileus, or megacolon (Johnson et al., 2021). High suspicion for megacolon or perforation should be raised if marked tenderness to palpation; toxin injury to the colon results in lost functionality and decreased/absent peristalsis (Sams & Kennedy-Malone, 2017). Sepsis secondary to bacteremia may occur, with mortality estimated from 4.5% to 16.7% for initial episode, whereas recurrent CDI has 33% increased risk of mortality (McDonald et al. 2018). Endoscopic evaluation via colonoscopy or flexible sigmoidoscopy may be undertaken when diagnosis is uncertain if patient does not clinically improve with standard therapies; however, endoscopy would be reserved on a case-by-case basis. The presence of adherent white and yellowish plaques that may coalesce, termed pseudomembranous colitis, are highly specific for *C. difficile* infection (Sams & Kennedy-Malone, 2017). However, the absence of pseudomembranous colitis does not exclude the presence of *C. difficile.*

Diagnostic Tests: Complete blood count and complete metabolic panel are useful for identifying leukocytosis, worsening renal function, and electrolyte abnormalities. Additional laboratory studies should include thyroid panel, lactic acid, stool cultures, and a two-step process for diagnosis of CDI. Computed tomography (CT) scan should be ordered if concerning abdominal examination or subjective symptoms to exclude megacolon or perforation. Stool testing is indicated in those with symptoms concerning for CDI, with three or more watery stools in a 24-hour period (Kelly et al., 2021). Stool testing should not be withheld if there are fewer than three watery stools in 24 hours, specifically if this is a high-risk individual for CDI. Diagnostic testing with stool samples should be a two-step process, whereby a test for glutamate dehydrogenase (GDH) or nucleic acid amplification testing (NAAT) is performed and, if positive, a toxin enzyme immunoassay (EIA) is performed (Kelly et al., 2021). Peri-rectal swabs for diagnosis of infection may also be used in the clinical scenario of paralytic ileus. If suspicion remains high for CDI despite negative testing, providers must use their best clinical judgment and treat appropriately.

Endoscopic evaluation via colonoscopy or flexible sigmoidoscopy may be indicated if persistent diarrhea and/or worsening clinical status occurs despite appropriate medical treatment. Diagnostic endoscopic evaluation is also helpful when the diagnosis is unclear, such as negative stool studies but persistent symptoms despite medical therapy.

Differential Diagnosis:

- Acute diarrhea caused by salmonella
- *Shigella*
- *Campylobacter jejuni*
- *E. coli* O157:H7
- *Cryptosporidium*
- *Giardia*
- *Microsporidia*
- *Isospora*
- *Cyclospora*
- Diarrhea associated with hyperthyroidism or diabetic neuropathy
- Irritable bowel syndrome
- Dietary causes, including nonabsorbable carbohydrates, caffeine, lactose intolerance, and gluten sensitivity
- Microscopic and collagenous colitis
- Pancreatic insufficiency
- Antibiotic-induced chemical effects
- Known antibiotic effects of bacterial and fungal overgrowth
- Food poisoning
- Bacterial or viral gastroenteritis
- Inflammatory bowel disease (IBD) (Kelly et al., 2021)

Treatment: Contact isolation must be employed for hospitalized individuals at first suspicion for CDI or known CDI (McDonald et al., 2018). Contact precautions should be continued until at least 48 hours after resolution of diarrhea; however, maintaining contact precautions while hospitalized can be continued if CDI rates are high in the area (McDonald et al., 2018). Patients with CDI in long-term care facilities should be in isolated rooms; however, if this is unavailable, patients should only be in a cohort with others who have the same organism (McDonald et al., 2018). Supportive measures to include oral and IV fluid replacement, low residue diet, and pharmacological therapy such as antiemetics are indicated. The offending antibiotic agent must be discontinued if clinically possible. A coexisting infection (e.g., urinary tract infection, pneumonia) would preclude complete discontinuation of all antibiotic therapy, as these conditions would still need treatment. Antidiarrheals and anti-motility agents have historically been avoided due to risk of megacolon, although further studies are needed to evaluate safety (McDonald et al., 2018).

Antibiotic treatment should be started empirically for those presenting with likely fulminant CDI instead of waiting on stool testing for confirmation; however, all other presentations need verification of positive CDI via testing so as to avoid unnecessary antibiotic therapy. Treatment of choice for initial non-severe and severe episodes is fidaxomicin 200 mg orally twice daily for 10 days (Johnson et al., 2021). If fidaxomicin is unavailable, vancomycin 125 mg orally four times a day for 10 days may be used; if neither are available, metronidazole 500 mg three times daily by mouth for 10 to 14 days may be used for non-severe episodes (Johnson et al., 2021). A fulminant presentation, which would be characterized by shock, ileus, hypotension, or megacolon, would require vancomycin 500 mg orally or nasogastric tube four times a day and IV metronidazole 500 mg three times a day (Johnson et al.,

© F.A. Davis Publishing

2021). If an ileus is present or the individual is unable to receive oral medications, vancomycin enemas would be indicated for direct topical therapy (Johnson et al., 2021; Kelly et al., 2021). Subsequent recurrences are treated similarly to initial recurrence, with the option of tapered/pulsed regimens of fidaxomicin or vancomycin (Johnson et al., 2021). If CDI recurrence within 6 months, adjunctive treatment using bezlotoxumab 10 mg/kg IV one-time dosing along with standard of care antibiotics is indicated; however, caution is advised, weighing risks and benefits in patients with history of congestive heart failure, if bezlotoxumab is to be used (Johnson et al., 2021). Fecal microbiota transplantation (FMT) should be offered after second recurrence of CDI (Johnson et al., 2021). FMT should also be considered in cases of severe or fulminant CDI, whereby antibiotic therapy has not been successful and/or patient is not an appropriate surgical candidate (Kelly et al., 2021).

Metronidazole and vancomycin are best absorbed via the oral route, but complicated clinical courses may require administration via other routes. Vancomycin is not highly effective intravenously, which leads to the need for colonic enemas. FMT should be delivered via colonoscopy or by oral capsules; enemas are reserved if no other methods available (Kelly et al., 2021).

PPI therapy does not have to be discontinued in patients with CDI, as long as benefits outweigh risks and there is an appropriate indication for PPI therapy (Kelly et al., 2021). Probiotic therapy is not indicated, as there is insufficient data to support their use in CDI prevention (McDonald et al., 2018). Surgical intervention may be indicated for those with fulminant CDI if an appropriate surgical candidate; total colectomy with end ileostomy or diverting loop ileostomy is performed if necessary. IBD patients with CDI should have minimum of 14 days antibiotic therapy, and FMT discussed in recurrent CDI (Kelly et al., 2021).

Follow-Up: The first month following treatment has been shown as crucial due to colonic flora disruption, raising concern for recurrence (McDonald et al., 2018). Risks of CDI continues for three months following prior antibiotic exposure (McDonald et al., 2018). Recurrence is identified as prior resolution with new onset diarrhea and a positive stool sample. Repeated stool testing during the same episode is not necessary, and stool testing to document a negative finding is not appropriate (McDonald et al., 2018). Those older than 65, immunocompromised, or with severe CDI on initial presentation are at highest risk for recurrence (Johnson et al., 2021). Therapeutic response should be based on clinical signs and symptoms, not repeat diagnostic testing.

Sequelae: Chronic colonization, paralytic ileus, toxic megacolon and fulminating colitis, chronic diarrhea, electrolyte imbalances, hypoalbuminemia, and reactive arthritis are complications of CDI.

Prevention/Prophylaxis: Infection control in health-care settings and reduction of risk factors are paramount. Contact isolation should be implemented without delay. Dedicated hospital equipment for the individual is necessary to prevent spread of infection. Proper hand washing is imperative. Equipment and rooms must be sanitized with bleach cleaning agents to kill spores, per facility protocol.

Referral: Signs and symptoms of ileus or fulminant disease, failure to respond to conventional therapy, and persistent diarrhea that is unexplained require referral. Inpatient older adults with signs of acute abdomen need a surgical referral. Gastroenterology consultation is recommended for bloody diarrhea, concern for secretory diarrhea, fecal incontinence, and failure to improve symptomatically with pharmacological therapy.

Education: Avoid unnecessary antibiotics. Universal precautions include utilizing hand washing with soap and water, along with bleach cleaning agents to sanitize all surfaces at home and in hospital settings. Do not use antidiarrheal agents. Continue PPI therapy if an appropriate indication exists for patient, and probiotic therapy is not recommended. Contact provider if recurrent diarrhea persists after treatment for CDI.

COLORECTAL CANCER

Signal Symptoms: A change in bowel habits, persistent diarrhea, bleeding from the rectum, blood in the stool, unexplained anemia, bloating, unexplained abdominal pain, increased gas, frequent abdominal distention and/or bloating, frequent abdominal cramps, vomiting, weight loss, fatigue, weakness, persistent constipation or feeling that the bowels do not completely empty or a feeling of needing to have a bowel movement that is not relieved by having one, rectal pressure, rectal pain, and/or reduction in diameter of stool (National Cancer Institute, 2020).

Description: About 70% of all cancers of the large intestine occur below the midpoint of the descending colon (descending 10%, sigmoid 10%, rectum 50%) (SEER, 2022). The sigmoid colon is the most common site for cancer of the colon. Rectal carcinoma is the most common cancer of the lower gastrointestinal (GI) tract (SEER, 2022). Most colorectal cancers appear to arise in polyps. The risk of cancer increases with the size of the polyp; 30% to 50% of polyps over 2 cm in size are malignant (SEER, 2022). Approximately 90% to 95% of large bowel tumors are adenocarcinomas (SEER, 2022). Gastrointestinal stromal tumors (GISTs) are rare neoplasms that represent approximately 1% to 2% of primary GI cancers (Ottaiano, et al., 2022). Leiomyosarcomas, melanomas, neuroendocrine tumors, and colorectal lymphomas are rare diagnoses (Ottaiano et al., 2022).

Etiology: Colorectal cancer results from complex interactions between inherited susceptibility and environmental factors, but the exact nature and contribution of these factors continues to be researched (National Cancer Institute, 2016). Lifestyle, genetic, and environmental factors have been associated with increased colorectal cancer risk. Increased consumption of red and processed meats is strongly associated with increased colorectal cancer risk, whereas high fruit/vegetable intake is inversely linked to colorectal cancer (Fan et al., 2017). Additional risk factors include smoking, excessive alcohol consumption, physical inactivity, and being overweight (Brenner & Chen, 2018).

Occurrence: Colorectal cancer is the third most common malignant neoplasm worldwide and the second leading cause of cancer deaths in men and women combined in the United States (Siegel et al., 2020). Worldwide, 916,000 deaths occurred in 2020 from colon and rectal cancer according to the World Health Organization (WHO, 2022). In 2022, an estimated 151,030 adults in the United States will be diagnosed with colorectal cancer. Specifically, it is predicted that there will be 106,180 new cases of colon cancer and 44,850 new cases of rectal cancer (Siegel et al., 2020). Although the majority of colorectal cancers are in adults aged 50 and older, 17,930 (12%) are diagnosed in individuals younger than age 50 (Cancer.org, 2020). Approximately 4.4% of men (1 in 23) and 4.1% of women (1 in 25) will be diagnosed with colorectal cancer in their lifetime. Lifetime risk is similar in men and women despite higher incidence rates in men because women have longer life expectancy (Siegel et al., 2020). Colorectal cancer incidence rates have been declining, largely attributable to the contribution of screening for prevention and early detection (Siegel et al., 2020)

Age: Although aging itself is a risk factor for the development of cancer, colorectal cancer incidence rates have been increasing since the mid-1980s in adults aged 20 to 39 years and since the mid-1990s in adults aged 40 to 59 years, with younger age-groups experiencing the steepest increase (Siegel et al., 2017). The median age of diagnosis has dropped from 72 years during 2001–2002 to 66 years during 2015–2016. The median age at colorectal cancer diagnosis is younger for rectal cancer (63 years) than for colon cancer (69 years) (Siegel et al., 2020).

Ethnicity: Colorectal cancer incidence and mortality are highest in non-Hispanic Blacks, followed closely by Native Americans and Alaskan Natives, and lowest in Asians/Pacific Islanders. During 2012–2016, colorectal cancer incidence rates in African Americans were about 20% higher than those in non-Hispanic Whites and 50% higher than those in Asians/Pacific Islanders. The disparity for mortality is twice that for incidence; colorectal cancer death rates in African Americans are almost 40% higher than those in non-Hispanic Whites and double those in Asians/Pacific Islanders (Cancer.org, 2020).

Contributing Factors: As previously discussed, lifestyle and dietary factors have been associated with the development of colorectal cancer. Additionally, there are hereditary risks. Lynch syndrome, a failure of cellular DNA repair genes that produces gene mutations, leads to an increased risk for colon cancers and other cancers (Sinicrope, 2018). Familial adenomatous polyposis is another genetic disorder in which the colon polyps and ultimately cancers can develop (Dinarvand et al., 2019). Genetic risk is suspected if someone is diagnosed with colon cancer at a much earlier age than is typical and/or has a strong family history of colon cancer that occurs at younger ages.

Signs and Symptoms: Clinical symptoms can include rectal pressure, passing bright red blood, constipation, bloating, diarrhea, weight loss, melenic stools, nausea, and loss of appetite. Patients presenting in the clinic with microcytic anemia should be evaluated for rectal bleeding and possible colorectal cancer.

Diagnostic Tests: According to U.S. Preventive Services Task Force USPSTF 2021 guidelines, colon cancer screening should begin at age 45 and continue through age 75 in individuals at average risk for colorectal cancer and with no personal or family history of colorectal cancer (U.S. Preventative Services Task Force [USPSTF] et al., 2021). Guidelines from the American College of Gastroenterology continue to screen for colorectal cancer for patients 50 and over but recommend screening for patients 45 years and older who are at average risk (de Kanter et al., 2022).

Individuals at moderate risk for developing colon cancer and/or with a personal or family history of colon cancer may need earlier or more frequent screening. People at high risk for colon cancer, such as those with Lynch's syndrome

© F.A. Davis Publishing

or polyposis syndromes (i.e., classic familial adenomatous polyposis [FAP]; attenuated FAP; MUTYH-associated polyposis [MAP]; Peutz-Jeghers' syndrome; juvenile polyposis syndrome; serrated polyposis syndrome) require enhanced colorectal surveillance and should be screened and monitored for other disorders as well, depending on the syndrome (Patel et al, 2022).

Several recommended colorectal cancer screening tests are available, and clinicians may consider many factors in deciding which test may be best for each person. Patient preference, screening method, preparation (e.g., bowel preparation), frequency of screening, location of screening, and follow-up procedures for abnormal findings may all play a role in determining which screening test is ultimately chosen. According to the USPSTF (USPSTF et al., 2021), recommended screening strategies include:

- High-sensitivity guaiac fecal occult blood test (HSgFOBT) or fecal immunochemical test (FIT) every year
- Stool DNA-FIT every 1 to 3 years
- Computed tomography (CT) colonography every 5 years
- Flexible sigmoidoscopy every 5 years
- Flexible sigmoidoscopy every 10 years + annual FIT
- Colonoscopy screening every 10 years

For patients aged 76 to 85, the decision to screen should be based on patient preferences, life expectancy, overall health, and prior screening history (Patel et al., 2022). The U.S. Multi-Society Task Force on Colorectal Cancer does not recommend routinely screening patients older than 85 years for colorectal cancer. It should be noted that patients at increased or high risk of colorectal cancer might need to start colorectal cancer screening before age 45, be screened more often, and/or get specific tests (Patel et. al., 2022).

A newer screening method, CT colonography or virtual colonoscopy, is a procedure that provides a computer-simulated endoluminal perspective of the air-filled distended colon. CT colonography requires a mechanical bowel preparation like that needed for barium enema because stool can simulate polyps (Biller & Scharg, 2021). Screening for colorectal cancer using a flexible sigmoidoscope is one of the few modalities that have been proven through randomized controlled trials to reduce colorectal cancer mortality and incidence (Biller & Scharg, 2021). Colonoscopy is the most accurate and versatile diagnostic test for colorectal cancer (Biller & Scharg, 2021). Colonoscopies can detect cancer and advanced lesions and are used for biopsy and diagnosis.

There is no diagnostic role for other routine laboratory tests in the diagnosis of colorectal cancer (Biller & Scharg, 2021). However, the advanced practice provider may see additional laboratory tests ordered for routine monitoring. These may include:

- *Complete blood count (CBC) with differential:* It should be noted that although colorectal cancer is often associated with iron-deficiency anemia, its absence does not reliably exclude the disease.
- *Comprehensive metabolic panel (CMP):* It should be noted that liver function tests lack sensitivity for detection of liver metastases.
- Tumor markers: Serum markers that have been associated with colorectal cancer include carcinoembryonic antigen (CEA) and CA 19-9. However, all these markers have a low diagnostic ability to detect primary colorectal cancer due to significant overlap with benign disease and low sensitivity for early-stage disease (Biller & Schrage, 2021). Neither serum CEA nor any other marker should be used as a screening or diagnostic test for colorectal cancer. However, CEA levels have value in the prognosis and follow-up of patients with diagnosed colorectal cancer (Biller & Schrage, 2021).

Radiological tests for staging include chest, abdomen, and pelvic CT either before or after resection (Biller & Schrage, 2021). A meta-analysis concluded that magnetic resonance imaging (MRI) is the preferred first-line imaging study for evaluating colorectal cancer liver metastases in patients who have not previously undergone therapy. In current practice, liver MRI is generally reserved for patients who have suspicious but not definitive findings on CT scan, particularly if better definition of hepatic disease burden is needed in order to make decisions about potential hepatic resection (Biller & Schrage, 2021). Positron emission tomography (PET) scans can be used as an adjunct to other imaging modalities for purposes such as evaluating patients who are thought to be present or future candidates for resection of isolated colorectal cancer liver metastases and localizing sites of disease recurrence (Biller & Schrage, 2021).

Differential Diagnosis:

- Diverticulitis
- Weight loss
- Blood in the stool
- Mass in the colon
- Prostatic carcinoma
- Sarcoma
- Inflammatory bowel disease
- Hemorrhoids
- Benign colonic polyps
- Peptic ulcer disease (PUD)
- Functional bowel disorders
- Infection
- Kaposi's sarcoma (KS)
- GISTs
- Lymphomas
- Carcinoid (well-differentiated neuroendocrine) tumors

Staging and Treatment: The Tumor, Node, Metastasis (TNM) staging system of the combined American Joint Committee on Cancer (AJCC)/Union for International Cancer Control (UICC) is the preferred staging system for colorectal cancer (Vogel et al., 2017). Patients should be referred to a surgeon for consideration of resection. Presence of metastatic disease does not rule out surgery. Radiographic, endoscopic (including biopsy), and intraoperative findings can be used to assign a clinical stage, whereas assessment of the pathological stage (termed pT, pN, pM) requires histological examination of the resection specimen (Vogel et al., 2017). The extent of treatment for colorectal cancer depends on how invasive the cancer is in the colon and surrounding

© F.A. Davis Publishing

sites, and the condition of the patient at the time of diagnosis. Surgery for colon cancer (including laparoscopic resection) should not be denied simply based on age. A comprehensive geriatric assessment may be useful in formulating an appropriate, individualized treatment plan for the older adult patient (Dolin et al., 2021). For patients with stages I–III disease, the standard of care is surgical resection followed by adjuvant therapy where appropriate (Brown & Koh, 2020).

Follow-Up: During and after treatment for colorectal cancer, oncology follow-up is essential. This may include serial imaging and laboratory testing depending on the cancer stage, treatment pursued, and progression of disease, among other patient specific factors. Primary care providers (PCPs) play an important role across the cancer continuum, from encouraging screening and accurate diagnosis to providing care during and after treatment for cancer and any comorbid conditions (Triantafillidis et al., 2017). PCPs should closely monitor for symptoms such as fatigue, weight loss, and change in bowel habits. Annual physical examinations are encouraged. Additional, PCPs can be instrumental in providing the patient, family, and caregiver support that is essential along the cancer trajectory.

Sequelae: The consequences of colorectal cancer can be broad and include complications such as obstruction, perforation, and possible need for colostomy, to loss of function, independence, and psychological distress. Bowel adhesions and chronic pain may also be a complication. Post-resection recurrence of colorectal cancer is common. According to an article by Brown and Koh (2020), locoregional recurrence occurs in 4% to 11.5% of patients following treatment of primary colon cancer with curative intent. For those who have had radiation directed at their rectum or at areas around their rectum, radiation proctitis with burning and diarrhea may occur. The liver and bone are two sites known for metastasis after colorectal cancer.

Prevention/Prophylaxis: The ACS recommends starting screening at age 45 for those patients at average risk. This can be done either with a sensitive test that looks for signs of cancer in the stool or with an examination that looks at the colon and rectum (ACG, 2021). For stool-based tests, clinicians should educate patients that these tests require an annual commitment. The gold standard for screening is delineated in Table 13-1. The results of epidemiological studies regarding the relationship between calcium intake and colorectal cancer risk have not always been consistent. A 2018 study looking at vitamin D and colorectal cancer found that higher circulating 25-hydroxyvitamin D was related to a statistically significant, substantially lower colorectal cancer risk in women and non-statistically significant lower risk in men (McCullough et al., 2019). As previously stated, avoiding smoking, physical activity and maintaining a healthy weight, and a diet high in fruits, vegetables, and whole grains has been shown to lower risk of colorectal cancer.

Referral: A gastroenterologist should be consulted for colonoscopy and biopsies can be done during the procedure if needed. A consultation with a surgical oncologist, usually found at a major medical centers, is advised. A team including a radiologist, oncologist, cancer surgeon, advanced practice provider (nurse practitioner [NP] and/or physician assistant [PA]), nutritionist, pharmacist, and nurse will develop a plan of care individualized to the patient and type of cancer. Ultimately the patient (and/or family caregiver where applicable) will decide the best course of action. Palliative care may be an appropriate choice.

Education: Teach older adults about the importance of monitoring for signs of colorectal cancer and to report any change in bowel habits. Primary care providers (PCPs) should discuss available screening options with patients.

TABLE 13-1 United States Multi-Society Task Force Guidelines for Colonoscopy Surveillance Post-polypectomy

TYPE OF POLYP	NUMBER OF POLYPS	RECOMMENDED FOLLOW-UP
Adenoma ≥10 mm	Piecemeal resection	6 mo, then 1 yr, then 3 yr
Adenoma	>10	1 yr. Consider genetic testing
Adenoma ≥10 mm	1–10	3 yr
Adenoma with villous component	1–10	
Adenoma with high-grade dysplasia	1–10	
Adenoma <10 mm	5–10	3 yr
	3–4	3–5 yr
	1–2	7–10 yr
Sessile serrated polyps (SSPs) <10 mm	5–10	3 yr
	3–4	3–5 yr
	1–2	5–10 yr
SSP ≥10 mm or SSP with dysplasia	Any number	3 yr
Traditional serrated adenoma	Any number	3 yr
Hyperplastic polyp ≥10 mm	Any number	3–5 yr
Hyperplastic polyps <10 mm	<20	10 yr

CONSTIPATION

Description: Constipation is broadly defined as bowel disturbances including reduced defecatory frequency, hard stools, significant straining, incomplete evacuation, and others (Bharucha & Wald, 2019; Forootan et al., 2018; Jani & Marsicano, 2018; Mounsey et al., 2015). Constipation ranks in the top five for most common gastrointestinal (GI) disorders diagnosed by physicians, results in 8 million annual referrals to gastroenterology, and poses an economic burden at $230 million annually (Bharucha & Wald, 2019; Jani & Marsicano, 2018).

Etiology: Colonic motility depends on the integrity of nervous system impulses, circular smooth muscle tone, and motor complexes stimulated by increasing intraluminal pressure generated by bulk. Any pathophysiological process that interferes with this process can cause constipation. Primary constipation includes slow transit constipation (possibly due to motor dysfunction, inadequate food intake, or alterations of the gut microbiome), normal transit constipation (such as irritable bowel syndrome constipation type, IBS-C), and defecatory disorders (resistance to evacuation or inadequate propulsion such as in dyssynergia, obstruction, rectal hyposensitivity, and structural abnormalities like rectoceles) (Bharucha & Wald, 2019). Secondary constipation is caused by any of a number of issues such as dehydration, inadequate fiber intake, metabolic diseases (diabetes, hypothyroidism, hypercalcemia), medications (including opioid-induced constipation, anticholinergics, and antidepressants), neurological disorders (such as dementia, Parkinson's disease, and multiple sclerosis), myopathic disorders (such as scleroderma), and structural issues (such as colon cancer or strictures) (Jani & Marsicano, 2018).

Occurrence: The prevalence of chronic constipation is 15% to 16% of the general population and higher in older adults (Bharucha & Wald, 2019; Jani & Marsicano, 2018).

Age: Constipation is more common in older adults with a prevalence of 33.5% compared to 16% in the general population (Bharucha & Wald, 2019). Older adults residing in long-term care facilities have a greater prevalence of constipation of around 50%, although it has been described as high as 80% (Lucak et al., 2021). The increase in older adults is likely multifactorial in etiology, including various physiological changes, lifestyle changes, increased medication burden and polypharmacy, and increased chronic disease burden (Lucak et al., 2021). At all ages, constipation is reported more frequently in women with a prevalence ratio of 1.5:1 in women compared to men. Additionally, women utilize laxatives and seek care for their constipation more frequently than men (Bharucha & Wald, 2019).

Ethnicity: Constipation tends to be more common in non-Whites (Bharucha & Wald, 2019).

Contributing Factors: There are multiple factors that can contribute to constipation (Bharucha & Wald, 2019; Forootan et al., 2018; Jani & Marsicano, 2018; Lucak et al., 2021). Medications that may contribute to constipation include analgesics (NSAIDs and opioids), antihypertensives (calcium channel blockers, clonidine), calcium supplements, narcotics, iron supplements, aluminum- and calcium-containing antacids, anti-Parkinson drugs, bile-binding medications (cholestyramine), and any drug that has anticholinergic side effects (Forootan et al., 2018; Jani & Marsicano, 2018; Lucak et al., 2021). Certain types of laxatives also may be constipating, such as stimulant laxatives (especially when overused), which may cause cathartic colon and laxative dependency, and bulk laxatives taken with insufficient fluids. Other potential causes include neurological disorders, such as Parkinson's disease, stroke, spinal cord disorders, dementia, and depression; metabolic factors such as hypokalemia, hypercalcemia, and

© F.A. Davis Publishing

chronic renal insufficiency; and institutionalization (including nursing home placement) (Forootan et al., 2018; Lucak et al., 2021). Finally, some identified risk factors include lower socioeconomic status, lower education, less physical activity, stress, and physical and/or sexual abuse (Bharucha & Wald, 2019).

Signs and Symptoms: The first part of an assessment should include the use of a tool to determine the person's normal pattern of bowel function. The most common tool is the Bristol Stool Chart, which classifies stools as hard to pass, ideal consistency, or difficult to control. Descriptions and pictures make it easy for patients to identify the type of stool. It is also helpful to include a food diary to determine dietary sources of the problem, including water and fiber intake. Other considerations are mobility, which affects bowel transit and also impacts ability to easily get on and off the toilet; duration of symptoms (age of onset); whether onset was gradual or sudden; proper environment for defecation; underlying medical conditions; history of abuse; associated symptoms; medications, including over-the-counter (OTC) and herbal supplements; and remedies already tried for relief (Bharucha & Wald, 2019; Jani & Marsicano, 2018; Lucak et al., 2021).

A thorough abdominal and rectal examination is necessary to rule out physical abnormalities and any warning signs, and then the data is compiled (Bharucha & Wald, 2019; Jani & Marsicano, 2018). The ROME IV diagnostic criteria are helpful in confirming the diagnosis of constipation, which must include two or more of the following six criteria:

- Fewer than three bowel movements in a week
- Straining at least at 25% of defecations
- Lumpy or hard stools in at least 25% of defecations
- Sensation of incomplete evacuation for at least 25% of defecations
- Sensation of anorectal obstruction/blockage for at least 25% of defecations
- Manual maneuvers to facilitate at least 25% of defecations (digital evacuation, support of the pelvic floor) (Jani & Marsicano, 2018)

Diagnostic Tests: All individuals should have a fecal occult blood test at the initial visit of a complaint of constipation. Additional diagnostic tests should be done if they can inform contributing causes or alter the treatment. Laboratory tests should include a complete blood count (CBC) but then be individualized for each patient based on their history and physical. Testing may include complete glucose, thyroid-stimulating hormone, electrolytes (including calcium), blood urea nitrogen (BUN), creatinine. A digital rectal examination can elicit structural abnormalities as well as anal tone and sequela of constipation such as fissures, rectal pain, and hemorrhoids. An abdominal radiograph may help to determine the extent and distribution of feces. Sigmoidoscopy or barium enema or both may be indicated in patients with a recent onset of constipation when a lesion is suspected or to evaluate for anatomic abnormalities. Other tests include balloon expulsion testing with manometry to check for dyssynergy; colonic transit study to diagnose slow transit constipation; barium defecography or pelvic magnetic resonance imaging (MRI) defecography to evaluate pelvic floor function and evaluate for abnormal structural problems such as prolapse, rectoceles, and enteroceles that can affect constipation. A colonoscopy should be done if the patient presents with alarm symptoms, anemia, or positive fecal occult blood (Bharucha & Wald, 2019; Lucak et al., 2021).

Differential Diagnosis: Because the diagnosis of constipation is very subjective and often a symptom of other issues, evaluation should focus on etiology and contributing causes to rule out potentially more insidious issues such as obstruction, fecal impaction, irritable bowel syndrome, structural defects, diverticular disease, and colorectal cancer (Jani & Marsicano, 2018; Lucak et al., 2021).

Treatment: After the specific etiology is established and factors contributing to constipation are identified, the appropriate pharmacological and nonpharmacological interventions are initiated. The primary aim of treatment is for the patient to have regular, predictable, and comfortable bowel movements. Ideally, this should be accomplished with diet and lifestyle changes such as fiber, water, and exercise. Adults should eat 20 to 35 g of fiber per day. Insoluble fiber found in whole wheat, whole grains, vegetables, and wheat bran is the best choice. An increase in fiber intake should be done over several weeks to prevent adverse effects like bloating, flatulence, and abdominal cramping. An adequate fluid intake of 1.5 to 2 L/day is also important and shown to improve frequency of stools, although may not be possible in patients with chronic diseases such as heart failure and kidney disease who may be on fluid restrictions. Fruits and fruit juices, especially prune and apricot which are high in sorbitol, are an alternative for those who cannot increase the fiber intake. It may take up to 4 weeks for the fiber and water effects to be noted, so the patient may need laxatives in the interim. Finally, timed toileting may be especially helpful in patients who have declining cognitive function (Bharucha & Wald, 2019; Forootan et al., 2018; Jani & Marsicano, 2018; Lucak et al., 2021).

Pharmacological treatments are recommended when diet and lifestyle changes are not sufficient. The recommendation is to start with bulk-forming agents and soluble fiber supplements. Psyllium or polycarbophil are commonly recommended, but they require increased fluid intake, which may not be appropriate for some older adults with heart and kidney disease. There are also multiple OTC soluble fiber supplement options available. Patients who fail to respond should be trialed on osmotic agents, such as polyethylene glycol (PEG), magnesium citrate-based laxatives (magnesium citrate), and nonabsorbable carbohydrates (lactulose), as a second-line treatment; use caution with some of these agents in older adults because they can cause electrolyte changes. Stimulant laxatives, such as senna, cascara, or bisacodyl, increase peristalsis and mucus production, and are generally safe as rescue agents or even more regular use (Bharucha & Wald, 2019). Stool softeners are often prescribed for older adults. These are not laxatives and may contribute to constipation, "the mush without the push." Discontinuing inappropriately prescribed stool softeners is an option for medication reduction in polypharmacy (Bharucha & Wald, 2019; Jani & Marsicano, 2018; Lucak et al., 2021).

© F.A. Davis Publishing

Newer prescription agents can be considered, and selection should be based on the presenting symptoms, the nature of the complaint, the side effects, speed of action, and patient acceptability. For treatment of either chronic constipation or IBS-C options include glucocorticoid (GC) receptor agonists (plecanatide, linaclotide), chloride channel activator (lubiprostone), and serotonin (5-HT4) receptor agonist (prucalopride). For opioid-induced constipation (OIC), consider use of peripherally acting μ-opioid receptor agonists (naloxegol, naldemedine, and methylnaltrexone) (Bharucha & Wald, 2019; Lucak et al., 2021).

Finally, there are additional nonpharmacological treatments for select patients. Those with pelvic floor dysfunction, defecatory disorders, or dyssynergy who do not respond to other treatment options may benefit from biofeedback therapy to retrain pelvic floor muscles and improve colonic transit and symptoms. This approach has been shown to improve colonic transit time in approximately 65% of patients with defecation disorder (Chiarioni et al., 2005). This may be especially useful in older adults with limited medication options. Finally, surgery is a treatment of last resort for patients with refractory symptoms, who do not have global gut hypomotility or defecation dysfunction. This is accomplished with an abdominal colectomy with ileorectal anastomosis. Careful consideration should be given in older adults who may have higher surgical risk (Bharucha & Wald, 2019; Lucak et al., 2021).

Follow-Up: Chronically constipated individuals often need to have combined nonpharmacological with regular or periodic pharmacological intervention. When laxatives are prescribed, these individuals should be reevaluated every 3 months for the side effects and the responses to treatment as well as any new warning signs or symptoms (Bardsley, 2015; Jani & Marsicano, 2018; Lucak et al., 2021).

Sequelae: Constipation, although uncomfortable, is rarely life threatening. When associated with pain, distention, or vomiting, constipation may be a sign of a life-threatening mesenteric infarction or a partial or complete bowel obstruction. Straining in older adults may have serious effects on the cerebral, coronary, and peripheral arterial circulation. If stool is not eliminated from the colon and the patient becomes dehydrated, stool may harden, resulting in fecal impaction, a large mass of compacted feces at the intestinal level that cannot be evacuated spontaneously. It has been estimated that 7% of long-term residents suffer from impactions yearly (Falcón et al., 2016). Also, although worrisome for many patients, colon cancer occurs very infrequently in chronically constipated patients (Bharucha & Wald, 2019).

Prevention/Prophylaxis: Adequate dietary fluid and fiber and regular exercise habits help to promote colonic mobility. Bowel elimination patterns should be monitored regularly in individuals who are unable to report bowel habits or bowel discomfort.

Referral: Hospitalization may be necessary in some cases of severe constipation and/or impaction, anorexia, dehydration, or nausea or vomiting. In fact, constipation results in approximately 92,000 hospitalizations a year (Morley, 2007). Patients with recent-onset constipation associated with bleeding, anemia, or family history of colon cancer; patients with chronic constipation with anemia, abdominal pain, and weight loss; and patients with recent-onset fecal incontinence should be referred to a gastroenterologist. Referral to a specialist also should be considered when there is a failure to alleviate constipation despite escalating attempts (Roque & Bouras, 2015).

Education: In addition to giving instruction in the dietary measures appropriate in preventing constipation, encourage older patients to maintain regular bowel habits and respond to the urge to defecate rather than suppress it. Patients should be encouraged to keep a dietary journal for a week to understand their diet habits that may need adjustment. Patients should also be educated on the role of regular exercise/movement in preventing constipation. Patient education regarding diet and exercise is challenging when patients have cognitive impairments, mood disorders, uncontrolled pain, or significant muscle weakness. Patients should be taught to take advantage of the gastrocolic reflex, which is strongest about 30 minutes after meal consumption and may be assisted at breakfast time by consuming a hot beverage. Trial of a small stool under the feet during defecation may help ease stool passage. Stooling time should be around 3 to 5 minutes, and not more than 10 minutes, to help prevent sequela such as hemorrhoids. All individuals should avoid the excessive use of laxatives as well as OTC medications known to have constipating side effects (Bardsley, 2015; Lucak et al., 2021; Mounsey et al., 2015).

DIVERTICULITIS

Signal Symptoms: Impaired cognitive status, lower quadrant pain, fever.

Description: Diverticulitis is an inflammatory condition that involves perforation of one or more colonic diverticula, which are herniations of the mucosa through the muscularis of the colon, usually occurring in the sigmoid or descending colon. Less commonly, right-sided colon diverticulitis may occur. Small bowel diverticulitis may also occur but is rare. Inflammation of the diverticulum begins at the apex when the narrow opening of the lumen is exposed to fecal residue. Mucosal erosion within the diverticulum also can occur, leading to diverticulitis.

Etiology: Diverticula are common in older adults. Age-related changes in the elastic matrix of the colon and the resulting sluggish fecal mass are thought to cause increased intraluminal pressure of the colon (Dumic et al., 2019). Diverticular disease is rare in societies that consume high-fiber diets. It is thought that a low-fiber diet produces less bulky stool and increased intracolonic pressure (Hanna & Kaiser, 2021). Diverticulitis is thought to develop when one or more diverticula are perforated (macroperforation or microperforation). Because this perforation is usually a localized process, free intraperitoneal air or diffuse peritoneal signs are usually not evident; their presence would indicate a more severe case and the possible need for surgical consultation. A pseudodiverticulum occurs when only the mucosa and submucosa of the colon are affected, such as in small bowel diverticulitis (Rangan & Lamont, 2020). Approximately 90% of all cases of diverticulitis involve the left colon and sigmoid (Dumic et al., 2019).

Occurrence: An estimated 70% of older adults develop diverticulosis by age 80 years (Dumic et al., 2019). Diverticulitis occurs more commonly in older women versus older men and younger males versus younger females (Hannah & Kaiser, 2021). Historically, development of diverticulitis in those with diverticulosis was felt to be approximately 10% to 25%; however, now estimates are lower ranging from 1% to less than 5% (Hanna & Kaiser, 2021).

Age: Diverticulitis is found most commonly in older adults aged 60 to 80 (Wan & Krisko, 2021).

Ethnicity: Diverticulitis confined to sigmoid and left colon is found more commonly in Westernized countries or populations that have begun to consume a refined Western diet; people of Asian descent are more likely to have right-sided diverticulitis (Dumic et al., 2019).

Contributing Factors: Although there are patients who may not have been diagnosed with diverticulosis prior to an acute case of diverticulitis, it is important for the nurse practitioner to recognize known risk for developing diverticulosis. Obesity, as well as sedentary lifestyle, has been found to contribute to diverticular disease. Advancing age is the primary nonmodifiable risk factor for developing diverticulitis (Dumic et al., 2019). Chronic constipation leading to colonic wall weakness raises intraluminal pressure (Hannah & Kaiser, 2021). Long-term use of NSAIDs, aspirin, antiplatelets, steroids, opioids, immunosuppressant drugs, and cigarette smoking increases the incidence of diverticulitis (Dumic et al., 2019; Hanna & Kaiser, 2021).

Signs and Symptoms: Clinical presentation of diverticulitis in an older adult may be suppressed despite the presence of severe disease. Mental confusion may be the first overt indication of diverticulitis in older adults with known diverticular disease. Most common grouping of signs and symptoms include escalating abdominal pain, fever, and elevated inflammatory markers (such as white blood cell [WBC] count and C-reactive protein [CRP]) (Hanna & Kaiser, 2021). Pain may be colicky in nature and reported in the flank, back, or right side of the abdomen. Patients may describe the pain as dull, aching, and intermittent. Patients may experience abdominal or perirectal fullness. If the bowel is inflamed adjacent to the bladder, the presentation may mimic a urinary tract infection, especially if the patient reports dysuria. Acutely ill patients with a moderate-to-severe episode of diverticulitis may present with lethargy, reflecting signs of fluid depletion and sepsis.

Bowel sounds may be normal in mild disease; however, bowel sounds become hypoactive until there is an obstruction, when a tinkling sound may be heard. Hyperresonance may reflect intestinal obstruction. Localized tenderness is usually present in the left lower quadrant. Rebound tenderness, involuntary rigidity, and guarding are signs of peritonitis. Bleeding and evidence of chronic anemia are not typically associated with diverticulitis, raising concern for underlying occult malignancy (Hanna & Kaiser, 2021).

Diagnostic Tests: A CBC, complete metabolic panel (CMP), amylase, lipase, urinalysis, CRP, sedimentation rate can initially be ordered (Wan & Krisko, 2021). A computed tomography (CT) scan is the best imaging modality with sensitivity of 93% to 97% and specificity near 100% for diagnosing diverticulitis and severity (Hanna & Kaiser, 2021). Normal

© F.A. Davis Publishing

amylase and lipase will help distinguish diverticulitis from other causes of acute abdominal pain. Urinalysis may reveal sterile pyuria due to adjacent colonic irritation; however, if mixed colonic flora are present, consider the presence of a colovesical fistula (Hanna & Kaiser, 2021). Endoscopic measures during acute episodes of diverticulitis are avoided due to risk of perforation.

