Effect of Blood Concentrations of Glucose, Amino Acids, and Lipids on Hunger and Feeding. A decrease in blood glucose concentration has been shown in experimental studies to cause hunger, which has led to the so-called *glucostatic theory of hunger and feeding regulation*. Similar studies have demonstrated the same effect for blood amino acid concentration and blood concentration of breakdown products of lipids such as the keto acids and some fatty acids, leading to the *aminostatic* and *lipostatic* theories of regulation. That is, when the availability of any of the three major types of food decreases, the desire for feeding is increased, eventually returning the blood metabolite concentrations back toward normal if the appropriate foods are available.

The following observations from neurophysiological studies of function in specific areas of the brain also support the glucostatic, aminostatic, and lipostatic theories: (1) a rise in blood *glucose* level *increases the rate of firing of glucoreceptor neurons in the satiety center in the ventromedial and paraventricular nuclei of the hypothalamus*, and (2) the same increase in blood glucose level simultaneously *decreases* the firing of *glucosensitive neurons* in the *hunger center of the lateral hypothalamus*. In addition, some amino acids and lipid substances affect the rates of firing of these same neurons or other closely associated neurons.

Temperature Regulation and Food Intake. When an animal is exposed to cold, it tends to increase feeding; when it is exposed to heat, it tends to decrease its caloric intake. This phenomenon is caused by interaction within the hypothalamus between the temperature-regulating system (see Chapter 74) and the food intake–regulating system. This is important because increased food intake in a cold animal (1) increases its metabolic rate and (2) provides increased fat for insulation, both of which tend to protect against the cold.

Feedback Signals From Adipose Tissue Regulate Food Intake. Most of the stored energy in the body consists of fat, the amount of which can vary considerably in different persons. What regulates this energy reserve, and why is there so much variability among individuals?

Studies in humans and in experimental animals indicate that the hypothalamus senses energy storage through the actions of *leptin*, a peptide hormone released from adipocytes. When the amount of adipose tissue increases (signaling excess energy storage), the adipocytes produce increased amounts of leptin, which is released into the blood. Leptin then circulates to the brain, where it moves across the blood-brain barrier by facilitated diffusion and occupies leptin receptors at multiple sites in the hypothalamus, especially the POMC and AGRP/NPY neurons of the arcuate nuclei and neurons of the paraventricular nuclei, as well as neurons in other areas of the brain including the brainstem.

Stimulation of leptin receptors in these central nervous system nuclei initiates multiple actions that decrease fat storage, including (1) decreased production in the hypothalamus of appetite stimulators, such as *NPY* and *AGRP*; (2) *activation of POMC neurons*, causing release of α-MSH and activation of melanocortin receptors; (3) increased production in the hypothalamus of substances, such as *corticotropin-releasing hormone*, that decrease food intake; (4) *increased sympathetic nerve activity* (through neural projections from the hypothalamus to the vasomotor centers), which increases metabolic rate and energy expenditure; and (5) *decreased insulin secretion* by the pancreatic beta cells, which decreases energy storage. Thus, leptin is an important means by which the adipose tissue signals the brain that enough energy has been stored and that intake of food is no longer necessary.

In mice or humans with mutations that render their fat cells unable to produce leptin or mutations that cause defective leptin receptors in the hypothalamus, marked hyperphagia and morbid obesity occur. In most obese humans, however, there does not appear to be a deficiency of leptin production because plasma leptin levels increase in proportion with increasing adiposity. Therefore, some physiologists believe that obesity may be associated with *leptin resistance*; that is, leptin receptors or postreceptor signaling pathways normally activated by leptin may be resistant to activation by leptin in obese people, who continue to overeat despite having very high levels of leptin.

Another explanation for the failure of leptin to prevent increasing adiposity in obese individuals is that there are many redundant systems that control feeding behavior, as well as social and cultural factors that can cause continued excess food intake even in the presence of high levels of leptin.

Summary of Long-Term Regulation. Even though our information on the different feedback factors in long-term feeding regulation is imprecise, we can make the following general statement: When the energy stores of

the body fall below normal, the feeding centers of the hypothalamus and other areas of the brain become highly active, and the person exhibits increased hunger, as well as the behavior of searching for food. Conversely, when the energy stores (mainly the fat stores) are already abundant, the person usually loses the sensation of hunger and develops a state of satiety. Although the precise feedback systems that regulate food intake and energy expenditure are not fully understood, rapid advances have been made in this field of research in recent years, with the discovery of many new orexigenic and anorexigenic factors.