Differential Diagnosis:

- Acute appendicitis—suspect if right lower quadrant symptoms or nonresolution with medical therapy
- Inflammatory bowel disease (Crohn's disease)
- Complicated peptic ulcer disease (PUD)—suspect if pneumoperitoneum or peritonitis
- Ischemic colitis—suspect if high-risk patient, bloody diarrhea, elevated lactic acid
- Pseudomembranous colitis—suspect if antibiotic use or diarrhea
- Vascular ectasia—consider leaking abdominal aortic aneurysm
- Carcinoma of the colon—suspect if weight loss or bleeding
- Urological disorders, such as infection or ureteric colic
- Gynecological carcinomas or abscesses
- Pelvic inflammatory disease
- Infectious colitis
- Small bowel obstruction
- Endometriosis
- Ovarian cyst
- Testicular torsion
- Gastroenteritis
- Bowel obstruction
- Irritable bowel syndrome
- Kidney stone (Hanna & Kaiser, 2021)

Treatment: Diverticulitis is found to be polymicrobial and results from bacteria normally found in the gastrointestinal (GI) tract; the selection of antibiotics for the treatment of diverticulitis needs to consider the most common bacteria found in the colon, which are gram-negative aerobic rods and anaerobic microorganisms (Hall et al., 2020). If diverticulitis is deemed uncomplicated, outpatient treatment consists of oral antibiotics that cover gram-negative organisms for 7 to 10 days. Options include ciprofloxacin and metronidazole, levofloxacin and metronidazole, trimethoprim-sulfamethoxazole and metronidazole, amoxicillin-clavulanate, and moxifloxacin (Hall et al., 2020). Inpatient treatment of diverticulitis is indicated if complicated presentation, older age with multiple comorbidities, sepsis, and failing a trial of outpatient management. Inpatient treatment consists of IV antibiotics for 3 to 5 days, transitioning to oral therapy to complete a total of 10 to 14 days (Hall et al., 2020). Additional supportive measures include IV fluids, pain control, and antiemetic therapy. Patients should be nothing by mouth (NPO) until pain improved, advancing diet slowly. Imaging should be repeated if no improvement in 48 to 72 hours (Hall et al., 2020). Percutaneous drainage may be necessary if large abscess. Before recommending outpatient treatment, ensure that there is a reliable support system available. Antibiotics may need to be adjusted if blood or fluid cultures obtained with specific organisms.

Follow-Up: Older adults with mild cases treated at home with prescribed therapy should expect improvement by the third day. If, however, patients are not able to tolerate fluids and/or fail to respond to antibiotics and pain control, refer for hospitalization. Hospitalized patients require daily monitoring for persistent signs and symptoms of diverticulitis, laboratory values, and response to treatment. Recurrence after diverticulitis episode is dependent on the initial severity of episode, ranging from 13% to 20%, with highest recurrent rates of 40% to 61% if abscess present (Hanna & Kaiser, 2021). Surgical consultation may be necessary if the patient does not respond to treatment and continues to have an elevated WBC count, fever, rebound tenderness, pain, and tachycardia during acute illness. Surgery performed electively is recommended for those with complicated features including strictures, smoldering diverticulitis, inflammatory mass, and fistulae (Hanna & Kaiser, 2021). Approximately 20% of patients with diverticulitis do not improve with medical treatment and will require surgical intervention (Hanna & Kaiser, 2021). A colonoscopy is recommended approximately 6 weeks after diverticulitis episode to exclude occult malignancy because a malignancy may mimic diverticulitis presentation (Hall et al., 2020; Hanna & Kaiser, 2021)

Sequelae: Complications include bowel perforation, peritonitis, abscess, fistulae to bladder, vagina, small bowel, or skin, stricture, and bowel obstruction (Hanna & Kaiser, 2021). Medical supportive management may fail in up to 20% of patients, requiring need for surgical intervention (Hanna & Kaiser, 2021). Older adults with known diverticulosis are at higher risk for ischemic colitis (Dumic et al., 2019). Complications from diverticulitis tend to be most severe in patients who are immunocompromised, including those with diabetes, chronic kidney disease, or cirrhosis or those on immunosuppressant therapies (Hanna & Kaiser, 2021). Risk of bleeding in diverticular disease increases in patients taking anticoagulants and antiplatelets, aspirin, steroids, and NSAIDs (Hanna & Kaiser, 2021). Bleeding is not typically seen in episodes of acute diverticulitis but may still occur although less common; bleeding and anemia should raise concern for occult malignancy (Hanna & Kaiser, 2021). Approximately 1% to 5% of patients with radiological imaging favoring diverticulitis could actually be heralding an underlying malignancy (Hanna & Kaiser, 2021). Patients may deal with post-infectious IBS following diverticulitis episode (Dumic et al., 2019).

Prevention/Prophylaxis: Recognition of early signs and symptoms of diverticulitis helps prevent severe cases. A high-fiber diet is helpful in reducing risk of diverticular disease (Hanna & Kaiser, 2021). Evidence does not support that the inclusion of nuts, seeds, corn, and popcorn in the diet contributes to the development of diverticulitis (Strate et al., 2008). Calcium channel blockers and statins have shown a protective effect in reducing risk of diverticulosis in older adults, so consideration should be made to use these agents in the older adult who could benefit from these agents for comorbidities (Dumic et al., 2019).

Referral: Severe episodes of diverticulitis require hospitalization with possible gastroenterology and surgery consultation. Patients with localized abscesses need to be referred for consideration of a CT scan–guided percutaneous drainage (Hanna & Kaiser, 2021). Repeated episodes or complicated

© F.A. Davis Publishing

presentation may require surgical consultation for an elective resection if appropriate surgical candidate.

Education: Provide information on a high-fiber diet or fiber supplementation or both (Hanna & Kaiser, 2021; Wan & Krisko, 2021). Teach patients to increase their fluid intake, unless otherwise cautioned, especially when taking fiber supplements. Diverticulitis recurs in approximately 13% to 20% of patients if uncomplicated episode with higher recurrence rates if abscess present (Hanna & Kaiser, 2021; Wan & Krisko, 2021). Encourage older adults with obesity to consider weight reduction, physical activity, and avoidance of tobacco products to reduce potential complications of diverticular disease (Wan & Krisko, 2021).

ESOPHAGITIS

Signal Symptoms:Dysphagia, regurgitation, pyrosis.

Description: Esophagitis is an inflammation of the lining of the esophagus.

Etiology: There are several different causes for esophagitis. Patients may develop esophagitis if they ingest medication improperly (medication esophagitis); ingest caustic chemicals; are exposed to radiation treatments (radiation esophagitis); have a bacterial, viral, or fungal infection (especially those patients who are immunocompromised); or have a history of gastroesophageal reflux disease (GERD; reflux esophagitis) (Dumic et al., 2019; Otaki & Iyer, 2021; Richter & Rubenstein, 2018; Wilkinson & Halland, 2020). *Candida albicans*, herpes simplex virus, and cytomegalovirus are the most common infectious causes (Dumic et al., 2019; Wilkinson & Halland, 2020). Bacterial esophagitis is rare but can coincide with a fungal or viral infection, making it difficult to diagnose. In GERD, erosive esophagitis is a common complication. Hiatal hernia, an intrinsic factor to the development of reflux esophagitis, increases in incidence with increasing age (Richter & Rubenstein, 2018). Eosinophilic esophagitis is a relatively new disorder described as a chronic immune or antigen-mediated esophageal disorder characterized as esophageal symptoms with endoscopic biopsies with more than 15 eosinophils per high-powered field and lack of pathological GERD (Dellon et al., 2013; Richter & Rubenstein, 2018).

Occurrence: It is estimated that between 6.4% and 15.5% of the population has esophagitis of some form (Richter & Rubenstein, 2018). One study found as many as 19% of the population suffers from asymptomatic esophagitis (Lee et al., 2016).

Age: Esophagitis can occur at all ages, and it occurs equally in men and women (Abid et al., 2005). However, medication-induced esophagitis is more common in older adults and is more prevalent in females (Abid et al., 2005). Hiatal hernias, more prevalent in older adults, are a known risk for erosive reflux esophagitis, and severe reflux esophagitis has been found more prevalent in patients 70 or older compared to 21 and younger (37% vs 12%) (Dumic et al., 2019; Johnson & Fennerty, 2004).

Ethnicity: Not significant.

Contributing Factors: In older adults, normal aging changes such as decreased salivation, gastric motility, and delayed gastric emptying can contribute to the development of esophagitis. Contributing factors to reflux esophagitis via persistent GERD regurgitation includes obesity, smoking, conditions that contribute to limited upper body mobility (such as spinal cord injuries), substances that can weaken the lower esophageal sphincter (coffee, peppermint, alcohol, spicy foods, citric fruits, chocolate, nifedipine, verapamil, and progesterone) (Commisso & Lim, 2019; Dumic et al., 2019; Otaki & Iyer, 2021; Richter & Rubenstein, 2018).

© F.A. Davis Publishing

Infectious agents are known to cause esophagitis in patients with certain viral, bacterial, parasitic, and fungal infections, such as in *Candida* esophagitis. Predisposing factors for patients who develop *Candida* esophagitis include radiation therapy, chemotherapy, certain hematological malignancies, AIDS, alcoholism, and malnutrition.

Medication-induced esophagitis ("pill esophagitis") is the result of altered pill passage through the esophagus (e.g., the pill becomes stuck or opens up) and subsequent prolonged mucosal contact, resulting in chemical irritation and mucosal inflammation. This can be contributed to by polypharmacy and impaired esophageal motility, which are more common in older adults (Dumic et al., 2019). Additionally, swallowing certain medications such as aspirin, tetracycline antibiotics, bisphosphonates, ferrous sulfate, captopril, certain chemotherapeutic agents, NSAIDs, quinidine, steroids, alendronate, alprenolol, vitamin C, phenytoin, calcium preparations, theophylline, and potassium chloride contributes to pill esophagitis (Dumic et al., 2019; Otaki & Iyer, 2021). Patients often report that insufficient fluid intake and not remaining upright after the medication is taken contributed to the symptoms of esophagitis (Aparanji et al., 2012; Dumic et al., 2019). Patients with cardiomyopathy with left atrial enlargement can have compression of the lower esophagus and subsequent impaired motility resulting in increased risk for pill esophagitis (Dumic et al., 2019).

Finally, several systemic disorders place patients at risk for esophagitis, including pemphigus vulgaris, bullous pemphigoid, Stevens-Johnson syndrome, lichen planus, inflammatory bowel disease, sarcoidosis, scleroderma, chronic granulomatous disease, and motility disorders of the esophagus (Aparanji et al., 2012).

Signs and Symptoms: A history of dysphagia and pain on swallowing (odynophagia) is common. Associated pyrosis, regurgitation, coughing, wheezing, and progressive hoarseness may occur, especially if associated with GERD. A fever may be present in patients with an infectious process. Patients should be questioned about medication usage, history of radiation treatments, smoking, and intake of substances that weaken the lower esophageal sphincter; sleeping habits; and use of any tight or restrictive clothing. Review patient medical history for chronic conditions that can contribute to esophagitis (Dumic et al., 2019; Otaki & Iyer, 2021; Richter & Rubenstein, 2018; Wilkinson & Halland, 2020).

Physical examination usually produces no positive findings for simple esophagitis but can be used to rule out other etiologies of abdominal pain. Oral thrush may be found in patients with *C. albicans*. Palpate for any upper abdominal masses or tenderness. Perform a rectal examination to detect any frank bleeding and stool guaiac to detect occult blood if gastrointestinal (GI) bleed is suspected, such as from erosive reflux esophagitis. Examine the oral cavity for sores and the skin for signs of immunosuppression or systemic diseases such as scleroderma or HIV/AIDS (Richter & Rubenstein, 2018; Zakharia & Tabibian, 2018).

Diagnostic Tests: If suspicion was aroused on the physical examination, stool should be checked using the guaiac test to determine whether there has been any intestinal bleeding. Laboratory studies are not required when antacids, position change, or both relieve pyrosis. For older adults who complain of persistent dysphagia or odynophagia with or without fever, a barium swallow or an endoscopy (with brush and biopsy if structural mucosal damage is suspected) or both are indicated. Also consider pH monitoring studies especially if the diagnosis is elusive or symptoms are refractory; however, in patients with eosinophilic esophagitis, the results are usually normal and, as such, pH monitoring can be utilized to rule out GERD over eosinophilic esophagitis in differential diagnosis (Akhondi, 2017; Otaki & Iyer, 2021).

Differential Diagnosis:

- Esophageal stricture (upper GI sinus)
- Esophageal carcinoma
- Cholecystitis and biliary colic
- GI foreign body
- Acute coronary syndrome
- Angina pectoris
- Myocardial infarction
- Peptic ulcer disease (PUD) (Dumic et al., 2019; Otaki & Iyer, 2021; Richter & Rubenstein, 2018)

Treatment: For infectious esophagitis, temporary symptomatic relief can be obtained with sucralfate slurry, 1 g/10 mL orally four times daily. Viscous lidocaine (2%), 15 mL orally every 4 hours as needed to swish and swallow, can be used for short-term temporary relief, unless contraindicated by potential drug interactions or history of cardiac or hepatic disease. For candida esophagitis, systemic therapy is the first-line treatment, rather than topical therapy; usually with fluconazole 200 mg to 400 mg daily for 14 to 21 days (Mohamed et al., 2019). For cases of herpes simplex virus–induced esophagitis in immunocompetent patients, spontaneous resolution is common, although oral acyclovir may be given to speed recovery. In immunocompromised patients, oral acyclovir is first-line treatment; for severe cases, IV antiviral therapy may be needed (Hoversten et al., 2019; Kadayakkara et al., 2016). Esophagitis from radiation can be treated with viscous lidocaine. For erosive esophagitis, use of proton pump inhibitors (PPIs) is recommended for 4 weeks, followed by reevaluation. In moderate to severe cases, PPIs have been found to be consistently superior to other options, including H_2 receptor blockers, in esophageal healing; however, agent selection and dose should be tailored to each patient (Kroch & Madanick, 2017).

Follow-Up: Patients should report progress at least 1 week after treatment. An endoscopy may be repeated if the patient is still symptomatic despite treatment compliance. Yearly endoscopy is recommended thereafter for patients with severe cases of esophagitis. Patients with eosinophilic esophagitis generally do not respond to treatment with PPIs and endoscopy with biopsy is completed to elicit the infectious etiology (Akhondi, 2017).

Sequelae: Ulceration and bleeding can occur if esophagitis is present. Barrett's esophagus with possible adenocarcinoma may be a long-term complication (Bujanda & Hachem, 2018; Dumic et al., 2019; Otaki & Iyer, 2021).

Prevention/Prophylaxis: Because of the high recurrence rate of esophagitis, patients should be instructed to follow all nonpharmacological measures unless otherwise instructed. Maintenance therapy for esophagitis may be prescribed for an extended time, although the dose and need should be periodically evaluated (Freedberg et al., 2017). Patient with

© F.A. Davis Publishing

Barrett's esophagus should take indefinitely a daily or twice daily PPI and undergo surveillance endoscopy with timing based on the dysplasia grade (Bujanda & Hachem, 2018).

Referral: A gastroenterologist should be consulted for the endoscopy and for patients with severe or nonresponsive esophagitis symptoms.

Education: Patients with reflux esophagitis should be instructed to raise the head of the bed 4 to 6 inches with shock blocks. Factors that increase abdominal pressure, such as wearing tight restrictive clothing, should be avoided. The patient should avoid smoking and ingestion of fatty foods, coffee, chocolate, mints, citric juices, alcohol, and large quantities of fluids with meals. Remind patients not to break or crush extended-release or delayed-release tablets. Teach the patient the importance of swallowing medications with an adequate amount of fluids. Patients with Barrett's esophagus should be educated on the need for indefinite PPI therapy and regular endoscopic surveillance (Commisso & Lim, 2019; Otaki & Iyer, 2021).

Clinical Recommendation	Evidence Rating	References
Topical steroids are the first-line treatment for eosinophilic esophagitis, rather than systemic steroids.	A	Dellon et al., 2013
Screening for Barrett's esophagus can be considered in men with more than 5 years of gastroesophageal reflux disease (GERD) symptoms and/or frequent GERD symptoms who also have two or more risk factors: age >50, White, central obesity, smoking history, and history of Barrett's esophagus and/or esophageal adenocarcinoma in a first-degree relative. GASTRIC CANCER

Signal Symptoms: The most common symptoms at diagnosis of gastric cancer are weight loss (62%) and ongoing abdominal pain (52%) (Mansfield, 2021). Weight loss is usually due to decreased caloric intake as a consequence of other reported presenting symptoms including nausea, early satiety, and dysphagia. Patients reported vague pain in the epigastric area which increased in both frequency and severity as the disease progressed. A palpable abdominal mass is the most common physical finding in gastric cancer and is usually indicative of advanced disease (Mansfield, 2021).

Description: Gastric cancer develops when cells in the stomach begin to grow rapidly and uncontrollably. Eventually, this rapid cell growth will begin to interfere with the normal functions of the stomach. Adenocarcinomas account for approximately 95% of gastric cancers (National Comprehensive Cancer Network [NCCN], 2021). Adenocarcinomas arise from the stomach mucosa, and they are classified as either intestinal type or diffuse type. Intestinal type adenocarcinomas tend have a better prognosis and are more likely to have gene mutations which allow for targeted therapies. Diffuse type adenocarcinomas tend to be more aggressive, spreading more quickly than intestinal type, and are usually harder to treat (American Cancer Society [ACS], 2021c).

Other, less common types of gastric cancers include gastrointestinal stromal tumors (GISTs), neuroendocrine (carcinoid) tumors, lymphomas and (even less commonly) squamous cell carcinomas, small cell carcinomas, and leiomyosarcomas (ACS, 2021c). GISTs develop in the stomach walls cells called interstitial cells of Cajal. These are the cells that communicate with the muscles of gastrointestinal (GI) tract, which are responsible for the movement of food and fluid. Some GISTs are more likely to grow and spread to other sites of the body (ACS, 2019). Neuroendocrine tumors (NETs) can be either slow or fast growing. NETs tend to act like both nerve cells and endocrine cells, controlling the release of digestive enzymes, the movement of food through the GI tract, and regulating the growth of other cells of the digestive tract (ACS, 2018). Lymphomas are a type of cancer that arise from lymphocytes. These usually originate in other parts of the body but can rarely begin in the walls of the stomach.

Cancers of the stomach tend to develop more slowly when compared to other cancers. Early-stage stomach cancer begins in the innermost layer of the stomach—the mucosa. Patients with tumors invading through the mucosa or with suspicious local lymph nodes on imaging are considered to have locoregional disease and may or may not be surgically resectable. Sometimes gastric cancer invades or wraps around blood vessels or other vital structures. Although cancer at this stage is still considered locoregional, it cannot be safely removed surgically and is therefore no longer curable (ACS, 2021d). Gastric cancers can spread through the lymphatic system, circulatory system, peritoneal seeding, and

© F.A. Davis Publishing

direct extension through the gastric wall (Mansfield, 2021). Gastric cancer that has invaded other organs is considered metastatic.

Etiology: The etiology of gastric cancer is multifactorial. The differences in types of gastric cancer may also yield different etiologies. The Lauren classification of gastric cancer was established in 1965 and is still the most frequently used by clinicians. This system divides gastric cancer into intestinal type and diffuse type; an indeterminate type was later added to include gastric cancers with rare histology (Machlowska et al., 2020). Despite type, the etiology of gastric cancer is associated with the interaction of bacterial, dietary, environmental, lifestyle and host risk factors.

Intestinal type gastric cancer is the most common, and has been associated with gastric mucosa metaplasia, progressing from chronic gastritis to atrophic gastritis, intestinal metaplasia, dysplasia, and finally, adenocarcinoma. *Helicobacter pylori* infections, pernicious anemia, and perhaps a diet high in salt all may lead to gastritis, which initiates the cascade (Shah et al., 2020). A reduction in hydrochloric acid caused by gastric atrophy leads to an increase in gastrin, which induces gastric epithelial cell proliferation. This can also happen after gastric resections, where the increase in gastric pH may allow settlement of bacteria that can produce mutagenic compounds. Inflammation from chronic gastritis can also damage epithelial cells causing an increase in free radicals and increased cell turnover (Chan & Wong, 2021c). Intestinal type tumor cells tend to group together in tubular formations (Lauwers & Kumarasinghe, 2020). These tend to be slow growing, occur more often in men, older people, and are predominately found in high-risk areas (Canadian Cancer Society, 2021; NCCN, 2021).

Diffuse type gastric cancer tends to arise from normal gastric mucosa, having no clear precancerous lesion (Chan & Wong, 2021c). The lack of cohesiveness allows individual cells to grow and invade neighboring tissues aggressively, metastasizing much faster than intestinal type gastric cancers (Lauwers & Kumarasinghe, 2020; Machlowska et al., 2020). This is caused by the acquired or hereditary mutation of E-cadherin, a cell adhesion protein, causing disorganization of gastric cells (Lauwers & Kumarasinghe, 2020). Diffuse gastric cancers have also been found to have a higher incidence in females, younger patients, and are more frequently found in low-risk areas (Machlowska et al., 2020; NCCN, 2021).

Occurrence: Each year, approximately 990,000 people are diagnosed with gastric cancer worldwide. Of those, it is estimated that 738,000 will die (Machlowska et al., 2020). In the United States, around 22,220 patients are diagnosed annually, of whom 10,990 are expected to die (Chan & Wong, 2021a). Gastric cancer accounts for approximately 1.5% of all new cancer diagnosis each year in the United States (ACS, 2021a). Men are two to three times more likely than women to be diagnosed with gastric cancer (Machlowska, 2020). The American Cancer Society (2021a) estimates that in 2021 within the United States 16,160 men and 10,400 women will be diagnosed with gastric cancer, with 6,740 men and 4,440 women dying from the disease.

The worldwide incidence of gastric cancer has declined since the 1980s; however, this is with wide geographic variability. Decreased incidence is noted in Western Europe, sub-Saharan Africa, Australia, and North America, while East Asia, South and Central America, and Eastern Europe have the highest incidence rates. Gastric cancer is the most commonly diagnosed cancer in men in Japan and Korea and is the leading cause of cancer death in China (NCCN, 2021).

Age: Gastric cancer affects older people most often. The average age at diagnosis is 68 years. Of patients diagnosed with gastric cancer, approximately 60% are older than 65 years (ACS, 2021a).

Ethnicity: Within the United States, gastric cancer has been found to disproportionately affect non-White minority groups. The annual incidence of gastric cancer is highest in Asian and Pacific Islanders (10/100,000) and non-Hispanic African Americans (10/100,000), followed by Hispanic Americans (9.6/100,000), Native Americans and Alaskan Natives (8.8/100,000), and non-Hispanic European Americans (5.3/100,000) (ACS, 2020).

Contributing Factors: As previously mentioned, gastric cancer is associated with bacterial, dietary, environmental, lifestyle and host risk factors. *H. pylori* is a gram-negative bacteria that causes inflammation to gastric mucosa, and DNA changes to gastric cells over time. (Shah et al., 2020). *H. pylori* infections additionally damage the gastric microenvironment, making it more susceptible to carcinogens (Machlowska et al., 2020). Chan and Wong reported that "*H. pylori* infection has been associated with an approximately sixfold increase in the risk of adenocarcinomas distal to the cardia, including both the intestinal and diffuse types" (2021c).

Numerous studies have been done to correlate dietary factors and the risk of gastric cancers. Diets high in salt and salt-preserved foods (salted fish, cured meats, salted vegetables) have been strongly linked with gastric cancer development because salt is thought to damage the stomach mucosa, which increases its susceptibility to carcinogens. The decline of gastric cancer worldwide has been partly attributed to refrigeration practices that eliminate the need for salt preservation of foods. Additionally, diets high in fried foods, processed meats, and alcohol and low in fruits and vegetables have been associated with a high risk of developing gastric cancers in epidemiological studies (Chan & Wong, 2021c).

There has been some linkage proposed between occupations in coal and tin mining, steel and iron processing, and manufacturing rubber with an increased risk of gastric cancer; however, further research is needed to determine the overall effect of these environmental effects and developing gastric cancer. Cigarette smoking has been contributed to a 1.53-fold increase in the risk of gastric cancer; however, this risk decreased after 10 years of smoking cessation (Chan & Wong, 2021c). Regular ingestion of alcohol has not consistently been shown to cause a direct increased risk of gastric cancer; however, most studies show a positive correlation between heavy alcohol consumption and gastric cancer (Machlowska et al., 2020). The data for this correlation are greatest among people who have three or more drinks per day (ACS, 2021b). Individuals with a low socioeconomic status have a twofold increase in risk of distal gastric cancers, while those with a higher socioeconomic status are at a higher risk of proximal gastric tumors.

Obesity, defined as having a body mass index (BMI) greater than or equal to 25 kg/m^2, was correlated with an increased

© F.A. Davis Publishing

risk of gastric cancer, and there was a positive correlation with occurrence of gastric cancer and the individual's BMI increasing (ACS, 2021b). Other medical conditions associated with an increased risk for gastric cancer include gastric polyps, gastric ulcers, pernicious anemia, and Epstein-Barr virus (EBV). The EBV has been associated with 5% to 10% of gastric cancers worldwide. The pathogenesis of gastric cancers caused by EBV is unclear; the virus may inhibit the expression of certain tumor suppressing genes (Chan & Wong, 2021c). History of previous abdominal radiation and having undergone gastric surgery, especially a partial gastrectomy (Billroth I or II), also increases an individual's risk for developing gastric cancer. Lastly, individuals with blood type A have a 20% increase in developing gastric cancer when compared to those with blood types O, B, or AB (Chan & Wong, 2021c).

Although most gastric cancers are sporadic, having a positive family history is an important risk factor and can account for a threefold increase in risk compared to persons without a family history. Aggregation of gastric cancers within families account for 10% of incidences, whereas gastric cancers that are truly hereditary are culpable for 1% to 3% worldwide. The ratio of those diagnosed with gastric cancers that have a family history is greater in Asian areas than in Europe and North America. This concludes that environmental factors more than genetic agents affect the risk of gastric cancer development in countries with higher incidences (Machlowska et al., 2020).

Signs and Symptoms: Early detection of gastric cancer is often difficult because of the typically ambiguous clinical presentation. Patients often describe a vague sensation of fullness after a meal that is relieved by belching, nonspecific complaints of abdominal pain of varying intensities, nausea, anorexia, dyspepsia, vomiting, and evidence of GI blood (hematemesis and melena), and changes in bowel habits. Dysphagia is most commonly reported by those with cancers in the proximal stomach and esophagogastric junction (EGJ) (Mansfield, 2021). Epigastric discomfort is present in more than 75% of patients, and the presentation may be similar to that of a gastric ulcer further complicating the presentation, as 25% of patients diagnosed with gastric cancer have previously had gastric ulcers (Mansfield, 2021). Weight loss and pallor, if the patient is anemic, may be the only signs noted during physical examination. Examination of the skin may reveal diffuse seborrheic keratosis (sign of Leser-Trèlat). A palpable mass in the abdomen is felt in less than 20% of patients.

Many patients with gastric cancer often do not become symptomatic until their disease becomes metastatic. Metastatic distribution most commonly involves the liver, peritoneal surface, and distant lymph nodes. Liver involvement is usually diffuse and not singularly palpable; however, it is often associated with an elevated serum alkaline phosphatase level. Ascites is often the first sign of peritoneal spread. Because gastric cancers can be spread through the lymphatic system, patients with metastatic disease often have enlargement of the left supraclavicular lymph nodes (Virchow node), a periumbilical nodule (Sister Mary Joseph's node), and left axillary node (Irish node). Additionally, in advanced disease a rigid rectal mass may be palpated (Blumer's shelf) and/or an enlarged ovary may be detected in females (Krukenberg's tumor) (Mansfield, 2021).

Diagnostic Tests: For patients presenting with symptoms of gastric cancer, the following laboratory studies should be considered: complete blood count (CBC) with indices to determine presence of anemia, comprehensive chemistry profile, and fecal occult blood test (FOBT) to detect bleeding in the intestinal tract if suspected. Patients will need to be referred for an endoscopy (EGD) to determine the location of the tumor, measurement of tumor size, determination of macroscopic stage (T1–T4) and to obtain biopsies to confirm histological type (Shah, et al., 2020; Smyth et al., 2020).

Once diagnosis has been confirmed by biopsy on EGD, the remaining work-up is used to establish disease stage based on the American Joint Committee on Cancer and the Union for International Cancer Control system based on tumor, node, metastasis (TMN) (Mansfield, 2021). On EGD, macroscopic type (T stage) characterizes the depth the primary tumor has grown into the layers of the stomach (Smyth et al., 2020). A chest abdominopelvic computed tomography (CT) scan with oral and IV contrast should be used to evaluate for metastatic disease (M stage). In the absence of distant metastatic disease, endoscopic ultrasonography (EUS) is the preferred tool to determine the depth of invasion of primary gastric tumors (T stage), as well as to accurately evaluate for nodal staging (N stage) and occult metastases (M stage) (Mansfield, 2021; NCCN, 2021). A pretreatment, staging laparoscopy with cytology is recommended to monitor for peritoneal dissemination in patients with a lesion greater than T1a who are surgical candidates, even if no signs of metastatic disease have been previously discovered (NCCN, 2021).

If metastatic disease is found on CT scan, the suspected lesion must be confirmed by biopsy due to the risk of false-positive findings. A paracentesis should be performed on patients with ascites, and the fluid should be examined for cytology and chemical evaluation. CT scans can miss peritoneal and hematogenous metastases smaller than 5 mm and do not precisely evaluate the depth of primary tumor invasion and existence of lymph node involvement. The use of positron emission tomography (PET) scans is controversial. The NCCN (2021) recommends PET scans if no evidence of metastatic disease has been found previously, as PET scans have can detect radiographically occult metastatic lesions in up to 10% of those with locally advanced disease (Mansfield, 2021).

Microsatellite instability (MSI) testing is recommended on all newly diagnosed patients. Human epidermal growth factor receptor 2 (HER2) and programmed death-ligand 1 (PD-L1) testing should be performed on the tumor biopsy if metastatic adenocarcinoma is documented or strongly suspected (NCCN, 2021). Next-generation sequencing (NGS), with included tumor mutation burden (TMB) testing should be done if enough tissue is available after the previously recommended testing. MSI, HER2, PD-L1 and TMB determination can be used to guide treatment choices in advanced disease.

Differential Diagnosis:

- Bacterial/viral gastroenteritis
- Crohn's disease
- Chronic/acute gastritis
- Esophageal cancer
- Esophageal stricture
- Esophagitis

© F.A. Davis Publishing

- Gastric ulcers
- Gastroesophageal reflux disease (GERD)
- Irritable bowel syndrome
- Malignant neoplasms of the small intestine
- Mesenteric ischemia
- Non-Hodgkin's lymphoma
- Peptic ulcer disease (PUD) (Recio-Boiles & Babiker, 2020)

Treatment: Endoscopic resection is used to treat early-stage gastric cancers that have not yet invaded the submucosa (<T1b). For gastric cancers that have penetrated the submucosa but not yet mediatized to the lymph nodes (T1bN0) a partial or complete gastric resection is recommended with lymphadenectomy (NCCN, 2021). In the United States typically at least 16 lymph nodes are removed with a gastrectomy, whereas in East Asian countries more lymph nodes are removed (ACS, 2021d). Surgery may be considered in the noncurative or palliative setting to treat or prevent complications such as bleeding, pain, or obstruction.

Patients with gastric cancers that have invaded the muscularis propria or deeper at presentation (≥T2) or have any lymph node involvement but no metastatic disease (any N, M0) are recommended to undergo perioperative chemotherapy with fluorouracil (5-FU) based treatment. If no perioperative chemotherapy is given, postoperative 5-FU based chemotherapy and/or radiation with a fluoropyrimidine base (IV 5-FU or oral capecitabine) is recommended depending on the pathological findings at surgery, lymph node involvement, and surgical margins (NCCN, 2021). Although certain regimens are favored, agents used should be chosen after considering the patient's performance status, comorbidities, and toxicity profile of each medication. The NCCN (2021) recommends a multidisciplinary team including all relevant disciplines discuss all cases of patients without metastatic disease be prior to the finalization of treatment plans.

Patients with unresectable, metastatic, or recurrent gastric cancer (if localized therapies are not indicated) should be treated with systemic agents to alleviate symptoms, improve quality of life, and extend survival. Again, 5-FU based regimens are preferred in the first line. For patients with HER2 overexpression, trastuzumab (Herceptin) can be added to the regimen for additional benefit without adding cytotoxic side effects. For patients with a PD-L1 score ≥5, nivolumab (Opdivo), an immunotherapy agent, can be added as well in the first line. Additional therapies include the vascular endothelial growth factor (VEGF) inhibitor ramucirumab (Cyramza), which attacks the cancer cells' ability to make blood vessels without affecting healthy cells, unlike standard chemotherapy. There are many other chemotherapy agents from different classes that can be used beyond the first line as single agents or in combination. An additional immunotherapy recommended for gastric cancer is pembrolizumab (Keytruda), an immunotherapy based on microsatellite high status, PD-L1 expression ≥1, or tumor mutation burden high (NCCN, 2021).

Follow-Up: Most gastric cancer recurrences (70% to 80%) happen within the first 2 years after completion of therapy, with almost all (90%) of recurrences occurring within 5 years (NCCN, 2021). Follow-up, or surveillance, is important to detect recurrence early, when burden of disease is likely to be small allowing for more treatment options.

In general, surveillance visits should occur every 3 to 6 months for the first 2 years, then every 6 to 12 months for the next 3 years, then annually. Evaluation with a CBC and chemistry profile should be obtained as needed. Patients with stage II or III disease should be monitored with a CT scan of the chest, abdomen, and pelvis with oral and IV contrast every 6 to 12 months for the first 2 years, then yearly for up to 5 years. Early-stage gastric cancers should be monitored with serial EGDs. Patients with stage I disease and greater should be monitored with EGDs as clinically indicated (NCCN, 2021).

Additionally, patients who underwent surgical resection should be monitored for nutritional deficiencies, including B_{12} and iron insufficiency (NCCN, 2021).

Sequelae: Malnutrition, hemorrhage, obstruction, possibly evasive cancer, metastases, pain, nausea, vomiting, fatigue, chemotherapy-related neuropathy and recurrence are complications from gastric cancer and its treatment. Additionally, patients may experience reflux, dumping syndrome, hypoglycemia, and diarrhea following a gastric resection (NCCN, 2021).

Prevention/Prophylaxis: Patients should restrict the use of food products that contain nitrates and are highly salted. Consumption of fruits, especially citrus fruits, and vegetables has been found to protect against gastric cancer, possibly because they contain vitamin C, folate, carotenoids, and phytochemicals, which may provide protection against carcinogenesis (Machlowska et al., 2020). As previously stated, infection with *H. pylori* has been associated with an increased risk of gastric cancer. According to Choi and associates (2018), in the setting of early gastric cancers status post resection, the incidence of metachronous gastric cancer was 50% lower among patients treated for *H. pylori* versus placebo over a 5.9-year period. Screening for gastric cancer is controversial and not currently recommended in the United States. In countries with a high incidence of gastric cancer, screening has contributed to earlier detection and a decline in gastric cancer mortality; however larger, randomized trials are needed (Chan & Wong, 2021b).

Referral: A gastroenterologist should be consulted for the endoscopy and complicated management problems, including annual follow-up endoscopy. Patients with stages I to III disease should be seen by a surgeon for possible resection. After receiving a surgical resection, patients may need to be followed by a nutritionist. Additionally, patients with gastric cancer should see a medical oncologist to evaluate for the role of neoadjuvant, adjuvant, or palliative chemotherapy and to follow the patient for surveillance visits if not done by the surgeon. Given the commonly advanced age, comorbidities, and the cognition of patients with gastric cancer, careful attention to emotional support and their quality of life need to be considered when caring for older adults. Referral to counseling or psychiatry should be considered on an as needed basis. For patients with advanced disease, referral for palliative care or local hospice should be made.

Education: After partial and complete gastrectomy, patients should be taught about the importance of adequate nutrition. Consuming six small meals throughout the day and not drinking liquids with meals may help with weight loss and symptoms of dumping syndrome. Gastrectomy patients

© F.A. Davis Publishing

should also be educated to avoid foods that cause acid production (tomatoes, spicy foods, caffeine, peppermint, chocolate, and citrus fruits) because these can increase indigestion. Regular, moderate exercise can help improve fatigue. Antidiarrheal medications and an increase in dietary fiber can improve diarrhea. Chemotherapy-induced neuropathic pain can be permanent; however, symptoms can be improved with duloxetine (Cymbalta). Supplementation with vitamins, especially vitamin B_{12} and vitamin D, and minerals, such as calcium and iron, should be prescribed (NCCN, 2019).

GASTRITIS

Signal Symptoms: Anorexia, nausea and vomiting, epigastric pain, gastroesophageal reflux disease (GERD) symptoms, or epigastric discomfort with tenderness.

Description: Gastritis is an acute or chronic inflammation of the mucosal lining of the stomach, established by histological findings on biopsy of inflammatory cells in the lamina propria, with further delineation of chronic gastritis as either atrophic or nonatrophic (Azer & Akhondi, 2021; Rugge et al., 2020). A number of conditions can cause gastritis including infection, autoimmune disorders, systemic disease, chemical (both endogenous and exogenous), radiation, and stress (Azer & Akhondi, 2021; Rugge et al., 2020). Patients may be asymptomatic; however, dyspepsia, iron-deficiency anemia, and macrocytic anemia may be found in older adults with atrophic gastritis (Lahner et al., 2020).

Etiology: Gastritis represents a group of disorders characterized by inflammation of the stomach lining. Each disorder has distinct clinical attributes, pathogeneses, and histological features; diagnosis must be done with histological interpretation of gastric tissues. Gastritis may be caused by parasitic, fungal, bacterial, or viral infectious agents; *Helicobacter pylori* is the most common culprit for gastritis globally (Azer & Akhondi, 2021). Chemical gastritis may occur secondary to bile reflux, alcohol use, NSAIDs, and doxycycline; physical agents such as radiation may also cause gastritis (Rugge et al., 2020). Autoimmune gastritis, resulting from chronic inflammatory processes, may lead to chronic atrophic gastritis; other autoimmune disorders such as thyroid disease, type 1 diabetes, and myasthenia gravis are associated with autoimmune gastritis (Azer & Akhondi, 2021; Lahner et al., 2020). Additional causes of gastritis that are rare include Crohn's disease, collagenous gastritis, eosinophilic gastritis, sarcoidosis-associated gastritis, lymphocytic gastritis, vasculitis-associated gastritis, and ischemic gastritis, which results in high mortality rate (Azer & Akhondi, 2021; Rugge et al., 2020). Atrophic gastritis is most often a result of chronic *H. pylori* and autoimmune gastritis (Lahner et al., 2020).

Occurrence: Exact incidence of gastritis is unknown.

Age: Although gastritis occurs in all ages, gastritis, specifically atrophic forms, are more common in the older adult (Dumic et al., 2019). Autoimmune gastritis is found more commonly in older adult women (Azer & Akhondi, 2021). Patients of all ages can be infected with *H. pylori*, with extensive atrophic damage no longer related only to older ages but rather with persistent *H. pylori* infection (Dumic et al., 2019).

Ethnicity: *H. pylori* infection is most common among Asians and Hispanics (Sonnenberg et al., 2020).

Contributing Factors: Many factors can precipitate the development of gastritis. Gastritis may be acute, chronic, or an exacerbation of chronic presenting acutely. Acute gastritis can be caused by physiological stressors, hypovolemic shock, portal hypertension, aspirin, NSAIDs, smoking, steroid use, alcohol, radiation, chemotherapy, gastric lymphoma, Crohn's disease, alcohol, bile reflux, autoimmune disorders, *H. pylori* and other bacterial, viral, and fungal infections (Azer & Akhondi, 2021). Stress, trauma, and burns can trigger this

© F.A. Davis Publishing

acute condition (Azer & Akhondi, 2021; Rugge et al., 2020). Autoimmune gastritis is related to the loss of parietal and chief cells and includes achlorhydria, hypergastrinemia, loss of pepsin and pepsinogen, and anemia (Azer & Akhondi, 2021). Chronic gastritis is predominantly a result of *H. pylori* infection. Autoimmune gastritis is seen with other autoimmune disorders that include thyroid diseases, myasthenia gravis, Addison's disease, type 1 diabetes, vitiligo, and oral lichen planus (Azer & Akhondi, 2021).

Signs and Symptoms: Anorexia, nausea (with or without vomiting), dyspepsia, epigastric pain worsened by eating, belching, and bloating are common with gastritis (Rahmawati, 2020). Physical examination may be unremarkable in cases of chronic gastritis. Palpate for abdominal masses and liver tenderness. Perform a rectal examination to test for occult blood if concern for occult blood loss. Any unexplained weight loss should be noted. Gastrointestinal (GI) bleeding may be exhibited by coffee-ground emesis, melena, hematochezia, or the passing of bright red blood in a nasogastric tube. Iron-deficiency anemia should raise suspicion for early autoimmune gastritis, but it may also be seen in other forms of gastritis (Azer & Akhondi, 2021; Lahner et al., 2020). Vitamin B_{12} deficiency is associated with atrophic gastritis; atrophic gastritis has also been linked with risk for osteoporosis (Clements et al., 2021).

Diagnostic Tests: Diagnostic studies include complete blood count (CBC) with indices to detect blood loss and anemia, stool guaiac test, and esophagogastroduodenoscopy (EGD) with biopsy, which is the definitive diagnostic test for gastritis and remains the gold standard. Histological examination of tissue specimens obtained during EGD assesses for *H. pylori* via stains, cultures, rapid urea test, or polymerase chain reaction (PCR) test (Azer & Akhondi, 2021). Noninvasive tests include urea breath test (UBT), fecal antigen test, and serologies; proton pump inhibitor (PPI) use will need to be restricted for 14 days and antibiotics for 28 days before UBT and fecal antigen testing (not serology) to ensure more accurate diagnosis and avoid false-negative results (Azer & Akhondi, 2021; Rugge et al., 2020). The serological testing for *H. pylori* is not able to distinguish between prior exposure or active infection; therefore, the utility of this test is limited in clinical scenarios. Noninvasive tests for *H. pylori* may be falsely negative in those with atrophic gastritis, so EGD with biopsy would be required to rule out infection (Lahner et al., 2020). Atrophic and autoimmune gastritis requires EGD with biopsy for histopathological diagnoses. Serum gastrin levels and pepsinogens assist in screening patients with concern for atrophic gastritis, followed by EGD for confirmation.

Differential Diagnosis:

- GERD
- Biliary tract disease
- Food poisoning
- Functional dyspepsia
- Peptic ulcer disease (PUD)
- Perforated or penetrated ulcer
- Gastric carcinomas
- Pancreatic disease
- Esophageal rupture
- Myocardial infarction (atypical presentation)
- Inflammatory bowel disease
- Zollinger-Ellison's syndrome
- Celiac disease
- Viral infections (Rugge et al., 2020)

Treatment: Patients with acute gastritis should avoid offensive agents that contributed to gastritis. If treatment for *H. pylori* is indicated, treatment options are delineated in Table 13-2. Iron or B_{12} supplementation may be necessary for iron-deficiency anemia and B_{12} deficiency. Dietary changes may be necessary

TABLE 13-2 ***Helicobacter pylori* Regimens for First-Line Treatment**

PATIENT CHARACTERISTICS FOR TREATMENT	MEDICATION AND DOSAGE
Patients who are not allergic to penicillin and have not previously received a macrolide	Standard dose PPI twice daily plus clarithromycin 500 mg twice daily, and amoxicillin 1000 mg twice daily for 10–14 days
	Or
	Bismuth quadruple therapy: PPI twice daily, bismuth subcitrate or subsalicylate 300 mg four times daily, tetracycline 500 mg four times daily, and metronidazole 500 mg three times daily
Patients who are allergic to penicillin and who have not previously received a macrolide	Standard dose PPI twice daily, clarithromycin 500 mg twice daily, metronidazole 500 mg twice daily for 10–14 days
	OR
	Bismuth quadruple therapy: PPI twice daily, bismuth subcitrate or subsalicylate 300 mg four times daily, tetracycline 500 mg four times daily, and metronidazole 500 mg three times daily
Patients who are allergic to penicillin, failed a course of prior therapy, or have previously received a macrolide	Bismuth quadruple therapy: PPI twice daily, bismuth subcitrate or subsalicylate 300 mg four times daily, tetracycline 500 mg four times daily, and metronidazole 500 mg three times daily
Patients who are not allergic to penicillin but have had macrolide exposure	Bismuth quadruple therapy: PPI twice daily, bismuth subcitrate or subsalicylate 300 mg four times daily, tetracycline 500 mg four times daily, and metronidazole 500 mg three times daily, or
	Standard dose PPI twice daily, levofloxacin 500 mg daily, amoxicillin 1000 mg twice daily

Source: *Chey et al., 2017*

© F.A. Davis Publishing

in those with eosinophilic gastritis (Azer & Akhondi, 2021). Lon-term PPI use may worsen atrophic gastritis precipitated by *H. pylori*, so patients should be assessed on a case-by-case basis for PPI necessity (Lahner et al., 2020). PPI therapy should be avoided in those with impaired gastric acid secretion due to atrophic damage (Lahner et al., 2020). Further studies are needed regarding prokinetic therapy in atrophic gastritis due to delayed gastric emptying in setting of reduced gastric acid (Lahner et al., 2020).

Follow-Up: *H. pylori* eradication should be documented after treatment, typically with noninvasive testing, but EGD with biopsy may be indicated if the presentation is complicated. Both PPI therapy and antibiotics should be held prior to noninvasive testing to avoid false-negative results. Surveillance EGD is recommended in extensive atrophic gastritis and intestinal metaplasia varying from 1 to 3 years, with earlier surveillance timing determined by presence of gastric cancer in a first-degree relative (Lahner et al., 2020). However, surveillance for atrophic gastritis without intestinal metaplasia located only in gastric antrum does not require EGD surveillance (Lahner et al., 2020).

Sequelae: *H. pylori* is a known risk factor for development of gastric cancer, and those with autoimmune atrophic gastritis are also at risk for gastric cancer and neuroendocrine tumors (Lahner et al., 2020). Vitamin B_{12} and iron absorption is affected in atrophic gastritis, leading to iron-deficiency anemia and pernicious anemia (Lahner et al., 2020). Iron-deficiency anemia may also be present in other forms of gastritis. Atrophic gastritis increases risk for osteoporosis (Azer & Akhondi, 2021; Lahner et al., 2020). Untreated, gastritis could progress to PUD, gastric bleeding, chronic gastritis, neuroendocrine tumors, mucosa-associated lymphoid tissue (MALT) lymphoma, depending on the etiology of gastritis (Azer & Akhondi, 2021).

Prevention/Prophylaxis: Prophylaxis with acid-suppressive drugs can reduce the incidence of acute stress gastritis. Older adults who are high-risk intensive care unit patients, including those with severe burns, central nervous system trauma, coagulopathy, sepsis, shock, multiple traumas, mechanical ventilation for longer than 48 hours, hepatic or renal failure, and a history of peptic ulcer or GI bleeding, benefit from prophylaxis medication to prevent acute gastritis. Alternative anti-inflammatory or nonnarcotic analgesics should be considered in the treatment of pain or inflammation in older adults with a history of gastritis, dyspepsia, or other upper GI clinical events

Referral: Consultation with a gastroenterologist for endoscopy and management of persistent dyspepsia is recommended.

Education: Advise patients to report any black, tarlike stools or frank bleeding to the health-care practitioner immediately. All alcohol, caffeine, salicylates, tobacco, and NSAID product use should be discontinued.

GASTROENTERITIS

Signal Symptoms: Sudden onset of diarrhea, abdominal pain with distention, nausea, vomiting.

Description: An infectious response of the gastrointestinal (GI) tract to various microorganisms that can be viral, bacterial, or parasitic in origin.

Etiology: Caused by exposure to toxins and drugs or viruses, bacteria, and parasites:

- Viruses such as norovirus, formerly called the Norwalk-like virus and astrovirus
- Bacteria such as *Salmonella, Campylobacter, Shigella, Escherichia coli*, and *Vibrio cholerae*
- Parasites such as *Giardia lamblia*

Occurrence: Approximately 30% to 40% of gastroenteritis diarrhea in the United States is thought to be viral in origin. Exact incidence of infectious gastroenteritis is unknown because of underreporting of symptoms. Noroviruses cause approximately 19 to 21 million cases of acute gastroenteritis each year and are the leading cause of outbreaks of gastroenteritis. Norovirus outbreaks peak in the winter months. Norovirus accounts for 56,000 to 71,000 hospitalizations, and 570 to 800 deaths annually (Stuempfig et al., 2021).

Age: Occurs at all ages, but its incidence and the mortality rate from infectious diarrhea are higher in older adults. Epidemic cases of gastroenteritis occur in nursing home populations and long-term care facilities are the most frequently reported settings of outbreaks transmitted through person-to-person contact or environmental contamination (Stuempfig et al., 2021).

Ethnicity: Not significant.

© F.A. Davis Publishing

Contributing Factors: Specific to the older adult population, age-related factors such as decreased motility, mucosal atrophy, and decreased gastric acidity inhibit natural defense mechanisms against infectious agents, as well as age-related changes in B-cell and T-cell function (Cardemil et al., 2017). The use of H_2 blockers, proton pump inhibitors (PPIs), antacids, anticholinergic drugs, and narcotics increases the potential for developing gastroenteritis. Gastroenteritis also can be caused by viral or bacterial infection, food intolerance, and organic (shellfish, certain mushrooms) or inorganic (sodium nitrate) poisons. Travel to another country with a change in surroundings or to an area of poor sanitation standards and facilities can contribute to the development of gastroenteritis. Nursing home populations are susceptible to epidemics because of contact with health-care workers who may not use proper hand washing techniques. Some viruses, such as norovirus, can be transmitted by an airborne route, particularly through aerosolized particles. Fecal-to-oral contact has been identified as a mode of transmission of organisms. Person-to-person contact is responsible for greater than 90% of norovirus outbreaks in health-care settings (Chen et al., 2017).

Signs and Symptoms: History of possible fecal-to-oral contact; exposure to other patients with gastroenteritis; and ingestion of certain food products such as mayonnaise, custards, fried rice, vegetables, beef, poultry, bean sprouts, or raw seafood should be explored. Try to estimate the length of time that has elapsed since the patient ingested the food product suspected of contamination. Travel to a foreign country or region that may have contaminated water should be recorded, as should any previous history of diarrhea and related symptoms, and the duration of the current episode. A sudden onset of diarrhea, abdominal pain with distention, flatulence, and vomiting may be reported; however, diarrhea is more common in women. Associated anorexia, headache, fatigue, dizziness, and myalgias are also symptoms of gastroenteritis. Fever may or may not occur in the older adult. Mental confusion may result from dehydration. The stool's color, odor, amount, and frequency should be described, and the presence of any blood or mucus in the stool should be discerned. Patient use of prescription drugs, over-the-counter (OTC) medications, and home remedies need to be included in the history. In the physical examination, the skin is checked for signs of rashes or dehydration, and the lymph nodes are assessed for lymphadenopathy. Abdominal examination may reveal distention, hyperactive bowel sounds, and tenderness. Rectal examination may be performed to check for bleeding, stool character, and presence of any fecal impaction (Stuempfig et al., 2021).

Diagnostic Tests: Complete blood count (CBC) with differential should be ordered. White blood count (WBC) shift to the left may suggest an infection, and a decreased hemoglobin value indicates anemia from possible blood loss. Serum electrolyte evaluation shows an increased sodium level in dehydrated patients and decreased potassium resulting from the diarrhea. Elevated serum creatinine and blood urea nitrogen (BUN) levels also occur in dehydration. Stool samples for blood, ova and parasite, leukocytes, and bacteria are ordered to try to identify the microorganism in patients with bloody diarrhea, dehydration, or signs of inflammatory disease, and symptoms lasting more than 3 to 7 days. Cultures in immunosuppressed patients are also warranted. Cultures may be obtained in traveler's diarrhea (Acree & Davis, 2017).

Differential Diagnosis:

- Fecal impaction
- Fecal incontinence
- Colorectal cancers
- Adverse reaction to medications
- Diverticulitis
- Malabsorption
- Pseudomembranous colitis if the patient has been prescribed an antibiotic within 2 months of onset of symptoms
- *Clostridioides difficile* (Sattar & Singh, 2021)

Treatment: Lost fluids and electrolytes must be replaced. Clear liquids and specially formulated rehydration liquids, such as Pedialyte, should be given as tolerated. Clear broths and crackers may be added to the diet as tolerated. Early refeeding decreases symptom duration and improves nutritional outcomes (Sattar & Singh, 2021). Patients should avoid caffeine, dairy products, alcohol, fruits, bran, vegetables, and red meats. Solid foods should be added gradually, starting with rice or potatoes. Physical activity should be limited to avoid unnecessary exertion. Care should be taken to prevent any skin excoriation or pressure sores. Antibiotic therapy is specific to the bacterial or parasitic organisms identified from the stool culture:

- *Campylobacter* strains have been shown to have fluoroquinolone resistance and are best treated by azithromycin or other macrolides. For all antibiotics, either single-dose therapy or 3 days of therapy are sufficient for resolution of symptoms.
- *G. lamblia* infection is treated with metronidazole, 250 mg three times daily for 5 to 7 days.
- Severe cases of traveler's diarrhea (enterotoxigenic *E. coli*) can be treated with azithromycin 500 mg daily for 3 days (Acree & Davis, 2017).

Follow-Up: Contact outpatients 4 days after the onset of symptoms to determine progress. Request nursing home staff to provide a verbal report of the patient's condition on the third or fourth day. Note any further outbreak of gastroenteritis. When contacting the patient at home, question if there have been any additional symptoms, including fever and neurological developments such as paresthesia, motor weakness, and cranial nerve palsies. For older adults with chronic diarrhea or other persistent GI symptoms, refer to a gastroenterologist. Reactive arthritis may occur after infections from *Shigella, Salmonella, Campylobacter*, or *Yersinia* (Sattar & Singh, 2021).

Sequelae: Dehydration, anemia, metabolic acidosis, and hypovolemic shock and sepsis can occur in untreated cases of severe infectious diarrhea.

Prevention/Prophylaxis: Older adults with travel plans to foreign destinations should be counseled to avoid contaminated water and other high-risk beverages and foods to prevent traveler's diarrhea (Shane et al., 2017)

Referral: Refer to a specialist when symptoms persist beyond 4 days, when severe dehydration develops, or when the patient has bloody stools.

© F.A. Davis Publishing

Education: Gastroenteritis, although generally self-limiting, can be debilitating. Infections with some microorganisms, such as *G. lamblia*, can become chronic and result in lactose intolerance, which is common in older adults. Any new case of diarrhea not resolved in 3 to 4 days requires health-care provider intervention. Use of OTC antiperistaltic agents, such as loperamide, is contraindicated in infectious diarrhea, but may be used in immunocompetent adults with acute watery diarrhea (Shane et al., 2017).

GASTROESOPHAGEAL REFLUX DISEASE

Signal Symptoms: Regurgitation, heartburn (retrosternal burning), hoarseness, chronic cough, water brash, globus sensation, atypical chest pain.

Description: Gastroesophageal reflux disease (GERD) is a common disorder characterized by heartburn (epigastric/retrosternal burning) and regurgitation (reflux of gastric contents into the esophagus and/or pharyngeal tissues) (Dumic et al., 2019; Otaki & Iyer, 2021; Richter & Rubenstein, 2018). Symptoms are often postprandial with more atypical, including respiratory manifestations, and atypical symptoms more common in older adults (Commisso & Lim, 2019; Dumic et al., 2019; Richter & Rubenstein, 2018). Multiple factors contributing to the presence and severity of GERD have been identified, such as lifestyle factors, obesity, stress, and others (Commisso & Lim, 2019).

Etiology: The presentation of GERD is a complex problem than involves reduced lower esophageal sphincter (LES) tone, transient relaxation of the lower esophageal sphincter relaxation (TLESR) at inappropriate times, and decreased peristalsis (Otaki & Iyer, 2021; Richter & Rubenstein, 2018).

Occurrence: The lack of a diagnostic standard makes defining prevalence of GERD difficult. However, in the United States GERD has been estimated to affect anywhere from 6% to 30% of patients, accounting for the most common outpatient GI presentation and an average of over 100,000 hospital admissions from 2003–2006 (Dumic et al., 2019; Richter & Rubenstein, 2018; Thukkani & Sonnenberg, 2010). Additionally, it is estimated that 20% of U.S. adults have GERD symptoms weekly and 15 million reporting daily symptoms (Soumekh et al., 2014). There does not appear to be difference in occurrence of GERD between genders in North America, although men tend to have a higher risk of erosive esophagitis, Barrett's esophagus, and esophageal adenocarcinoma (Richter & Rubenstein, 2018).

Age: While the prevalence of GERD in older adults is thought to be equivalent to younger ages, it is felt that older adults tend to be less symptomatic or manifest with atypical symptoms due to factors such as decreased pain perception, less acidity of gastric contents, or increased in atrophic gastritis. However, older adults tend to suffer more complications; GERD remains prevalent and is one of the most common disorders in nursing home patients (Commisso & Lim, 2019; Dumic et al., 2019; Otaki & Iyer, 2021; Richter & Rubenstein, 2018; Sandhu & Fass, 2018)

Ethnicity: Prevalence of GERD appears to be similar across racial and ethnic backgrounds in the United States, although Whites tend to have a higher rate of complications, such as Barrett's esophagus, erosive esophagitis, esophageal adenocarcinoma, and strictures (Richter & Rubenstein, 2018).

Contributing Factors: Although some have proposed a minor genetic link to GERD, the overall contribution seems to be more related to environmental factors (Richter & Rubenstein, 2018). Intrinsic factors that contribute to the development of GERD include LES incompetence, alterations in GI tract bicarbonate levels, hiatal hernia, esophageal motility disorders, delayed gastric emptying, and gastric distention (Commisso & Lim, 2019; Dumic et al., 2019; Otaki & Iyer, 2021; Richter & Rubenstein, 2018). Patients with certain medical conditions

© F.A. Davis Publishing

that affect gastric motility such as stroke, diabetes, scleroderma, myasthenia gravis, and Parkinson's disease are also at risk for developing GERD (Bashashati et al., 2014).

There have been several environmental factors linked to GERD, including medications, obesity, tobacco, diet, and alcohol. Medications that can trigger GERD include nitrates, calcium channel blockers, benzodiazepines, antidepressants, lidocaine, tricyclic antidepressants, beta agonists, theophylline, sedatives, narcotics, anticholinergics; often they lower the LES tone. NSAIDs, aspirin, steroids, iron sulfates, gelatin capsules, antibiotics, potassium chloride tablets, vitamin C, quinidine, and bisphosphonates contribute to esophagitis, local erosions, or ulcers, which can present similarly to GERD. Obesity is a major risk factor for GERD (odds ratio [OR] 1.73), and abdominal obesity specifically is associated with many GERD complications (Eusebi et al., 2018; Richter & Rubenstein, 2018). Foods that can induce GERD include caffeine, mints, chocolate, carbonated drinks, alcohol, spicy foods, and citrus fruits; low-fiber diet has also been associated with increased GERD symptoms (Commisso & Lim, 2019; Ness-Jensen et al., 2016; Richter & Rubenstein, 2018). Other lifestyle factors associated with GERD include smoking, alcohol consumption, and stress (Commisso & Lim, 2019; Eusebi et al., 2018; Richter & Rubenstein, 2018). Exercise and GERD have a complex relationship with increased leisurely exercise being found protective, but certain exercises (such as stooping, weightlifting, and others that increase intra-abdominal pressure) are associated with increased GERD symptoms (Commisso & Lim, 2019).

Signs and Symptoms: Determine patients' precipitating factors related to the development of GERD, length of time they have been experiencing symptoms, description of the symptoms, and what regimens and/or lifestyle changes they have tried. Patients should be questioned about medication usage, smoking, alcohol, and intake of substances that can weaken the LES; sleeping habits; and use of any tight or restrictive clothing. Determine whether any activity triggers GERD, such as bending over, exercise, or being recumbent. Review the patient's dietary habits and elicit if there are food products that the patient regularly ingests that aggravate symptoms of GERD.

Question the patient about history of heartburn and regurgitation such as, pyrosis, belching, halitosis, nausea, atypical chest pain (radiation of pain to back, neck, and/or jaw), hoarseness, recurrent laryngitis, cough, choking, pharyngeal tightness, globus sensation, persistent clearing of the throat, sore throat, and chronic obstructive pulmonary disease (COPD) exacerbations (Otaki & Iyer, 2021; Richter & Rubenstein, 2018). Question about the presence of warning symptoms such as dysphagia, odynophagia, anorexia, weight loss, vomiting, or symptomatic anemia that could represent GERD complications such as erosive esophagitis with bleeding, Barrett's esophagus, esophageal adenocarcinoma, or others (Otaki & Iyer, 2021; Richter & Rubenstein, 2018). Review the medications the patient is taking to determine whether any medications reduce the LES pressure, decrease the LES pressure, and/or irritate the esophageal mucosa, such as NSAIDs. Question the patient about any previous history and/or treatment for *Helicobacter pylori*. Ask about any family history of esophageal cancer or hiatal hernia (Bashashati et al., 2014).

Physical examination usually produces no positive findings. Conduct a thorough examination of the oral cavity and a respiratory examination. Palpate for any upper abdominal masses or tenderness. If warranted by the patient's symptoms, perform a rectal examination to detect any melena.

Diagnostic Tests: If suspicion was aroused on the physical examination, stool should be checked using the guaiac test to check for intestinal bleeding. Laboratory studies are not required when antacids, position change, or both relieve pyrosis. Esophageal pH and manometry testing can be informative, although a proton pump inhibitor (PPI) trial is more appropriate in primary care as it is non-invasive, inexpensive, with sensitivity of 68% to 83% (Otaki & Iyer, 2021). For older adults with atypical symptoms, barium swallow or an endoscopy can be considered. Any patient presenting with laryngopharyngeal symptoms of GERD should be considered for a laryngoscopy (Otaki & Iyer, 2021; Vaezi et al., 2018). Additionally, patient's with extraesophageal symptoms such as chest pain or pulmonary symptoms, should be evaluated for other causes of these because symptoms are often multifactorial (Vaezi et al., 2018). Although a majority of GERD patients have a negative endoscopy, this should be considered for refractory symptoms, atypical symptoms, or warning symptoms.

Differential Diagnosis:

- Nonulcer dyspepsia
- Esophageal spasms
- Esophagitis
- Gastritis
- Eosinophilic esophagitis
- Functional dyspepsia
- Gastroparesis
- Esophageal stricture (upper gastrointestinal (GI) sinus)
- Esophageal carcinoma
- Cholecystitis
- Peptic ulcer disease (PUD)

(Richter & Rubenstein, 2018)

Treatment: The goals for the treatment of GERD include reducing symptoms, healing esophagitis, managing esophageal healing, improving quality of life, and preventing complications (Kroch & Madanick, 2017). Lifestyle changes and other nonpharmacological measures are key to symptom management, even though patients can be doubtful about their effectiveness (Commisso & Lim, 2019). These include weight management, avoidance of smoking, alcohol, trigger foods/beverages (such as high-fat, spicy, or acidic foods; mint; carbonated drinks; and caffeine), increased dietary fiber, and avoidance of late-night intake. Medications to suppress acid, such as antacids, H_2 receptor blockers, and PPIs, should be initiated for patients felt to have GERD (Otaki & Iyer, 2021; Wilkinson & Halland, 2020). Of these, PPIs remain the mainstay of treatment, given the rapid relief of GERD symptoms and esophageal healing that result from PPI treatment, and are one of the most prescribed classes of medication (Brisebois et al., 2018; Hussain et al., 2018; Otaki & Iyer, 2021). Once-a-day dosing is beneficial to aid in medication compliance, although increased frequency may be required depending on clinical response. A step-down approach can be initiated in patients with GERD by reducing

© F.A. Davis Publishing

the dosage of the PPI or by adding an H_2 blocker in the evening. While PPIs can be used long-term in patients who are unable to sustain remission without them, there are potential adverse effects, such as risk for *Clostridioides difficile* infection, vitamin and mineral deficiencies (magnesium, B_{12}, iron), and decreased bone mineral density (increased risk for fracture) (Brisebois et al., 2018; Commisso & Lim, 2019; Hussain et al., 2018; Otaki & Iyer, 2021). Subsequently, agent and dosage should be tailored to the individual patient with the dosage and need for the drug periodically reviewed to use the lowest effective dose (Freedberg et al., 2017; Kroch & Madanick, 2017). Pharmacological recommendations are listed in Table 13-3.

Follow-Up: Review lifestyle changes and the impact modifications have had on the patient's symptoms of GERD, presence of potential complications or warning symptoms (Maret-Ouda et al., 2020). Evaluate compliance with the medication regimen. Decisions should be made about any medication adjustments or plans for further testing or referral.

Sequelae: Several sequelae of GERD are possible, especially if left untreated or undertreated. These can include esophagitis with/without erosion and bleeding, esophageal stricture, Barrett's esophagus, and esophageal adenocarcinoma (Maret-Ouda et al., 2020). GERD is a risk for Barrett's esophagus with significant odds ratios (ORs) for weekly versus infrequent symptoms (OR 2.33), duration of 5 years versus less than a year (OR 3.0), and age of onset with weekly symptoms before age 30 versus later (OR 31.4) (Shaheen et al., 2016). Additional identified risks for Barrett's esophagus include obesity, smoking, family history of Barrett's, and hiatal hernia. Older adults are also at risk for developing pulmonary complications of GERD, such as chronic cough, recurrent pneumonitis, and aspiration pneumonia. Given the reflux of gastric content to the pharynx, dental erosions are also a possible sequela.

Prevention/Prophylaxis: Prevention of GERD should be aimed at eliminating or at least modifying the extrinsic factors that contribute to the development of the condition. Patients should be encouraged to make lifestyle adjustments and avoid potentially harmful medications or lifestyle choices (such as smoking) to prevent further complications.

Referral: A gastroenterologist should be consulted for the endoscopy and for patients with anemia, severe or nonresponsive reflux disease, dysphagia, odynophagia, unexplained weight loss, or evidence of hemorrhage. When a patient presents with laryngopharyngeal reflux, they should be referred for an indirect or direct laryngoscopy. If a patient presents with dysphagia, odynophagia, unexplained weight loss, or GI bleeding, or if a patient did not respond to initial therapy, refer to a gastroenterologist for further testing and evaluation/treatment.

TABLE 13-3 Pharmacological Recommendations for Gastroesophageal Reflux Disease

Treatment of Erosive or Nonerosive Gastroesophageal Reflux Disease

Proton Pump Inhibitors

DRUG	GERD DOSAGE
Dexlansoprazole	30–60 mg daily
Esomeprazole	20–40 mg daily
Lansoprazole	15–30 mg daily
Omeprazole	20–40 mg daily
Pantoprazole	20–40 mg daily
Rabeprazole	10–20 mg daily
H_2-RECEPTOR ANTAGONISTS	**GERD DOSAGE**
Nizatidine	150–300 mg q12hr
Famotidine	10–20 mg q12hr
Cimetidine*	400 mg q6hr or 800 mg q12hr
Ranitidine**	N/A

**Cimetidine is not recommended for use in older adults.*

***All ranitidine formulations (prescription and over-the-counter) were pulled from the U.S. market in 2020 by the Food and Drug Administration due to concerns of N-nitrosodimethylamine (NDMA) contamination (U.S. Food and Drug Administration, 2020)*

Education: Patients with GERD should be instructed to raise the head of the bed 4 to 6 inches with shock blocks or a foam wedge that can be placed at the head of the bed. The patient should avoid smoking and ingestion of coffee, mint, chocolate, and fatty, spicy, and acidic foods; increased dietary fiber may also be protective against GERD (Commisso & Lim, 2019; Otaki & Iyer, 2021). A food diary can help identify individualized trigger foods and substances that should be avoided. Remind patients not to break or crush extended-release or delayed-release tablets and to take medications with a full glass of water. Patients should avoid eating a meal for at least 3 hours before becoming recumbent. Decreasing abdominal pressure, such as avoiding restrictive clothing, may be helpful although evidence is limited. Oral PPIs should be administered 30 to 60 minutes before a meal (Katz et al., 2013).

Clinical Recommendation	Evidence Rating	References
Screening for Barrett's esophagus can be considered in men with more than 5 years of GERD symptoms and/or frequent GERD symptoms who also have two or more risk factors: age >50, White, central obesity, smoking history, and history of Barrett's esophagus and/or esophageal adenocarcinoma in a first-degree relative.	B	Shaheen et al., 2016
For patients with diagnosed Barrett's esophagus without dysplasia, endoscopic surveillance should occur every 3–5 years.	B	Shaheen et al., 2016

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. HEPATITIS A, B, AND C (VIRAL)

Signal Symptoms:

Acute Hepatitis A, B, and C: Can include fever, fatigue, abdominal pain, nausea, vomiting, jaundice, loss of appetite, diarrhea, dark urine, joint pain, clay-colored stool (Abutaleb & Kottilil, 2020; Centers for Disease Control and Prevention [CDC], 2020a, 2021a; Foster, 2019; Linder & Malani, 2017)

Chronic Hepatitis B and C: Most with chronic hepatitis B are asymptomatic, although some may develop cirrhosis or hepatocellular carcinoma (HCC) with symptoms associated with those conditions (CDC, 2020b, 2021a).

Description: The virus is transmitted primarily via the fecal-oral route after close contact with an infected person, although contact with feces or consumption of contaminated food or water are known vectors (Abutaleb & Kottilil, 2020; CDC, 2020a; Foster, 2019; Linder & Malani, 2017). After the virus is taken up in the gastrointestinal (GI) tract, it circulates to the liver where viral replication and pathology occurs followed by transaminitis 7 days later and (possible) symptoms a month later that peak 7 to 10 days after onset (Lemon & Walker, 2019; Walker, 2019). Some patients may only show mild symptoms or no symptoms, although asymptomatic hepatitis A is more common in children than adults (Linder & Malani, 2017; Shin & Jeong, 2018). Acute hepatitis A typically self resolves after 2 months, with no chronic disease or carrier state and typically no reinfection due to antibody production from initial exposure (Abutaleb & Kottilil, 2020; CDC, 2020a; Linder & Malani, 2017). However, as many as 15% of patients can have relapsing infection with recurrent symptoms within 6 months of initial infection (Abutaleb & Kottilil, 2020; CDC, 2020a). Acute liver failure is rare, occurring in 1 out of every 300 infections, and death can occur in approximately 10% of hepatitis A liver failure patients; these are more common in patients with pre-existing liver disease (Abutaleb & Kottilil, 2020; CDC, 2020a; Linder & Malani, 2017; Shin & Jeong, 2018).

Hepatitis B (HBV) is a partly double-stranded DNA virus with ten distinct genotypes and is transmitted through infected body fluids like semen, blood, and saliva (CDC, 2020b; Lin & Kao, 2017; Wilkins et al., 2019). Once in the person's system, hepatitis B makes its way to the liver and infects hepatocytes, where it causes acute infection and can damage the liver. After HBV exposure, symptoms typically present an average of 90 days later (if at all). Approximately 95% of adults will recover completely, while the remaining 5% progress to chronic hepatitis B infection (CDC, 2020b). The partly double-stranded DNA of the HBV can be repaired by the host cell into a covalently closed circular DNA (cccDNA), which is what allows chronic hepatitis B to persist despite antiviral treatment (Li et al., 2018; Lin & Kao, 2017). Hepatitis B carries with it a high level of morbidity and mortality, with 15% of adults dying prematurely from cirrhosis or HCC, although treatment helps reduce this risk (Wilkins et al., 2019).

Hepatitis C virus (HCV) is an RNA-based virus that is transmitted primarily through blood-blood contact or through body fluids that contain blood and is the only chronic viral disease that is consistently curable with the use of antiviral medications (Andrews, 2018; CDC, 2021a; Wilkins et al., 2015). HCV is responsible for more deaths in the United States than the next 60 reportable diseases combined, including tuberculosis and HIV (Andrews, 2018). Patients who contract HCV develop acute HCV infection, which can be either eradicated by the body or progress to chronic hepatitis C infection. It is estimated that about half of people who contract HCV will clear the infection spontaneously while half will progress to chronic infection (Seo et al., 2020). Of those with chronic hepatitis C infection, 5% to 25% will develop cirrhosis within 10 to 20 years; among these patients there is a 1% to 4% risk of HCC and 3% to 6% risk of developing decompensated cirrhosis; in patients with decompensated HCV cirrhosis, the 1-year mortality rate is 15% to 20% (Thomas & Seeff, 2005). Hepatitis C has been the number 1 etiology for liver transplantation for a number of years but fell to number 3 in 2016, likely due to development of highly effective and well-tolerated treatment regimens (Vyhmeister & Enestvedt, 2021).

Etiology: Hepatitis A is caused by ingestion of the viral particles via fecal-oral route, typically after close contact with an infected individual. Other means of transmission and infections are through sexual contact with an infected individual or ingestion of contaminated food or water (Abutaleb & Kottilil, 2020; CDC, 2020a; Foster, 2019; Linder & Malani, 2017). Transmission and infection are more common in certain individuals who are at higher risk, as discussed below.

© F.A. Davis Publishing

Hepatitis B is transmitted by infected body fluids, such as blood, semen, and saliva, that are able to enter the system through breaks in the skin or mucous membranes (CDC, 2020b). Such transmission activities include sex with an infected person, injection drug use, sharing of injection drug paraphernalia, maternal-newborn transmission during childbirth, infected body fluid contact with an open wound, or sharing items that can break the skin/mucous membranes (such as a razor or toothbrush) with an infected person. Individuals considered high risk for HBV include infants born to mothers who are infected with HBV, men who have sex with men (MSM), sex partners of infected persons, people who inject drugs (PWID), household contacts of infected persons, individuals at risk for occupational exposure (such as health-care workers and public safety workers), and patients on hemodialysis (CDC, 2020b).

For HCV, the primary means of transmission are through injection drug use and birth to an HCV-infected mother (Andrews, 2018; CDC, 2021a) with vertical transmission during childbirth responsible for the highest risk of HCV in children (Baden et al., 2014). Injection drug use accounts for 60% of annual acute HCV infections and approximately 65% of PWID are positive for hepatitis C, indicating exposure or active infection (Guss et al., 2018; Wu et al., 2019). Other less common means include having sex with an HCV-infected partner (especially MSM), sharing personal care products, undergoing health-care procedures, getting tattooed with contaminated supplies, receiving blood products (very rare after 1992), and being exposed to occupational hazards such as needle sticks. Although transmission through sex is uncommon, the risks increase in sexual contact where blood is exposed, such as anal sex, sex during menses, and sex with a partner with open lesions; however, HCV is more infectious than HBV or HIV when transmitted through IV drug use or intranasal drug use (Andrews, 2018).

Occurrence: Hepatitis A is more common in developing countries, although unvaccinated adult individuals in developed countries are at higher risk of becoming ill from hepatitis A infection (Abutaleb & Kottilil, 2020). In the United States, infections tend to occur as outbreaks, such as in food service via contaminated food (especially fruits and vegetables), daycare centers (from infants and children transmitting to unvaccinated adults), in specific communities (such as Native American tribes in the United States), and in areas with poor sanitation (Abutaleb & Kottilil, 2020; Cheek et al., 2011; Linder & Malani, 2017; Purpari et al., 2019). An outbreak in San Diego, California, among mostly boys and men who experienced frequent homelessness, injection drug use, and MSM behavior may indicate a shift in hepatitis A infection from food and water contamination to poor sanitation related to homelessness, overcrowding, and injection drug use (Abutaleb & Kottilil, 2020; Wooten, 2019). Other outbreaks have also been linked to homelessness, which seems to support this notion (Linder & Malani, 2017). Although the rate of hepatitis A infection in the United States had declined 95% from 1996–2011, the CDC noted approximately 15,000 cases from 2016–2018, which is a 294% increase compared to 2013–2015 (Foster, 2019).

In 2019, there were an estimated 20,700 cases of acute hepatitis B with an incidence rate of 1.0 per 100,000 people (CDC, 2021c). This is a slight decrease from an estimated 21,600 cases (incidence 1.0 per 100,000) in 2018 and 21,900 cases in 2015 (incidence 1.1 per 100,000) in 2015 (CDC, 2020b; Wilkins et al., 2019). Overall, the incidence of hepatitis B has been relatively stable from 2011 to 2018 fluctuating from 0.9 to 1.1 per 100,000 persons (CDC, 2020b). It is estimated there are between 850,000 to 2 million persons in the United States living with chronic hepatitis B (CDC, 2020b; Wilkins et al., 2019). Finally, in 2018 there were 1,649 deaths with HBV listed as an underlying or contributing cause of death on death certificates in the United States, although this is felt to be a conservative estimate with the actual deaths from HBV likely higher (CDC, 2020b).

In 2019, for hepatitis A and B, males had nearly twice the incidence of infection than females, which has been the case for hepatitis B for 15 years (CDC 2021f, 2021i). With hepatitis A, however, there are no differences in disease severity between sexes after the infection is contracted (Chang & Liaw, 2019).

In 2019, 4,136 cases of acute hepatitis C were reported, although the estimate for the true number of cases is around 57,500 with an incidence rate of 1.3 per 100,000 people (CDC, 2021d). This represents an increase in both reported and estimated cases each year since, starting in 2012 with 1,778 reported and 24,700 estimated (CDC, 2021k). It is estimated that 2.4 million people were living with hepatitis C from 2013–2016 (CDC, 2021a). Since 2011, males have had an accelerated increase in incidence compared to females, and in 2019 the incidence in males was 60% higher than females (CDC, 2021m). However, data for hepatitis C are difficult to ascertain due to the asymptomatic nature of the disease and the fact that many patients with chronic HCV are unaware of their infection (Office of Infectious Disease and HIV/AIDS Policy, 2016). In 2018, a total of 15,713 deaths had HCV as an underlying or contributing cause, although this is also a conservative estimate as most people who die lack HCV documentation on their death certificates (CDC, 2021a).

Age: In 2019, adults aged 60 and older in the United States represented the lower end of the incidence rates based on age for Hepatitis A, B, and C (CDC, 2021e, 2021h, 2021l; Shin & Jeong, 2018). However, patients older than age 40 who contract hepatitis A have a higher risk of severe disease and poor outcomes (Shin & Jeong, 2018). In hepatitis B, the younger the age of infection, the more likely a person is to develop chronic hepatitis B infection rather than clear the virus (Trépo et al., 2014). Finally, in hepatitis C, contracting the virus at an older age does not eliminate the associated risk of HCC.

Ethnicity: In 2019, the incidence rate for acute hepatitis A in the United States was highest in the White, non-Hispanic population (6.8/100,000) (CDC, 2021g). The lowest incidence rate of acute hepatitis A was in individuals of Asians/Pacific Islander descent at 0.7/100,000.

In 2019, the highest incidence rate of acute hepatitis B was in the White and non-Hispanic population of the United States (at 1.0/100,000), although this was closely followed by Black, non-Hispanic groups at 0.9/100,000 (CDC, 2021j). The lowest incidence rate of acute hepatitis B in the United States in 2019 was in those of Asian/Pacific Islander descent

© F.A. Davis Publishing

(similar to hepatitis A) at 0.3/100,000. Although the incidence rates for various ethnic groups have been relatively stable since 2004, the Native American/Alaskan Native population dropped from a peak rate of 1.8/100,000 in 2008 to 0.6/100,000 in 2019. Likewise, the Black, non-Hispanic population has dropped from a peak of 3.0/100,000 in 2005 to 0.9/100,000 in 2019 (CDC, 2021j).

In the United States in 2019, the Native American/Alaskan Native population had the highest incidence rate for acute hepatitis C at 3.6/100,000, with the second highest rate among the White, non-Hispanic population at 1.4/100,000 (CDC, 2021n). The lowest incidence of acute hepatitis C in 2019 was found in the Asian/Pacific Islander population at 0.2/100,000.

Contributing Factors: Although hepatitis A is primarily transmitted via the fecal-oral route by close contact with infected individuals (including sexual contact) and consumption of contaminated food or water, there are multiple risk factors for hepatitis A. These include MSM, travel to a country where hepatitis A is endemic, occupation with exposure risk, homelessness, and IV drug use (CDC, 2021d). Patients at risk for severe disease such as acute liver failure and death are older patients (>40 years old), those with pre-existing liver disease, and those who are immunocompromised (such as patients who are HIV positive) (CDC, 2020a; Linder & Malani, 2017; Shin & Jeong, 2018).

Because hepatitis B is transmitted by contaminated body fluids such as semen, saliva, and blood, the risk factors are easily understood (CDC, 2020b). Individuals at high risk for contracting hepatitis B via body fluids/blood include PWIJ because of potential of sharing infected or used needles or drug preparation paraphernalia. Also, household contacts of people who are infected with hepatitis B are at increased risk because of the potential for inadvertently contacting blood from open wounds, shared razors, toothbrushes (with gingival bleeding), and others. Health-care workers and public safety workers are at increased occupational exposure because of the potential for inadvertent needle sticks, spitting, and splatter of body fluids. Infants born to mothers infected with hepatitis B can contract hepatitis B through placental exchange or passing the infection from body fluids during childbirth. Finally, sexual partners of HBV-positive persons are at high risk due to body fluid exchange during sex; this is especially true with the MSM population, especially if sex is vigorous enough to have potential blood exchange (CDC, 2020b).

Because hepatitis C is transmitted by blood and blood-containing body fluids the individuals at risk are those who share blood or body fluids (Andrews, 2018; CDC, 2021a; Guss et al., 2018; Wilkins et al., 2015). One of the largest at-risk populations includes individuals born between 1945 and 1965, likely due to no universal precautions and other processes in vaccination, medical equipment sterilization, and dental care at that time. This population has a sixfold increased prevalence compared to other age-groups, and they represent 81% of persons with chronic HCV (Reilley et al., 2016). People who have used injection drugs (even long ago) are at increased risk for HCV because of the potential for sharing needles or drug preparation paraphernalia, which can introduce contaminated blood to an uninfected individual. Anecdotally, pockets of populations with high levels of HCV infection often have the same HCV genotype because the virus is spread among injection partners. People with HIV are also at increased risk for HCV, primarily PWID, because both viruses are transmitted through blood if needles are shared. Blood transfusion or organ/tissue transplant recipients are currently at low risk due to adequate blood and tissue testing for HCV. However, this testing was initiated in 1992; therefore, people who received blood or tissue/organ donations before then are at high risk. Those with occupational risk such as health-care or public service workers are at increased risk because of potential needle sticks, bleeding wounds, and others. Finally, children born to mothers who are positive for HCV are at high risk for HCV infection due to body fluid and blood transmission during the birth process and mother-baby placental exchange during fetal maturity (CDC, 2021a).

Signs and Symptoms: Although hepatitis A, B, and C are different viruses with different modes of transmission, risk groups, and rates of complication, they all affect the liver. Therefore, signs and symptoms are common amongst them. Symptoms that patients may have from acute viral hepatitis (from hepatitis A, B, C) include fever, fatigue, abdominal pain, nausea, vomiting, loss of appetite, diarrhea, dark urine, joint pain, and clay-colored stool (Abutaleb & Kottilil, 2020; CDC, 2020a, 2021a; Foster, 2019; Linder & Malani, 2017). Many of these symptoms are nonspecific and therefore unless more obvious or ominous symptoms or signs develop, many patients may not seek care. This is the basis for why, for example, approximately 40% of people with hepatitis C are unaware of their infection status (Office of Infectious Disease and HIV/AIDS Policy, 2016).

Physical examination and routine laboratory testing elicit signs such as jaundice or bilirubinemia and, because they are more ominous, should trigger testing for liver diseases including acute viral hepatitis. With chronic hepatitis B and C, patients are often asymptomatic until their disease progresses enough to result in advanced liver disease, which presents with its own set of signs and symptoms such as encephalopathy, palmar erythema, splenomegaly, hepatomegaly, spider telangiectasias, abdominal swelling (from ascites), lower extremity edema, anorexia, easy bruising/bleeding (from thrombocytopenia), and others (Butterworth, 2019; Martin et al., 2014; Smith et al., 2019). Additionally, there have been previously reported extrahepatic manifestations of hepatitis A, including rash, kidney injury, myocarditis, and Guillain-Barré syndrome (Allen et al., 2018).