Importance of Having Both Long- and Short-Term Regulatory Systems for Feeding

The long-term regulatory system for feeding, which includes all the nutritional energy feedback mechanisms, helps maintain constant stores of nutrients in the tissues, preventing them from becoming too low or too high. The short-term regulatory stimuli serve two other purposes. First, they tend to make the person eat smaller quantities at each eating session, thus allowing food to pass through the gastrointestinal tract at a steadier pace so that its digestive and absorptive mechanisms can work at optimal rates rather than becoming periodically overburdened. Second, they help prevent the person from eating amounts at each meal that would be too much for the metabolic storage systems once all the food has been absorbed.

Obesity

Obesity can be defined as an excess of body fat. A surrogate marker for body fat content is the body mass index (BMI), which is calculated as:

$$\text{BMI} = \frac{\text{Weight in kilograms}}{\text{Height in meters}^2}$$

In clinical terms, a person with a BMI between 25 and 29.9 kg/m^2 is deemed overweight, and a person with a BMI greater than or equal to 30 kg/m^2 is considered obese. BMI is not a direct estimate of adiposity and does not take into account the fact that some individuals have a high BMI as a result of a large muscle mass. A better way to define obesity is to actually measure the percentage of total body fat. Obesity is usually defined as 25% or greater total body fat in men and 35% or greater total body fat in women. Although percentage of body fat can be estimated with various methods, such as measuring skin-fold thickness, bioelectrical impedance, or underwater weighing, these methods are not routinely used in clinical practice, where BMI is commonly used to assess obesity.

The adverse impact of obesity on the risk for various disorders such as cirrhosis, hypertension, heart attack, stroke, and kidney disease appears to be more closely associated with increased visceral (abdominal) adiposity than with increased subcutaneous fat storage, or storage of fat in the lower parts of the body such as the hips. Therefore, many clinicians measure waist circumference or sagittal abdominal diameter as indicators of abdominal obesity. In the United States a waist circumference greater than 102 centimeters in men and 88 centimeters in women or a waist/hip ratio of greater than 0.9 in men and 0.85 in women is often considered to indicate abdominal obesity in adults.

The prevalence of obesity in children and adults in the United States and in many other industrialized countries is rapidly increasing, rising by more than 30% during the past decade. Approximately 70% of adults aged 20 and over in the United States are overweight or obese, and more than 35% of those adults are obese.

Obesity Results From Greater Intake Than Expenditure of Energy

When greater quantities of energy (in the form of food) enter the body than are expended, the body weight increases, and most of the excess energy is stored as fat. Therefore, excessive adiposity (obesity) is caused by energy intake in excess of energy output. For each 9.3 calories of excess energy that remains in the body, approximately 1 gram of fat is stored.

Fat is stored mainly in adipocytes in subcutaneous tissue and in the intraperitoneal cavity, although the liver and other tissues of the body often accumulate significant amounts of lipids in obese persons. The metabolic processes involved in fat storage were discussed in Chapter 69.

It was previously believed that the number of adipocytes could increase substantially only during infancy and childhood and that excess energy intake in children led to *hyperplastic obesity,* associated with increased numbers of adipocytes and only small increases in adipocyte size. In contrast, the development of obesity in adults was thought to increase only adipocyte size, resulting in *hypertrophic obesity*. However, research studies have shown that new adipocytes can differentiate from fibroblast-like preadipocytes at any period of life and that the development of obesity in adults is accompanied by increased numbers, as well as increased size, of adipocytes. An extremely obese person may have as many as four times as many adipocytes, each containing twice as much lipid, as a lean person.

Once a person has become obese and a stable weight is obtained, energy intake once again equals energy output. For a person to lose weight, energy intake must be *less* than energy expenditure.

Decreased Physical Activity and Abnormal Feeding Regulation as Causes of Obesity

The causes of obesity are complex. Although genes play an important role in programming the powerful physiological mechanisms that regulate food intake and energy metabolism, lifestyle and environmental factors may play a major role in many obese people. The rapid increase in the prevalence of obesity in the past 20 to 30 years emphasizes the important role of lifestyle and environmental factors because genetic changes could not have occurred so rapidly. Still, genetic factors may predispose many people to the environmental influences that are driving the rising prevalence of obesity in most industrialized and developing countries.

Sedentary Lifestyle Is a Major Cause of Obesity. Regular physical activity and physical training are known to increase muscle mass and decrease body fat mass, whereas inadequate physical activity is typically associated with decreased muscle mass and increased adiposity. For example, studies have shown a close association between sedentary

behaviors, such as excessive screen time (e.g., television watching), and obesity.

About 25% to 30% of the energy used each day by the average person goes into muscular activity, and in a laborer, as much as 60% to 70% is used in this way. In obese people, increased physical activity often increases energy expenditure more than food intake, resulting in significant weight loss. Even a single episode of strenuous exercise may increase basal energy expenditure for several hours after the physical activity is stopped. Because muscular activity is by far the most important means by which energy is expended in the body, increased physical activity is often an effective means of reducing fat stores.

Abnormal Feeding Behavior Is an Important Cause of Obesity. Although powerful physiological mechanisms regulate food intake, important environmental, social, and psychological factors also can cause abnormal feeding behavior, excessive energy intake, and obesity.

As discussed previously, the importance of environmental factors is evident from the rapid increase in the prevalence of obesity in most industrialized countries, which has coincided with an abundance of high-energy foods and sedentary lifestyles.

Psychological and social factors may contribute to obesity in some people. For example, people often gain large amounts of weight during or after stressful situations, such as the death of a parent, a severe illness, or even mental depression. It seems that eating can be a means of relieving stress.

Childhood Overnutrition May Contribute to Adult Obesity. One factor that may contribute to obesity is the prevalent idea that healthy eating habits require three meals a day and that each meal must be filling. Many young children are forced into this habit by overly solicitous parents, and the children continue to practice it throughout life.

The rate of formation of new fat cells is especially rapid in the first few years of life, and the greater the rate of fat storage, the greater the number of fat cells. The number of fat cells in obese children is often as much as three times that in normal children. Therefore, it has been suggested that overnutrition of children—especially in infancy and, to a lesser extent, during the later years of childhood—can lead to a lifetime of obesity. In fact, studies have shown that approximately 80% of obese children become obese adults.

Genetic Factors as a Cause of Obesity. Obesity definitely runs in families. However, it has been difficult to determine the precise role of genetics in contributing to obesity because family members generally share many of the same eating habits and physical activity patterns. Current evidence suggests that 20% to 25% of cases of obesity may be caused by genetic factors.

Genes can contribute to obesity by causing abnormalities of (1) one or more of the pathways that regulate the feeding centers and (2) energy expenditure and fat storage. Three of the monogenic (single-gene) causes of obesity are (1) *mutations of POMC and MCR-4*, the most common monogenic forms of obesity discovered thus far; (2) *congenital leptin deficiency* caused by mutations of the leptin gene, which are very rare; and (3) *mutations of the leptin receptor*, which are also rare. All these monogenic forms of obesity account for only a very small percentage of obesity.

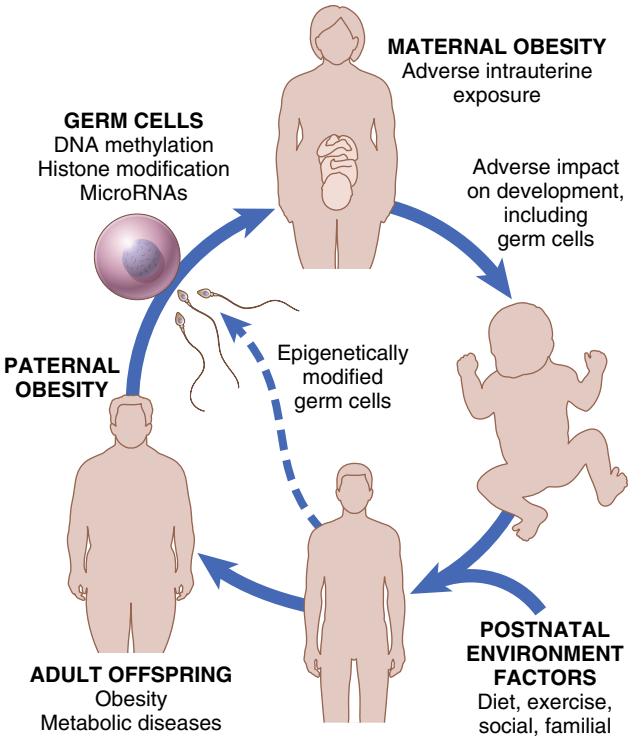

Figure 72-3. Possible interactions of adverse intrauterine environment, epigenetic, and development factors in programming increased risk for obesity in multiple generations. The intrauterine environment of an obese mother may influence development of the embryo, including epigenetic effects on germ cells that become sperm or oocytes. The sperm and oocytes of male and female parents may also be altered by epigenetic changes that occur secondary to obesity, thus predisposing subsequent generations to increased risk for developing obesity.