Diagnostic Tests: Laboratory diagnosis of hepatitis A is accomplished with serological testing for anti-hepatitis A IgM antibodies (Abutaleb & Kottilil, 2020; CDC, 2020a). Hepatitis A immunoglobulin M (IgM) typically peaks a month after exposure and can last up to a year, and it can also be found in cases of recent immunization; false positives have been reported in certain patients, including some with autoimmune diseases (Abutaleb & Kottilil, 2020). Hepatitis A IgG follows after about 1 week, lasts for life, and confers immunity to future hepatitis A infection (Abutaleb & Kottilil, 2020). Hepatitis A RNA levels can be ordered, although is typically not necessary given availability of antibody testing. Finally, in the absence of hepatitis A antibody testing, a clinical diagnosis can be made in the presence of acute illness with any sign/symptoms of acute viral hepatitis AND the

© F.A. Davis Publishing

presence of jaundice or serum bilirubin >3.0 mg/dL or elevated alanine aminotransferase (ALT) levels >300 IU/L, and the absence of a more likely diagnosis (CDC, 2020a). Additional testing, including hepatic function panel, prothrombin time (PT) test/International Normalized Ratio (INR), imaging of the liver, and others can be investigated for decompensating disease and subsequent liver failure, although this is out of the scope of primary care.

Certain individuals should undergo screening for hepatitis B as recommended by both the U.S. Preventative Services Task Force (USPSTF) and/or the CDC. Screening is recommended for high-risk individuals as well as individuals who are HIV positive, those who are pregnant, persons born in regions of the world with a ≥2% HBV prevalence (such as Africa, Asia, and Eastern Europe), U.S.-born persons not vaccinated as infants whose parents were born in regions with a very high prevalence of HBV infection (i.e., ≥8%), patients on immunosuppression, infants born to people who are positive for hepatitis B surface antigen (HBsAg), patients on hemodialysis or chemotherapy, persons who are potential source of hepatitis B that could be spread to others (such as blood and/or tissue donors), and individuals with unexplained transaminitis (elevated aspartate aminotransferase [AST] or ALT) (CDC, 2020b; Wilkins et al., 2019). Screening involves testing for HBsAg and, if positive, a follow-up test for hepatitis B surface antigen antibody (anti-HBs) and hepatitis B core antigen antibody (anti-HBc) to differentiate infection versus immunity (Abara et al., 2018; Weinbaum et al., 2009; Wilkins et al., 2019).

Additionally, patients with certain risk factors should undergo routine, ongoing screening if those risk factors/behaviors are persistent. This includes PWID, intranasal drug use, persons who have sex with HCV-infected persons (especially MSM and unprotected sex) and persons who have certain medical conditions such as end-stage renal disease with ongoing hemodialysis (CDC, 2021a; Wilkins et al., 2015).

For patients with acute hepatitis B, testing and monitoring for clearance versus development of chronic state should be undertaken by a specialist. Evaluation for clearance versus chronic infection typically involves testing for hepatitis B e-antigen (HBeAg), detectable in early acute disease, and serum HBsAg, which indicates chronic hepatitis B if present for more than 6 months. Routine follow-up for signs of chronic HBV, reactivation of quiescent HBV (sudden flare-up of hepatitis B DNA in previously inactive chronic disease or resolved hepatitis B), fibrosis, cirrhosis, and liver failure can include trending AST/ALT levels, various ratios of antigen and antibody testing, HBV DNA levels, complete blood count (CBC) with platelets, INR (CDC, 2021c; European Association for the Study of the Liver, 2017; Terrault et al., 2016; Wilkins et al., 2019).

The CDC recommends one-time screening for all adults as well as screening for pregnant women during each pregnancy (CDC, 2021a).

Testing for hepatitis C beings with testing for hepatitis C antibodies (anti-HCV) through any of a number of assays (CDC, 2021a; Guss et al., 2018; Wilkins et al., 2015). Hepatitis C antibody testing has a sensitivity and specificity of 95% and 99%, respectively (AASLD/IDSA HCV Guidance Panel, 2015). If the HCV antibody test is positive, confirmation with a quantitative or qualitative test for HCV RNA should be performed, although quantitative testing will be required to determine viral load if treatment is desired (CDC, 2021a; Guss et al., 2018; Wilkins et al., 2015). If a patient has a negative HCV antibody test and may have been exposed within the last 6 months, then HCV RNA should be tested every 4 to 8 weeks for a minimum of 6 months or repeat HCV antibody testing should be performed at least 12 weeks later (likely more cost-effective) (Wilkins et al., 2015). Further testing and work-up will be required prior to initiating treatment.

Differential Diagnosis:

- Liver cancer
- Alcoholic hepatitis
- Autoimmune hepatitis
- Drug-induced liver injury
- Nonalcoholic steatohepatitis
- Shock-induced liver injury
- Congenital hepatic fibrosis
- Portal hypertension
- Schistosomiasis

Treatment: There is no treatment for routine, nonsevere hepatitis A infection (Abutaleb & Kottilil, 2020; Linder & Malani, 2017; Shin & Jeong, 2018). Rather, care is typically supportive including hydration and symptomatic management of fever and nausea/vomiting, and other symptoms until they resolve. For patients who develop liver failure, which is typically rare, liver transplant may be the only treatment available to prevent death and quick referral to a transplant center is critical (Abutaleb & Kottilil, 2020; Shin & Jeong, 2018). Certain direct-acting antiviral medications have shown promise in cell culture studies, although there has been difficulty in identifying and enrolling patients in clinical trials before acute infection resolution (Abutaleb & Kottilil, 2020).

Treatment of hepatitis B can be quite complex. Additionally, because of the HBV cccDNA accumulation in hepatocytes, patients can have persistent chronic hepatitis B despite antiviral treatments (Li et al., 2018; Wilkins et al., 2019). Because of this complexity, treatment is best undertaken by gastroenterology specialists who treat hepatitis B, infectious disease specialists, or hepatology specialists. Treatment need should be evaluated through ALT and HBV DNA as well as liver disease presence/severity and should be individualized to each patient (Ghany, 2017). The goal of HBV treatment is immunological cure, defined as loss of HBsAg with sustained suppression of HBV DNA, and normalization of ALT; these goals are correlated with improved outcomes and are possible with current therapies (Wilkins et al., 2019). It has been shown that treating pregnant women who are HBsAg positive can reduce the risk of perinatal transmission (Wilkins et al., 2019). Treating patients with chronic hepatitis B who develop decompensated cirrhosis can improve liver function, increase survival, and prevent need for liver transplantation, especially if treatment is initiated early in their decompensation; like any patient with decompensated cirrhosis, they should be referred to a liver transplant center for evaluation for liver transplant (European Association for the Study of the Liver, 2017).

There are eight approved hepatitis B treatment medications in the United States that span two classes: peginterferon alfa-2a agents (given subcutaneously) and oral nucleoside/nucleotide analogues (Terrault et al., 2016). There are multiple contraindications and precautions associated with each

© F.A. Davis Publishing

medication, such as renal function impairment, history of seizure disorders, diabetes, cardiovascular diseases, neuropsychiatric disorders, and hemorrhagic cerebrovascular events (CVA). Potential adverse effects range from mild to severe and can include flu-like symptoms, headache, fatigue, bone marrow suppression, acute renal failure, Fanconi's syndrome, lactic acidosis, pancreatitis, and others (Terrault et al., 2016). Primary care providers who have patients with hepatitis B undergoing treatment should monitor for potential adverse effects and contact the treating specialist as needed.

Treatment of hepatitis C has evolved tremendously in recent years. Prior to initiating treatment, several other work-up tests need to be completed. Serological testing pretreatment includes CBC, complete metabolic panel (CMP), HCV genotype, HIV testing, and quantitative HCV RNA (if not already completed) (Guss et al., 2018). CBC and CMP should be done at baseline and 4 weeks after treatment initiation. Genotype (1a, 1b, 2, 3, 4, 5, or 6) testing impacts the specific medications that can effectively treat the patient. The most common genotypes in the United States are genotypes 1a/1b (75%), genotype 2 or 3 (20% to 25%); genotypes 4 to 6 are rarer in this country (Guss et al., 2018). The viral load (determined with quantitative HCV RNA) impacts the length of treatment required. Additionally, patients should be evaluated for liver fibrosis or cirrhosis with either liver biopsy (gold standard) or noninvasive methods such as ultrasound elastography as degree of fibrosis/cirrhosis impacts treatment options (Guss et al., 2018).

Although primary care treatment is becoming more common, patients with complicated disease as with advanced fibrosis/cirrhosis, HIV co-infection, and renal disease should be referred to gastroenterology (with HCV treatment experience) or hepatology (Guss et al., 2018). Patients should be evaluated for likely compliance before initiating treatment (Wilkins et al., 2015). The standard of "cure" is sustained viral response at 12 weeks after treatment (SVR-12), although HCV RNA should be tested 4 weeks into therapy as well as 12, 24, and 48 weeks after completion of treatment (Guss et al., 2018). Patients should also be warned that re-infection, typically through high-risk behaviors, is possible after cure. Treatment duration ranges from 8 to 12 weeks depending on patient-specific factors, and medications involve 1 to 3 pills a day depending on the treatment option selected.

In regard to age, treatment for HCV should not be withheld solely due to age, and treatment should be offered to all patients older than 18 years who are eligible for treatment based on patient-specifics, except those with a life expectancy of 12 or fewer months (Ghany et al., 2020; Guss et al., 2018; Pan et al., 2020). A study was done that examined the efficacy of direct-acting antiviral (DAAs) in a large cohort of older adults in the United States. This study found that older patients represent a large, increasing population of patients with HCV and have strong indications for treatment because they tend to present with more advanced liver disease (Pan et al., 2020). It has been found that the efficacy of DAAs on treating hepatitis C in older patients is not significantly impacted (Pan et al., 2020). Table 13-4 shows approved DAA hepatitis C treatment regimens.

TABLE 13-4 Hepatitis C Treatment Medications

MEDICATION	GENOTYPE(S) TREATED
Sofosbuvir/velpatasvir	1–6
Elbasvir/grazoprevir	1, 4
Daclatasvir	1, 3
Glecaprevir/pibrentasvir	1–6
Ombitasvir, paritaprevir, ritonavir	4
Ombitasvir, paritaprevir, ritonavir, dasabuvir	1
Ledipasvir/sofosbuvir	1, 4, 5, 6
Simeprivir	1
Sofosbuvir	1–6
Sofosbuvir/velpatasvir/voxilaprevir	1–6 (with prior treatment experience)

Follow-Up: Follow-up for acute hepatitis A is focused on reevaluating liver function and serological testing, checking for any decompensation of the liver, and ensuring resolution of symptoms and the causative infection. Referral to gastroenterology or hepatology may be indicated depending on the clinical course.

Patients with chronic hepatitis B who are not treatment candidates require ongoing monitoring including ALT levels every 3 months for the first year and every 6 months after that, as well as HBV DNA levels for any elevated AST or ALT; patients who are not treatment candidates may become candidates in the future depending on their clinical progression (Ghany, 2017; Terrault et al., 2016, 2018). These patients should also undergo regular HCC screening because nearly half of all cases of HCC are in patients with chronic HBV (Tang et al., 2018). Screening with alpha fetoprotein (AFP), liver ultrasound, or both has mixed reviews. A randomized controlled trial found 37% reduction in mortality for these patients who did undergo routine screening, but a Cochrane review found insufficient evidence to support screening with ultrasound and/or AFP (Aghoram et al., 2012; Zhang et al., 2004). Regardless, if either test is abnormal, then computed tomography (CT) or magnetic resonance imaging (MRI) should be ordered (Tang et al., 2018). Patients should also be seen regularly to assess for HBV reactivation, signs and symptoms of cirrhosis, and signs and symptoms of decompensation.

Follow-up for patients with hepatitis C can vary depending on whether the patient has been treated or not. For patients currently on treatment, they should be monitored for compliance with therapy, adverse effects, and newly developing comorbidities (Wilkins et al., 2015). For patients who were treated, follow-up HCV RNA levels at 12 weeks after treatment (SVR-12/"cure"), 24 weeks after treatment, and 48 weeks after treatment should be performed (Guss et al., 2018). Additionally, patients should be monitored for any ongoing high-risk behaviors that could justify ongoing, yearly testing for HCV antibody/reinfection. It should be noted, however, that liver fibrosis and/or cirrhosis due to HCV can be improved or reversed after treatment and

© F.A. Davis Publishing

therefore reevaluation for level of fibrosis can be evaluated in the future after treatment (Hytiroglou & Theise, 2018).

Prevention/Prophylaxis: The best prevention for hepatitis A is vaccination. There are two types of vaccines currently available, including single-antigen hepatitis A vaccines (2 doses, 6 months apart) and combination vaccines (hepatitis A and hepatitis B; 3 doses given at month 0, 1, and 6) (Abutaleb & Kottilil, 2020; CDC, 2020a). Hepatitis A vaccination is currently recommended by the CDC Advisory Committee on Immunization Practices (ACIP) for all children younger than 18 years old, those at increased risk for hepatitis A infections, people at increased risk for severe disease from hepatitis A infections, those with occupational exposure hazards, unvaccinated individuals in areas experiencing a hepatitis A outbreak, and any individual who requests a vaccination (CDC, 2020a). Additional prevention measures include proper sanitation measures, especially hand hygiene in food services, as well as enteric precautions for patients with hepatitis A requiring hospitalization (Abutaleb & Kottilil, 2020).

Prevention of hepatitis B is best accomplished with high-risk behavior avoidance, vaccination, or both. In general, avoiding high-risk behaviors, such as not using injection drugs, practicing safe sex, using universal precautions in high-risk occupational settings, and not sharing personal care products (razors, toothbrushes, and others), can help decrease the risk of HBV exposure. ACIP also recommends HBV vaccination in several populations. These include all infants within 24 hours of birth, unvaccinated children younger than 19 years old, people with hepatitis C or HIV, people with chronic liver disease of other etiology (alcoholic liver disease, fatty liver disease, autoimmune hepatitis, etc.), people who are incarcerated, people traveling internationally to regions with ≥2% prevalence of HBV, patients at high risk of HBV exposure, and any individual seeking HBV protection (CDC, 2020b; Schillie, Vellozzi, et al., 2018; Wilkins et al., 2019). The hepatitis B virus (HBV) can survive outside the body for 7 or more days but can be killed with bleach and other viricidal cleaning solutions (CDC, 2020b).

There are currently three single-antigen (HBV only) vaccines and one combination vaccine (HBV/HCV) available for adults in the United States (CDC, 2020b). The vaccine schedule is usually 3 doses initially, 1 month after the initial doses, and 6 months after the initial doses. One formulation (Heplisav-B) is approved for 2 doses separated by 1 month (CDC, 2020b, 2021b; Schillie, Vellozzi, et al., 2018). Post-vaccination testing for immunity (anti-HBs >10 mIU/mL) is only indicated in patients who are at risk for being a nonresponder, such as immunocompromised patients, hemodialysis patients, health-care workers, and sexual partners of persons who are HBsAg positive (Kao, 2015; Schillie, Harris, et al., 2018). For nonresponders, revaccination can be completed with either a full repeat series followed by post-vaccination testing or a single dose followed by post-vaccination testing and completion of the series if still a nonresponder. More than two vaccine series is not recommended except in hemodialysis patients who should undergo annual testing and booster if anti-HBs <10 mIU/mL (CDC, 2020b; David et al., 2015; Schillie, Harris, et al., 2018).

There is currently no vaccine available for hepatitis C. Patients with hepatitis C should be assessed for alcohol intake and encouraged to decrease or abstain from alcohol to prevent accelerating progression of liver disease (European Association for Study of Liver, 2014; World Health Organization [WHO], 2014). Treatment should not be withheld from patients who do consume alcohol (Wilkins et al., 2015); however, some feel this is controversial. Finally, patients with hepatitis C or at risk for hepatitis C should be encouraged to receive vaccination against hepatitis A and B to prevent further liver injury (AASLD/IDSA HCV Guidance Panel, 2015).

Referral: In most cases of acute hepatitis A, referral is not usually necessary, especially in mild or asymptomatic cases. However, the patient may benefit from a referral to gastroenterology or hepatology to evaluate and monitor liver serologies, liver function, and to check for other liver diseases that may increase the patient's risk of chronic liver disease and eventual liver failure.

All patient who are positive for hepatitis B should be referred to gastroenterology, infectious disease, or hepatology for evaluation and consideration of HBV treatment. Additionally, they should be referred to a transplant center for evaluation of possible liver transplant if they develop decompensated cirrhosis (Wilkins et al., 2019). Although primary care is invaluable in education, prevention (vaccination), and ongoing evaluation for complications of hepatitis B, treatment of the virus and management of potentially complex liver disease is a specialty domain.

Patients requiring treatment of hepatitis C should be referred to gastroenterology (with experience treating HCV) or hepatology if the primary care provider is not experienced in treatment. Additionally, patients with complicated disease (advanced fibrosis, cirrhosis, renal disease, HIV co-infection, and others) should be referred to gastroenterology or hepatology (Guss et al., 2018) because they should begin lifetime screening for HCC and monitoring for decompensation. Patients who have hepatitis C as well as other comorbidities that predispose them to ongoing liver damage or reinfection, such as excessive alcohol intake, injection drug use, metabolic syndrome (risk for nonalcoholic fatty liver disease [NAFLD] and nonalcoholic steatohepatitis [NASH]) should be referred to the appropriate specialists as needed.

Education: Patients with hepatitis A should be educated on proper hygiene and sanitation. They should be given information on preventing the spread of hepatitis A, the possibility of relapse within 6 months when they will again be contagious, and symptoms of worsening liver function. They should also be informed of the importance of testing, possible vaccination, and possible postexposure prophylaxis in individuals with whom they have had close contact. Finally, they should be educated on means of risk reduction, both for infection and for spreading the infection while they are shedding viral particles.

Patients with hepatitis B should receive counseling on high-risk behavior avoidance, such as practicing safe sex, abstinence from IV drug use, and proper hygiene (such as not sharing personal care products with others). Also, these patients should be advised to avoid or at least limit alcohol intake to prevent further liver injury that can hasten cirrhosis and/or decompensation. For similar reasons, they should be counseled on lifestyle management to reduce excess body weight and metabolic complications that can also lead to NAFLD (Terrault et al., 2018). Finally, they should be

© F.A. Davis Publishing

educated on signs and symptoms that could herald worsening liver disease, reactivation of HBV, and/or decompensated cirrhosis and to seek care immediately.

Patients who are candidates for treatment should be educated about the need for medication compliance as well as compliance with follow-up visits and laboratory testing. Patients with hepatitis C, either active or posttreatment, on the transmission, risk factors, pathophysiology, and prevention of hepatitis C. HCV cure does not eliminate the risk of reinfection, so patients should be educated to abstain from high-risk behaviors (Wilkins et al., 2015). Finally, those with liver fibrosis or cirrhosis should be educated on signs and symptoms of advanced fibrosis, cirrhosis, and their associated sequelae.

Clinical Recommendation	Evidence Rating	References
One-time screening for hepatitis C is recommended for all adults aged 18 years and older.	B	Ghany et al., 2020
Periodic hepatitis C virus (HCV) testing is recommended in all adults at high risk for infection.	B	Wilkins et al., 2015

HERNIA

Signal Symptoms: A dull dragging sensation with an inguinal hernia; male patients may report pain and swelling in the scrotum; patients with strangulated abdominal hernia usually have a tender mass with associated fever, nausea, and vomiting.

Description: A hernia is the protrusion of tissue through a weakened section in the abdominal wall. Abdominal wall hernias usually occur at the groin (inguinal and femoral) and abdominal (umbilicus, epigastric, spigelian, pelvic, flank, and incisional) (Ansari, 2020; Shakil et al., 2020, Suneja et al., 2020). Hernias are classified by their severity as reducible, incarcerated, or strangulated. A reducible hernia moves easily through the anatomical defect. An incarcerated hernia does not return to a normal position automatically or when manipulated externally. A strangulated hernia results when an incarcerated hernia develops edema with ischemia to the entrapped bowel (Ansari, 2020); strangulation is more common with femoral hernias than inguinal hernias (HerniaSurge Group, 2018).

In addition to these classifications, inguinal hernias may be either direct or indirect. A direct inguinal hernia passes through the posterior inguinal wall, whereas an indirect or congenital inguinal hernia enters in through the internal abdominal inguinal ring along the spermatic cord through the inguinal passage, to exit out the external inguinal ring (Shakil et al., 2020).

Etiology: Hernias may be either acquired or present from birth. Hernia development has been linked to recurrent Valsalva's maneuvers and dysfunctional connective tissue resulting from malnutrition or long-term steroid use. In older women, a history of multiple pregnancies and relaxation of the pelvic musculature, combined with loss of extraperitoneal fat, are considered etiological factors in the development of an obturator hernia (Mindaye et al., 2020).

Occurrence: In the United States, more than 700,000 herniorrhaphies for inguinal and femoral are performed annually. The most common type of hernia is the inguinal hernia, which accounts for 96% of all cases, followed by the femoral hernia, which accounts for 4% of groin hernias (Shakil et al., 2020). Approximately 175,000 patients annually in the United States are scheduled for umbilical hernia repair (Netto et al., 2021).

Age: The incidence of femoral and obturator hernias in women increases with age. The incidence of male indirect (congenital) hernias decreases with age, but that of direct inguinal hernias increases (Shakil et al., 2020). The incidence of abdominal wall hernias in older adults has been on the increase (Buretta et al., 2020).

Ethnicity: Not significant.

Contributing Factors: Family history, previous contralateral hernia, male sex, older age, abnormal collagen metabolism, radical prostatectomy, radiation therapy, and low body mass index (BMI) are known risk factors for the development of an inguinal hernia (HerniaSurge Group, 2018; Shakil et al., 2020). In fact, indirect inguinal hernias are eight to ten times more common in men than in women. (Shakil et al., 2018). Abdominal hernias often develop in patients with a history of chronic cough, ascites, abdominal surgery, and chronic peritoneal dialysis, and symptomatic prostatism can

© F.A. Davis Publishing

contribute to development of a hernia because of the associated risk factor of increased intra-abdominal or intrathoracic pressure (Ansari, 2020; HerniaSurge Group, 2018). Increasing body mass index (BMI) and older age were found to directly related to incarceration of noninguinal abdominal wall hernias in patients hospitalized for hernias (Sneiders et al., 2019). Incisional abdominal hernias can be found in patients with abdominal organ transplants (Singh et al., 2020). Chronic straining for bowel movements, straining to urinate, and lifting heavy objects may be precursors to hernia formation. For women, a weakened pelvic floor after childbirth can contribute to the development of femoral herniation. Additionally, older women are three to five times more likely than men to develop a femoral hernia than an inguinal hernia (HerniaSurge Group, 2018). Older women who are underweight and have a history of chronic illness can develop obturator hernias, a rare condition (Mindaye et al., 2020). Hernias also may form at the site of a surgical incision or a large scar. Patients with known liver cirrhosis with ascites have a 20% chance of developing an umbilical hernia (Ansari, 2020). Family history of organ herniation is also recognized as an intrinsic factor contributing to the development of hernias.

Signs and Symptoms: Patients with hernias of the groin (femoral or inguinal) may initially be asymptomatic (HerniaSurge Group, 2018). When patients present with signs and symptoms suggestive of a hernia, question them about how long the discomfort (swelling, pain, mass) has been present. Ask whether the pain is aggravated by any activity, such as heavy lifting or positioning. Inquire about abdominal surgical history. Question whether there is a family history of hernias (Ansari, 2020). Patients may report a dull dragging sensation with an inguinal hernia (Shakil et al., 2020). Male patients may report pain and swelling in the scrotum. Hernias may be asymptomatic, only to be discovered during a routine physical examination. A reducible hernia presents as a nontender mass that becomes more pronounced after a Valsalva's maneuver. An incarcerated hernia, also a nontender soft mass, is found in the abdominal, femoral, or inguinal area and remains even after gentle manipulation. Patients with strangulated abdominal hernia usually have a tender mass with associated fever, nausea, and vomiting. No attempt should be made to reduce a strangulated hernia.

Physical examination reveals decreased flatus, high-pitched or tinkling bowel sounds, abdominal distention, and tenderness of the mass. When examining a patient with a suspected hernia, assess the patient in both the supine and standing position, first observing the suspected mass before change in position. Have the patient also perform the Valsalva's maneuver. If possible, attempt to identify the location of the hernia sac and the fascial opening of the hernia when palpating the abdomen (Shakil et al., 2020). Identify the border of the suspected hernia. Although rare, a patient with a chest wall bulge on the lower chest wall may have an abdominal intercostal hernia (Sagar et al., 2019). For a suspected inguinal hernia, ask the patient to flex the leg on the side you will examine and then gently palpate the groin area. Then, with fingertips placed over the femoral area, external ring and internal ring should be inserted up into the inguinal canal (Shakil et al., 2019; Suneja et al., 2020).

Gross screening for an inguinal hernia in a male patient is made easier with the patient coughing because "hernia bulges can be felt either against the examining finger (direct hernia) or at the tip of the finger, as it approaches the internal ring (indirect hernia)" (Amerson, 1990, p. 484). A femoral hernia can often be elicited by having a patient cough or strain; the bulge will be felt below the inguinal ligament (Suneja et al., 2020). A positive Howship-Romberg's sign, which is pain experienced with internal rotation of the hip along with intestinal obstruction, has been found in patients diagnosed with an obturator hernia (Saeed et al., 2019). A mass is detected in the femoral triangle; patients experience pain down the medial aspect of the thigh all the way to the knee as a result of compression of the obturator nerve (Suneja et al., 2020).

Diagnostic Tests: In an uncomplicated asymptomatic hernia, laboratory and diagnostic tests are unwarranted. The use of ultrasound should be avoided in evaluating an apparent inguinal hernia; however, remains useful in the diagnosis of occult hernias (Shakil et al., 2020). If there is questionable strangulation from a prolonged incarcerated hernia, laboratory studies for complications may reveal leukocytosis, elevated serum amylase, and guaiac-positive stool. The use of higher resolution multidetector computed tomography (CT) scan allows for a clearer image of the anatomy studied. Axial CT scan should be requested first if a hernia is suspected (Matzke et al., 2017). Abdominal series are done postoperatively to look for signs of perforation (free air) or obstruction of the bowel (multiple air-fluid levels).

Differential Diagnosis:

- Femoral lymphadenopathy
- Femoral artery aneurysm
- Psoas abscess
- Undescended testicle
- Vasitis
- Muscle strain (Ansari, 2020; Shakil et al., 2020)

Treatment: Small, direct inguinal hernias and painless, indirect inguinal hernias do not need immediate attention; however, surgery generally is recommended within 1 week of diagnosis. Patients who are not surgical candidates can be fitted for a truss and monitored for signs of prolonged incarceration. Patients with a small, direct, nonpainful hernia should be observed for reduction of the hernia when supine. Surgical repair of strangulated inguinal, umbilical, and femoral hernias is recommended immediately unless the patient is a poor surgical risk. For patients with cirrhosis and ascites, they benefit from elective umbilical hernia repair (Guo et al., 2021). These patients need to be hospitalized, receive IV solutions, and remain on nothing by mouth (NPO) status. Patients who are not surgical candidates can be fitted for a truss and monitored for signs of prolonged incarceration. For small umbilical hernias (<2 cm), a suture repair is often recommended whereas mesh is often used for larger umbilical hernias (Köckerling et al., 2021; Koebe et al., 2021).

Follow-Up: For patients with reducible hernias, observation of the hernia during subsequent physical examination is recommended. Patients suspected of having an incarcerated hernia should be followed up within 1 week to determine whether they are experiencing any tenderness of the mass

© F.A. Davis Publishing

and if a general surgeon has seen them. For the postoperative patient who has had a herniorrhaphy, assess for wound healing and recurrence of the hernia.

Sequelae: An untreated inguinal, umbilical, or femoral hernia may become incarcerated and strangulated, with subsequent intestinal gangrene. The likelihood of incarceration is greatest for femoral hernias (Ansari, 2020). Postsurgical complications of a herniorrhaphy include wound hematomas and superficial wound infections. Nerve entrapment is a serious complication of an inguinal herniorraphy. Additional complications from hernia repair include bowel, bladder, and vascular injuries (HerniaSurge Group, 2018). In one study, 17% of patients who had laparoscopic ventral hernia repair needed subsequent abdominal surgery for reasons such as unplanned bowel obstruction (Patel et al., 2017). Approximately 50% of hernia recurrence occurs within 5 years, and an additional 20% occurs 15 to 20 years after surgical repair (Slater et al., 2014). The mortality rate is increased for patients who have undergone an emergent abdominal wall hernia repair (Surek et al., 2021). For patients undergoing umbilical hernia repair, there is a slight risk (5%) of developing a concomitant paraumbilical hernia (Netto et al., 2021).

Prevention/Prophylaxis: Cessation of cigarette smoking is recommended to reduce intrathoracic pressure from chronic coughing. Encourage the use of fiber, fluids, and stool softeners for patients who strain with defecation. Patients should avoid lifting heavy objects without proper support. As a preventive measure, encourage weight reduction for patients with obesity, especially those who have had prior abdominal surgery.

Referral: Refer the patient to a general surgeon when a hernia is detected. A strangulated hernia requires immediate attention.

Education: Inform the patient with a reducible hernia of the potential complications of an untreated hernia and the importance of reporting immediately any new clinical signs and symptoms, such as increase in pain, swelling, and/or fever. Teach patients to avoid straining to defecate or urinate. Encourage smoking cessation to reduce the probability of a chronic cough. Instruct the patients on proper techniques for lifting heavy objects. Weight reduction should be encouraged for patients with obesity. Patients also should be advised to discuss with their surgeon postoperative restrictions and plan for rehabilitation and home support given the probable restrictions to activity (Shakil et al., 2020).

IRRITABLE BOWEL SYNDROME

Signal Symptoms: Abdominal pain (may be described as colicky, pain relieved by defecation), altered defecation (constipation or diarrhea), abdominal distention, change in stool frequency, and the sensation of incomplete evacuation; patients often complain of associated symptoms such as bloating, fatigue, flatulence, passage of mucus, and abdominal distention (Wilkinson & Gill, 2021).

Description: Irritable bowel syndrome (IBS) is a chronic functional gastrointestinal (GI) disorder characterized by chronic abdominal pain and altered bowel function, in the absence of an attributable structural or biochemical cause (Ford et al., 2017). The subtypes of IBS are diarrhea prominent (IBS-D), constipation prominent (IBS-C), mixed diarrhea and constipation (IBS-M), and unspecified (IBS-U) (Aboubakr & Cohen, 2021; Ford et al., 2020).

Etiology: Although IBS is felt to be due to multiple interacting factors, the exact etiology remains uncertain and is likely multifactorial (Ford et al., 2017, 2020; Wilkinson & Gill, 2021). It has been proposed that IBS, as a functional disorder, is best understood in the context of the biopsychosocial model and alterations in the gut-brain pathway. Distortions in the normal gut-brain neuropathway can results in increased visceral hypersensitivity and altered bowel transit time and motility. Many IBS patients can also have coexisting psychological conditions such as depression or anxiety, as well as other chronic pain syndromes (fibromyalgia, chronic fatigue, and others) and other functional GI syndromes such as functional dyspepsia. (Wilkinson & Gill, 2021). While the focus remains on distortions of intestinal motility and altered visceral sensation, research has begun to investigate other contributing factors, such as immune causes, changes in

© F.A. Davis Publishing

intestinal flora (gut microbiota), food sensitivities, GI infections ("postinfectious IBS") and genetic predispositions (Aboubakr & Cohen, 2021; Ford et al., 2017, 2020; Wilkinson & Gill, 2021).

Occurrence: While IBS is a common GI complaint, its true prevalence is difficult to estimate due to a lack of biomarkers and a reliance on symptoms clusters for diagnosis (Ford et al., 2020; Wilkinson & Gill, 2021). However, estimates of prevalence range from 5% to 17% (Aboubakr & Cohen, 2021; Ford et al., 2020).

Age: The majority of patients with IBS are diagnosed at a younger age, typically younger than 50 years old (Ford et al., 2020). In fact, compared to the 5% to 17% prevalence in the general population, estimates are 7.3% of adults 60 and older (Lovell & Ford, 2012). Because most cases of IBS present by age 50 years, this syndrome is often a chronic condition in older adults for which treatment and management are still needed.

Ethnicity: IBS has a higher prevalence among Whites than among other ethnic groups (Minocha, 2005). However, comprehensive data are hard to find.

Contributing Factors: There have been multiple factors associated with IBS, including female sex (prevalence of IBS is significantly higher in women than in men [Sperber et al., 2017]), family history of IBS, and genetic contributors (Ford et al., 2017, 2020). Patients with IBS also tend to have coexisting psychiatric and/or psychological diagnoses, including stress and anxiety, and somatic disorders such as fibromyalgia and chronic fatigue syndrome (Aboubakr & Cohen, 2021; Ford et al., 2020; Wilkinson & Gill, 2021). Traumatic life events, such as physical or sexual abuse, may trigger the onset of IBS (Ford et al., 2017; Wilkinson & Gill, 2021). Certain food triggers have been identified, such as foods high in fermentable oligosaccharides, disaccharides, monosaccharides, and polyols (FODMAPs) which can include fructose, lactose, sorbitol, and other substances. Additionally, alterations in the gut microbiota (possibly from food triggers) have also been examined and associated with IBS (Ford et al., 2017, 2020).

A very common contributor to IBS is acute GI infection, such as bacterial, viral, or protozoa infections, which can result in postinfectious IBS (Aboubakr & Cohen, 2021; Ford et al., 2017, 2020; Wilkinson & Gill, 2021). While symptoms may be transient, they can morph into chronic IBS with one study finding 15% of postinfectious IBS patients having persistent symptoms 8 years after onset (Ford et al., 2020). Recent findings have indicated that the 5-HT (serotonin) concentration was higher in patients with IBS diarrhea type (IBS-D) and lower in those with IBS constipation type (IBS-C) than the general population (Camilleri, 2018). Various other contributors to IBS and symptom severity can include GI mucosal inflammation, abdominal or pelvic surgery, poor coping skills, lack of social support, and maladaptive thoughts (Ford et al., 2020).

Signs and Symptoms: A thorough dietary history is essential to establish a differential diagnosis of IBS, ruling out the possibility of food intolerances such as celiac disease or lactose intolerance. Review recent travel history with the patient for possible travel-related GI exposures. Explore the patient's psychosocial history to determine the relationships between stressful events and exacerbation of IBS as well as coexisting psychological/psychiatric diagnoses such as depression or anxiety. Determine when the symptoms initially began and typical symptoms pattern including the time of day when the pain and GI disturbances usually occur and any known triggers. A thorough GI review of systems is important in patients with IBS because GI conditions such as celiac disease and functional GI disorders such as functional dyspepsia, functional diarrhea, and functional bloating are often found in patients presenting with IBS symptoms (Ford et al., 2020; Wilkinson & Gill, 2021). A report of postprandial abdominal pain may suggest biliary tract disease, pancreatitis, or peptic ulcer disease (PUD). Patients often present with a change in stool pattern, such as constipation, diarrhea, or both that is associated with abdominal pain. However, patients with IBS rarely have nocturnal stools (Wilkinson & Gill, 2021).

Abdominal pain may be described as colicky, located in the lower abdomen, and associated with defecation or altered stool frequency/consistency. Pain is often relieved by defecation. Abdominal bloating and subsequent distention, mucus in the stool, and the sensation of incomplete evacuation are other presenting symptoms (Aboubakr & Cohen, 2021; Ford et al., 2020; Wilkinson & Gill, 2021). It should be noted that patient presentations with IBS can be highly variable (Wilkinson & Gill, 2021).

Patients should be assessed for extragastrointestinal symptoms, which are common and can include back pain, gynecological and urinary symptoms, headache, and fatigue. Older adults tend to have greater incidence of rectal urgency with fecal incontinence than younger patients (Minocha, 2005). Patients should be questioned for the presence of alarm symptoms, including onset after 50 years old, unintentional weight loss, family history of GI malignancy (such as colorectal cancer), GI bleeding, nocturnal diarrhea, and progressively worsening symptoms. The presence of any of these demands further investigation for the presence of more insidious pathologies (Aboubakr & Cohen, 2021; Wilkinson & Gill, 2021).

The physical examination is usually unremarkable, although there may be nonspecific abdominal tenderness on examination (Aboubakr & Cohen, 2021). Presence of an abdominal mass, lymphadenopathy, hepatosplenomegaly, or ascites in a patient with IBS should prompt further investigation (Wilkinson & Gill, 2021). A routine digital rectal examination generally reveals a tender rectum that is either empty or full of hard, firm feces. It is important to discern whether there are any disorders that may contribute to difficult or painful defecation, such as fissures, external hemorrhoids, or rectocele. Detection of a rectal mass on digital rectal examination is concerning and must be further evaluated to rule out malignancy. Additionally, the presence of any rectal bleeding is a warning sign and should be further investigated as is iron-deficiency anemia (Aboubakr & Cohen, 2021; Ford et al., 2020; Wilkinson & Gill, 2021).

Diagnostic Tests: IBS is often underdiagnosed because it is frequently not recognized (Wilkinson & Gill, 2021). IBS is not a diagnosis of exclusion, with current data recommending the use of a clinical diagnosis of IBS based on symptom application to Rome IV criteria. In the absence of warning signs or symptoms, exhaustive diagnostic work-up is typically of low

© F.A. Davis Publishing

yield, expensive, and of little other benefit (Ford et al., 2017, 2020). For example, a randomized controlled trial in Denmark compared suspected IBS patients with one group diagnosed with the symptom-based diagnostic approach with another group who underwent extensive serum and stool testing as well as flexible sigmoidoscopy to exclude an organic cause. The two approaches did not differ in patient quality of life, IBS symptoms, or patient satisfaction; however, costs were much lower in the symptom-based diagnosis approach (Begtrup et al., 2013).

The Rome IV criteria for the diagnosis of IBS is the most recent iteration of these criteria (see Table 13-5). A diagnosis of IBS based on Rome IV criteria requires recurrent abdominal pain with onset at least 6 months prior, occurring on average one day a week for the past 3 months, and association with two of three additional symptoms: the pain related to defecation, the pain is associated with a change in frequency of stool, or the pain is associated with a change in the form of the stool (Aboubakr & Cohen, 2021; Ford et al., 2017; Wilkinson & Gill, 2021). Again, the patient should be evaluated for warning signs or symptoms as discussed above. IBS can be further categorized into four subtypes, based on the predominant bowel habit utilizing the Bristol Stool Scale (see Table 13-6).

As previously discussed, an extensive work-up for IBS is not supported by current data. However, some limited testing may be appropriate, based on patient presentation, to rule out other possible etiologies. In general, it is reasonable to order a complete blood count (CBC) (for infection or anemia), C-reactive protein (CRP) and fecal calprotectin (for inflammatory bowel disease) (Ford et al., 2017, 2020; Wilkinson & Gill, 2021). Also, celiac disease serologies are justified in patients with suspected IBS because there is a near three times increased likelihood of celiac disease in patients with suspected IBS (Irvine et al., 2017). Additional testing should be based on the predominant bowel habit and further suspicions raised by the symptom review and examination.

If diarrhea is the presenting symptom, there are some additional testing options that may be useful, depending on the patient's particular presentation. For acute onset of symptoms, there should be consideration for *Clostridioides difficile* testing, especially in the setting of recent confinement to a health-care facility, recent antibiotic use, or other causes of altered GI flora, such as intestinal infection. Other testing that can be considered with diarrhea are stool culture and ova and parasite examination. Patients with IBS-D should have CRP and celiac serologies completed. Fecal calprotectin, in addition to CRP, can test for possible inflammatory bowel diseases. If there is the possibility of bile salt diarrhea, empiric trial of a bile salt sequestrant such as cholestyramine hydrogen breath testing can also be considered if small intestinal bacterial overgrowth (SIBO) is suspected, particularly in patients with high risk, such as previous gastric or intestinal surgery or intestinal structural abnormality (e.g., jejunal diverticulosis) (Aboubakr & Cohen, 2021; Ford et al., 2020; Wilkinson & Gill, 2021).

For patients with constipation who meet Rome IV criteria, the diagnosis is pretty certain unless there are obstructive symptoms. In addition to testing recommended for all IBS patients such as thyroid serologies, a plain abdominal x-ray series may elicit excessive stool burden or obvious masses. If obstructive symptoms are present (such as excessive straining or incomplete evacuation) or digital rectal examination suggests a defecatory disorder, then motility testing, anorectal manometry, or balloon expulsion testing can be pursued. If a possible rectal mass is detected on rectal examination, ultrasonography and/or flexible sigmoidoscopy should be pursued (Aboubakr & Cohen, 2021; Ford et al., 2020).

Colonoscopy is not generally warranted for patients suspected of IBS unless warning signs are present or endoluminal examination for screening purposes is due. In a study of 466 patients with IBS-D or IBS-M who underwent colonoscopy, inflammatory bowel disease was only detected in 2%, and no cases of colorectal cancer were discovered (Chey et al., 2010). Colonoscopy (and sometimes upper endoscopy) should be pursued in patients with a family history of colorectal cancer or irritable bowel disease or warning signs or symptoms, such as hematochezia or melena, heme-positive stool on examination, unintentional weight loss, or iron-deficiency anemia (Aboubakr & Cohen, 2021; Ford et al., 7, 2020). If a colonoscopy is being performed on patients suspected of IBS-D, whether due to family history, regular screening, or alarm symptoms, then random colon biopsies should be performed to evaluate for microscopic colitis (Aboubakr & Cohen, 2021). If upper endoscopy is being performed, regardless of cause, biopsies can be taken for celiac disease evaluation given the increased association between IBS patients and celiac disease (Ford et al., 2020). It should be reinforced that extensive testing on all IBS patients is not supported by the evidence and patients with diagnosed IBS have less than a 5% likelihood

TABLE 13-5 Rome IV Criteria for the Diagnosis of Irritable Bowel Syndrome

Symptoms present on average 1 day a week in the past 3 months (with symptom onset at least 6 months previously) with at least two of the following features:

- Related to (improved or worsened) with defecation
- Onset associated with a change in stool frequency
- Onset associated with a change in stool form or appearance

Source: *Ford et al., 2017*

TABLE 13-6 Irritable Bowel Syndrome Subtypes

TYPE	DESCRIPTION
IBS with predominant diarrhea (IBS-D)	Loose stool >25% of the time and hard stool <25% of the time
IBS with predominant constipation (IBS-C)	Hard stool >25% of the time and loose stool <25% of the time
IBS with mixed symptoms of constipation and diarrhea (IBS-M)	Hard stool >25% of the time and loose stool >25% of the time
Unclassified IBS (IBS-U)	Bowel movements cannot be accurately categorized as one of the other three subtypes

© F.A. Davis Publishing

of being given an alternative diagnosis in the future (El-Serag et al., 2004).

Differential Diagnosis:

- Food intolerances (lactose intolerance, fructose intolerance)
- Medication effects
- Parasitic infection
- Biliary tract disease
- Opioid-induced constipation (OIC)
- Neoplasms
- Chronic pancreatitis
- Narcotic abuse
- Celiac disease
- Crohn's disease
- Ulcerative colitis
- Ischemic colitis
- Microcytic colitis
- Thyroid dysfunction
- GI infection (viral, bacterial, protozoan)
- Chronic idiopathic constipation (CIC)
- Colorectal cancer
- Functional diarrhea
- Functional abdominal bloating/function abdominal distention (Aboubakr & Cohen, 2021; Wilkinson & Gill, 2021).

Treatment: The management of IBS depends on the presentation of the patient's condition, most bothersome symptoms, and with the goal of improving quality of life. For all patients with IBS, treatment should be individualized and start with reassurance and education including pathophysiology, natural history of the disease, and realistic expectations with current treatment limitations; care should be taken to be empathetic and nondismissive (Aboubakr & Cohen, 2021; Ford et al., 2020; Wilkinson & Gill, 2021). In all patients with mild symptoms that do not significantly impair quality of life, treatment tends to focus on diet, potentially exacerbating modifying medications, and use of over-the-counter (OTC) options for symptom flares. If symptoms do not respond, or are moderate to severe, pharmacological interventions can supplement mild treatment recommendations.

For patients of all IBS types, soluble or dietary fiber has been shown to be effective; insoluble fiber such as wheat bran can potentially increase bloating and cramping symptoms (Aboubakr & Cohen, 2021; Camilleri, 2018; Ford et al., 2017; Pietrzak et al., 2018). Dietary modifications include avoiding identified trigger foods and a low FODMAP diet (especially with IBS-D); trials of lactose and gluten elimination diets may be helpful, although strong evidence is lacking (Aboubakr & Cohen, 2021; Camilleri, 2018; Ford et al., 2017, 2020; Pietrzak et al., 2018; Wilkinson & Gill, 2021). Avoiding large meals, gas-producing foods (such as cruciferous vegetables), and caffeine may also be helpful (Böhn et al., 2015). Additional treatments that may improve global IBS symptoms include use of probiotics, exercise, and peppermint oil (Aboubakr & Cohen, 2021; Camilleri, 2018; Ford et al., 2020; Pietrzak et al., 2018). Finally, research has shown a benefit to tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), and serotonin and norepinephrine reuptake inhibitors (SNRIs) as gut-brain neuromodulators to bring about improvement in abdominal symptoms as well as treat anxiety related to effects of the disease; specific classes tend to be favored for IBS-D or IBS-C and are further discussed below (Aboubakr & Cohen, 2021; Camilleri, 2018; Pietrzak et al., 2018; Wilkinson & Gill, 2021).

For IBS-D, first-line treatment should consist of fiber, dietary changes, and OTC antimotility agents such as loperamide (Aboubakr & Cohen, 2021; Pietrzak et al., 2018; Wilkinson & Gill, 2021). Loperamide (2 mg to 4 mg taken up to four times a day) acts as a opioid receptor agonist, increases colonic transit time, and reduces fluid secretion improving diarrhea, frequency, and urgency; however, loperamide has little effect on abdominal pain (Pietrzak et al., 2018; Wilkinson & Gill, 2021). Other common treatments for IBS-D not responsive to first-line treatments include antispasmodics such as dicyclomine (up to 20 mg up to four times daily before meals) and hyoscyamine (0.125 mg to 0.25 mg every 4 hours as needed). These are generally well tolerated, but their use in older adults should be cautious due to anticholinergic side effects (Aboubakr & Cohen, 2021; Pietrzak et al., 2018; Wilkinson & Gill, 2021). Peppermint oil (200 mg to 750 mg two to three times daily) has also been shown to be safe and more effective than placebo as an antispasmodic that can reduce pain, bloating, and urgency; it generally does not affect bowel habits, however (Aboubakr & Cohen, 2021). Rifaxamin (550 mg three times a day for 2 weeks) is a gut-limited antibiotic that is safe, even in older adults, and can improve symptoms; treatment can be repeated up to twice a year. Finally, eluxadoline (75 mg to 100 mg twice daily) is an opioid receptor agonist–opioid receptor antagonist that acts specifically on opioid receptors in the gut to improve both pain and diarrhea symptoms. However, it is contraindicated in patients who have had a cholecystectomy, sphincter of Oddi's disease, biliary obstruction, pancreatitis, or severe liver impairment and in those who consume three or more alcoholic drinks a day; it may cause pancreatitis, and any patients who develop pancreatitis-like symptoms should stop the medication and contact their provider (Camilleri, 2018; Pietrzak et al., 2018; Wilkinson & Gill, 2021).

Alosetron, a selective 5-HT_3 antagonist, is approved by the U.S. Food and Drug Administration (FDA) for IBS-D treatment in females only, but significant adverse side effects such as ischemic bowel and toxic megacolon limits this use in routine practice (Camilleri, 2018; Pietrzak et al., 2018). Historically, this drug resulted in adverse effects and was at one point pulled from the market. However, after prescribing guidelines were updated by the FDA, it gained an improved safety profile. Providers who choose to prescribe this drug must be aware of all risks and benefits and have a dedicated prescribing outline to meet safety requirements. Close follow-up is recommended, and prescribing should be done by an experienced provider who is familiar with the full ramifications of this drug. Because of the risks and limited prescribing indication, it is not a commonly used medication. Ondansetron (4 mg up to three times a day) is a less potent serotonin (5-HT_3) receptor agonist that can improve urgency and frequency of loose stools, and with a demonstrated excellent safety profile, is a good alternative to alosetron.

For IBS-C, like with IBS-D, first-line treatments should consist of medications for IBS regardless of subtype, diet, and other nonpharmacological treatments. Antispasmodics

© F.A. Davis Publishing

can also be effective with IBS-C in reducing abdominal pain (Pietrzak et al., 2018; Wilkinson & Gill, 2021); patients, especially older adults, should be cautioned against possible worsening anticholinergic effects, which can also worsen constipation, although they are generally well tolerated. Another initial option is polyethylene glycol (17 g once daily in 4 to 8 ounces of a beverage), an FDA-approved osmotic laxative used for short-term constipation; however, although it has been shown to improve constipation, it has little effect on abdominal discomfort. Other osmotic laxatives include lactulose, sorbitol, and mannitol (Aboubakr & Cohen, 2021; Pietrzak et al., 2018; Wilkinson & Gill, 2021). OTC stimulant laxatives are an option but may worsen abdominal cramping and are generally reserved for patients with dysmotility disorders or OIC (Aboubakr & Cohen, 2021).

There are a few second-line pharmacotherapeutics for patients with IBS-C who do not respond to first-line treatment. The first group is considered prosecretory agents. One class is the guanylate cyclase-C agonists linaclotide (72 mcg to 145 mcg daily for chronic constipation; 290 mcg daily for IBS-C, both on an empty stomach) and plecanatide (3 mg to 6 mg daily), which increase chloride secretion into the colon increasing stool softness, increasing colonic transit, and decreasing pain (Aboubakr & Cohen, 2021; Pietrzak et al., 2018; Wilkinson & Gill, 2021). While doses of linaclotide vary for indication, the medication is often titrated to a dose based on patient response rather than type of constipation. Another prosecretory agent is lupiprostone (8 mcg or 24 mcg twice daily on a full stomach) and is a chloride channel activator that increases stool softness, increases colonic transit, and decreases pain (Aboubakr & Cohen, 2021; Pietrzak et al., 2018; Wilkinson & Gill, 2021). Finally, tegaserod (6 mg twice daily in women younger than 65 years old) is a serotonin (5-HT_4) receptor agonist that has significant side effects including headache, abdominal pain, and a low risk for ischemic cardiac events and therefore is not often prescribed; it is contraindicated in patients older than 65 years, and renal function must be closely monitored in all patients (Aboubakr & Cohen, 2021; Wilkinson & Gill, 2021).

For patients with IBS-M, general treatment measures such as antidepressants (TCAs, SSRIs, SNRIs) as well as diet, trigger avoidance, probiotics, and other options discussed above can be initiated for symptom improvement. Often, these patients require recommendations from both IBS-C and IBS-D treatments as their stools are typically variable. They can utilize the recommendation needed at the time, based on if they are having predominantly constipation or diarrhea.

Follow-Up: For patients with chronic IBS, a positive relationship between the health-care provider and the patient is mutually beneficial. It should be the focus and intent of the provider to educate the patient on the disease and expected outcomes. The patient should be often reminded of the chronic nature of IBS with flares and remissions of symptoms; they will frequently report symptoms in different ways depending on their current state of control. The provider should be intentional about not being dismissive and should have empathy for the patient who can have symptoms that are debilitating and significantly affect quality of life. Dietary intervention and stress-reduction techniques (as well as other coping strategies) should be reviewed and evaluated on an ongoing basis. In patients with newly diagnosed IBS, evaluation of persistent symptoms and treatment response should be executed to ensure no further work-up is needed for possible missed diagnosis other than IBS, especially with the development of any warning symptoms (Pietrzak et al., 2018; Wilkinson & Gill, 2021).

Sequelae: Patients with IBS have been found to have multiple comorbidities that need to be considered. Functional dyspepsia, depression, and anxiety are common comorbidities in patients with IBS, often for similar biopsychosocial and brain-gut axis etiologies as IBS (Aboubakr & Cohen, 2021; Ford et al., 2017, 2020). Complications may develop because of other pathological processes mistaken for IBS symptoms. Patients with uncontrollable diarrhea are at risk for dehydration because of fluid and electrolyte loss; this is especially true in older adults. Fecal impaction may result from chronic constipation, especially in an immobile, cognitively impaired older patient.

Prevention/Prophylaxis: The patient should become familiar with stress-reduction techniques and coping mechanisms, which are especially useful during emotionally stressful situations. Patients should avoid all food products that are known to irritate their bowels (Wilkinson & Gill, 2021). Patients with known food intolerance must read nutrition labels and be informed of the inactive contents of medications, which may contain irritating substances.

Referral: Refer patients to a gastroenterologist for colonoscopic imaging as appropriate for screening or warning signs or symptoms. Refer again if patients exhibit persistent symptoms such as abdominal pain, severe constipation, or uncontrollable diarrhea despite compliance with treatment. Patients may benefit from psychotherapy to help with anxiety and depression symptoms, which can improve symptoms associated with gut-brain based disorders like IBS. Psychotherapy (such as cognitive behavioral therapy, hypnotherapy, mindfulness) can be an effective nonpharmacological treatment in patients with IBS (Aboubakr & Cohen, 2021). Biofeedback can be effective for patients who have IBS-C with obstructive symptoms (Ford et al., 2017).

Education: Inform patients that because the increase of dietary fiber could aggravate their IBS symptoms, they should increase it gradually to the recommended dose. This risk can be reduced with soluble or dietary fiber rather in insoluble fiber (Aboubakr & Cohen, 2021; Camilleri, 2018; Ford et al., 2017; Pietrzak et al., 2018). Eating smaller, frequent meals and avoiding known triggers and FODMAPs may ease the IBS symptoms in older adults and enhance overall quality of life; however, these ideas require education and explanation (Ford et al., 2020). Inform patients with chronic IBS that although the disease itself does not lead to a more serious illness, any change in symptoms should be reported to the health-care practitioner.

LIVER CANCER

Signal Symptoms: Cachexia, jaundice.

Description: The liver is the most common organ in the body for metastasis from other cancers. Common sites of primary tumors that metastasize to the liver are the lungs, colon, pancreas, stomach, breast, and gallbladder. Hepatocellular carcinoma, intrahepatic cholangiocarcinoma, angiosarcoma and hemangiosarcoma, and hepatoblastoma are primary liver cancers. Hepatocellular carcinoma is associated with cirrhosis of the liver (American Cancer Society [ACS], 2021a).

Etiology: The hepatic filtration of arterial and portal venous blood is a major reason for the high prevalence of metastases from primary cancerous sites in the body to the liver. Metastases also may result from an extension from an abdominal tumor or through the lymphatic system. Malignant tumors of the liver are primarily adenocarcinomas.

Occurrence: Primary liver cancer, rare in the United States, accounts for about 2% of all cancers or approximately 42,000 cases per year (National Cancer Institute [NCI], 2021). It is more common for cancer in the liver to have metastasized from another part of the body rather than be a primary liver cancer. Men are about 2.5 times more likely than women to develop liver cancer (ACS, 2021b; NCI, 2021).

Age: Median age of diagnosis is 65 years (NCI, 2021).

Ethnicity: The incidence of liver cancer is highest in Native Americans/Alaskan Natives (ACS, 2021b; NCI, 2021).

Contributing Factors: The most common risk factor is chronic hepatitis B or C infection, which leads to cirrhosis. The risk increases in people who drink more than six alcoholic drinks per day (ACS, 2021b). Additional risk factors include hemochromatosis, obesity, type 2 diabetes, porphyria cutanea tarda, alpha-1 antitrypsin deficiency, and Wilson's disease (ACS, 2021b; National Comprehensive Cancer Network [NCCN], 2021).

Signs and Symptoms: Complaints of weakness, malaise, weight loss, sweating, and anorexia may be reported. Pain in the upper abdomen can be associated with the cancer and also may be reported. Physical examination reveals cachexia. Auscultation may reveal a bruit over the tumor and tenderness of the liver. Hepatomegaly and ascites may be present. A mass may be palpable. In more advanced cases, jaundice may appear (NCCN, 2021).

Diagnostic Tests: Patients at high risk for hepatocellular carcinoma (HCC) should be screened using ultrasound and alpha fetoprotein (AFP) every 6 months (NCCN, 2021). Identification of a liver nodule that is smaller than 1 cm

© F.A. Davis Publishing

should be reimaged with an ultrasound in 3 to 6 months. Nodules that are larger than 1 cm should be reimaged with abdominal computed tomography (CT) scan or contrast-enhanced magnetic resonance imaging (MRI). Nodules that demonstrate arterial hypervascularity and venous or delayed phase washout are diagnostic for HCC. Those nodules that do not demonstrate arterial hypervascularity and venous or delayed phase washout should be reimaged with another contrast-enhanced study such as a CT scan or MRI, and percutaneous biopsy should be completed. A CT of the chest and bone scan should be ordered if clinically indicated.

Laboratory testing should include a complete blood count (CBC), hepatitis panel, bilirubin, alkaline phosphatase, aspartate aminotransferase (AST), alanine aminotransferase (ALT), prothrombin time (PT), International Normalized Ratio (INR), blood urea nitrogen (BUN), and creatinine. Laboratory findings may be nonspecific and are related to the underlying liver disease. Findings may include thrombocytopenia, hypoalbuminemia, hyperbilirubinemia, and hypoprothrombinemia. Additionally, patients may have mild anemia and electrolyte disturbances (NCCN, 2021). Serum alkaline phosphatase, AST, ALT, and gamma-glutamyl transpeptidase (GGT) are often abnormal in a nonspecific pattern. PT/INR may be elevated.

Differential Diagnosis:
- Cirrhosis
- Chronic hepatitis B or C infection
- Metastatic malignancy to the liver

Treatment: All patients should be evaluated by an experienced multidisciplinary team for available treatment options. Advancements in the surgical treatment of hepatic metastatic cancers include tumor ablation and microscopic glass beads containing a radioactive element. Surgical resection of the liver is beneficial only if the patient has a resectable tumor; even so, the survival rate remains low. Liver transplant may be considered in patients with early-stage liver cancer, as well as advanced disease. Systemic therapy may be considered as adjuvant treatment or in patients who are not candidates for surgery. Recommended first-line treatment includes atezolizumab plus bevacizumab, sorafenib, or lenvatinib. Checkpoint inhibitors may be considered in some circumstances (NCCN, 2021).

Follow-Up: Patients and family members should be given the opportunity to explore adjunctive methods of pain relief and relaxation. After diagnosis of liver cancer, the focus should be on holistic palliative care, including the intervention of hospice and services.

Sequelae: The prognosis is poor because the tumor grows rapidly and often metastasizes to the lungs or bones. The survival rate is only 4 to 6 months.

Prevention/Prophylaxis: The hepatitis B vaccine is recommended for high-risk patients. Treatment of hepatitis C is recommended. Avoidance of chemical exposure, as part of occupational safety, is suggested. Annual ultrasound screening for patients with chronic hepatitis B or cirrhosis should be considered as a preventive measure for liver cancer (ACS, 2021b).

Referral: Refer the patient to an oncologist when the diagnosis of liver cancer is suspected. Local hospice care services should be contacted for care for the patient and family.

Education: Although no further medical treatment is aimed at reversal of the disease, the patient needs to know that you will collaborate with the hospice nurses to provide for the patient's comfort throughout the disease process. The patient can be referred to http://www.liverfoundation.org/support/ for basic information about liver cancer.

Clinical Recommendation	Evidence Rating	References
Prevention of hepatocellular carcinoma (HCC) should focus on preventing infection with hepatitis B virus (HBV) and hepatitis C virus (HCV), treating patients with viral hepatitis who are candidates for treatment, avoiding environmental toxins, and attempting to prevent the development of cirrhosis in patients with liver disease.	A	ACS, 2021b
Patients with chronic HBV infection who are at increased risk for HCC should undergo routine surveillance.	A	ACS, 2021b NCCN, 2021
All patients with cirrhosis, regardless of etiology, should undergo surveillance for HCC.	B	NCCN, 2021
Surveillance in high-risk patients should be performed with ultrasonography every 6 months rather than annually.	B	NCCN, 2021

NONALCOHOLIC FATTY LIVER DISEASE

Signal Symptoms: Fatigue, right upper quadrant pain or fullness, possible hepatomegaly.

Description: Nonalcoholic fatty disease (NAFLD) is the most common chronic liver disease in Western countries (Westfall et al., 2020). NAFLD refers to a spectrum of liver disorders that include simple steatosis (fatty liver) and nonalcoholic steatohepatitis (NASH). NASH is characterized by hepatocyte injury, inflammation, and fibrosis, which can ultimately lead

© F.A. Davis Publishing

to cirrhosis and end-stage liver disease (Patel & Siddiqui, 2019). Risk factors for the development of NASH include elevated fasting blood glucose, low high-density lipoprotein (HDL) and elevated fasting cholesterol (Sivell, 2019). Alcohol use must be minimal to meet the criteria for NAFLD (Chalasani et al., 2018). The maximum intake of alcohol is two standard drinks a day for men and one for women (USDA, 2020)

Etiology: While the exact mechanism for the NALFD is unknown (Wilkins et al., 2011), development of NAFLD has been associated with diabetes, obesity, insulin resistance, hypertension, and dyslipidemia (Kudaravalli, & John, 2021). Insulin resistance is the most important risk factor for the development of NAFLD. It has been suggested that there may be a genetic predisposition to NAFLD, especially in patients who also develop metabolic syndrome (Westfall et al., 2020).

Occurrence: NAFLD is the most common liver disease in the United States (Patel & Siddiqui, 2019). It has been predicted that NAFLD will become the most frequent indication for liver transplantation by 2030. In the United States, it is estimated that 100 million adults will be affected by NAFLD by 2030 and the prevalence will continue to rise (Westfall et al., 2020).

Age: The majority of patients diagnosed with NAFLD are in their 40s or 50s (Iqbal et al., 2019). The risk of nonalcoholic steatohepatitis, cirrhosis, and hepatocellular carcinoma (HCC) is increased in the older adults with NAFLD (Chalasani et al., 2018; Li et al., 2018).

Ethnicity: Hispanics have the highest rate of NAFLD while studies have shown an increase in metabolic syndrome in South Asian populations, which could progress to NAFLD (Sivell, 2019).

Contributing Factors: The most common risk factors associated with the development of NAFLD are obesity (body mass index [BMI] >30 kg/m^2)—especially central obesity—diabetes, metabolic syndrome, hypertension, dyslipidemia, and insulin resistance (Sivell, 2019; Westfall et al., 2020). NAFLD may be present in patients who have jejunoileal bypass or gastric bypass or who have experienced starvation and/or protein energy malnutrition. Also at risk are patients receiving parental nutrition (Mitra & Ahn, 2017). Drug-induced NAFLD can be caused by aspirin, cocaine, valproate, highly active antiretroviral, tetracycline, NSAIDs, amiodarone, tamoxifen, methotrexate, and corticosteroids. In patients with coexisting conditions, such as ulcerative colitis, Graves' disease, or type 1 diabetes, consider an autoimmune cause for NAFLD (Croke & Sampson, 2012). Genetic factors such as high-risk allele of the patatin-like phospholipase domain-containing protein 3 gene have been found in patients with NAFLD (Westfall et al., 2020). There is evidence that NAFLD is linked to other chronic disease such as sleep apnea, colorectal cancer, osteoporosis, psoriasis, and endocrine diseases such as polycystic ovary syndrome and hypothyroidism (Westfall et al., 2020). Increased age has been shown to be a risk factor for developing NAFLD and NASH and advanced fibrosis (Neuschwander-Tetri, 2017)

Signs and Symptoms: Most patients with NAFLD are asymptomatic (Sivell, 2019). Patients may present with fatigue, jaundice, pruritus, right upper quadrant discomfort or fullness (Westfall et al., 2020). Inquire about weight loss. On examination, look for evidence of jaundice of the skin, scleral icterus, and spider angiomas. Patients may have unexplained abnormal liver blood tests as part of a routine physical or drug monitoring such as statins. On physical examination, patients with NAFLD may have hepatomegaly (Kudaravalli & John, 2021).

Diagnostic Tests: NAFLD is a diagnosis of exclusion. The most common abnormal laboratory tests are elevated alanine aminotransferase (ALT) and aspartate aminotransferase (AST) (Chalasani et al., 2018), especially in patients with type 2 diabetes (Sheng et al., 2018). ALT and AST may be elevated two to five times the upper limits. It is important to exclude other causes of elevated transaminase levels. Hepatitis A, B, and C need to be ruled out, as does autoimmune hepatitis. Check ferritin and iron levels to rule out hemochromatosis (Westfall et al., 2020). Consider ruling out Wilson's disease, thyroid disease, celiac disease, and alpha-1 antitrypsin deficiency. A fasting glucose or A1c level, lipid panel, prothrombin time (PT), albumin, and total bilirubin should be obtained (Sivell, 2019; Westfall et al., 2020). With a sensitivity of 82% to 89% and a specificity of 93% for identifying a fatty liver, an ultrasonography of the liver will assist in the diagnosis of NAFD by identifying fatty infiltration (Sivell, 2019). A transient elastography is routinely used to grade fibrosis based on liver stiffness (Li et al., 2018). A liver biopsy should be considered for patients who are likely to have a more advanced liver disease, including those with morbid obesity, diabetes, advanced age, and an AST/ALT ratio greater than 1. Liver biopsy remains the gold standard for the patient with suspected NASH, hepatic stenosis, and fibrosis and cirrhosis (Chalasani et al., 2018). Patients with persistent elevations in liver enzymes despite lifestyle changes may be considered for liver biopsy. Patients should be screened for alcohol and drug use.

Differential Diagnosis:

- Alcoholic hepatitis
- Autoimmune hepatitis
- Hepatitis B
- Hepatitis C, particularly
- Thyroid disease
- Alpha-1 antitrypsin disease
- Medication-induced hepatitis
- Wilson disease (Kudaravalli & John, 2021, Westfall et al., 2020; Wilkins et al., 2013)

Treatment: Management of NAFLD should focus primarily on risk factors such as insulin resistance and hyperlipidemia (Chalasani et al., 2018; Westfall et al., 2020). Patients who are overweight or obese with NAFLD should consider making lifestyle changes that include following a Mediterranean diet that focuses on weight loss (Neuschwander-Tetri, 2017). It has been shown that weight loss and exercise reduce liver enzymes levels and steatosis (Westfall et al., 2020). Weight loss should not exceed 1 to 2 pounds a week. For patients with end-stage liver disease, weight loss should not be recommended due to the risk of protein calorie malnutrition. Any alcohol use should be prohibited (Li et al., 2018).

Treatment for hyperlipidemia in patients with NAFLD cirrhosis is recommended to prevent cardiovascular disease; however, avoid this in patients with decompensated cirrhosis

© F.A. Davis Publishing

(Li et al., 2018). Medications for the treatment of insulin resistance (pioglitazone, rosiglitazone) have been shown to improve transaminases levels and decrease hepatic steatosis (Westfall et al., 2020). Obese patients who are unable to lose weight with lifestyle changes should be considered for bariatric surgery; individual risk for complications from surgery need to first be evaluated (Neuschwander-Tetri, 2017). Hepatitis A and B vaccine should be given to patients without serological evidence of immunity (Westfall et al., 2020). Patients should be monitored for weight loss.

Sequelae: NAFLD in older adults is often more severe and can carry a worse prognosis than in the younger population. Complications include portal hypertension, gastroesophageal varices, cirrhosis, hepatic failure, and HCC (Li et al., 2018; Maurice & Manousou, 2018; Neuschwander-Tetri, 2017; Sivell, 2019). Risk factors for the development of HCC in NAFLD include the older age, type 2 diabetes, and cirrhosis (Li et al., 2018). The most common cause of death in patients with NAFLD is cardiovascular disease (Maurice & Manousou, 2018).

Prevention/Prophylaxis: Weight loss and engaging in regular physical activity should be encouraged in patients with obesity (Westfall et al., 2020). Patients with diabetes, hypertension, and hyperlipidemia should be closely monitored and managed to help prevent the progression of NAFLD.

Referral: Consider referral to a specialist when the clinical parameters are indicating a severe disease state. Patients whose liver enzymes remain elevated despite weight loss, those who are morbidly obese, those with AST/ALT twice the upper limits of normal and those with NASH whose clinical picture suggests the likelihood of cirrhosis should be referred (Westfall et al., 2020).

Education: Patients should be advised that NAFLD is usually caused by the same conditions that cause an increased risk for cardiovascular disease. Lifestyle choices should be reviewed with the patient at each encounter as the management of NAFLD is directed at risk factors, specifically, diabetes, elevated lipids, and obesity and the patient's progress toward making changes toward a healthy diet and a regular exercise regimen (Kudaravalli & John, 2021).

PEPTIC ULCER DISEASE

Signal Symptoms:

Gastric Ulcers: History of dyspepsia, epigastric pain, pain that radiates to the back after the ingestion of a meal.

Duodenal Ulcers: Pain 1 to 3 hours after a meal (patients with gastric ulcers have pain immediately on eating), and resolution of pain at times with eating. Nocturnal pain may occur in duodenal ulcers in the older adult; definitive symptoms may be absent, and vomiting and anorexia may be reported instead of epigastric pain.

Description: Peptic ulcer disease (PUD) involves ulcerations of the mucous membrane of the stomach or duodenum into the submucosa (Lanas & Chan, 2017). The disease is classified according to the nature and anatomical location of the lesion. Gastric ulcers generally are found along the lesser curvature of the stomach between antral and acid-screening mucosa, occurring anywhere in the stomach, from the cardia to the pylorus. Duodenal ulcers develop in the duodenal bulb or in the immediate postbulbar area (Dunlap & Patterson, 2019).

Etiology: The etiology of PUD is characterized best as an imbalance between the noxious agents to which the gastrointestinal (GI) mucosa is exposed (primarily hydrochloric acid and pepsin) and the protective factors (mucus production, bicarbonate secretion) that the mucosa uses to resist destruction from such noxious agents. An increase in destructive influences (e.g., with NSAID use) can destroy the mucosa, leading to the development of an ulcer (Narayanan et al., 2018). *Helicobacter pylori* and NSAIDs or aspirin products are the predominant risk factors for PUD (Dunlap et al., 2019; Lanas & Chan, 2017; Narayanan et al., 2018). Historically, *H. pylori* was more prevalent as a culprit for PUD, but NSAIDs and other caustic substances have become more prominent (Malfertheiner & Schulz, 2020). Although rare, non–*H. pylori* bacteria have been found to contribute to PUD; identification requires special histological stains such as Giemsa,

© F.A. Davis Publishing

Steiner, or Whartin-Starry silver stain (Da Cunha & Dharan, 2021). Approximately 20% of cases will not be related to *H. pylori*, aspirin products, or NSAIDs (Lanas & Chan, 2017). Additional etiologies could include ischemic injury, medication-induced (alendronate, steroid therapy, potassium chloride, chemotherapy), viral etiologies (cytomegalovirus [CMV] and herpes simplex virus [HSV]), gastric bypass procedures with ulcers at anastomotic sites, tumors (such as lymphoma), Cameron's ulcer, Crohn's disease, eosinophilic gastroduodenitis, and idiopathic ulcers (Malfertheiner & Schulz, 2020; Narayanan et al., 2018; Sivakumar & Stubbs, 2021).

Occurrence: Approximately 4.5 million people will experience PUD annually, with an approximate 5% to 10% prevalence of PUD globally (Prasad & Friedman, 2018; Rothermel & Edwards, 2020). Gastric ulcers may be more prevalent in older women, with duodenal ulcer occurrence more common in men (Sivakumar & Stubbs, 2021).

Age: Majority of those affected by PUD are aged 25 to 64 years (Dunlap & Patterson, 2019).

Ethnicity: Prevalence of PUD secondary to *H. pylori* is higher in Mexican Americans (60%) compared to non-Hispanic Americans (30%) (Narayanan et al., 2018).

Contributing Factors: *H. pylori* infection is a factor in more than 90% of duodenal ulcers and 70% to 90% of gastric ulcers (Sivakumar & Stubbs, 2021). Use of aspirin and other NSAIDs—because of their ability to inhibit prostaglandin synthesis—has been shown to increase the risk of PUD (Malfertheiner & Schulz, 2020). Other medications, including selective serotonin reuptake inhibitors (SSRI)s, steroids, aldosterone antagonists, and anticoagulants combined with NSAIDs or aspirin result in increased risk of acute bleeding (Lanas & Chan, 2017).

Additional risk factors for developing PUD include tobacco and alcohol use, gastrinoma, family history of ulcers, and significant stressors on the body such as acute critical illness (Dunlap & Patterson, 2019).

Signs and Symptoms: Patients presenting with symptoms of PUD must be evaluated for alarm symptoms, which would prompt diagnostic endoscopy instead of empiric treatment, specifically if older than age 55 (Narayanan et al., 2018; Sarfraz, 2018). In older adults, definitive symptoms may be absent. Alarm signs and symptoms, known as red flags, would include overt GI bleeding (melena and/or hematochezia), iron-deficiency anemia, unintentional weight loss, dysphagia or odynophagia, persistent vomiting, palpable abdominal mass, family history of upper GI cancers, and symptoms present at age 55 and older (Dunlap & Patterson, 2019; Narayanan et al., 2018; Sivakumar & Stubbs, 2021). Overt GI such as melena or hematochezia may be the first sign heralding PUD, occurring in in almost 50% of patients, as classic symptoms may have been absent prior to presentation (Lanas & Chan, 2017; Sivakumar & Stubbs, 2021). Acute onset of epigastric pain that is persistent could be indicative of perforation (Lanas & Chan, 2017). Mortality for perforation may be up to 20%, depending on the patient's age at presentation and coexisting medical conditions (Lanas & Chan, 2017).

Approximately two-thirds of PUD presentations may have nonspecific or silent symptoms (Altwejry et al., 2020). Most common symptoms if present would include epigastric pain with characteristics of burning or gnawing, intermittent abdominal pain with periods of relief, nausea, vomiting, possible weight loss (Altwejry et al., 2020; Lanas & Chan, 2017; Sivakumar & Stubbs, 2021). Patients with gastric ulcers have a history of abdominal pain that is worsened by eating and may be relieved by antacids, whereas duodenal ulcers exacerbate pain at night or several hours after eating, and pain may resolve while eating (Dunlap & Patterson, 2019; Lanas & Chan, 2017; Sivakumar & Stubbs, 2021).

Physical examination of a patient with PUD may be normal (Dunlap & Patterson, 2019). If PUD is significant or advanced, tenderness of epigastric abdomen may be noted; however, 30% of older adults will not have palpation tenderness (Dunlap & Patterson, 2019; Sarfraz, 2018). Perforation signs would include rigidity of the abdomen and absence of bowel sounds; a gastric outlet obstruction would be suspected if succession splash heard upon auscultation (Dunlap & Patterson, 2019; Sarfraz, 2018). Digital rectal examination should be performed, with hemoccult testing obtained; findings of melena or hematochezia could indicate upper GI bleeding or rapid transit upper GI bleeding if the latter is appreciated (Dunlap & Patterson, 2019; Sarfraz, 2018).

Diagnostic Tests: Esophagogastroduodenoscopy (EGD) with a biopsy for the detection of peptic ulcer, malignancy, and *H. pylori* remains the gold standard in diagnostic testing for this disease, especially in patients 55 years or older and/or with alarm symptomatology (Dunlap & Patterson, 2019; Lanas & Chan, 2017). Patients younger than 55 without alarm signs or symptoms, no concern for gastric carcinoma, or living in area of increased prevalence of gastric carcinoma or *H. pylori*, may be tested for *H. pylori* and treated without undergoing diagnostic endoscopy (Dunlap & Patterson, 2019; Narayanan et al., 2018). EGD is still recommended for any patient with alarm signs or symptoms regardless of age.

Diagnostic tests for *H. pylori* include a stool antigen or urea breath test (UBT); however, serological antibody testing for *H. pylori* is not helpful for identifying active versus past infection and for this reason is not recommended to exclude presence of *H. pylori* (Altwhejry et al., 2020; Dunlap & Patterson, 2019; Narayanan et al., 2018). Serological antibody testing for *H. pylori* shows results as positive or negative, and this is not able to identify active versus past infection; therefore, it is not helpful in diagnosing the presence of active *H. pylori* infection. Proton pump inhibitor (PPI) use will need to be restricted for 14 days and antibiotics for 28 days before UBT and fecal antigen testing to avoid false-negative results (Sivakumar & Stubbs, 2021).

Laboratory tests including a complete blood count, serum chemistries, fecal occult blood testing, amylase, and lipase can be drawn to help exclude other differential diagnoses or confirm anemia and occult GI bleeding; however, there is no blood test that can determine the presence of PUD (Dunlap & Patterson, 2019; Sivakumar & Stubbs, 2021).

Differential Diagnosis:

- Abdominal aortic aneurysm
- Acute coronary syndrome
- Angina

© F.A. Davis Publishing

- Celiac disease
- Crohn's disease
- Esophagitis
- Gastritis
- Gastroenteritis
- Gastric carcinoma
- Gastroesophageal reflux disease (GERD)
- Gallbladder disease
- Mesenteric ischemia
- Irritable bowel syndrome
- Pancreatitis (acute or chronic)
- Zollinger-Ellison's disease
- Nonulcer dyspepsia (Dunlap & Patterson, 2019; Sarfraz, 2018; Sivakumar & Stubbs, 2021)

Treatment: PUD should be managed according to the etiology. NSAIDs and aspirin should be stopped if feasible, especially if the offending cause of PUD. For PUD not related to *H. pylori* infection, treatment with PPIs for at least 6 to 8 weeks should result in ulcer healing as long as the offending medication is no longer used; complicated PUD will require longer therapy up to 12 weeks (Narayanan et al., 2018). If NSAIDs/aspirin therapy is essential for the patient to continue, PPIs should be continued prophylactically to reduce recurrence (Dunlap & Patterson, 2019). Sucralfate has been shown effective for treatment of duodenal ulcers secondary to NSAIDs only and not effective for treatment of gastric ulcers (Narayanan et al., 2018).

Surveillance EGD around 6 to 8 weeks after diagnosis, should be performed for gastric ulcers due to potential risk of harboring malignancy (Dunlap & Patterson, 2019; Narayanan et al., 2018). Further biopsies should be undertaken if persistent ulcer disease is noted at surveillance EGD. Refractory ulcers greater than 5 mm that do not respond to 8 to 12 weeks of appropriate PPI therapy should raise concern for alternative etiology, including hypersecretory state, infectious or infiltrative processes, cocaine, Crohn's disease, carcinoma, or noncompliance (Sivakumar & Stubbs, 2021).

Acute GI bleeding due to PUD is associated with a mortality rate of 10% depending upon associated comorbidities, requiring inpatient treatment and IV PPI therapy (Altwejry et al., 2020). Fluid resuscitation with crystalloid solutions should be started immediately upon presentation to a medical facility, with the goal of maintaining hemoglobin above 7 g/dL (Lanas & Chan, 2017). IV PPI should be started upon presentation, as this reduces the risk of bleeding and rebleeding post EGD (Narayanan et al., 2018). PPI infusion should be continued following EGD if bleeding stigmata noted or intervention for hemostasis was performed (Narayanan et al., 2018). EGD is indicated for acute GI bleeding, with hemostatic intervention for therapeutic purposes; the first 72 hours following intervention are critical because recurrent bleeding is most likely during this time (Chiu, 2019). Angiography with embolization may be needed for persistent bleeding ulcers (Chiu, 2019). Surgery may be necessary if unable to perform endoscopic or embolization therapies fail. Perforated PUD carries a mortality rate of 30%, prompting surgical intervention emergently if appropriate surgical candidate; contained perforations may be appropriate for medical supportive treatment including IV PPI, nothing by mouth (NPO) status, and antibiotics (Altwejry et al., 2020; Narayanan et al., 2018). Finally, gastric outlet obstruction due to PUD requires IV PPI possible endoscopic therapy with dilation, or surgery (Altwejry et al., 2020).

H. pylori eradication is paramount to reduce the risk of recurrence of PUD and reduce risk of gastric cancer secondary to *H. pylori* (Chey et al., 2017; Narayanan et al., 2018; Sivakumar & Stubbs, 2021). The full course of therapy for 10 to 14 days should be taken to avoid incomplete therapy and potential persistent bacteria. Choice of regimen is based on prior antibiotic exposures and treatments. Multiple regimens are available, including rescue therapies for those who have failed prior treatment. Eradication testing should be performed 4 weeks following therapy via breath test, fecal test, or endoscopic biopsy (Chey et al., 2017). For those who have failed multiple regimens and providers are unable to document eradication, endoscopic biopsy for culture and sensitivity is recommended (Narayanan et al., 2018).

Follow-Up: Confirm eradication of *H. pylori* 4 weeks after treatment therapy via stool antigen test or urea breath test (Chey et al., 2017). It is important that PPI therapy be held for at least 14 days prior to documenting eradication. Surveillance EGD for gastric ulcers to document healing.

Sequelae: Complications originating from PUD in older adults include gastric bleeding with accompanying anemia, larger gastric ulcers than in younger counterparts, higher surgical risk with 30-day morbidity and mortality compared to younger patients, and increased risk of persistent ulcers and bleeding due to polypharmacy (Dumic et al., 2019).

Prevention/Prophylaxis: Any patients with previous history of GI bleeding, *H. pylori* infection, multiple and/or high NSAID use (including aspirin), corticosteroid use, or polypharmacy as well as older adults are at risk for developing PUD (Dumic et al., 2019). Signs and symptoms of impending recurrence of PUD, including epigastric pain, anorexia, melena, and weight loss, should be identified early. The use of NSAIDs and aspirin along with antiplatelets and anticoagulation lead to increased risk of bleeding (Malfertheiner & Schulz, 2020). Prophylactic PPI use may prevent PUD if NSAIDs/aspirin products are necessary to continue (Lanas & Chan, 2017).

Referral: Refer the patient to a gastroenterologist for initial endoscopy and for treatment of upper GI bleeding. PPI therapy, compared with histamine blockers and placebo, has been shown to reduce mortality after upper GI bleeding secondary to PUD (Narayanan et al., 2018). Refer again if epigastric pain and dyspepsia persist despite treatment and if signs of GI bleeding are present.

Education: Avoidance of aspirin and other NSAIDs and tobacco is essential. Reduction of stressful events, coffee (including decaffeinated forms) and other caffeine products, and alcohol is recommended. Caution patients about taking over-the-counter (OTC) medication preparations without professional advice. Patients with history of GI bleeding should notify the health-care provider of any recurrent symptoms and overt bleeding, such as melena or hematochezia. Patients treated for *H. pylori* should have eradication documented, and surveillance EGD should be completed for all gastric ulcers to ensure healing.

© F.A. Davis Publishing

There is a decreased mortality rate from bleeding peptic ulcers when proton pump inhibitor (PPI) therapy is utilized for treatment after diagnosis.	A	Narayanan et al., 2018
Treat patients with peptic ulcer disease (PUD) symptoms and *H. pylori* infection with standard protocol to reduce the risk of ulcer recurrence and promote healing.	A	Chey et al., 2017 Narayanan et al., 2018 Sivakumar & Stubbs, 2021
Upper endoscopy is needed for patients with PUD who are older than 55 years and/or with alarm symptoms, or in those with ulcers who do not improve with therapy.	A	Narayanan et al., 2018 Sarfraz, 2018

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. For information about the SORT evidence rating system, go to https://www.aafp.org/afp/2004/0201/p548.html.