It is likely that many gene variations interact with environmental factors to influence the amount and distribution of body fat.

Parents May Contribute to Obesity in Their Offspring Through Epigenetic Mechanisms. Parents who are overweight or obese may also increase the risk for obesity and associated disorders in their offspring through "*epigenetic*" mechanisms that alter gene expression in the absence of a change in the DNA sequence (**Figure 72-3**). Epigenetic effects of parental obesity have been proposed to occur through alterations in *DNA methylation*, *histone modifications*, and *expression of microRNAs* that may influence gene expression in the offspring. Based mainly on studies in experimental animals, it has been suggested that epigenetic changes in the parents' gametes (sperm from the father and oocytes from the mother) as well as an adverse intrauterine environment and epigenetic changes in the developing fetus' *germ cells* (embryonic cells that give rise to the gametes) may contribute to obesity in the immediate offspring as well as in subsequent generations. However, additional research is needed to further assess the impact of germ cell epigenetics in predisposing human beings to become obese.

Regardless of the precise contribution of genetic, epigenetic and environmental factors, it is clear that the percentage of children affected by obesity has increased steadily in

many countries, including the United States, where obesity prevalence in children has more than tripled since the 1970s.

Neurogenic Abnormalities as a Cause of Obesity. We previously pointed out that lesions in the ventromedial nuclei of the hypothalamus cause an animal to eat excessively and become obese. Progressive obesity often develops in people with hypophysial tumors that encroach on the hypothalamus, demonstrating that obesity in human beings, too, can result from damage to the hypothalamus.

Although hypothalamic damage is almost never found in obese people, it is possible that the functional organization of the hypothalamic or other neurogenic feeding centers in obese individuals is different from that in persons who are not obese. Also, abnormalities of neurotransmitters or receptor mechanisms may be present in the neural pathways of the hypothalamus that control feeding. In support of this theory, an obese person who has reduced to normal weight by strict dietary measures usually develops intense hunger that is demonstrably far greater than that of a normal person. Also, diet-induced weight loss in obese people is associated with substantial "*metabolic adaptation,*" which refers to slowing of metabolic rate and energy expenditure by greater amounts than predicted for the change in body composition caused by loss of fat and muscle mass. This phenomenon suggests that the "set points" of an obese person's feeding and metabolic control systems are at a much higher level of nutrient storage than that of a nonobese person.

Studies in experimental animals also indicate that when food intake is restricted in obese animals, marked neurotransmitter changes occur in the hypothalamus that greatly increase hunger and oppose weight loss. Some of these changes include increased formation of orexigenic neurotransmitters such as NPY and decreased formation of anorexigenic substances such as leptin and α-MSH. Studies in humans have confirmed that diet-induced weight loss is accompanied by increased levels of hunger-stimulating hormones (e.g., ghrelin) and decreased levels of hormones (e.g., leptin) that reduce hunger. These hormonal changes persist for at least 1 year after the weight loss, perhaps explaining, in part, why it is so difficult for most people to achieve sustained weight loss by dieting alone.

Treatment of Obesity

Treatment of obesity depends on decreasing energy input below energy expenditure and creating a sustained negative energy balance until the desired weight loss is achieved. The current National Institutes of Health (NIH) guidelines recommend a decrease in caloric intake of 500 Calories (kilocalories) per day for overweight and moderately obese persons (BMI >25 but <35 kg/m^2) to achieve a weight loss of approximately 1 pound each week. A more aggressive energy deficit of 500 to 1000 Calories per day is recommended for persons with BMIs greater than 35 kg/m^2. Typically, such an energy deficit, if it can be achieved and sustained, will cause a weight loss of about 1 to 2 pounds per week, or about a 10% weight loss after 6 months. However, it is important to prevent vitamin deficiencies during the dieting period.

For most people, increasing physical activity is also an important component of successful long-term reductions in adiposity. Almost all current guidelines for treatment of obesity therefore recommend lifestyle modifications that include increased physical activity combined with a reduction in caloric intake.