CASE STUDY

A 71-year-old woman presents with a 4-week history of dyspepsia and abdominal pain that she describes as gnawing. She states that for years she has had occasional heartburn, but she cannot recall having abdominal pain like she is experiencing now. She states that she also has arthritis and has taken ibuprofen every day for the past 2 years. For her stomach pain she has been taking Tums extra strength a couple of times a day. She states that the pain began soon after visiting her sister, who is a nurse at a mission in Nicaragua.

Chief Complaint: "My stomach hurts and wakes me up from my sleep. I find myself belching after meals and I feel bloated."

Objective: Blood pressure (BP) 118/70 mm Hg, heart rate (HR) 90 beats/min, respiratory rate 18 breaths/min, BMI 29.

1. How will you use this information to prepare for today's visit?
2. What additional subjective data are you seeking?
3. What additional objective data will you be assessing for?
4. What are the differential diagnoses that you are considering?
5. What laboratory tests will help you rule out some of the differential diagnoses?
6. What is your treatment and specific information on the prescription you will give to this patient?
7. What are the potential complications from the treatment ordered?
8. What additional specific laboratory tests will you consider ordering?
9. What additional patient teaching may be needed?
10. What type of specialist will you be consulting for this patient?

CHAPTER 14

Renal and Urological Disorders

Laurie Kennedy-Malone

ASSESSMENT

Development of renal and urological conditions increases with age (Preminger, 2019). When assessing the renal and urological system, the practitioner needs to take into consideration the comorbidities that are often experienced by older adults, such as diabetes and hypertension, that can contribute to the development of kidney disease and alter urological function. Consider asking focused questions to determine changes in renal or urological system.

- Address urination pattern to include frequency, urgency, nocturia and incontinence.
- Determine whether there is any pain upon urination and the location of the pain.
- Inquire about the ability to start or maintain the stream of urine.
- Address the color of urine to include any evidence of blood.
- Assess daily fluid intake, including caffeine, and what time it is consumed.
- Note any medications that are either prescribed for or directly impact the renal or urological system.
- Inquire about family history of renal or urological disorders.

Pain that originates in the kidneys or ureters is often localized to the flanks or lower back and may radiate into the ipsilateral iliac fossa, upper thigh, testis, or labium. Typically, pain caused by obstructing calculi is colicky and may be prostrating; it is more constant if caused by infection (Capilouto & Williams, 2021). Patients with acute kidney injury may experience drowsiness, confusion, appear inattentive and speech may be slurred, whereas patients with chronic kidney disease often appear weak, experiencing malaise (Maddukuri, 2020a).

Acute urinary retention distal to the bladder causes agonizing suprapubic pain; chronic urinary retention causes less pain and may be asymptomatic. Dysuria is a symptom of bladder or urethral irritation. Prostatic pain manifests as vague discomfort or fullness in the perineal, rectal, or suprapubic regions. In men with bladder obstruction, a thorough history may reveal episodes of urinary hesitancy, straining, decrease in force and caliber of the urinary stream, and terminal dribbling. Incontinence has various forms in men (Andriole, 2020). If patients report passing air with urine, this is known as pneumaturia and could be a sign of vesicovaginal, vesicoenteric, or ureteroenteric fistula; Crohn's disease; abscess; colon cancer; or emphysematous pyelonephritis (Maddukuri, 2020b)

Health-Related Concerns of the Older Male

The genitourinary and reproductive systems of the older person assigned male sex at birth undergo more gradual changes. Pubic hair turns gray and becomes sparse. Penile size decreases slightly. Scrotal contents hang lower; the testes decrease in size and firmness, and less sperm are produced due to an increase in connective tissue in the tubules. Testosterone production declines slowly, resulting in slower arousal and more prolonged difficulty reaching orgasm. Ejaculation is less intense and shorter, with less seminal fluid and rapid detumescence. Prostatic tissue enlargement is common, frequently resulting in nocturia, urinary hesitancy, decreased urine flow, retention (sometimes with overflow incontinence), and less forceful ejaculation (Gunes et al., 2016).

When taking the history related to the genitourinary and reproductive systems of the older male patient, ask about difficulty urinating, hesitancy, decreased force of stream, frequency with decreased amount, dribbling, incontinence, or nocturia. If you suspect that the patient has developed benign prostatic hyperplasia, consider administering the American Urological Association Symptom Index (AUA-SI) which is an eight-item questionnaire addressing urological symptoms to determine the perceived severity of an enlarged prostate (Barry et al., 2017).

Ask about rashes or lesions that have developed or reoccurred. If nocturia is present, establish its onset and frequency, and explore possible contributing factors other than prostatic enlargement, such as sleep apnea, use of diuretics, caffeine or alcohol ingestion, increased fluid consumption in the evening, habit of frequent urination, mild heart failure, or dependent edema. Other pertinent questions concern such urinary symptoms as urgency, dysuria, hematuria, or documented urinary tract infection (UTI). Inquire about the older male's sexual health and, if he is experiencing erectile dysfunction (ED), whether he has sought any treatment (Savoy et al., 2020).

© F.A. Davis Publishing

Physical Examination of the Genitourinary System

The physical examination focuses on the skin, costovertebral angle, abdomen, rectum, groin, and genitals (Maddukuri, 2020a, 2020b). In women with urinary symptoms, pelvic examination is usually done, which is discussed in detail in Chapter 15, Gynecological Disorders.

Skin

For patients in whom you suspect chronic kidney disease, examine the skin for any evidence of xerosis due to sebaceous and eccrine sweat gland atrophy, any pallor due to anemia of chronic disease, hyperpigmentation due to increased melanin deposits, evidence of petechiae or ecchymoses due to platelet dysfunction or yellow to brown skin caused by urochrome deposits.

Costovertebral Angle

The costovertebral angle is formed by the 12th rib and lumbar spine. In severe infection, placing the palm of the hand on the area and applying pressure may be adequate to elicit pain. In other patients, pain may only occur with blunt striking of the back, flanks, and with a fist. Noted costovertebral tenderness may indicate pyelonephritis, calculi, or urinary tract obstruction.

Abdomen

While rare to view fullness of the upper abdomen, it can be a nonspecific finding of hydronephrosis or a kidney or abdominal mass. To test for bladder distension and urinary retention, percussion that elicits dullness suggests bladder distention. Under most circumstances even a full bladder cannot be percussed above the symphysis pubis (Maddukuri, 2020a) because over 1,000 mL of urine is required to result in a bladder extending above the symphysis pubis.

Prostate

Routine examination of the prostate is controversial, and there is limited evidence that it is useful in prostate cancer screening (Naji et al., 2018). For examination of the prostate through the rectum, the patient is placed in the left lateral decubitus position or standing and leaning forward over the examination table with toes pointed inward, for easier access to the anorectal area. The examiner uses a well-lubricated, gloved finger, advanced above the anal canal, to palpate the anterior wall of the rectum for the prostate gland. The gland is normally heart shaped with a central groove that can be felt. The normal surface is smooth, elastic, and nontender on palpation. Absence of the central groove in a smooth gland or protrusion of the gland more than 1 cm into the rectum is typical of benign prostatic hyperplasia (Andriole, 2020). A boggy, tender prostate is suspicious for prostatitis. A hard, irregular nodule may indicate carcinoma. Either finding requires further work-up.

Groin and Genitals

The inguinal canal is palpated for hernia and the inguinofemoral areas are palpated for lymphadenopathy. If an inguinal and/or genital hernia is suspected, the palpation should be done with patients standing. Inguinal hernia or adenopathy may explain scrotal or groin pain. The scrotum needs to be examined for any lesions and palpated for swelling or masses. Gross asymmetry, swelling, erythema, or discoloration of the testes may indicate infection, torsion, tumor, or other mass. Normally the left testicle is hanging lower than the right testicle; if elevation of one testis is noted, it may be indicative of testicular torsion (Marchese, 2016). Horizontal testicular lie (bell-clapper deformity) indicates increased risk of testicular torsion. Cremasteric reflex may be absent with testicular torsion (Mellick et al., 2021). Location of irregularities in relation to the testis and the degree and location of tenderness may help differentiate among scrotal irregularities (e.g., spermatoceles, epididymitis, hydroceles, tumors). If swelling is present, the area should be transilluminated to help determine whether the swelling is cystic or solid (Suneja et al., 2020).

The penis is examined with and without retracting the foreskin. Note if on the penis there are any lesions to include herpes simplex, chancre, or chancroid (Chipollini et al., 2019). If red, raised hyperkeratotic lesions on the scrotum are detected, consider Fordyce's disease, a benign condition. Look for evidence of intertrigo, which could be caused by *Candida* (Chipollini, 2019). Peyronie's disease can also be assessed with inspection of the penis. This disease results in fibrous plaques that can be felt in the penile shaft. If noted, inquire about any problems with priapism, curvature of erections, ulcers, and discharge.

ACUTE KIDNEY INJURY

Signal Symptoms: Decreased urine output, fatigue, anorexia, weakness, edema, pruritus

Description: Acute kidney injury (AKI) is defined as the abrupt loss and abnormality in kidney function over 6 hours to 1 week with a duration of less than 3 months (Levey, 2020). This decrease in estimated glomerular filtration rate (eGFR) leads to impaired control of acid-base balance and electrolytes and fluid balance. Acute renal disease (ARD) has been coined to define the continuing pathological processes and adverse events developing after AKI (Gameiro, 2018). According to the United States Renal Data System (USRDS) 2020 report, the rate of hospitalization of patients with AKI has increased by approximately 40% over the years of 2009–2018. Patients with AKI without prior diagnosis of chronic kidney disease (CKD) who were discharged alive from hospitalization had a 6-month probability of 0.4% of development of end-stage renal disease (ESRD) (USRDS, 2020). In patients with previous diagnosis of CKD who developed AKI, the 6-month probability of development of ESRD was 2.0% (USRDS, 2020). Patients hospitalized with AKI without pre-existing CKD survived for one year after discharge, the probability of being diagnosed with CKD within the year following discharge was nearly 50% (USRDS, 2020).

Etiology: Renal function with urine formation is based on four steps that occur in specific areas of the kidney. First, blood from the renal arteries is delivered to the glomeruli and filtered, resulting in an ultrafiltrate. The ultrafiltrate, free from protein and blood elements, then flows into the renal tubules, which reabsorb and secrete solute and/or water from the ultrafiltrate. The final tubular fluid, urine, leaves the kidney, draining through the renal pelvis and ureter and into the

© F.A. Davis Publishing

bladder, leaving the body through the urethra. Any disruption in the process of urine formation can result in the deterioration of renal function and AKI.

Further breakdown of the definition of AKI by Kidney Disease: Improving Global Outcomes (KDIGO) (2012) is any increase in serum creatinine (SCr) by greater than or equal to 0.3 mg/dL within 48 hours or increase in the SCr greater than or equal to 1.5 times baseline within the prior 7 days, or urine volume less than 0.5 ml/kg/hour for 6 hours. Serum creatinine is a by-product of muscle metabolism that is excreted unchanged by the kidneys. Changes in SCr and urine output are indicators of a change in eGFR. Normal eGFR varies according to age, sex, and body size. In young adults, it is 120 to 130 mL/min and declines with age starting after 40 years. Assessment of renal function is made by eGFR, and it is the most widely accepted and most useful overall index of kidney function (KDIGO, 2012). Patients who have extremes of muscle mass, such as the frail older adult, the critically ill, patients with cancer, body builders, or those with unusual diets, will have inaccurate eGFR. Creatinine clearance (CrCl), where urine is collected over 24 hours and the amount of creatinine is measured, is a better measurement in these patients and will give a much better indication of the GFR in patients recovering from AKI.

The RIFLE criteria (Risk, Injury, Failure, Loss and End Stage) were developed as a system of diagnosis and classification for the broad range of acute kidney impairment (KDIGO, 2012):

- **Risk:** 1.5-fold increase in SCr or 25% decrease in GFR, or urinary output <0.5 ml/kg/hr × 6 hours
- **Injury:** 2-fold increase in SCr or 50% decrease in GFR or urinary output <0.5 ml/kg/hr × 12 hours
- **Failure:** 3-fold increase in the SCr or 75% decrease in GFR, SCr >4.0 or acute rise in the Scr >0.5, urinary output <0.3 ml/kg/hr × 24 hours or anuria × 12 hours
- **Loss:** Complete loss of kidney function >4 weeks
- **End-Stage Renal Disease:** failure >3 months

Identification of the cause of AKI is important for proper management and treatment. Prerenal AKI is decreased renal perfusion precipitated by an abrupt change in volume status. Postrenal AKI is caused by obstruction in an area of the kidney that decreases elimination and removal of urine. Prerenal and postrenal causes can be determined by using fractional excretion of sodium (FENa), which measures the amount of filtered sodium in the urine. If the FENa is <1%, this indicates decreased perfusion to the kidney but no damage to the kidney because it is still able to absorb sodium and water. If the FENa is >2%, intrinsic or postrenal damage is indicated because the kidney is unable to hold onto to sodium and water. Postrenal AKI indicates obstruction of urine from the glomerulus into the bladder. Usually this can be caused by nephrolithiasis or an enlarged prostate but could also be caused by other conditions that would compress the ureter, such as pregnancy or abdominal tumor.

Occurrence: Although risk for AKI increases with age, it can occur at any age or ethnicity. Across age-groups, a higher percentage of men are affected by AKI than women (USRDS, 2020).

Age: Although AKI can occur at any age, its incidence is highly associated in patients 75 years of age or older (USRDS, 2020).

Ethnicity: Blacks were diagnosed with AKI 70% more frequently than Whites in 2018 (USRDS, 2020).

Contributing Factors: Patients with underlying CKD are more likely to develop AKI. The leading cause of CKD is diabetes, followed by hypertension. Having either condition or both increases the risk of the development of AKI. USRDS (2020) reports that 41.8% of patients hospitalized in 2018 had diabetes with CKD. Factors that predispose the patient to vascular diseases, such as smoking, hyperlipidemia, claudication, stroke, myocardial infarction, and atrial fibrillation, should be noted. Patients with new onset atrial fibrillation who are not anticoagulated are at high risk for renal artery emboli.

Prerenal AKI is a physiological response to renal hypoperfusion without tubular injury. It can be caused by depletion of intravascular volume resulting from vomiting, diarrhea, hemorrhage (either surgical or gastrointestinal [GI]), excessive diuresis, or burns. Sepsis, hypoxemia, anaphylactic shock, pancreatic disease, and liver disease will also cause AKI due to decreased intravascular volume. In addition, any condition that affects the renal vascular system, such as renal artery stenosis, renal vein thrombosis, hemolytic uremia syndrome, and sickle cell anemia will cause AKI. Medications, particularly cyclosporine, tacrolimus, angiotensin-converting enzyme (ACE) inhibitors, NSAIDs, radiopaque dye, and amphotericin, will also induce AKI due to reduction in renal blood flow.

Conditions that cause intrinsic AKI are focused on the area of the kidney that is damaged. This can be tubular damage, glomerular damage, interstitial damage, and vascular damage. The most common cause of damage to the structures of the kidney is prolonged hypoperfusion and destruction/damage to the cells by nephrotoxins. Vascular damage to the kidney caused by postinfectious or other type of glomerulonephritis leads to glomerular AKI. Interstitial damage is caused by systemic lupus erythematosus, sarcoidosis, certain viruses (Epstein-Barr, cytomegalovirus, and HIV), certain medications (NSAIDs, sulfonamides, proton pump inhibitors) and certain bacterial infections. Tubular damage can be causes by radiographic contrast dye, ethylene glycol, rhabdomyolysis, tumor lysis syndrome, and myeloma.

Postrenal causes of AKI include any condition in which there is an impediment of the excretion of urine anywhere from the collecting tubules to the urethra. In the tubules, crystal or protein particles can precipitate, causing obstruction. Ureteral obstruction can be caused by calculi, clots, fungus balls, tumors, or trauma. Bladder obstruction, either mechanical or chemical, will also cause postrenal AKI. Prostatic disease, either hypertrophy or cancer, is the most common type of postrenal AKI.

Signs and Symptoms: Predominant symptoms are usually those of the underlying illness or injury that precipitates the AKI. The patient may have symptoms directly resulting from alterations in kidney function, such as decreased urine output, flank pain, edema, or hypertension. The patient may have noticed a change in their urine consistency or color, such as foamy urine, which indicates proteinuria, or dark brown/red urine that could be indicative of red blood cells (RBCs). Patients may have nausea, vomiting, and diarrhea, leading to volume depletion. Specific questions regarding use of medications that can cause renal injury, including NSAIDs and antihypertensive medications such as ACE inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) and recent antibiotic use, need to be asked of the patient. Factors that predispose the patient to vascular disease and a detailed history of hypertension, diabetes mellitus, smoking, hyperlipidemia, claudication,

© F.A. Davis Publishing

stroke, myocardial infarction, and atrial fibrillation should be noted. In addition, ask patients whether they have experienced any fatigue, arthritis, weight loss, cough, hemoptysis, arthralgias, or sinus symptoms, which may indicate a systemic illness, such as vasculitis or systemic lupus erythematosus. Use of illicit drugs, such as cocaine, ecstasy, and heroin, can also cause AKI. In addition, questioning about past history of drug use, tattoos, and piercings, which increase the risk for hepatitis B, hepatitis C, and HIV, can lead to glomerular disease.

Recent imaging studies requiring the use of radiographic contrast agents should be explored due the increased incidence of development of AKI with these agents (Davenport et al., 2020). A past history of cancer, specifically prostate, cervical, or bladder cancer, could be indicative of obstruction of the urinary tract. Any family history of kidney disease increases the risk of a patient developing kidney disease in their lifetime. Patients with signs and symptoms of renal failure, such as weakness, easy fatigability, anorexia, altered mental status, weight loss, dysgeusia, nausea, cold intolerance, neuropathy, tremor, asterixis, seizures, and uremic fetor (where the patient has an ammonia-like or urine-like odor to the breath) may be suffering from ESRD and need to be admitted to the hospital for further evaluation and treatment.

Physical examination includes assessment of weight, orthostatic blood pressure, mucous membranes, and skin turgor and neck veins for the presence of volume depletion or overload. A funduscopic examination positive for atrioventricular nicking, exudates, or arterial narrowing is indicative of hypertension. Cardiac examination may reveal an S_3, indicative of volume overload or heart failure. The presence of a pericardial rub may indicate pericarditis, a late finding in ESRD. Lung assessment may reveal tachypnea and rales. Skin assessment should include inspection for any rash, skin lesions, livedo reticularis, or purpura that may indicate vasculitis or autoimmune disease. Periorbital, pretibial, and presacral edema can indicate advancing renal disease from any cause. Abdominal assessment should include auscultation for renal or abdominal bruits as well as evaluation for abdominal masses, costovertebral angle tenderness, and bladder distention. Assess for asterixis, a tremor of the wrist when it is extended, which is commonly seen in patients with ESRD.

Diagnostic Tests: Urinalysis is a noninvasive tool that can provide information regarding AKI. Urine is analyzed for sediment, specific gravity, urine sodium, urine protein, and urine creatinine levels. The appearance of certain urinary casts, cylindrical particles associated with certain diseases, assists in determination of the cause of the AKI. Specific gravity reflects the ability of the kidney to concentrate urine and can reflect a patient's volume status. To determine prerenal or postrenal AKI, FENa should be utilized. Further laboratory tests may show hyperkalemia, hypocalcemia, hyponatremia, and acidosis. A complete blood count (CBC) should also be drawn to evaluate for leukocytosis and anemia.

Radiographic studies are performed to assist in the diagnosis and cause of AKI. Renal ultrasound is most common and can be used to assess kidney size, obstruction, and the presence of masses. Upon imaging of kidneys with AKI, they are usually normal size. If masses are noted on the kidneys with ultrasound, an abdominal computed tomography (CT) scan will help to identify the lesion. Renal biopsy is only performed when laboratory data have been unrevealing and no reversible causes are identified as the cause of AKI. The procedure is performed percutaneously, and the most common complication is bleeding. Assessment of the patient's activated partial thromboplastin time (aPTT), prothrombin time (PT)/International Normalized Ratio (INR), and platelet count must be performed before the biopsy. Renal biopsy is avoided in patients who have a "solitary" kidney, either from congenital absence or acquired absence, such as nephrectomy for renal cell carcinoma.

Differential Diagnosis:
- Gastroenteritis
- Sepsis
- Glomerulonephritis
- Benign prostatic hypertrophy
- Nephrolithiasis
- Lupus nephritis
- Atypical hemolytic uremic syndrome

Treatment: Treatment is based on the cause of AKI. In volume depletion, fluid resuscitation with isotonic saline and/or packed RBCs is used to reestablish circulating volume. Vasopressors to maintain blood pressure may also be needed. Withdrawal of the offending medication and avoidance of other nephrotoxic agents is extremely important. Dose adjustment of renally metabolized medications is also warranted. Antihypertensive medications should be judiciously titrated to avoid any further renal hypoperfusion. In obstructive AKI, treatment of the obstruction often results in renal recovery. Usually, rapid correction of prerenal and postrenal causes leads to full recovery of kidney function. Avoid exogenous sources of potassium, such as nutritional supplementation and IV fluids. Treatment of hyperkalemia includes administration of IV calcium gluconate, insulin, beta-2 agonists (albuterol), dextrose, and potassium-removing agents. Hyperphosphatemia may also occur in AKI, and calcium acetate or calcium carbonate can be used to reduce absorption of phosphorus from the GI tract. Platelets are often dysfunctional in AKI, and desmopressin (DDAVP) may be required to activate platelets. Due to lower levels of circulating erythropoietin and decreased bone marrow responsiveness, anemia is often found in AKI, requiring transfusion of RBCs to increase oxygen-carrying capacity to the kidney.

If there is no recovery in kidney function after correction of the cause of the AKI, hemodialysis may need to be initiated. This is especially important in the face of continued acid-base disturbances, electrolyte abnormalities, volume overload, and uremia. The risk of developing ESRD is higher in patients who already have CKD and sustain dialysis-requiring AKI.

Follow-Up: Patients who are unable to fully recover to their previous level of kidney function will need to be closely monitored and followed by a nephrologist. Follow-up with a nephrologist 3 to 4 weeks after discharge to evaluate serum creatinine is important. Patients who have a new diagnosis of CKD stages 1 through 5 will require follow-up with a nephrologist for the remainder of their lives. For patients with concomitant conditions of hypertension, diabetes, and strict disorders, it is highly advised that current practice guidelines be followed.

Sequelae: CKD is a direct result of AKI because a return to previous level of kidney function is low. Patients with CKD are at increased risk for progression to ESRD, which requires renal replacement therapy. In addition, they are at increased risk for cardiac sequelae, including coronary artery disease,

© F.A. Davis Publishing

heart failure due to fluid overload, electrolyte derangements, cerebrovascular accident (CVA), and peripheral vascular disease. A nephrologist will manage comorbidities associated with CKD, including anemia of chronic disease, secondary hyperparathyroidism, and hypertension. Tight glycemic control will also assist to slow progression of CKD.

Prevention/Prophylaxis: Prevention of AKI begins first with identifying those at risk for CKD, especially patients with underlying diabetes and hypertension. Close monitoring of serum creatinine and urine for albuminuria is paramount. Prompt referral to nephrology when there is an increase in creatinine is important. Patients with a past history of AKI should be educated on the avoidance of nephrotoxic medications, such as NSAIDs and radiopaque contrast, to prevent further progression of kidney damage. Clinicians should ensure that medication dosages, especially those that are renally secreted, are adjusted appropriately for a patient's glomerular filtration rate once their new GFR baseline is determined following AKI.

Referral: Patients who have AKI are usually hospitalized for management of the cause of the AKI. Prompt evaluation and management by a nephrologist is warranted to prevent further kidney damage. After resolution of the AKI and discharge from the hospital, follow-up with a nephrologist is strongly encouraged for ongoing assessment and management of serum creatinine and eGFR until recovery or plateauing occurs. Patients may not return to their previous level of creatinine after an AKI event.

Education: Patients should be educated on signs of heart failure as well as avoidance of certain over-the-counter (OTC) medications that would precipitate AKI. Patients should be instructed to avoid diets high in salt and to strive for less than 2 grams of sodium per day (KDIGO, 2012). In addition, tight glycemic control, with hemoglobin A1c (Hb A1c) of less than 7%, as well as optimal blood pressure control of 120/80 mm Hg or less is paramount. Smoking cessation and maintenance of healthy body weight are also important in maintaining healthy kidney function.

BENIGN PROSTATIC HYPERPLASIA (BENIGN PROSTATIC HYPERTROPHY)

Signal Symptoms: Urinary frequency, nocturia, urgency, hesitancy, weak or intermittent urine stream, straining to void, sensation of incomplete voiding, dysuria, terminal dribbling, incontinence.

Description: Benign prostatic hyperplasia (BPH), also called benign prostatic hypertrophy, is the benign growth of the prostate that may lead to obstruction of the bladder outlet. Cellular elements of the prostate are involved, and dysfunction in normal cell apoptosis with excessive growth of epithelial and stromal cells within the prostate occurs (Ng & Baradhi, 2021).

Etiology: Originates in the transitional and periurethral zones of the prostate and is hormonally influenced by testosterone and dihydrotestosterone (DHT) production.

Occurrence: Occurs universally in older men; genetics is thought to play a part in males who develop it at a younger age.

Age: Seen in 50% of men older than 50 years and in 90% of men by age 85 years.

Ethnicity: A recent study found that Black men are significantly less likely than White men to undergo surgical treatment for lower urinary tract symptoms/BPH (Antoine et al., 2021).

Contributing Factors: Risk factors include age older than 40, metabolic syndrome, obesity, type 2 diabetes, genetic predisposition, high alcohol intake, and being inactive (Langan, 2019; Ng & Baradhi, 2021).

Signs and Symptoms: Lower urinary tract symptoms (LUTS) occur on a continuum and do not necessarily reflect the degree of prostatic enlargement. The onset of symptoms is gradual and includes increased frequency of urination, nocturia, hesitancy, urgency, and weak urinary stream. These

© F.A. Davis Publishing

symptoms are not specific for BPH and progress gradually over a period of years.

The American Urological Association (AUA) has developed a self-administered 8-measure Symptom Index (AUA-SI) helpful in addressing the occurrence and symptom severity (1 to 7 mild; 8 to 19 moderate; 20 to 35 severe) (Barry et al., 1992).

History elements should include:

- Urinary storage (frequency, urgency, nocturia), voiding symptoms (strength of stream, hesitancy, intermittency, straining to urinate), and post-void dribbling
- History of type 2 diabetes, which can cause frequency and diuresis
- Symptoms of neurological disease
- Sexual dysfunction, which is correlated with BPH
- Gross hematuria or pain in the bladder region suggestive of a bladder tumor or calculi
- Smoking history, which is a risk factor for bladder cancer
- History of bladder/prostate surgery, urethral trauma, urethritis, or urethral instrumentation that could lead to urethral stricture
- Family history of BPH and prostate cancer
- Treatment with drugs that can impair bladder function (anticholinergic drugs), increase outflow resistance (sympathomimetic drugs), or cause mobilization of fluids (diuretics)

Physical examination includes a digital rectal examination (DRE) and neurological assessment. The prostate may be enlarged or normal-sized. It should feel smooth, with a rubbery consistency and nontender. Nodularity or extreme hardness raises suspicions of malignancy whereas tenderness may indicate prostatitis. Prostate size does not correlate with degree of obstruction or severity of symptoms as the clinician cannot assess the periurethral zone where symptoms originate.

Diagnostic Tests: Urinalysis is recommended to rule out alternative diagnosis. If the urinalysis is positive for nitrates or large leukocytes and the patient has urinary tract infection (UTI) symptoms, a urine culture should be done. Ketones, blood, protein, or glucose could indicate other causes of the LUTS. Prostate-specific antigen (PSA) testing can be considered in those with a 10-year life expectancy and those patients who desire to be screened for prostate cancer. If screening is agreed upon, PSA is measured before starting a 5-alpha reductase inhibitor because this medication may lower future readings and can influence prostate cancer screening results. PSA may be elevated in BPH, prostatitis, acute urinary retention, catheterization, recent ejaculation, and prostate cancer (Ng & Baradhi, 2021). Creatinine and an ultrasound to check the bladder residual should be measured if renal insufficiency or obstructive uropathy is suspected. Upper tract imaging, transrectal ultrasound, flow studies, and cystourethroscopy are not indicated unless surgery is planned or there is a need to rule out other conditions.

Differential Diagnosis:

- Prostate cancer (may coexist with BPH)
- Bladder cancer
- Urethral stricture/bladder neck contracture
- Urinary infections (UTI, prostatitis)
- Cardiovascular disease (edema, diuretic use) can worsen urinary symptoms
- Neurogenic bladder
- Neurological disease causing voiding dysfunction (hyper/hypoactivity of the bladder, hypercontractility of the bladder neck)
- Endocrine disease (long-standing uncontrolled diabetes can cause decreased sensation, bladder underactivity, and incomplete bladder emptying; glucosuria can cause increased urine production worsening LUTS)
- Polydipsia from overintake of fluids

Treatment: For patients with mild symptoms and an AUA-SI score less than 8 or for those with moderate to severe symptoms who have not developed the complications of LUTS or bladder outlet obstruction (renal insufficiency, urinary retention, or recurrent infection), a program of watchful waiting and instruction to avoid medications known to worsen symptoms is prescribed (AUA Education and Research, Inc., 2010). Medication groups to be avoided include decongestants and other sympathomimetics and anticholinergics (Valladales-Restrepo & Machado-Alba, 2019). Patients should be instructed in lifestyle self-management such as limiting fluids in the evening, limiting alcohol and caffeinated beverages, Kegel exercises for urgency episode, timed voids, and double voiding to help with bladder emptying (Schreiber, 2017).

For mild-to-moderate symptoms, alpha-adrenergic blockers such as alfuzosin (Uroxatral), doxazosin (Cardura), terazosin (Hytrin), and tamsulosin (Flomax) relax smooth muscle of the bladder neck and prostate and can increase peak urinary flow rate; all alpha-adrenergic blockers are equally effective with symptom relief between 1 and 4 weeks (AUA Education and Research, Inc., 2010). Tapering terazosin, tamsulosin, and doxazosin as well as evening dosing minimizes postural hypotension. Those patients who are scheduled for cataract surgery in the next few months should not start an alpha blocker due to an increased risk of floppy iris syndrome. Alfuzosin has the lowest studied risk of causing floppy iris syndrome in the future (Silverstein, 2018). Dutasteride (Avodart) and finasteride (Proscar), and 5-alpha reductase inhibitors, block the conversion of testosterone to dihydrotestosterone, the major intraprostatic androgen in men, and are used when prostate enlargement is identified. Side effects include decreased libido, ejaculatory dysfunction, gynecomastia, and impotence. Treatment for 6 months or longer is needed for maximal benefit. Finasteride and an alpha blocker used concurrently slow the progression of BPH; the greatest effect is seen in patients with significantly enlarged prostates. Phosphodiesterase type 5 (PDE5) inhibitors have been shown to be beneficial with symptom relief. Tadalafil 5 mg has been approved for treatment of BPH/LUTS and is comparable in symptom relief to alpha blockers with rare side effects. In those patients with ED and BPH, this is a reasonable alternative to alpha blockers. Side effects are rare but can include headache, indigestion, back pain, flushing, and nasal congestion (Jung et al., 2017; Pattanaik et al., 2018). Tadalafil cannot be taken at the same time of day as an alpha blocker due to risk of hypotension.

For moderate to severe LUTS caused by BPH (AUA-SI score >20), surgery is an option. Surgery is recommended in those with renal insufficiency, recurrent UTIs, recurrent bladder stones, refractory urinary retention, or refractory gross hematuria (AUA Education and Research, Inc., 2018). In recent years, many treatments have proliferated in this category. Transurethral resection of the prostate (TURP) has been the standard for years, with open prostatectomy for glands of

© F.A. Davis Publishing

more than 40 g. Other treatment options include the transurethral incision of the prostate (TUIP) for gland enlargement of less than 30 g. Holmium laser enucleation (HoLEP), photoselective vaporization of the prostate (PVP), and thulium laser enucleation of the prostate (ThuLEP) use lasers for treatment of small to large prostates and in those patients who are at higher risk for bleeding. Urolift (prostatic urethral lift), which uses mechanical clips, and Rezum (water vapor thermal therapy), which uses steam to induce localized cell death, are newer options for those with smaller prostates (<80 g) that are sexual side effect sparing and can be done in the office with select patients. Aquablation is a newer therapy using high pressure water to resect the smaller prostate (30 to 80 g) that is done under general anesthesia but has limited data (Parsons et al., 2020).

Follow-Up: Scheduling of follow-up depends on the course of treatment. AUA symptom scores can assess treatments. Patients receiving alpha blockers should be followed in 2 to 4 weeks, whereas those started on 5-alpha reductase inhibitors should be seen in 6 months with a follow-up PSA if screening for prostate cancer. Depending on age, risk factors, and informed decision making regarding PSA testing (see prostate cancer section), consider annual PSA and DRE for prostate cancer. Annual urinalysis is typically done.

Sequelae: Untreated BPH can lead to urinary retention and bladder outlet obstruction requiring catheterization and/or surgery. Chronic issues can lead to renal insufficiency, UTIs, bladder stones, and bladder diverticula. Side effects of medical treatment include retrograde ejaculation, decreased libido, or orthostatic hypotension. Surgical sequelae can include retrograde ejaculation and urethral stricture.

Prevention/Prophylaxis: Prevention of obesity and diabetes can help reduce the risk of BPH.

Referral: BPH symptoms that do not respond to medical management, urinary retention, abnormality found on digital examination, incontinence, hematuria, and neurological disease that impacts LUTS should be referred to urology for evaluation. Consider collaborative management for drug therapy.

Education: Lifestyle measures to address include weight loss and diabetes control to reduce risks. Educate the patient about BPH and its treatment options and side effects. Instruct the patient to avoid any drugs that can increase retention or cause symptoms to flare up, including caffeine, alcohol, sedatives, over-the-counter (OTC) sleeping pills, and OTC cold and allergy remedies. Instruct the patient to report hematuria, UTI symptoms, or worsening LUTS. There is not enough evidence to support any herbal supplements for BPH.

Clinical Recommendation	Evidence Rating	References
Watchful waiting is an option; the need for medical treatment is based on symptoms (American Urological Association [AUA] symptom score) and the degree of patient bother.	C	AUA Education and Research, Inc. (2010)
Alpha-adrenergic antagonists are equally effective and work rapidly; patients can expect moderate improvement in symptoms.	A	Langan, 2019

BLADDER CANCER

Signal Symptoms: Painless hematuria (most common presenting symptom), urinary frequency or urgency, urinary tract infection (UTI), flank pain, mild suprapubic pain; often asymptomatic.

Description: The majority of bladder cancers are urothelial carcinoma or transitional cell; 1% to 2% are squamous cell cancer; and the rest are adenocarcinoma, small cell carcinoma, or sarcoma (American Cancer Society [ACS], 2021a). In bladder cancer, the posterior and lateral walls of the bladder are involved more frequently than the superior wall. Bladder cancer can be categorized as *superficial*, *invasive*, and *metastatic*. Superficial, or early, bladder cancer occurs when the lesion is located on the surface of the mucosa or when the tumor penetrates the mucosa and submucosa only. Invasive bladder cancer develops when lesions pervade the bladder muscularis or the perivesical fat. Metastatic bladder cancer is characterized by lymph node, visceral, or bone tissue involvement.

Etiology: Bladder cancer has been linked to smoking, chemical exposure, and exposure to certain medications such as

© F.A. Davis Publishing

cyclophosphamide (ACS, 2021b). Squamous cell bladder cancer has been linked to chronic infection with *Schistosoma haematobium* (Saginala et al., 2020).

Occurrence: In the United States, each year more than 83,000 new cases of bladder cancer are diagnosed, and more than 17,000 deaths can be attributed to bladder cancer. Bladder cancer is the sixth most common type of cancer (National Cancer Institute [NCI], 2021) and is almost three times more common in men than in women (National Comprehensive Cancer Network [NCCN], 2021).

Age: Median age of diagnosis is 73 years. Bladder cancer is rarely diagnosed in patients younger than the age of 40 years (NCCN, 2021).

Ethnicity: In the United States, White males have the highest risk, with roughly twice the incidence seen in African American and Hispanic men (NCI, 2021). The incidence in White and Black women is about the same. Hispanic women have a lower incidence compared with White and Black women (NCI, 2021).

Contributing Factors: Smokers are three times more likely to develop bladder cancer as compared with non-smokers. Some industrial chemicals have been linked with bladder cancer, including benzidine and beta-naphthylamine. Additionally, painters, machinists, printers, hairdressers, and truck drivers are at increased risk due to chemical exposure. Use of the medication pioglitazone has been linked with an increased risk of bladder cancer. Dietary supplements that contain aristolochic acid have been associated with urothelial cancers. Infections of the urinary tract, long-term indwelling catheters, renal and bladder stones, and chronic bladder irritation have been linked to bladder cancer (ACS, 2021b). Family history of bladder cancer can also increase risk. Family members may share some changes in the *GST* and *NAT* genes. Inherited genetic syndromes such as Lynch's syndrome, Cowden's disease, and a mutation in the retinoblastoma gene (*RB1*) can also increase the risk (ACS, 2021b; Saginala et al., 2021). Pelvic irradiation, certain drugs (e.g., cyclophosphamide) can contribute to the development of bladder cancer. *S. haematobium* infection is prevalent in Africa and the Middle East and has been associated with the development of bladder cancer (Saginala et al., 2020).

Signs and Symptoms: Gross, painless hematuria, pyuria, burning, and urinary frequency are common in the presentation of bladder cancer. The presence of unexplained hematuria in a patient older than 40 years denotes urothelial cancer until proved otherwise. Symptoms of advanced cancer may include pelvic or flank pain and lower extremity edema, resulting from lymphatic or venous blockage. Patients also may complain of abdominal pain, anorexia, and bone pain.

The physical examination may be normal in most patients; however, the clinician should palpate the pelvic area to identify a solid pelvic mass, palpate and percuss for evidence of any kidney enlargement, and perform a prostate examination on men and a pelvic examination on women. Additionally, the examination should be directed toward searching for possible sites of metastasis in the lungs, liver, bone, and lymph nodes.

Diagnostic Tests: Cystoscopy is the gold standard for the initial diagnosis and staging of bladder cancer (NCCN, 2021). Cytology should also be considered. Examination under anesthesia (EUA) should be performed to determine whether or not a palpable mass is present and, if present, whether or not it is mobile. An EUA during cystoscopy is effective at identifying locally advanced disease, which may present as gross extravesical extension, invasion of adjacent organs, or pelvic sidewall involvement. If a mass is felt, the bimanual examination is repeated after the resection to see if it is still present. Urine biomarkers may be checked through a few commercially available tests. Advantages of these tests include high sensitivity, but these tests are also associated with higher costs (Zhu et al., 2019).

Imaging studies may be used to define the location and the extent of the tumor, as well as to detect sites of multifocal disease. A computed tomography (CT) scan of the abdomen and pelvis should be performed with and without contrast, including delayed images to identify defects in the collecting system. Although CT scan provides better visualization of tumors than ultrasound, it may miss tumors less than 1 cm in size, particularly those in the bladder trigone or dome, and it cannot differentiate depth of bladder wall invasion (i.e., mucosal versus lamina propria or muscularis propria). Magnetic resonance imaging (MRI) may be considered in patients with poor renal function or in patients with iodinated contrast allergy. A positron emission tomography (PET) scan may be performed in patients with at least cT2 disease or in high-risk patients in whom metastatic disease is suspected. MRI of the brain with and without contrast is reserved for patients who are symptomatic or with small cell histology (NCCN, 2021).

Differential Diagnosis:

- Neurogenic bladder
- Nephrolithiasis
- UTI
- Benign prostatic hypertrophy
- Other genitourinary cancers (Perazella, 2021)

Treatment: Management of bladder cancer depends on the stage of the disease. Neoadjuvant chemotherapy, concurrent chemoradiation therapy, or adjuvant chemotherapy may be given to patients who are a candidate for cystectomy. Patients who are not candidates for cystectomy may be given concurrent chemoradiation therapy or radiation alone. Checkpoint inhibitors are recommended as second-line therapy (NCCN, 2021). Advanced disease generally requires surgery, radiation, and chemotherapy with combination agents. The patient's age and health status at the time of diagnosis must be considered in the management of bladder cancer (NCCN, 2021).

Follow-Up: Patients with superficial low-grade bladder cancer require a cystoscopy at designated intervals, although the value of repeated testing has been questioned. The need for supplemental nutritional support, pain management, prevention of complications such as skin breakdown, and an advance directive should be discussed during future follow-up care. Patients with a urostomy may need assistance from an ostomy nurse.

Sequelae: Metastasis to other parts of the body can occur. Survival of the untreated patient may be less than 2 years.

Prevention/Prophylaxis: Encourage patients who smoke to quit and exhort all patients to decrease exposure to harmful chemicals.

© F.A. Davis Publishing

Referral: Refer patients with clinically significant hematuria to a urologist. An oncologist also may be involved in the patient's management of the disease. Patient and family support is important at this time; information pertaining to hospice services should be provided. Patients with a urostomy may seek support from a local chapter of the United Ostomy Associations of America (UOAA) at 1-800-826-0826 or https://www.ostomy.org/.

Education: Older adults with bladder cancer may need to be educated about palliative support measures with a diagnosis of metastatic bladder cancer or when the disease becomes terminal.

CHRONIC KIDNEY DISEASE

Signal Symptoms: Fatigue, anorexia, altered mental status, weakness, dysgeusia, pruritis, nausea, vomiting, edema.

Description: Chronic kidney disease (CKD) continues to be a growing worldwide problem. According to Centers for Disease Control and Prevention (CDC) data, more than 1 in 7 Americans, or around 35 million people, have CKD in the United States (CDC, 2021). CKD, when left undiagnosed and untreated, will progress to end-stage renal disease (ESRD), requiring renal replacement therapy in order for the patient to survive. With the increased prevalence of diabetes and an aging population, incidence of CKD will continue to rise. Early detection of CKD remains paramount to decrease the progression to ESRD. CKD is a silent disease, and often patients are unaware they have it until it is too late.

Etiology: CKD is defined as abnormalities of kidney structure or function, present for more than 3 months (Kidney Disease: Improving Global Outcomes [KDIGO], 2012). This can be from long-term diseases, such as diabetes or hypertension, or by the development of acute kidney injury (AKI). Decrease in glomerular filtration rate (GFR) and the presence of albuminuria are indicative of kidney damage. Certain markers, such as urine sediment abnormalities, electrolyte abnormalities, abnormalities noted on imaging, can also be noted with CKD (Table 14-1). Criteria for defining CKD are shown in Box 14-1.

Diabetes continues to be the leading cause of CKD, followed by hypertension (United States Renal Data System [USRDS], 2020). Other causes of kidney disease include glomerulonephritis, inherited polycystic disease, autoimmune diseases, infections, excessive use of nephrotoxic medications, and urological diseases.

TABLE 14-1 Markers for Kidney Damage

Markers of kidney damage (one or more)	Albuminuria (AER ≥30 mg/24 hr; ACR ≥30 mg/g [≥3 mg/mmol])
	Urine sediment abnormalities
	Electrolyte and other abnormalities due to tubular disorders
	Abnormalities detected by histology
	Structural abnormalities detected by imaging
	History of kidney transplantation
Decreased GFR	GFR <mL/min/1.73 m² (GFR categories G3a–GS)

AER, albumin excretion rate; ACR, albumin-to-creatinine ratio; GFR, glomerular filtration rate

Reprinted with permission from Kidney Disease: Improving Global Outcomes (KDIGO) CKD Work Group. (2013). KDIGO 2012 clinical practice guideline for the evaluation and management of chronic kidney disease. Kidney International, *3(1), 1–150.*

Occurrence: According to CDC data, more than 1 in 7 Americans, or around 35 million people have CKD in the United States (CDC, 2021). CKD affect more females than males (USRDS, 2020).

Age: Although CKD can affect any age-group, CKD is four times more prevalent among older (aged greater than or equal to 65) than younger individuals (USRDS, 2020). Despite being more prevalent in the older population, CKD

© F.A. Davis Publishing

BOX 14-1
Criteria for Definition of Chronic Kidney Disease

- Duration greater than 43 months (documented or inferred)
- Glomerular filtration rate (GFR) <60 mL/min/1.73 m^2 (GFR categories G3a–G5)
- Evidence of kidney damage from structural abnormalities or functional abnormalities other than decreased GFR, such as albuminuria, urinary sediment abnormalities, renal tubular disorders, or pathological abnormalities

Source: KDIGO, 2013

has actually decreased in this age-group since 2003–2006 (USRDS, 2020).

Socioeconomic Factors: Prevalence of CKD is higher among individuals with lower income: 17.4% of those below the poverty line versus 14.4% among those above (USRDS, 2020). It also affects those with lower education: 17.2% among those with less than a high school education compared to 13.1% with some college (USRDS, 2020).

Geographic Location: CKD was least prevalent in the states of Wyoming, Alaska, and Vermont and most prevalent in the states of Louisiana, Alabama, Florida, and Hawaii (USRDS, 2020).

Ethnicity: Blacks have a higher prevalence of CKD than Whites, according to USRDS data. Hispanics/Latino Americans continue to have the lowest incidence of CKD.

Contributing Factors: Diabetes mellitus is the leading cause of CKD and is the leading risk factor in the development of CKD. Hypertension, both a cause and a consequence of renal disease, closely follows. Autoimmune disorders, such as systemic lupus erythematosus, and malignancy, such as renal tumors or multiple myeloma, also increase the risk of kidney dysfunction. Vascular disease, chronic pyelonephritis, nephrolithiasis, systemic infections, and gout will also predispose a patient to chronic kidney disease. Certain medications, such as NSAIDs, especially when used in excessively high doses, will cause CKD. Radiopaque dye will also cause kidney damage, either leading to AKI or further accelerating CKD. AKI often predisposes a patient to the development of CKD. A family history of renal disease is an important risk factor in the development of CKD. People of color have an increased risk of CKD and are more likely to progress from CKD to ESRD. In addition, the presence of inherited disease, such as autosomal dominant polycystic kidney disease, will lead to development of CKD.

Exposure to toxins can also play a role in the development of CKD. Exposure can be occupational, environmental, or recreational. There is a strong association between smoking and development of CKD. Chronic smoking causes nephrosclerosis, which is caused by microvascular atherosclerosis, resulting in hypertension. Illicit substances associated with CKD include heroin and cocaine. Recently, methamphetamines and ecstasy use have been associated with CKD. Methamphetamines cause accelerated hypertension, causing renal damage. Ecstasy use can lead to rhabdomyolysis, drug-induced vasculitis, and severe hyponatremia. Cocaine use is associated with acute rises in blood pressure, leading to AKI from hypertension. Rhabdomyolysis, either drug or exercise-induced, will cause kidney damage. Transmittable disease, such as hepatitis and HIV, will also cause kidney damage leading to CKD. Exposure to heavy metals such as lead, cadmium, mercury, and organic solvents has been strongly linked to CKD; thus, screening for occupational hazards is a must.

Signs and Symptoms: CKD is a silent disease and does not produce symptoms until renal injury is quite advanced. Many individuals are unaware that they have CKD until it progresses to stages 3 or 4. In stages 1 and 2, blood urea nitrogen (BUN) and creatinine levels are normal or nearly normal, and acid-base, fluid, and electrolyte balances are maintained through the adaption of remaining nephrons. In stage 3, there is moderate impairment of GFR, and BUN and creatinine levels begin to increase. The patient usually remains asymptomatic, but levels of erythropoietin and parathyroid hormone are abnormal. Early symptoms of kidney disease, if any, may be similar to other illnesses. Only when the patient develops stage 4 or 5 of kidney disease do more profound symptoms of CKD occur. These include fatigue, loss of appetite, weight loss, dyspnea, anascara, confusion and difficulty with concentration, pruritus, dysgeusia, and foul-smelling breath (KDIGO, 2012).

Although diagnosis of kidney disease is based heavily on laboratory data and diagnostic imaging, a careful and through history may lead to clues associated with the diagnosis of CKD. Careful review of any kidney disease in the family is imperative, including questions relating to any hereditary diseases, such as autosomal dominant polycystic kidney disease. If the patient has a past history of pregnancy, ask whether there were any complications, including proteinuria, pre-eclampsia, or gestational diabetes. Any past urological conditions could indicate postrenal causes of CKD.

Any history of diabetes mellitus or hypertension should immediately raise a strong suspicion for the presence of CKD. In addition, cardiac issues such as heart failure and liver issues such as cirrhosis can lead to cardio-renal and hepato-renal disease. Disorders of the urinary tract, recent systemic infections, unusual rashes, or skin lesions should also raise suspicion of CKD. A through medication history should also be obtained to identify medications that may be contributing or causing CKD.

Diagnostic Tests/Tools: As stated previously, estimation of GFR is the best indicator to level of kidney function and functioning renal mass (KDIGO, 2012). There are varying stages of estimated GFR (eGFR) which indicates the degree of kidney damage. Albuminuria is a defining marker of renal injury regardless of GFR, often occurring before any rise in serum creatinine.

Spot urine albumin/creatinine ratio is the preferred screen as it detects lower levels of proteinuria. Low levels of proteinuria (30 to 300 mg) were once thought to be insignificant, but it is now known that modest albuminuria is significant for CKD. Severe albuminuria is significant for increased mortality and ESRD. Dipstick urinalysis should not be used for screening. eGFR and albuminuria should be assessed yearly in patients with CKD and with increased frequency in those patients who have high risk of rapid progression of CKD.

© F.A. Davis Publishing

There are number of equations that are utilized to determine eGFR based on serum creatinine. The Cockcroft Gault equation is used to estimate GFR to determine dosing of medications. The Modification of Diet in Renal Disease study equation was developed in 1999 and is the current recommended eGFR calculator for reporting in adults (KDIGO, 2012). It uses serum creatinine, age, sex, and race for estimation of GFR based on body surface area (BSA). The Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation was developed in 2009 and the uses the same four variables as the Modification of Diet in Renal Disease equation but has less bias and greater accuracy at higher eGFR. The CKD-EPI equation is currently utilized by clinic laboratories in the United States for GFR reporting and is recommended by KDIGO to be used for calculation of eGFR. In addition, serum cystatin C is a filtration marker that has emerged as an alternative to serum creatinine. It has been found to more accurately estimate eGFR because it reaches a steady state much faster than creatinine. It is often used when there is a decreased eGFR without the presence of structural disease, risk factors for CKD, or albuminuria (Gaitonde et al., 2017). eGFR in CKD patients is more accurate because of their steady state of kidney function. AKI often has every fluctuating eGFR as the kidney recovers from the damage. A creatinine clearance (CrCl), in which a volume of urine is collected over 24 hours and the amount of creatinine secreted is measured, is a more accurate indicator of eGFR because it is a direct measurement.

Other markers are also used to determine damage to kidneys, such as abnormalities in urinary sediment and abnormal findings on imaging studies. Examination of the urinary sediment for white blood cells (WBCs), red blood cells (RBCs), or casts may indicate the presence of acute kidney disease (AKD) or CKD and requires further investigation. Imaging studies should also be performed to suggest the cause of CKD. Ultrasound examination may indicate the presence of kidney stones, hydronephrosis, cysts, or masses. Small kidneys on ultrasound suggest CKD, whereas "large" kidneys may indicate tumors, cysts, or infiltrating diseases. A computed tomography (CT) scan may reveal tumors, obstructions, cysts, or calculi.

Further laboratory data that should be assessed in patients with possible CKD include complete blood count (CBC) and electrolytes. Fasting lipids and hemoglobin A1c (Hb A1c) should be evaluated in patients with diabetes. Serum and urine protein electrophoresis, complement levels, antineutrophil cytoplasmic antibody, antinuclear antibody, and viral studies (including hepatitis B and C and HIV) should also be performed.

Differential Diagnosis:

- AKI
- Cirrhosis
- Uropathic obstruction
- Nephrotic syndrome
- Tubulointerstitial disease

Treatment: Referral to a nephrologist should occur if (1) GFR is less than 30 mL/min, (2) there is a decline in GFR greater than 3 mL/min, (3) albuminuria is present, (4) it is difficult to control hypertension, and (5) there is unexplained anemia with GFR less than 60 mL/min (Gaitonde et al., 2017). Further investigation using the previous diagnostic tests will assist the nephrologist in the determination of the cause of the CKD. A patient may also have to undergo renal biopsy to fully determine the level of severity/damage the illness has caused as well as to obtain a definitive diagnosis. Once the stage of CKD is identified, management of CKD is aimed primarily at preventing progression of the disease through medications, risk factor reduction, lifestyle changes, and education of the patient and family regarding kidney disease. Eventually there is decline in kidney function to ESRD. Patients then must decide between renal replacement therapy—hemodialysis or peritoneal dialysis—in order for the patient to survive or opt for no renal replacement therapy and end-of-life care.

Patients with CKD have a greater risk for cardiovascular disease than those without. As stated previously, hypertension is both a cause and a sequela of kidney disease. It is associated with a faster decline in kidney function by increasing albuminuria and furthering the development of cardiovascular disease. Thus, reducing the risk of progression of CKD and advancement of cardiovascular disease is paramount. Reduction of blood pressure to target levels is the most important treatment step in managing CKD. Patients who are at greatest risk for complications or already have evidence of cardiovascular disease may need more aggressive blood pressure control, ideally in the 120/80 mm Hg or less range.

Multiple medications are frequently required in CKD patients to achieve goal blood pressure. Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin-receptor blockers (ARBs) are first-line treatment in patients with CKD and increased albuminuria, with or without diabetes. These agents reduce albuminuria and slow the rate of decline in kidney function in both diabetic and nondiabetic kidney disease. When beginning a patient on an ACEI or ARB, serum creatinine and serum potassium should be measured within 2 to 4 weeks after initiation or increase in either the ACEI or ARB dosing (KDIGO, 2021). Continue the ACEI or ARB therapy unless serum creatinine rises by more than 30% within 4 weeks of initiation of treatment or increase in dose (KDIGO, 2021). Consider dose reduction or discontinuation of the ACEI/ARB with symptomatic hypotension or uncontrolled hyperkalemia (KDIGO, 2021). Furthermore, sodium restriction of less than 2 g per day is recommended for blood pressure control (KDIGO, 2021) and moderate-intensity physical activity greater than or equal to 150 minutes per week is also recommended.

Increased salt and water retention occur with CKD leading to edema, necessitating initiation of a diuretic. Thiazide diuretics often become less effective as GFR falls below 40 mL/min due to decreased renal blood flow. Usually a loop diuretic, such as furosemide, torsemide, or bumetanide, is used. Side effects of loop diuretics include hypokalemia and hypomagnesemia, which can lead to increased cardiovascular risk of arrhythmias. Thus, serum electrolytes should be monitored, and the patient should be instructed to report any paresthesias, rash, or tinnitus.

Calcium channel blockers (CCBs) are effective agents that can be used to lower blood pressure in CKD patients; however, there are differences between these medications' effects on reducing proteinuria. Nondihydropyridine CCBs (verapamil, diltiazem) reduce proteinuria among patients with advanced nephropathy, whereas dihydropyridine CCBs (nifedipine, felodipine, amlodipine) will not have this effect unless coupled with an ACEI or ARB. The major side effect of CCBs is lower extremity edema, which is usually not resolved with the addition of diuretic.

© F.A. Davis Publishing

Beta blockers such as carvedilol, metoprolol, or bisoprolol should be used in patients with CKD when a proper dose of ACEI, ARB, or CCB is not enough to lower blood pressure. Although these agents do not provide any renoprotective effects, they do assist in reducing cardiovascular mortality in high-risk patients. Beta blockers should be avoided in patients with bradycardia or heart block.

Central alpha-adrenergic agonists decrease the effects of sympathetic activity to lower blood pressure. Vasodilators such as hydralazine and minoxidil are often used as fourth-line agents when other antihypertensive treatments have failed. Vasodilator therapy does not reduce proteinuria and has not been shown to improve renal outcomes. Side effects of minoxidil include increased hair growth and risk of pericardial effusion. Hydralazine is the leading cause of drug-induced lupus syndrome and should be avoided in any patient with an autoimmune disease.

Tight glycemic control in CKD patients reduces cardiovascular disease and CKD progression risk in both type 1 and 2 diabetes mellitus. An Hb A1c of less than 7.0% is the goal of patients with diabetes and CKD (KDIGO, 2020). Although achieving this can be difficult for some patients and is associated with increased risk of hypoglycemia, tight control reduces not only albuminuria but also retinopathy and neuropathy. Patients with type 2 diabetes mellitus and CKD should first be treated with metformin and sodium-glucose cotransporter-2 inhibitor (SGLT2i) (KDIGO, 2020). If eGFR is less than 30 ml/min, then these should be discontinued (KDIGO, 2020). Insulin can be used to treat diabetes in CKD, and doses should be tailored to attain the goal Hb A1c while avoiding hypoglycemia. Insulin types and doses should be individualized to each patient and to the patient's level of CKD. If a patient is unable to achieve glycemic targets despite use of metformin and SGLT2i, KDIGO (2020) recommends use of glucagon-like peptide 1 (GLP-1).

Anemia is a common complication of CKD. It worsens as kidney function declines, becomes prevalent in CKD stage 3, and continues through stage 5 into ESRD. The primary cause of anemia is decreased secretion of erythropoietin from decreased functioning renal cells, resulting in fatigue, decreased exercise capacity, decreased cognition, and impaired immunity, leading to decreased quality of life. Workload of the heart is increased with anemia, leads to left ventricular hypertrophy and cardiomyopathy, and increases the patient's risk of death from ischemic heart disease and heart failure. Evaluation of patients with CKD and anemia, regardless of age or CKD stage, should include iron complete blood count, reticulocyte count, iron studies, serum ferritin, serum transferrin saturation, serum B_{12}, and folate level (KDIGO, 2020). Iron can be given either orally or intravenously. IV is usually reserved for severely depleted patients and those on hemodialysis. Erythropoietin-stimulating agents (ESA) can be given once iron deficiency is corrected, other causes of anemia have been excluded or treated, and hemoglobin is consistently below 10 g/dL. Epoetin alfa, darbepoetin alfa, and methoxy polyethylene glycol-epoetin beta are erythropoietin receptor activators for the treatment of anemia associated with CKD. All correctable causes of anemia should be addressed prior to initiation of ESA therapy (KDIGO, 2020).

Changes in mineral metabolism and bone structure begin early in CKD. This not only encompasses bone disease but also vascular and soft tissue calcification. As kidney function worsens and GFR continues to decline, the kidney must work harder to excrete phosphorus. This then reduces the formation of the active form of vitamin D (1,25D). Low levels of 1,25D, coupled with low serum calcium levels from decreased gut absorption, lead to a rise in parathyroid hormone. This leads to secondary hyperparathyroidism due to hypocalcemia, hyperphosphatemia, and low 1,25D levels. The increased parathyroid hormone affects bone metabolism and increased bone turnover, causing decreased cortical bone and bone strength. This increases risk of fracture and causes increased "bone pain" in patients with CKD. Development of secondary hyperparathyroidism can be decreased by dietary restriction of high-phosphate foods such as fast food, dairy products, colas, and processed food products. A phosphate binder, which binds to the phosphate in food and is eliminated in the bowel movement, is also prescribed. Calcium acetate, lanthanum carbonate, sevelamer carbonate, sucroferric oxyhydroxide, and ferric citrate are the common phosphate binders used today. Patients who have high levels of parathyroid hormone should be assessed for hyperphosphatemia, hypocalcemia, high phosphorus intake, and vitamin D deficiency (KDIGO, 2017).

Patients with CKD are also at increased risk for malnutrition and hypoalbuminemia. These are associated with poor outcomes when the time comes for the patient to initiate dialysis. The restriction of protein in the CKD population has been a topic of ongoing debate. Current recommendations from KDIGO (2012) include a protein intake of 0.8 g/kg/day in patients with CKD. Patients need to be monitored for malnutrition with serum albumin levels and body weight assessments.

Smoking cessation is strongly encouraged in patients with CKD. Smoking compounds the risk for cardiovascular mortality in patients with CKD and hastens progression of kidney disease. Smoking risks and smoking cessation should be addressed with each office visit.

Unfortunately, despite optimal treatment and practices by the patient, kidney disease may continue to progress until kidney failure occurs. Patients then develop uremia, which is the accumulation of toxins within the blood. This leads to anorexia, nausea, vomiting, asterixis, muscle weakness, platelet dysfunction, pericarditis, mental status changes, and possibly coma. At this point, dialysis is initiated to "clean" the blood of these toxins and will need to continue throughout the patient's lifetime.

Follow-Up: Care of the patient with CKD is in the hands of the nephrologist for the rest of the patient's life span. Unfortunately, timely referral to help keep the patient from progression to ESRD is often not done. In addition, some patients are not aware that they have CKD. It has been found that the worse the patient's kidney function is, the more aware they are of their disease (CDC, 2012). According to Levin et al., (2013), any patient with the following criteria should be referred to nephrology for further evaluation:

- AKI or abrupt sustained fall in GFR
- eGFR less than 30 mL/min/1.73 m^2
- A consistent finding of significant albuminuria (albumin-to-creatinine ratio greater than 300 mg/g [greater than 30 mg/mmol]) or albumin excretion rate greater than 300 mg/24 hours

© F.A. Davis Publishing

- Progression of CKD
- Urinary red blood cell (RBC) casts, RBC 420 per high-power field sustained and not readily explained
- CKD and hypertension refractory to treatment with four or more antihypertensive agents
- Persistent abnormalities of serum potassium
- Recurrent or extensive nephrolithiasis
- Hereditary kidney disease

The goal of the nephrologist is to avoid any further progression of CKD. Tight glycemic control, optimal blood pressure control, dietary phosphate restriction, and management of anemia are paramount. Patient education of CKD continues with every office visit as well. In addition, once the patient reaches stage 4, options classes are held with the family and the patient to discuss dialysis modalities (i.e., peritoneal dialysis or hemodialysis). Patients with CKD with GFR <30 mL/min who are expected to reach ESRD should be informed, educated, and referred for kidney transplantation regardless of socioeconomic status, sex, gender identity, or race/ethnicity (Chadban et al., 2020). If the patient chooses not to proceed with dialysis, referral should be made for palliative care to discuss end-of-life decisions.

Sequelae: The major sequela of CKD is ESRD. In addition, CKD is associated with an increased risk of cardiovascular disease. Thus, lifestyle changes, such as maintaining healthy body weight, restriction of salt and high-fat diet, active participation in an exercise program, smoking cessation, limited alcohol intake, and tight glycemic and blood pressure control are important, not only to reduce cardiac risk, but also to slow progression of kidney disease. For older adults with CDK and diabetes mellitus, there is an increased risk of developing cognitive impairment, dementia, sarcopenia, and frailty (Clemens et al., 2019).

Prevention/Prophylaxis: Early screening for albuminuria in patients at risk for CKD is paramount. In addition, risk factors associated with CKD, including level of GFR, level of albuminuria, age, sex, race/ethnicity, elevated blood pressure, hyperglycemia, dyslipidemia, smoking, obesity, history of cardiovascular disease, ongoing exposure to nephrotoxic agents, and others, should not be ignored (KDIGO, 2012). Tight glycemic control, optimal blood pressure control, tobacco cessation, low-salt diet, avoidance of nephrotoxic medications, and maintaining optimal weight with healthy lifestyle all assist in reducing the risk of CKD.

Referral: All patients with CKD should be referred to a nephrologist for ongoing monitoring.

Education: Patients with CKD are educated regarding their disease and the manifestations of this disease. Continued education regarding low-sodium and low-protein diet, compliance with medications, tight glycemic control, and avoidance of NSAIDs and contrast dye is important. Patients are encouraged to continue to follow up with their primary care physician for other aspects of their health care.

CYSTITIS

Signal Symptoms: Dysuria, frequency, urgency, suprapubic tenderness, hematuria, new or worsening incontinence (Godbole et al., 2020). Fever and systemic symptoms usually are absent in infection limited to the lower tract.

Description: Cystitis is a pathogenic invasion of the mucosal wall of the bladder, causing an inflammatory reaction. It results from an ascending infection via the urethra of bowel flora organisms from the perineum (Cortes-Penfield et al.,

© F.A. Davis Publishing

2017). Cases of cystitis are classified as complicated or uncomplicated. Uncomplicated cases (the focus of this entry) are defined as acute genitourinary symptoms with evidence of pyuria and bacteriuria in a nonpregnant person with no history of abnormal urinary tract anatomy or function (Ashraf et al., 2020; Medina & Castillo-Pino, 2019). Complicated cystitis occurs in individuals whose urinary tract does not function properly due to structural or functional abnormalities. Many diseases and genitourinary interventions such as obstructive lesions, instrumentation, foreign bodies, and neurological diseases are contributing factors in complicated cystitis. In the older adult, there is considerable variation in the clinical characteristics of cystitis.

Asymptomatic bacteriuria (ASBU) is the presence of one or more species of bacteria growing in the urine at specified quantitative counts ($\geq 10^5$ colony-forming units [CFU]/mL or $\geq 10^8$ CFU/L), irrespective of the presence of pyuria, with no corresponding urinary tract symptoms. This condition is prevalent in older adults, especially those who live in nursing homes (Cortes-Penfield, 2017; Henderson et al., 2019; Nicolle et al., 2019). The U.S. Preventive Services Task Force (USPSTF), American Urological Association (AUA), and Infectious Disease Society of America (IDSA) have found that evidence does not support the routine screening of nonpregnant adults for ASBU and that no benefit is derived from it (Ashraf et al., 2019; Henderson, et al., 2019; Nicolle et al., 2019). Differentiating between ASBU and urinary tract infection (UTI) is a challenge in the older adult. In long-term care facilities, it is quite common to misdiagnose ASBU as a UTI. In cases where a urine culture is positive without urinary symptoms, it is recommended to evaluate for other causes before initiating antibiotics (Cortes-Penfield, 2017; Nicolle et al., 2019).

Etiology: The most common organism identified in the older adult with cystitis is *Escherichia coli* (Ashraf et al., 2019; Nicolle et al., 2019). Other commonly isolated organisms include *Klebsiella, Proteus*, and *Enterococcus* species, which are found in nursing home residents (Cortez-Penfield et al., 2017; Godbole et al., 2020; Scott & Liang, 2021). Older adults with indwelling catheters or anatomical abnormalities are susceptible to UTIs that are caused by gram-negative rods (*Proteus, Klebsiella, Serratia*, and *Pseudomonas*) (Medina & Castillo-Pino, 2019). It is not uncommon with indwelling catheters to isolate more than one species in a urine culture. The prevalence of multidrug-resistant organisms is higher in long-term care residents and is attributed in part to more frequent and inappropriate use of antibiotics (Scott & Liang, 2021).

Occurrence: UTIs cause 15.5% of hospitalizations and 6.2% of deaths attributable to an infectious disease in patients older than the age of 65 years (Biggel et al., 2019). Approximately 50% of antimicrobial use in hospitals and up to 75% of antibiotic use in long-term care facilities may be inappropriate or unnecessary (Morrill et al., 2016; Muhammad, 2020).

Age: Incidence of UTI increases with age but is difficult to calculate due to ASBU.

The incidence of ASBU increases with age, with 5% or fewer cases occurring among healthy premenopausal women, and a 15% or greater incidence in women and men between ages 65 and 80 years, and continues to climb after age 80 to as high as 40% to 50% of long-term care residents older than age 80 (Biggel et al., 2020; Cortez-Penfield et al., 2017; Godbole et al., 2020). Estimates suggest the overall incidence of UTIs in older men and women is in the range of 1 infection per 14 to 20 person-years (Cortez-Penfield et al., 2017). ASBU is found 100% of patients with long-term indwelling catheters and 3% to 5% of instances of short-term catheter use (Godbole et al., 2020).

Ethnicity: Not significant.

Contributing Factors: Predisposing factors to the development of cystitis in older adults include indwelling catheters, urethral or condom catheters, incontinence (urinary and fecal), poor perineal hygiene, cognitive impairment, neurological conditions that impair bladder emptying, diabetes, and neurogenic bladder (Soria & Khoujah, 2021). Other predisposing factors to cystitis include sexual intercourse, functional disability, sickle cell disease, prior antibiotic therapy, genetic predisposition, functional or structural genitourinary tract abnormalities (including urethral strictures, pelvic floor dysfunction, ureteral weakness, and vesicoureteral reflux or renal calculi) (Soria & Khoujah, 2021). Frail older adults in institutionalized settings are at additional risk due to lack of adequate fluids and immobility.

The older adult's compromised anatomical defenses related to decline of aging allow bacterial ascent of the genitourinary tract and subsequent colonization of pathogens (Badalato & Kauffman, 2016). Benign prostatic hyperplasia (BPH), incontinence, urinary retention, instrumentation, and institutionalization are all contributing factors to the increase in the prevalence of cystitis in older adult men (Soria & Khoujah, 2021). The length of the male urethra provides a protective barrier against ascending bacterial infection, especially before age 50 years (McLellan & Hunstad, 2016).

The woman's shorter urethra is an anatomical difference that explains why women are more susceptible to UTIs over their lifetime. Additionally, the urethra's proximity to rectal and vaginal flora increases the risk of cross-contamination. The loss of estrogen resulting in vaginal atrophy in older adult women and an increase in vaginal pH, leading to subsequent colonization with pathogenic bacteria are also factors (Zeng et al., 2020).

Signs and Symptoms: The older community-dwelling adult presents with similar symptoms of UTI as a younger person but may present with an atypical presentation of mental confusion, anorexia, malaise, and incontinence especially for patients with indwelling catheters or the frail older adults (Long & Koyfman, 2018). Nonspecific symptoms such as functional decline, increased confusion, and other nonspecific signs may be mistakenly attributed to cystitis in the absence of urinary tract symptoms and should be thoroughly examined in the differential (Long & Koyfman, 2018). Patient should be asked about their social history, including sexual activity, in the older adult. Sexually transmitted diseases and human immunodeficiency virus are increasing in the older adult, so it is important to evaluate carefully to rule out other potential diagnoses (Tran & Leonard, 2017). Women may report pelvic pain, vaginal or cervical discharge, bleeding that may indicate an ascending infection, sexually transmitted infection or disease, or a gynecological cancer.

© F.A. Davis Publishing

If fever, flank pain, and other systemic symptoms are reported, consider obstruction such as renal calculi, urinary retention, and hydronephrosis as differentials when ordering diagnostic tests.

The physical examination must include a detailed history when someone presents with dysuria. It is important to characterize the timing, severity, duration, and persistence of the symptoms. Pain at the beginning of urination suggests a urethral problem such as urethritis. Pain at the end of urination may arise from the bladder or prostate. Other bladder symptoms, such as frequency, urgency, incontinence, hematuria, malodorous urine, and nocturia must be explored. The history should include the presence of flank pain, nausea, fever, and other systemic symptoms which may represent a complicated UTI (Godbole et al., 2020). A history of dysuria, UTIs, sexually transmitted infections, and recent sexual activity should be included.

In addition to dysuria, men with prostatitis may have deep perineal pain and obstructive urinary symptoms, whereas those with epididymo-orchitis may have localized testicular pain. Lesions from herpes simplex virus of the vulvar or penile area may cause dysuria.

Vaginal examination in women should rule out discharge, irritation, and erythema in women who have recurrent symptoms or who do not respond to treatment (Ashraf et al., 2020). In men, the prostate gland should be examined gently to assess for enlargement, bogginess, and tenderness to rule out prostatitis, which is considered a complicated UTI.

Diagnostic Tests: Urine dipstick is used as a quick method for ruling out UTI as the cause of urinary symptoms. Urine dipstick testing detects the presence of leucocyte esterase also known as pyuria and nitrites which identifies gram-negative bacteria. Nitrites are unable to identify gram-positive bacteria, *Enterococci* and *Pseudomonas* because these organisms are unable to reduce nitrates to nitrites (Ashraf et al., 2020; Cortes-Penfield et al., 2017).

Testing for UTI should be ordered only when clinical symptoms such as dysuria are present (Cortes-Penfield et al., 2017). The presence of greater than 105 colony-forming units/mL of a single bacterium in a culture of freshly voided urine is generally considered to be a significant bacteriuria (Pipili & Grapsa, 2019). Collection of a urinalysis and culture specimen without contamination is critical. A patient must be able to give a clean specimen with less than 15–20 epithelial cells per high power field (HPF) (Ashraf et al., 2020). If the epithelial cells are elevated, then contamination has occurred due to contact with the genital surface. Older adults may often have difficulty in collecting a clean-catch urine specimen due to coordination, mobility, or cognitive issues (Ashraf et al., 2020; Cortes-Penfield et al., 2017). If unable to collect a clean-catch specimen, an in-and-out catheterization of the bladder is acceptable the risk of a UTI developing is about 1% (LaRocco et al., 2016). Staff collecting urine specimens may use methods that are not recommended such as obtaining the urine from a chronic urinary catheter, urine collection bag, urinal, or bedpan that are contaminated with bacteria, which may affect the integrity of the urine culture results. Urine specimens should be sent to the laboratory immediately or refrigerated because bacteria grow rapidly when the specimen is left at room temperature.

The diagnosis of UTI cannot be solely based on urine culture results because bacteriuria may be present in asymptomatic patients. In older adults, the rate of ASBU is so high that bacteriuria cannot be excluded as an abnormal finding (Ashraf et al., 2020). The presence of bacteria in the urine may indicate one of the following conditions: contamination of the specimen, UTI, or ASBU (Nicolle et al., 2019). Use test results coupled with history and examination findings to derive a diagnosis. The accepted standard for bacteriuria is at least 10^5 colony-forming units (CFUs) per one mL of a single organism in the urine of an uncatheterized patient or $\geq 10^3$ CFU/mL greater than or equal to one bacterial species in the urine of a catheterized patient (Ashraf et al., 2020; Nicolle et al., 2019). Lower bacteria counts may be reflective of a UTI in patients with urinary symptoms.

Pyuria is the presence of an increased number of polymorphonuclear leukocytes which indicates an inflammatory reaction in the urinary tract, and is generally defined as a positive leukocyte esterase on urine dipstick or greater than or equal to 10 white blood cells (WBCs) per HPF (Ashraf et al., 2020). Pyuria is sensitive but not specific for UTI, particularly among catheterized patients. Pyuria can be seen in patients with catheter use, sexually transmitted diseases, renal tuberculosis, interstitial nephritis, or ASBU (Nicolle et al., 2019). The absence of pyuria is a strong indicator that a UTI is not present (Cortes-Penfield et al., 2017). The presence of pyuria is not an indication to initiate antibiotics. Dependence on pyuria alone for diagnosis of UTI would lead to inappropriate antibiotic prescribing because pyuria is a common finding in ASBU (Ashraf et al., 2020; Cortes-Penfield et al., 2017; Nicolle et al., 2019).

Although considered a complicated UTI, catheter-associated UTI (CAUTI) is widely recognized as the most common healthcare-associated infection (Anger et al., 2019). Careful consideration needs to be taken to differentiate between ASBU and CAUTI. The AUA stresses the need for careful surveillance because of the potential risk of multidrug-resistant organisms (Anger et al., 2019). Experts agree that ASBU in the face of an indwelling catheter does not require antibiotic treatment, even though administration rates remain as high as 32% (Ashraf et al., 2020; Cortes-Penfield et al., 2017). McGeer criteria were developed in 1991 to provide standardized guidance for epidemiological surveillance in long-term care facilities. Updates to the guidelines were made in 2012, making significant changes to the diagnosis of UTI with and without the presence of an indwelling catheter. All symptoms must be new or acutely worse, alternative noninfectious causes of symptoms should be evaluated/considered before deemed an infection, and identification of infections are not to be based on a single piece of evidence and should always consider the clinical presentation (Cortes-Penfield et al., 2017).

Older adults are at a high risk of adverse events from antibiotic use; using active monitoring while waiting for urine culture results is acceptable if the patient is clinically stable (Cortes-Penfield et al., 2017). Active monitoring requires frequent vital sign monitoring, assessment for early sepsis, ongoing hydration, and nursing staff reporting changes in condition. If the patient begins to decline, implementation of empirical antibiotics is recommended pending availability of urine culture sensitivities.

© F.A. Davis Publishing

Differential Diagnosis:
- Urethritis
- Prostatitis
- Epididymitis
- Vaginitis
- Obstructive uropathy
- Sexually transmitted infections
- Complicated pyelonephritis

Treatment: In 2010, Infectious Disease Society of America (IDSA) published guidelines for the treatment of UTI recommending four antibiotics for the treatment of uncomplicated UTIs in women: nitrofurantoin, fosfomycin, pivmecillinam (which is not available in the United States), and trimethoprim-sulfamethoxazole. There were no recommendations made for UTI in men or in the treatment of complicated UTI. Choosing an antibiotic should be based on the susceptibility from the urine culture results. Other considerations are allergy history, drug interactions, renal function, frequency of dosing, side-effect profile, local antibiogram data, and insurance coverage and cost (Godbole et al., 2020).

First-Line Agents: Nitrofurantoin-(monohydrate/macrocrystalline) is indicated in uncomplicated UTI, recurrent UTI, and UTI prophylaxis. Nitrofurantoin is well tolerated and has good susceptibility to uropathogens, but it is not appropriate in those with upper urinary tract disease due to poor levels in tissue and blood (Cortes-Penfield et al., 2017). Dosing of nitrofurantoin is 100 mg by mouth for 5 days for uncomplicated and recurrent UTI. Although the U.S. Food and Drug Administration (FDA) recommended against using nitrofurantoin in patients with a creatinine clearance (CrCl) of 60 mL/minute, recent data suggest that nitrofurantoin can be used effectively for cystitis regardless of renal function (Cortes-Penfield et al., 2017). The risk of pulmonary toxicity is greater in adults with a creatinine clearance (CrCl) <30 mL/min, and the Beers criteria recommend against use of nitrofurantoin in older adults >65 years with a CrCl <30 mL/min (Ashraf et al., 2020; Cortes-Penfield et al., 2017).

Trimethoprim-sulfamethoxazole (TMP/SMX) is indicated for uncomplicated UTI and recurrent UTI where resistance rates to *E. coli* are less than 20% (Cortes-Penfield et al., 2017). Dosing of TMP/SMX is 800 mg/160 mg twice daily for 3 days.

Fosfomycin is indicated in the treatment of UTI. Unfortunately, its use is limited by availability, cost, and lack of standardized susceptibility testing (Ashraf et al., 2020; Babiker et al., 2019). It should be reserved for treatment of acute simple UTI. It is a single dose oral agent that is mixed with water to administer. Fosfomycin is susceptible in extended spectrum beta-lactamase uropathogens (Ashraf et al., 2020; Babiker, 2019).

Second-Line Agents: Fluoroquinolones to treat UTIs has become very common due to their high oral bioavailability, broad spectrum, and its short course treatment. The FDA in 2016 advised that due to the serious side effects associated with fluoroquinolones use, they are not recommended in uncomplicated UTI when other treatment options are available (Ashraf et al., 2020; Buehrle et al., 2021; Cortes-Penfield et al., 2017; Cowart et al., 2019). The serious risks of fluroquinolone use outweigh the benefits. Black box warnings by the FDA include tendinitis/tendon rupture, peripheral neuropathy, central nervous system effects, exacerbation of myasthenia gravis, aortic dissection, retinal detachment, QT prolongation, hypoglycemia/hyperglycemia, and *Clostridioides difficile* (Buehrle et al., 2021; Cowart et al., 2019).

Uropathogens are known to have high susceptibility to aminoglycosides but the lack of oral formulations of these drugs; the need to monitor serum drug levels; and the risk of major adverse events including nephrotoxicity, vestibular toxicity, and ototoxicity limit the role of this class in treating UTIs outside of the inpatient setting (Ashraf et al., 2020, Cortes-Penfield et al., 2017).

Duration of Treatment: There is more evidence that demonstrates short-course antibiotics for treatment of CAUTI and therapy lasting longer than 7 days do not prevent recurrence and increase the risk of *C. difficile.* Longer treatment is still recommended in those with UTI with bacteremia, pyelonephritis, and perinephric abscess (Ashraf et al., 2020; Cortes-Penfield et al., 2017).

Treatment recommendations have been changing to reflect trends in pathogen resistance, antibiotic adverse effects, and best evidence-based practice. Current recommendations include multiple treatment regimens based on the needs of the patient. All providers should be aware of the patient's renal function or pre-existing renal disease before prescribing an empirical antibiotic (or any medicine for that matter). Always encourage good hydration and the use of analgesics such as acetaminophen and short-term NSAID therapy for fever and pain. Phenazopyridine 100 to 200 mg by mouth every 8 hours for 3 days can be added to these regimens for the relief of dysuria.

Follow-Up: Follow-up test-of-cure urinalysis and urine cultures are not indicted for uncomplicated cases of cystitis in which symptoms resolve on antibiotics (Ashraf et al., 2020). Relapse occurs when symptoms persist despite antimicrobial treatment. Additional evaluation is warranted for other potential causes that may be causing ongoing symptoms. Cystitis treated with the correct antimicrobial therapy is resolved in 90% of the cases. Recurrence is seen in about 25% to 50% of women after a UTI (Ashraf et al., 2020; Peck & Shepherd, 2021). Change in treatment is warranted if the organisms are resistant to the original treatment.

Sequelae: Untreated symptomatic cystitis can lead to kidney damage, pyelonephritis, sepsis, shock, and death.

Prevention/Prophylaxis: Strategies for prevention of recurrent uncomplicated cystitis include reduction of frequency of intercourse, abstaining from spermicidal use, proper perineal hygiene and voiding habits, and removal of unnecessary indwelling urinary catheters. Prophylactic use of antibiotics by patients with indwelling catheters is not recommended (Assadi, 2018). For older adults who require frequent instrumentation of the lower genitourinary tract or who have frequent cystitis, suppressive antimicrobial therapy may be considered on an individual basis (Assadi, 2018).

Antibiotic use is a driver of antibiotic resistance. A systematic review of randomized trials looked at long-term antibiotics for prevention of recurrent urinary tract infection in older adults. Long-term use was defined as at least 6 months. Researchers reviewed 53 studies; only four were eligible for inclusion and no studies included older men. Three studies

© F.A. Davis Publishing

found long-term antibiotics reduced the risk of recurrence of UTI by 24% (Ahmed et al., 2017). There was not statistically significant increase in risk of adverse events. One trial showed 90% of urinary and *Escherichia coli* isolates were resistant to trimethoprim-sulfamethoxazole after 1 month of prophylaxis use (Ahmed et al., 2017). The outcome revealed that although long-term use helps with recurrence the benefit when the antibiotic is discontinued is lost. The studies that were reviewed were not definitive about length of treatment, risks of antibiotic resistance, or effects in the older male. More studies need to confer the risk versus benefit of long-term use. Antibiotic prophylaxis should be compared with nonantibiotic prophylaxis with evidence of efficacy (such as vaginal estrogen creams).

Cranberry supplements have been publicized as a remedy for prevention of UTI. It is thought that cranberry products acidify the urine thereby preventing UTI. Another mechanism may be that they may inhibit *E. coli* from adhering from the lining of the bladder wall. Current evidence does not support the use of cranberry products in the prevention of UTI (Ashraf et al., 2020).