Pharmacological Management of Obesity. Various *drugs for decreasing the degree of hunger* have been used in obesity treatment. The most widely used drugs are *amphetamines* (or amphetamine derivatives), which directly inhibit the feeding centers in the brain. One drug for treating obesity combines *phentermine,* a sympathomimetic that reduces food intake and increases energy expenditure, with *topiramate,* which has been used as an anticonvulsant drug. The danger in using sympathomimetic drugs is that they simultaneously overexcite the sympathetic nervous system and raise blood pressure. A commonly used sympathomimetic drug, *sibutramine,* was removed from the United States market in 2010 for obesity treatment because clinical studies demonstrated that it increased the risk for myocardial infarction and stroke. Another drug developed for treatment of obesity is *lorcaserin,* which activates serotonin receptors in the brain and promotes increased POMC expression. However, the FDA requested the withdrawal of lorcaserin from the market in 2020 due to safety concerns. *Bupropion*, a dopamine and norepinephrine reuptake inhibitor, stimulates POMC neurons and is used in combination with *naltrexone,* an opioid receptor antagonist, to treat obesity. Synthetic *Glucagon-like peptide-1* (GLP-1) *agonists*, a class of drugs used to treat type 2 diabetes mellitus, also stimulates POMC neurons to cause satiety and modest weight loss.

Another class of medications, the *sodium-glucose transporter 2* (SGLT 2) *inhibitors,* promote mild weight loss by preventing reabsorption of glucose as well as water in the renal tubules and are also used in treating type 2 diabetes mellitus.

Still another group of drugs works by altering lipid absorption by the gut. For example, *orlistat, a lipase inhibitor, reduces the intestinal digestion of fat,* causing a portion of the ingested fat to be lost in the feces and therefore reducing energy absorption. However, fecal fat loss may cause unpleasant gastrointestinal side effects, as well as loss of fat-soluble vitamins in the feces.

All of the drugs that are currently approved for long-term treatment of obesity produce modest weight loss, usually only 5% to 10%, or less in some cases, and are most effective when used in combination with lifestyle modifications aimed at increased physical activity and a healthier diet.

Surgical Treatment of Obesity. For morbidly obese patients with BMIs greater than 40 kg/m^2, or for patients with BMIs greater than 35 kg/m^2 and conditions such as hypertension or type 2 diabetes that predispose them to other serious diseases, various surgical procedures can be used to decrease the fat mass of the body or to decrease the amount of food that can be eaten at each meal.

Gastric bypass surgery involves construction of a small pouch in the proximal part of the stomach that is then connected to the jejunum with a section of small bowel of varying lengths; the pouch is separated from the remaining part of the stomach with staples. *Gastric banding surgery* involves placing an adjustable band around the stomach near its upper end; this procedure also creates a small stomach pouch that restricts the amount of food that can be eaten at each meal. A third procedure that is now becoming more

widely used is *vertical sleeve gastrectomy,* which removes a large part of the stomach with the remaining part stapled back together. These surgical procedures generally produce substantial weight loss in obese patients. The gastric bypass and vertical sleeve procedures often lead to rapid *remission of type 2 diabetes mellitus and hypertension*, important complications of obesity, even before substantial weight loss has occurred. These procedures are major operations, however, and their long-term effects on overall health and mortality are still uncertain.

Inanition, Anorexia, and Cachexia

Inanition is the opposite of obesity and is characterized by extreme weight loss. It can be caused by inadequate availability of food or by pathophysiological conditions that greatly decrease the desire for food, including psychogenic disturbances, hypothalamic abnormalities, and factors released from peripheral tissues. In many cases, especially in persons with serious diseases such as cancer, the reduced desire for food may be associated with increased energy expenditure, resulting in serious weight loss.

Anorexia can be defined as *a reduction in food intake caused primarily by diminished appetite,* as opposed to the literal definition of "not eating." This definition emphasizes the important role of central neural mechanisms in the pathophysiology of anorexia in diseases such as cancer, when other common problems, such as pain and nausea, may also cause a person to consume less food. *Anorexia nervosa* is an abnormal psychic state in which a person loses all desire for food and even becomes nauseated by food; as a result, severe inanition occurs.

Cachexia is a metabolic disorder of increased energy expenditure leading to weight loss greater than that caused by reduced food intake alone. Anorexia and cachexia often occur together in many types of cancer or in the "wasting syndrome" observed in patients with acquired immunodeficiency syndrome (AIDS) and chronic inflammatory disorders. Almost all types of cancer cause both anorexia and cachexia, and anorexia-cachexia syndrome develops in more than half of persons with cancer during the course of their disease.

Central neural and peripheral factors are believed to contribute to cancer-induced anorexia and cachexia. Several inflammatory cytokines, including *tumor necrosis factor-α, interleukin-6, interleukin-1β,* and a *proteolysis-inducing factor*, have been shown to cause anorexia and cachexia. Most of these inflammatory cytokines appear to mediate anorexia by activation of the *melanocortin system* in the hypothalamus. The precise mechanisms by which cytokines or tumor products interact with the melanocortin pathway to decrease food intake are still unclear, but blockade of hypothalamic melanocortin receptors greatly attenuates their anorexic and cachectic effects in experimental animals. Additional research, however, is necessary to better understand the pathophysiological mechanisms of anorexia and cachexia in persons with cancer and to develop therapeutic agents to improve the nutritional status and survival of these individuals.

Starvation

Depletion of Food Stores in the Body Tissues During Starvation. Even though the tissues prefer to use carbohydrate rather than fat or protein for energy, the quantity of carbohydrate normally stored in the entire body is only a few hundred grams (mainly glycogen in the liver and muscles), and it can supply the energy required for body functions for only perhaps half a day. Therefore, except for the first few hours, the major effects of starvation are progressive depletion of tissue fat and protein. Because fat is the prime source of energy (100 times as much fat energy as carbohydrate energy is stored in the average person), the rate of fat depletion continues unabated, as shown in **Figure 72-4**, until most of the fat stores in the body are gone.

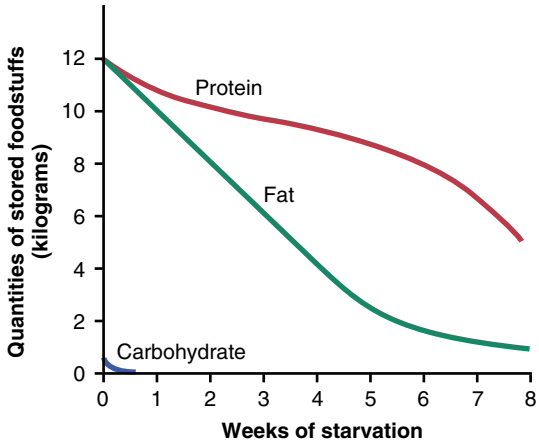

Figure 72-4. Effect of starvation on the food stores of the body.

Protein undergoes three phases of depletion: rapid depletion at first, followed by greatly slowed depletion, and finally rapid depletion again shortly before death. The initial rapid depletion is caused by the use of easily mobilized protein for direct metabolism or for conversion to glucose and then metabolism of glucose mainly by the brain. After the readily mobilized protein stores have been depleted during the early phase of starvation, the remaining protein is not so easily removed. At this time, the rate of gluconeogenesis decreases to 30% to 50% of its previous rate, and the rate of depletion of protein becomes greatly decreased. The lessened availability of glucose then initiates a series of events that leads to excessive fat utilization and conversion of some of the fat breakdown products to ketone bodies, producing *ketosis,* which is discussed in Chapter 69. The ketone bodies, like glucose, can cross the blood-brain barrier and can be used by the brain cells for energy. Therefore, about two-thirds of the brain's energy is now derived from these ketone bodies, principally from β-hydroxybutyrate. This sequence of events leads to at least partial preservation of the protein stores of the body.

There finally comes a time when the fat stores are almost depleted, and the only remaining source of energy is protein. At that time, the protein stores once again enter a stage of rapid depletion. Because proteins are also essential for the maintenance of cellular function, death ordinarily ensues when the body proteins have been depleted to about half their normal level.

Vitamin Deficiencies in Starvation. The stores of some vitamins, especially the water-soluble vitamins—the vitamin B group and vitamin C—do not last long during starvation. Consequently, after a week or more of starvation, mild vitamin deficiencies usually begin to appear, and after

Table 72-3 Recommended Daily Dietary Intakes of Vitamins for Adult Men and Women

	Amount	
Vitamin	Men	Women
A (Retinol)	900 μg (3000 IU)	700 μg (2333 IU)
B_1 (Thiamine)	1.2 mg	1.0 mg
B_2 (Riboflavin)	1.3 mg	1.0 mg
B_3 (Niacin)	16 mg	14 mg
B_5 (Pantothenic acid)	5 mg	5 mg
B_6 (Pyridoxine)	1.3 mg	1.3 mg
B_9 (Folic acid)	0.4 mg	0.4 mg
B_{12}	2.4 μg	2.4 μg
C (Ascorbic acid)	90 mg	75 mg
D (Calciferol)	15 μg (600 IU)	15 μg (600 IU)
E (Alpha-tocopherol)	15 mg (22.4 IU)	15 mg (22.4 IU)
K	120 μg	90 μg

IU, International units.

Adapted from the US Department of Health and Human Services, National Institutes of Health, Office of Dietary Supplements. https://ods.od.nih.gov/factsheets/list-VitaminsMinerals/.

several weeks, severe vitamin deficiencies can occur. These deficiencies can add to the debility that leads to death.