Methenamine is approved by the FDA for prophylaxis or suppression of recurrent UTI. Methenamine works as an antiseptic and has not shown that organisms develop resistance. In an acidic environment, methenamine is hydrolyzed to ammonia and formaldehyde (Chwa et al., 2019; Snellings et al., 2019). The urine pH must be acidic (pH below 5.5) for it to convert to formaldehyde; if urine acidification is not possible, then its use should be discouraged (Chwa et al., 2019; Snellings et al., 2019). Patients who are chronically catheterized and unable to retain urine are poor candidates because methenamine works in the bladder. Avoid use of sulfanomides in patients taking methenamine. Also avoid using methenamine in those with renal or hepatic dysfunction and in those with gout. Studies have shown efficacy as an antibiotic-sparing alternative (Chwa et al., 2019). In a retrospective, observational study, methenamine use was associated with a longer time to develop a UTI in older adults with varying degrees of kidney function. In fact, the effectiveness of methenamine appeared to be similar regardless of kidney function (Snellings et al., 2019). Future research is needed to determine an effective dose and duration of use in the older adult.

Postmenopausal women often experience vaginal atrophy manifested by vaginal dryness, itching, urinary incontinence, and painful sexual intercourse. These symptoms may imitate UTI, resulting in being treated with unnecessary antibiotics. Vaginal estrogen preparations may help reduce the incidence of UTI and associated symptoms that may reflect UTI. Concerns that using estrogen in the postmenopausal woman may potentially increase cancer risk and cardiovascular disease have existed, particularly in those women using systemic estrogen (Fox et al., 2021). However, an observational study found that the risk of cardiovascular disease and cancer did not increase in postmenopausal women using vaginal estrogen (Ferrante et al., 2021.) A randomized clinical trial found vaginal estrogen was effective in prevention of UTI in postmenopausal women with an active diagnosis of recurrent UTI (Ferrante et al., 2021). Local estrogen therapy may be helpful in reducing recurrent UTI and to treat atrophic vaginitis.

Referral: In complicated cystitis that has progressed to pyelonephritis or urosepsis, consultation with a urologist, urogynecologist, or infectious disease specialist is recommended for hospitalization. This recommendation can also be applied to recurrent UTI.

Education: Adequate hydration remains a cornerstone in the prevention and treatment of any infectious process. Have the patient perform timed and double voiding to lower the postvoid residual of those suspected of urinary retention serving as a nidus for infection. Patients should also be instructed to complete the full course of antibiotic therapy prescribed unless notified by their provider.

ERECTILE DYSFUNCTION

Signal Symptoms: None; noncompliance with medication regimen, responses on sexual history query or questionnaire.

Description: Erectile dysfunction (ED), previously known as impotence, is the consistent inability to achieve and maintain an erection sufficient for sexual satisfaction (McCabe et al., 2016). In a broader sense, ED encompasses problems with arousal, libido, orgasm, sensation, and relationships (Khera, 2020).

Etiology: ED may be caused by medications, vascular, endocrine, neural, psychological issues, and lifestyle and interpersonal stressors (see Contributing Factors).

Occurrence: An estimated 20 to 30 million U.S. men experience chronic ED (Irwin, 2019).

Age: Incidence of ED increases with age. The prevalence is approximately 52% for men between ages 40 and 70 years; in men older than 70 years, prevalence is increased further. Men older than 70 years with chronic medical problems, such as diabetes, have a prevalence of more than 90%. Because the condition is often underreported, the percentage is probably higher. Approximately 25% of erectile problems are related to drugs (Irwin, 2019).

Ethnicity: Not significant.

Contributing Factors: ED causes are often multifactorial (Irwin, 2019):

- Stress
- Long-term alcohol use
- Tobacco use
- Sedentary lifestyle
- Obesity (Pizzol et al., 2020)
- Interpersonal conflict
- Pelvic surgery/trauma
- Underlying chronic issues (diabetes, hypertension, hyperlipidemia, sleep apnea, atherosclerosis, chronic kidney disease [CKD], depression).
- Recreational drug use (cocaine, marijuana, opiates)
- Antiandrogens, anticholinergics, anticonvulsants, antidepressants (including selective serotonin reuptake inhibitors, monoamine oxidase inhibitors, tricyclic antidepressants), antipsychotics, levodopa, lithium, centrally acting depressants (sedatives/hypnotics, tranquilizers, opiates)
- H_2 blockers, stimulants such as amphetamines, beta blockers, spironolactone, methadone, cytotoxic agents, antihypertensives (clonidine, methyldopa, thiazides, calcium channel blockers), urological drugs (alpha blockers), anti-inflammatories (baclofen, naproxen)

Various processes are involved, including effect on libido, neurochemical mediation, and drug side effects.

Signs and Symptoms: There may be no reported symptoms unless the provider includes a sexual history, is aware of the potential for ED when prescribing certain medications, and asks about baseline sexual activity at that time, then periodically reassesses this during follow-up visits. The patient should be asked about sexual interest, sexual ability, and sexual activity. Patients with a prior diagnosis of diabetes, hypertension, dyslipidemia, or depression are at increased risk (Irwin, 2019).

History should include prescribed and over-the-counter (OTC) medications and supplements, alcohol use, tobacco use, and use of recreational drugs. The CAGE test for alcoholism, a screening questionnaire for depression, or other psychological screens as needed may be included as part of the history. A history of surgical procedures, especially of procedures involving the prostate, bladder, or colorectal area, and including the lymphatic channels, may reveal potential sources of ED (Artemi et al., 2019). The Sexual Health Inventory for Men (SHIM) is a five-item questionnaire that can be used to assess the presence and extent of erection difficulties (Rosen et al., 1999).

Physical examination is performed to look for any systemic signs that could contribute to the ED. Evaluate the

© F.A. Davis Publishing

patient's overall appearance and mobility, then assess the vital signs, specifically checking for orthostatic hypotension. Severe obesity could be a risk for sleep apnea and lower testosterone. Palpation of the thyroid may reveal a goiter. Gynecomastia may be related to certain drugs or a decrease in overall testosterone.

Diminished peripheral pulses suggest a circulatory problem. Lack of sensation or inability to discriminate between sharp and dull may indicate peripheral neuropathy, especially if the history is positive for diabetes. Abnormal reflexes point to a neurological problem. Decreased mobility may indicate a neurological or musculoskeletal problem contributing to ED. Examination of the genital area may reveal testicular atrophy or penile plaques, as seen in patients with hypogonadism or Peyronie's disease. Assess for the bulbocavernosus reflex; absence of this reflex indicates penile neuropathy (Khera, 2020).

Diagnostic Tests: Laboratory testing is not necessary for a diagnosis but can help to determine the possible causes of ED and help expose other chronic issues that are often associated with it. Testosterone is one blood test that is not typically done with health maintenance screening, but if found to be unequivocally low, should be addressed. Diagnostics may include (Agronin, 2021):

- Fasting glucose and hemoglobin A1c (Hb A1c)
- Complete blood count (CBC)
- Comprehensive metabolic profile
- Thyroid-stimulating hormone
- Lipid profile
- Serum total testosterone fasting between 8 and 10 a.m.
- Serum prolactin

Treatment: Depends on patients' preferences, ideally improving quality of life and reducing the risk of chronic disease. Lifestyle recommendations should be advised for all, specifically diet and exercise and tobacco cessation. Address untreated depression. Optimal treatment of chronic diseases that affect hormones, mental health, and the endothelium can help to improve treatment of ED.

If newer onset ED is thought to be related to a medication, decrease the dose, eliminate the medication, or substitute another medication from available drugs that do not cause ED. If this is not possible, or if the patient continues to experience the problem, treatment options include oral, intraurethral, or intracavernosal medications; vacuum erection devices; or penile prosthesis (Irwin, 2019).

Phosphodiesterase-5 (PDE-5) inhibitors may be considered after cardiac risk factors, chronic illness, medication assessment, and underlying etiology are examined. Medications in this classification include sildenafil citrate (Viagra), vardenafil (Levitra), tadalafil (Cialis), and avanafil (Stendra). Tadalafil has a longer duration and avanafil has a rapid onset. During sexual stimulation, nitric acid is released into the corpus cavernosum, resulting in increased cyclic guanosine monophosphate (cGMP) levels, which prevents smooth muscle relaxation and increases blood flow to the penis. PDE-5 inhibitors enhance this effect by inhibiting an enzyme that degrades cGMP in the corpus cavernosum. These medications are contraindicated with nitrates and in advanced heart disease; cytochrome influences include increased plasma levels with inhibitors of CYP3A4 or CYP2D9 and decreased plasma levels with inducers of CYP3A4. Side effects include headache, flushing, urinary tract infection (UTI), abnormal vision (blue-green, blurring, photosensitivity), nasal congestion, diarrhea, dizziness, and rash. PDE-5 inhibitors are effective in treating drug-induced ED in patients taking antidepressants/antipsychotics and antihypertensives/diuretics (Burnett et al., 2018; Khera, 2020).

Follow-Up: Individualize follow-up according to cause and treatment. Periodic reassessment of treatment for recurrence of the problem is helpful. For medication treatment, monitor for side effects and response.

Sequelae: Disruption of sexual function may result in depression or relationship problems. Complications may arise from treatment.

Prevention/Prophylaxis: Avoid prescribing medications with a high risk for causing ED and include a sexual history in routine history and physical examination whenever prescribing a new medication with ED as a potential side effect. Optimize overall cardiovascular health through encouragement of Mediterranean diet and regular exercise.

Referral: Refer patients to a urologist to evaluate for other causes or multifactorial causes of ED. If blood work indicates lower testosterone levels, consider referral to endocrinology or urology to discuss possible supplementation because decreased testosterone has been found to impact erections. For other types of treatment, such as penile implants or injection, refer the patient to a urologist specializing in this area. Also refer patients who are experiencing the problem to a support group. Refer for psychological services when indicated.

Education: Teach the patient about possible medication side effects and that they cannot be used in conjunction with nitrates. Educate the patient about normal age-related changes in sexual functioning and how to adapt.

NEPHROLITHIASIS

Signal Symptoms: Vague flank pain, hematuria, renal colic, abdominal pain.

Description: In the Western Hemisphere, most cases of nephrolithiasis (the presence of calculi [kidney stones]) result from calcium salts, uric acid, cystine, struvite, and medications forming crystals that become attached to the kidney, eventually developing into stones. Calculi range in size from microscopic to several centimeters in diameter. Calculi often attempt to travel through the urinary system and out through the urine. Pain occurs when the calculi become lodged (Curhan et al., 2021).

Etiology: Kidney stones develop from the supersaturation of urine with stone-forming material. The abundance of solutes begins to develop into crystals. The crystals adhere to one another forming stones. Approximately 80% of diagnosed kidney stones contain calcium; 10% to 15% are struvite stones, resulting from urinary tract infections; 3% to 10% are uric acid calculi; 1% contain cystine: and 1% are formed from medications (Alelign & Petros, 2018).

Occurrence: One out of 11 Americans will be diagnosed with a kidney stone in their lifetime. Approximately 50% of patients who have had previous urinary calculi have a recurrence within 10 years.

Age: Men 60 and older have the highest incidence of nephrolithiasis in the male population. The episodes of kidney stones in females aged 20 to 39 have doubled and now surpass their male counterparts in this age-group (Chen et al., 2018). Men are more likely than women to form uric acid stones; struvite stones are more common in women due to the higher incidence of urinary tract infections (Alelign & Petros, 2018).

Ethnicity: The incidence of kidney stones is most prevalent among Whites followed by Mexican Americans. The lowest occurrence is found in Blacks.

Contributing Factors: A major contributing factor to the development of calculi is decreased fluid intake leading to high concentration of urine. Certain food substances that increase the likelihood of kidney stone formation include dairy products, chocolate, green leafy vegetables (calcium oxalate stones), and meat and fish (cystine stones). Certain medications, such as triamterene, indinavir, guaifenesin, and sulfa, can also contribute to the development of nephrolithiasis (Alelign & Petros, 2018). A history of hyperparathyroidism, sarcoidosis, Cushing's syndrome, Paget's disease, and immobilization may contribute to the development of calcium phosphate stones. Chronic urinary tract infections (UTIs) are precursors to struvite stone formation. Family history has also been found to contribute to stone development. Bowel disorders that cause chronic acidic urine states, such as patients that have undergone bariatric surgeries, can increase nephrolithiasis frequency. Increased urine calcium and uric acid with decreased urine pH has been found in individuals with obesity. Patients with diabetes tend to excrete more oxalate increasing risk of development in calcium oxalate stones (Chen et al., 2018).

Signs and Symptoms: Patients may experience abrupt, severe, colicky pain in the abdomen or flank that radiates to the groin. The pain sensation can begin as vague flank pain (Capilouto & Williams, 2021). Pain spreading downward suggests movement of the stone along the ureter. Associated nausea and vomiting may occur. Hematuria is also common (Fontenelle & Sarti, 2019). Physical examination may reveal local abdominal and costovertebral angle tenderness. Men complaining of groin pain should have a testicular examination to rule out testicular torsion or epididymitis. Women with pain radiating to the labia should have a pelvic examination to rule out possible ovarian torsion, cysts, pelvic inflammatory disease, and tumors.

Diagnostic Tests: For patients who have not yet passed a stone, urine collection for recovery of stones or gravel should be ordered. Urinalysis can reveal the presence of leukocytes, bacteria, and blood, which can be indicative of UTI. The presence of crystals in urinalysis can aid in the determination of the type of stone present. A computed tomography (CT) scan of the abdomen and pelvis without contrast using low-radiation protocols is the preferred imaging study. It is readily available at most facilities and presents the highest diagnostic accuracy of stone size, location, and potential complications. Ultrasound of the kidneys and bladder are recommended second-line to minimize radiation exposure. Although abdominal plain films are inexpensive and quick, they can fail to detect radiolucent stones, small stones, or obstructions (Curhan et al., 2021).

Differential Diagnosis:

- Papillary necrosis
- Hydronephrosis
- Ileus
- Diverticulitis
- Appendicitis
- Bowel obstruction
- Mesenteric ischemia
- Ovarian cyst
- Testicular torsion
- Constipation
- Arterial aneurysm
- Cholecystitis
- Acute cystitis
- Pyelonephritis
- Ectopic pregnancy
- Prostatitis
- Renal cell carcinoma
- Narcotic seekers

Treatment: Size and location of the stone, coupled with the length of time since the onset of symptoms, directs treatment. Stones less than or equal to 5 mm usually pass on their own without intervention. A stone larger than 10 mm requires referral to a urologist for possible intervention that may include extracorporeal shock-wave lithotripsy, ureteroscopy stone removal, or percutaneous nephrolithotomy. Patients not in distress and without obstruction may benefit from the use of alpha blockers, which have been shown to aid in the passage of 44% of stones 5 to 10 mm (Rule et al., 2020). NSAIDs have been found to be more effective in pain management than narcotics with fewer side effects (Fontenelle & Sarti, 2019).

© F.A. Davis Publishing

Follow-Up: For those at high risk of recurrence, a repeat CT scan or ultrasound is recommended in 1 to 2 years. At this time, also review with the patient the need for metabolic work-up, family history, health conditions associated in stone formation, and compliance with dietary restrictions and fluid requirements.

Sequelae: Immediate complications of unresolved kidney stones include obstruction, urinary tract infection, and sepsis. A high incidence of recurrence of kidney stone formation exists. Metabolic causes of kidney stones need to be ruled out when dietary measures are unsuccessful. Patients with nephrolithiasis are also commonly afflicted with chronic health conditions including chronic renal failure, hypertension, diabetes, and cardiovascular disease (Alelign & Petros, 2018).

Prevention/Prophylaxis: An adequate daily fluid intake is essential. Patients should be encouraged to drink 2 to 3 liters daily. To prevent recurrent stones, review the patient's dietary habits to discern if there are any excessive food products that may be factors in kidney stone formation (calcium, purine, protein).

Referral: Refer the patient to a urologist when:

- Obstruction is detected.
- The stone is more than 10 mm.
- The stone has not passed within 4 weeks of conservative measures for stones <10 mm.
- The patient has complicated diagnostic reports.
- The patient has severe nausea and vomiting, intractable pain, urosepsis, anuria, or renal failure.

Education: Inform all patients with nephrolithiasis that there is a high probability of a second occurrence of a kidney stone. Advise the patient, if possible, to strain urine with the provided strainer when experiencing symptoms of kidney obstruction. A daily fluid intake of 2 to 3 L is recommended. Provide information about any food restrictions that may be deemed necessary to prevent specific stone formation (Alelign & Petros, 2018).

Clinical Recommendation	Evidence Rating	References

PROSTATE CANCER

Signal Symptoms: Early stage often asymptomatic. Obstructive voiding symptoms (hesitancy, intermittent urinary stream, decreased force of stream) are generally indicative of advanced disease.

Description: Prostate cancer is a malignant neoplasm of the prostate, which is a male sex accessory gland. The prostate has been equated to the size of a walnut, encircling the urethra like a doughnut. The role of the prostate is to secrete fluid into the ejaculate that accompanies sperm and seminal fluid to make up semen. Ninety-five percent of prostate cancers are adenocarcinomas.

Etiology: Approximately one-half of prostate cancers demonstrate a genetic component. Testosterone has been identified as a prerequisite for the development of prostate cancer. Prostate cancers exhibit high levels of androgen receptors (Leslie et al., 2019).

Occurrence: Prostate cancer is the second leading cause of cancer death in men, second only to lung cancer (American Cancer Society [ACS], 2021). Prostate cancer is the most common cancer in men, with approximately 1 in 8 being diagnosed. The older adults are more frequently affected, with 60% of cases diagnosed after age 65 years; 45% of cancer deaths are between ages 60 and 79 and 50% at 80 and above (Seigel, 2021).

Age: Mean age at diagnosis is 66 years (ACS, 2021).

Ethnicity: Black men in the United States have the highest incidence of prostate cancer in the world, with Asian and Hispanic men at lower risk than White men (ACS, 2021). Diagnosis in Black men tends to be at a more advanced stage, and disease-specific survival is lower in this group (ACS, 2019).

Contributing Factors: Age greater than 50 years, being African American, and diets high in fat are contributing factors. Family history appears significant with a 2.5-fold increased risk with a first-degree relative affected before age 50 years. The risk is even greater if the affected relative is a brother rather than a father, if the affected relative is younger than 55 years, or if two or more first-degree relatives are affected. (ACS, 2021; Leslie et al., 2019). Individuals with a first- or second-degree family member with a history of

© F.A. Davis Publishing

metastatic prostate, ovarian, male breast cancer, female breast cancer below 46, colorectal cancer or endometrial cancer at age younger than 51, or pancreatic cancer are considered at a higher risk. Familial genetic carriers of the *BRCA2* or *HOXB13* gene are at increased risk for prostate cancer. (National Comprehensive Cancer Network [NCCN], 2021)

Signs and Symptoms: There are usually no symptoms with early disease. Symptoms generally occur in advanced stages, making early detection desirable. Obstructive voiding symptoms (hesitancy, intermittent urinary stream, decreased force of stream) generally reflect locally advanced disease with growth into the urethra or bladder neck. Locally advanced tumors may result in hematuria and hematospermia. If rectal obstruction occurs, a large bowel obstruction or difficulty in defecation may be present. Prostate cancer that has spread to the regional pelvic lymph nodes occasionally causes edema of the lower extremities or discomfort in pelvic or perineal areas. Metastasis occurs most often to the bone, resulting in pain and pathological fractures.

Diagnostic Tests: Screening discussion should be held with men around the age of 50 years who do not possess comorbidities that restrict life expectancy to less than 10 years, unless risk factors dictate earlier. Controversy continues in terms of screening recommendations. Table 14-2 reflects current screening statements by expert groups and the date declared.

A digital rectal examination (DRE) is the only method for physically examining the prostate, with awareness that only part of the gland can be palpated, allowing for irregularities to be missed. DRE is considered abnormal if the prostate is enlarged, asymmetrical, nodular, or tender. The effectiveness of DRE for prostate cancer screening is not well established and is considered to have low sensitivity. A prostate-specific antigen (PSA) blood test and a DRE may detect cancer at an earlier stage than if no screening is performed.

A PSA is a glycoprotein expressed by normal and neoplastic prostate tissue and is excreted in the ejaculate to liquefy semen (Freedland, 2021). Escape of PSA in large amounts into the bloodstream occurs when the basement membrane of the prostate epithelial cells is disrupted. Both the PSA and DRE may produce false-positive or false-negative results. A PSA level of 4.0 ng/mL or greater historically has been used to recommend referral for further evaluation or biopsy, which remains a reasonable approach for men at average risk for prostate cancer. Five-alpha reductase inhibitors finasteride and dutasteride are known to lower PSA levels. If a PSA is noted to be elevated, a DRE (if not done before), a repeat PSA 4 to 6 weeks after elevation, and work-up for benign disease are done.

Parametric magnetic resonance imaging (MRI), if available is now recommended and utilized pre-biopsy to help image for aggressive lesions in those with an elevated PSA. If the MRI is used for detection, the area can then be targeted on the biopsy. Biopsies are taken on each side with specific focus on the lesion if imaged with the MRI (Eklund et al., 2021; NCCN, 2021).

Differential Diagnosis:
- Benign nodule prostate growth
- Subacute prostatitis
- Prostatic intraepithelial neoplasia
- Prostate stones

Treatment: Treatment depends on stage of the tumor, anticipated effects of treatment, and the age, general health, and life expectancy of the patient. The Gleason score determines the grade of prostate cancer. The Gleason score grades tumors on a 1 to 5 range based on the degree of glandular differentiation and structural architecture. Grade 1 represents the most well-differentiated appearance, and grade 5 represents the most poorly differentiated. The primary and secondary architecture are added together to create the score (i.e., 3 + 4 = 7). Treatment options include active

TABLE 14-2 Recommendations for Prostate Cancer Screening

GROUP / SOCIETY	RECOMMENDATION
American Cancer Society (2018)	• Beginning at 50 years of age, asymptomatic men who have at least a 10-year life expectancy should have an opportunity to make an informed decision with their physician about screening. • Men at high risk, including African American men and men who have a first-degree family history (father or brother) of prostate cancer diagnosed before 65 years of age, should receive this information beginning at 45 years of age. • Men at highest risk with more than one first-degree relative with prostate cancer should have conversation about screening at age 40. • When screening is performed, PSA testing should be used with or without digital rectal examination. Frequency of testing depends on PSA level.
American Urological Association (Carter et al., 2013; Reconfirmed 2018)	• Use shared decision making for men 55 to 69 years of age. • Individualize screening decisions for higher-risk men 40 to 54 years of age. • Do not screen men younger than 40 years, older than 70 years, or who have a life expectancy of less than 10 to 15 years.
National Comprehensive Cancer Network (2021)	• General screening starts at 45 for average risk patients. • Screen earlier at age 40 if patient is of African ancestry; 40 if carrying germline mutations or if there is a suspicious family history. • Continue screening until 75 (continue in select cases).
U.S. Preventive Services Task Force (2018)	• Use shared decision making for men 55 to 69 years of age. • Do not screen men older than 69 years.

© F.A. Davis Publishing

surveillance for a tumor of incidental histological findings, to radical prostatectomy, radiation, or androgen deprivation therapy. Gleason score 6 cancer should be handled conservatively using active surveillance, a practice involving PSA monitoring, and repeat biopsies with the goal of delayed treatment unless the Gleason score changes.

Follow-Up: Follow-up depends on current treatment and patient-specific risk. It may be best shared by the cancer specialist and the primary provider. Routine history and physical examinations, cardiovascular health screenings, surveillance for diabetes, depression screening, annual quality of life assessment, and evaluation and management of any sexual dysfunction should be considered.

- PSA: The frequency is dependent on whether on active surveillance (every 3 months) or has been treated with prostatectomy, radiation, or androgen deprivation therapy.
- DRE: Annually after radiation but may be discontinued if PSA is undetectable. Discontinue after radical prostatectomy (NCCN, 2021).

For patients with radical prostatectomy, any PSA greater than 0.2 ng/mL is abnormal and raises concern for recurrence or progressive cancer. Patients with radiation therapy often do not have a PSA that drops to an undetectable level. Surveillance is based on the nadir. There is concern for recurrence if the PSA raises 2 ng/mL above the nadir or is continually rising after radiation treatment. (NCCN, 2021)

Sequelae: Complications of treatment may include incontinence, erectile dysfunction (ED), mild colitis, and radiation cystitis. After nerve-sparing prostatectomy, urinary continence returns in under 6 months in about 50% of men. The rate of ED after radiation ranges from 10% to 80%.

Prevention/Prophylaxis: PSA screening remains controversial because many of the prostate cancers detected are low-grade and slow-growing. In 2012, the USPSTF recommended against screening for prostate cancer, with the American Urological Association (AUA) (Carter et al., 2013) opting for PSA testing after a discussion with shared decision making. In 2018 the U.S. Preventive Services Task Force (USPSTF) adjusted recommendations for shared decision making with initial potential screening at age 55. The American Cancer Society (ACS) (2018) recommends that asymptomatic men who have at least a 10-year life expectancy have an opportunity to make an informed decision with their health-care provider about whether to be screened for prostate cancer. Men at average risk should receive this first information beginning at age 45 to 50 years. Men at higher risk, including African Americans and men with a first-degree relative (father or brother) diagnosed with prostate cancer before age 65 years, should receive this information at age 45 years. Men with an appreciably higher risk (multiple family members diagnosed with prostate cancer before age 65 years) should receive this information at age 40 years. Asymptomatic men with less than a 10-year life expectancy based on age and health status should not be offered prostate cancer screening. Screening, when completed, is recommended with PSA with or without DRE.

Referral: Because the major harm with PSA screening is overtreatment and given the variability in how prostate cancer is handled, referral to academic urology practice and providers that treat most low-grade prostate cancer with active surveillance is preferred.

Education: Review risk factors and significance of reporting family history. Used informed decision making prior to testing.

Clinical Recommendation	Evidence Rating	References
Participate in informed decision making after shared discussion of risks and benefits of screening.	C	American Cancer Society, 2018
Health-care providers should periodically discuss prostate cancer screening with men who are expected to live at least 10 years and are old enough to be at significant risk for prostate cancer.	B	Carter et al., 2013 (Reconfirmed, 2018)
When screening, perform with prostate specific antigen testing every 2 to 4 years in those of average risk.	B	Carlsson & Vickers, 2020
Stop screening after age 69 or earlier if comorbidities limit life expectancy to less than 10 years.	C	Hoffman, 2021

A = consistent, good-quality, patient-oriented evidence; B = inconsistent or limited-quality, patient-oriented evidence; C = consensus, disease-oriented evidence, usual practice, expert opinion, or case series. PROSTATITIS

Signal Symptoms: Myalgia, cloudy urine, and urinary symptoms such as dysuria, frequency, and urgency are classic symptoms and may be associated with fever, chills, and malaise. Swelling of the prostate can also cause complaints of pain at the tip of the penis, hesitancy, and intermittency (Coker & Dierfeldt, 2016). Sexual dysfunction, psychological issues, and urogenital pain may occur in chronic cases (Khan et al., 2017; Su et al., 2020).

© F.A. Davis Publishing

Description: Prostatitis includes both acute and chronic bacterial prostatitis and prostatitis syndrome, also termed chronic pelvic pain syndrome (CPPS). The National Institutes of Health Consensus Classification of Prostatitis identifies four categories of prostatitis based on clinical presentation: type I, acute bacterial prostatitis; type II, chronic bacterial prostatitis; type III, CPPS with either type IIIA inflammatory components or type IIIB noninflammatory components; and type IV, asymptomatic prostatitis. Acute bacterial prostatitis is an acute bacterial infection of the prostate and, if left untreated, it can progress to sepsis or development of prostatic abscess. By definition, an organism must be identified with culture. Chronic prostatitis is defined by symptoms being present for at least 3 months and urine cultures obtained over the course of the illness repeatedly growing the same bacterial strain. CPPS is pelvic pain in the absence of bacteria localized to the prostate (Su et al., 2020).

Etiology: Most common pathogens in prostatitis include *Escherichia coli, Klebsiella, Proteus mirabilis, Enterococcus faecalis*, and *Pseudomonas aeruginosa* (Coker & Dierfeldt, 2016; Su et al., 2020).

Occurrence: Prevalence of prostatitis in men is approximately 8% to 16%; however, only 5% to 10% were found to have a bacterial source (Davis & Silberman, 2021). Men who have had one occurrence of bacterial prostatitis have an increased chance of having a recurrence and 10% chance of developing chronic pelvic pain.

Age: Bimodal incidence peaks between 20 and 40 years and older than 60 years (Gill & Shoskes, 2016).

Ethnicity: Not significant.

Contributing Factors: History of urinary tract infection (UTI), history of sexual abuse, functional or anatomical anomalies (phimosis, stricture), presence of indwelling catheter, unprotected vaginal/anal intercourse, recent prostate or transurethral biopsy/surgery. Diabetes and other immunocompromised states increase the risk for developing (Davis & Silberman, 2021).

Signs and Symptoms: The predominant symptom is pain in the prostate, perineum, scrotum, testes, penis, urinary bladder, or lower back. Acute bacterial prostatitis frequently includes symptoms similar to acute cystitis or pyelonephritis, including malaise, low back and perineal pain, high fever, chills, dysuria, inability to empty the bladder, nocturia, and urinary retention. Men are acutely ill and may look toxic (Davis & Silberman, 2021). In chronic bacterial prostatitis, symptoms can be subtle and variable and are similar to those of an acute bladder infection, such as frequency, urgency, dysuria, perineal discomfort, low back pain, and urinary dysfunction (Khan et al., 2017; Su et al., 2020).

Physical examination may reveal a tender, boggy prostate on rectal examination. The prostate gland may be warm, swollen, firm, or irregular. Prostatic massage with acute infection is contraindicated because it increases the risk for bacteremia, is very painful, and has no benefit. Suprapubic tenderness should be evaluated for retention and costovertebral tenderness should be assessed due to the differential of pyelonephritis (Davis & Silberman, 2021).

Diagnostic Tests: Diagnosis of acute bacterial prostatitis is often done by report of symptoms. Suspected acute prostatitis diagnostics include midstream urinalysis and urine culture. If a patient has urethral discharge or has risk for sexually transmitted infection, test for urine gonorrhea and chlamydia. If the patient meets sepsis criteria, send them to the emergency department where a complete blood count (CBC) with differential, basic metabolic panel, lactic acid, and blood cultures will be run. Urine should be a midstream collection, and the presence of more than 10 white blood cells (WBCs) per high-power field (HPF) suggests a positive diagnosis. Suspected chronic prostatitis/CPPS tests include urinalysis, urine culture, and postvoid residual, if sensation of incomplete emptying of bladder is present. Persistent suspected chronic bacterial prostatitis should be referred to a urologist, who may do further testing that includes two-glass preprostatic and post prostatic massage test. In most cases, imaging is not required unless an abscess is suspected, and a computed tomography (CT) scan or ultrasound can be ordered. If prostate-specific antigen (PSA) screening is planned, it should be deferred for at least a month until acute symptoms have resolved (Meyrier & Fekete, 2020).

Differential Diagnosis:

Acute Bacterial Prostatitis:

- Acute cystitis: rapid onset and rapid response to antimicrobial therapy
- Urethritis: clinical diagnosis, mucopurulent or purulent urethral discharge; typically no prostatic tenderness
- Pyelonephritis: positive costovertebral angle tenderness, may have hematuria, may have abdominal pain; more common in younger patients; no prostatic tenderness.
- Acute urinary retention: physical assessment of distended bladder; if acute prostatitis not strongly suspected, straight catheterization should relieve most symptoms
- Benign prostatic hyperplasia (BPH) (see BPH in this chapter): prostate enlarged but not tender
- Urinary tract stones: acute, crampy pain on urination; sludge or gravel may be seen in urine specimen, especially if the specimen is strained; may be accompanied by nausea, vomiting; prostate not tender
- Bladder cancer: voiding symptoms present but prostate not tender
- Prostate cancer: enlarged possibly nodular prostate that may cause lower urinary tract symptoms, but prostate not tender

Chronic Bacterial Prostatitis:

- Chronic prostatitis/chronic pelvic pain syndrome with no evidence of bacterial source
- Noninflammatory bladder, prostate, or pelvic floor issues can present with similar symptoms (BPH, high tone pelvic floor, lower back issues)

Treatment: Empiric antibiotics are indicated in acute bacterial prostatitis while awaiting culture results; they are culture-based in chronic bacterial prostatitis, with empiric therapy started while awaiting any results of the culture (Meyrier & Fekete, 2020). Predominant infectious organisms are gram negative, so Bactrim DS twice daily, ciprofloxacin (Cipro) 500 mg twice a day, or levofloxacin (Levaquin) 500 mg daily are first-line therapy. Because the prostate has lower absorption abilities, antibiotics for acute infections without hospitalization or risk factors should be continued for 2 to 4 weeks. Those with a history of a prostate abscess, a persistently painful rectal examination, or bacteriuria should

© F.A. Davis Publishing

be continued on antibiotics for at least 4 weeks and up to 6. If the patient is acutely ill on presentation with fever, intolerance of oral medications, urinary retention, or concern for sepsis, the health-care provider should consider hospitalization and parenteral antibiotics (Su et al., 2020)

Patients should be evaluated for need of stool softeners if defecation is painful or difficult. Evaluate the need for analgesics, antipyretics, or anti-inflammatory medications and warm water baths.

Patients with chronic prostatitis or relapse should also receive extended antimicrobial therapy for 2 to 6 weeks. (Davis & Silberman, 2021; Su et al., 2020).

Follow-Up: For patients with acute bacterial prostatitis, a repeat urine culture a week after initiating treatment is recommended. If positive, consider changing antibiotics based on culture. Refer patients with symptoms of BPH, intractable infection, or prostatodynia to urology.

Sequelae: Unresolved acute prostatitis can lead to bacteremia or pyelonephritis. If acute prostatitis is not completely treated it can lead to chronic prostatitis and pelvic pain. Prostatic abscess rarely occurs as a complication of acute bacterial prostatitis except in patients who are immunocompromised.

Prevention/Prophylaxis: Reduce the need for catheterization. Educate on use of protection if participating in anal sex. Compliance with antibiotics in acute infections is important for prevention of chronic prostatitis and CPPS.

Referral: Refer patients with symptoms of BPH, intractable infection, or prostatodynia to a urologist.

Education: Educate the patient and family regarding the cause of symptoms and treatment. Explain the need for extended antibiotics and importance of adherence with treatment. Emphasize that prostatitis can recur and to report symptoms at onset.

Clinical Recommendation	Evidence Rating	References
Antimicrobial therapy should be guided by bacterial cultures and sensitivities for chronic bacterial prostatitis.	B	Su et al., 2020
Optimal duration of antibiotic treatment for acute bacterial prostatitis is 2–4 weeks.	C	Davis & Silberman, 2021 Su et al., 2020
Initial outpatient treatment is with trimethoprim-sulfamethoxazole or a fluoroquinolone unless a specific resistant organism is suspected.	C	Su et al., 2020
Refer to the hospital if elevated temperature, inability to tolerate oral medications, signs of sepsis, or urinary retention is present.	C	Davis & Silberman, 2021

CASE STUDY

Mrs. C., a 66-year-old woman, presents to your practice with a complaint of recent onset of leaking urine. She has no prior history of this. On further questioning you discover that she is newly married, after being widowed for 15 years, during which time she had no sexual partners. She and her new husband have just returned from a cruise, and she reports that he is a "passionate" lover and she is having difficulty meeting his needs for daily intercourse. Other symptoms that Mrs. C. reports are vaginal burning and general discomfort "down there."

Medications: Takes fish oil at bedtime, vitamin D_3 1,000 IU daily. No known drug allergies.

Vital signs: Blood pressure (BP) 128/76 mm Hg, pulse 82 (regular), respiratory rate 16 breaths/min, temperature 98.2°F (oral), BMI 23.4.

A staff member has obtained a urine specimen for dipstick. Findings are as follows:

Nitrite—negative

Leukocyte esterase—negative

Blood—trace

Protein—trace

Glucose—negative

Ketones—negative

Specific gravity—1.015

CHAPTER 15

Gynecological Disorders

Evelyn Duffy and Mary Franklin

ASSESSMENT

Assessment of the sexual and reproductive systems is best accomplished using a framework of trauma-informed care. Trauma-informed care encompasses six principles: psychological safety, trustworthiness and transparency, peer support, collaboration, empowerment, and humility and responsiveness (Trauma Informed Care Implementation Resource Center, 2021). Implementing these principles in the assessment of sexual and reproductive health includes measures such as obtaining history questions with the patient dressed, conducting the interview seated so that patient and provider are at eye level, starting with less-sensitive questions first, explaining the rationale for questions and physical examination procedures, and having the patient decide what clothing to remove or leave on for the physical examination.

A comprehensive medical, surgical, social, and family history may reveal medications, conditions, or historical factors that affect the reproductive system. Although a comprehensive obstetrical history is generally not relevant to the care of the older adult, historical factors that should be elicited include number of births (increased risk pelvic organ prolapse), gestational diabetes (increased risk of type 2 diabetes) and pre-eclampsia (increased risk of hypertension and stroke). The review of systems (ROS) should include specific questions about vasomotor symptoms, urinary incontinence, vaginal bleeding, and issues with sexual activity such as decreased libido or pain. Older adults are often hesitant to discuss these sensitive issues. Establishing a relationship with the patient, having a nonjudgmental approach, and explaining the purpose of history questions all help reduce patient discomfort with this section of the ROS. Reassuring patients that not only are issues such as decreased libido or incontinence common, but that there are treatment options, encourages the report of bothersome symptoms.

A complete sexual history for the older adult includes eliciting information about 4 Ps: sexual Practices, number and types of Partners, Protection against and history of sexually transmitted infections, and Pleasure in sexual practice (Savoy et al., 2020). The clinician should record the timing and results of cervical cancer screening and mammograms.

Physical examination related to the reproductive system will vary based on the presenting symptom. Routine clinical breast examinations are not universally recommended. If clinical breast examinations are performed, they can be discontinued when screening mammograms are discontinued. Age-related changes in the female breast include the atrophy of glandular breast tissue and replacement with fat and connective tissue. There may be a decrease in breast size or breasts may become pendulous and less firm, due to loss of elasticity. Areolar nipple ducts may be palpable, feeling stringy and firm. The inframammary ridge assumes more prominence. Axillary hair decreases. Age-related changes in the male breast may include gynecomastia.

Physical examination of the breast includes both inspection and palpation. Inspection is performed in the seated position and the patient performs three maneuvers: hands on hips, hands over head, and leaning forward. The examiner is assessing for symmetry, skin changes, lumps, dimpling, and nipple retraction. Palpation of the breasts is done in a supine position and includes both light and deep palpation and examining all of the breast tissue from the clavicle to the top of the rib cage, including the axillary area. Palpation using a stripe pattern has been shown to provide the most reliable results.

Atrophic changes related to age are common in the reproductive system of those assigned female sex at birth. Pubic hair becomes gray and sparse, and the labia flatten. Vaginal epithelium is thinner, drier, and itchy, with less rugae; decreased secretions and alkalinity predispose patients to painful intercourse, friability, and vaginitis (Alvisi et al., 2019; Angelou et al., 2020; Faubion et al., 2017; Manda, et al., 2021; Mitchell & Waetjen, 2018; Nappi et al., 2019; Scavello et al., 2019). The vagina becomes shorter, narrower, and less elastic; tissue is pale pink and shiny. Sexual abstinence intensifies atrophic changes. Undergarments and incontinence often irritate sensitive external structures (Manda et al., 2021). The uterus becomes smaller, and ovaries are not palpable due to atrophy. The pelvic floor muscles, sacral ligaments, and other supporting structures relax, increasing the risk of pelvic organ prolapse.

Routine examination with a speculum and bimanual examination is not recommended. If an examination is needed for symptoms, accommodations may be needed to accomplish the examination. Alternatives to the lithotomy position include examining in the side-lying position with one leg straight or bending the knees with heels against the

© F.A. Davis Publishing

buttocks (avoids use of stirrups). Patients with arthritis may be more comfortable if pain medication is taken before the examination. Equipment should be assembled and ready to limit time spent in the examining position. Applying a water-soluble lubricant to the speculum before insertion is important for comfort. The narrow Pederson speculum, in an adult or pediatric size, may be chosen for those with a narrow introitus. To examine for pelvic organ prolapse, a half speculum is used, retracting the anterior vagina and the posterior vagina separately (American College of Obstetricians and Gynecologists [ACOG] & The American Urogynecologic Society, 2019).

On bimanual examination, the ovaries should not be palpable, and the uterus should be small and firm. Cervical cancer screening with Pap or human papillomavirus (HPV) testing is no longer recommended for those older than age 65 who have had adequate prior screening and are not at high risk for cervical cancer and those younger than age 65 who have had a complete hysterectomy for noncancerous reasons (U.S. Preventive Services Task Force [USPSTF], 2018).

BREAST CANCER

Signal Symptoms: None; breast mass, axillary mass, skin changes, unilateral black or bloody nipple discharge.

Description: Breast cancer is the most common noncutaneous cancer in U.S. women, accounting for 30% of all new cancer cases and 15% of all cancer deaths in 2021 (American Cancer Society [ACS], 2021a). Breast cancer was estimated to affect 49,290 with *in situ* disease and 281,550 with invasive disease and to result in 43,600 deaths in 2021 (ACS, 2021a). Men represent approximately 1% of breast cancer incidence and deaths (ACS, 2021a). Incidence and death rates for breast cancer increase with age, peaking at ages 70 to 74. The incidence of breast cancer decreases after age 80, possibly due to reduced screening (ACS, 2019a; U.S. Cancer Statistics Working Group, 2020). Currently, women living in the United States have approximately a 13% or one in eight lifetime risk of developing breast cancer (Breastcancer.org, 2021). At the time of diagnosis, 64% of cancers are localized, and only 6% of initial diagnoses are for metastatic disease. The 5-year survival rate for localized breast cancer is 99%, for regional disease is 86%, and for metastatic disease is 26% (ACS, 2019a).