Vitamins

Daily Requirements of Vitamins. A vitamin is an organic compound needed in small quantities for normal metabolism that cannot be manufactured in the cells of the body. Lack of vitamins in the diet can cause important metabolic deficits. **Table 72-3** lists the amounts of important vitamins required daily by the average adult man and woman. These requirements vary considerably, depending on such factors as body size, rate of growth, amount of exercise, pregnancy, and lactation.

Storage of Vitamins in the Body. Vitamins are stored to a slight extent in all cells. Some vitamins are stored to a major extent in the liver. For example, the quantity of vitamin A stored in the liver may be sufficient to maintain a person for 5 to 10 months without any intake of vitamin A. The quantity of vitamin D stored in the liver is usually sufficient to maintain a person for 2 to 4 months without any additional intake of vitamin D.

The storage of most water-soluble vitamins, especially vitamin C and most vitamin B compounds, is relatively slight. Absence of vitamin C in the diet can cause symptoms within a few weeks and can cause death from *scurvy* in 20 to 30 weeks. When a person's diet is deficient in vitamin B compounds, clinical symptoms of the deficiency can sometimes be recognized within a few days (except for vitamin B_{12}, which can last in the liver in a bound form for a year or longer).

Vitamin A

Vitamin A occurs in animal tissues as *retinol*. This vitamin does not occur in foods of vegetable origin, but *provitamins* for the formation of vitamin A do occur in abundance in many vegetable foods. These provitamins are the yellow and red *carotenoid pigments*, which, because their chemical structures are similar to that of vitamin A, can be changed into vitamin A in the liver.

Vitamin A Deficiency Causes "Night Blindness" and Abnormal Epithelial Cell Growth. One basic function of vitamin A is its use in forming retinal pigments of the eye, which is discussed in Chapter 51. Vitamin A is needed to form the visual pigments and, therefore, to prevent night blindness.

Vitamin A is also necessary for normal growth of most cells of the body and especially for normal growth and proliferation of the different types of epithelial cells. When vitamin A is lacking, the epithelial structures of the body tend to become stratified and keratinized. Vitamin A deficiency manifests itself by (1) scaliness of the skin and sometimes acne; (2) failure of growth of young animals, including cessation of skeletal growth; (3) failure of reproduction, associated especially with atrophy of the germinal epithelium of the testes and sometimes with interruption of the female sexual cycle; and (4) keratinization of the cornea, with resultant corneal opacity and blindness.

In vitamin A deficiency, the damaged epithelial structures often become infected (e.g., conjunctivae of the eyes, linings of the urinary tract, and respiratory passages). Vitamin A has been called an "anti-infection" *vitamin.*

Thiamine (Vitamin B_1)

Thiamine operates in the metabolic systems of the body principally as *thiamine pyrophosphate;* this compound functions as a *cocarboxylase*, operating mainly in conjunction with a protein decarboxylase for decarboxylation of pyruvic acid and other α-keto acids, as discussed in Chapter 68.

Thiamine deficiency *(beriberi)* causes decreased utilization of pyruvic acid and some amino acids by the tissues but increased utilization of fats. Thus, thiamine is specifically needed for final metabolism of carbohydrates and many amino acids. Decreased utilization of these nutrients is responsible for many debilities associated with thiamine deficiency.

Thiamine Deficiency Causes Lesions of the Central and Peripheral Nervous Systems. The central nervous system normally depends almost entirely on the metabolism of carbohydrates for its energy. In thiamine deficiency, utilization of glucose by nervous tissue may be decreased by 50% to 60% and is replaced by utilization of ketone bodies derived from fat metabolism. The neuronal cells of the central nervous system frequently show chromatolysis and swelling during thiamine deficiency, changes that are characteristic of neuronal cells with poor nutrition. These changes can disrupt communication in many portions of the central nervous system.

Thiamine deficiency can cause *degeneration of myelin sheaths* of nerve fibers in both the peripheral nerves and the central nervous system. Lesions in peripheral nerves frequently cause them to become extremely irritable, resulting in "polyneuritis," characterized by pain radiating along the course of one or many peripheral nerves. Also, fiber tracts in the cord can degenerate to such an extent that *paralysis* occasionally results; even in the absence of paralysis, the muscles atrophy, resulting in severe weakness.

Thiamine Deficiency Weakens the Heart and Causes Peripheral Vasodilation. *Cardiac failure* eventually develops in a person with severe thiamine deficiency because of weakened cardiac muscle. Furthermore, the venous return of blood to the heart may be increased to as much as two times normal, because thiamine deficiency causes *peripheral vasodilation* throughout the circulatory system, presumably as a result of decreased release of metabolic energy in the tissues, leading to local vascular dilation. The cardiac effects of thiamine deficiency are due partly to high blood flow into the heart and partly to primary weakness of the cardiac muscle. *Peripheral edema* and *ascites* also occur to a major extent in some people with thiamine deficiency, mainly because of cardiac failure.

Thiamine Deficiency Causes Gastrointestinal Tract Disturbances. Among the gastrointestinal symptoms of thiamine deficiency are indigestion, severe constipation, anorexia, gastric atony, and hypochlorhydria. All these effects presumably result from failure of the smooth muscle and glands of the gastrointestinal tract to derive sufficient energy from carbohydrate metabolism.

The overall picture of thiamine deficiency, including polyneuritis, cardiovascular symptoms, and gastrointestinal disorders, is frequently referred to as *beriberi*—especially when the cardiovascular symptoms predominate.

Riboflavin (Vitamin B_2)

Riboflavin normally combines in the tissues with phosphoric acid to form two coenzymes, *flavin mononucleotide* (FMN) and *flavin adenine dinucleotide* (FAD). They operate as hydrogen carriers in important oxidative systems of the mitochondria. NAD, operating in association with specific dehydrogenases, usually accepts hydrogen removed from various food substrates and then passes the hydrogen to FMN or FAD. Finally, the hydrogen is released as an ion into the mitochondrial matrix to become oxidized by oxygen (described in Chapter 68).

Deficiency of riboflavin in experimental animals causes severe dermatitis, vomiting, diarrhea, muscle spasticity that finally becomes muscle weakness, coma, and decline in body temperature, followed by death. Thus, severe riboflavin deficiency can cause many of the same effects as a lack of niacin in the diet; presumably, the debilities that result in each case are due to generally depressed oxidative processes within the cells.

In the human being, there are no known cases of riboflavin deficiency severe enough to cause the marked debilities noted in animal studies, but mild riboflavin deficiency is probably common. Such deficiency causes digestive disturbances, burning sensations of the skin and eyes, cracking at the corners of the mouth, headaches, mental depression, forgetfulness, and so on.

Although the manifestations of riboflavin deficiency are usually relatively mild, this deficiency frequently occurs in association with deficiency of thiamine, niacin, or both. Many deficiency syndromes, including *pellagra, beriberi, sprue*, and *kwashiorkor,* are probably due to a combined deficiency of a number of vitamins, as well as other aspects of malnutrition.

Niacin (Vitamin B_3)

Niacin, also called *nicotinic acid*, functions in the body as coenzymes in the form of nicotinamide adenine dinucleotide (NAD) and NAD phosphate. These coenzymes are hydrogen acceptors and combine with hydrogen atoms as they are removed from food substrates by many types of dehydrogenases. The typical operation of both these coenzymes is presented in Chapter 68. When niacin deficiency exists, the normal rate of dehydrogenation cannot be maintained; therefore, oxidative delivery of energy from the foodstuffs to the functioning elements of all cells cannot occur at normal rates.

In the early stages of niacin deficiency, simple physiological changes such as muscle weakness and poor glandular secretion may occur, but in the case of severe niacin deficiency, actual tissue death ensues. Pathological lesions appear in many parts of the central nervous system, and permanent dementia or many types of psychoses may result. In addition, the skin develops a cracked, pigmented scaliness in areas that are exposed to mechanical irritation or sun irradiation; thus, in persons with niacin deficiency, the skin is unable to repair irritative damage.

Niacin deficiency causes intense irritation and inflammation of the mucous membranes of the mouth and other portions of the gastrointestinal tract, resulting in many digestive abnormalities that can lead to widespread gastrointestinal hemorrhage in severe cases. It is possible that this condition results from generalized depression of metabolism in the gastrointestinal epithelium and failure of appropriate epithelial repair.

The clinical entity called *pellagra* and the canine disease called *black tongue* are caused mainly by niacin deficiency. Pellagra is greatly exacerbated in people on a corn diet because corn is deficient in the amino acid tryptophan, which can be converted in limited quantities to niacin in the body.

Pantothenic Acid (Vitamin B_5)

Pantothenic acid is mainly incorporated in the body into *coenzyme A* (CoA), which has many metabolic roles in the cells. Two of these roles discussed at length in Chapters 68 and 69 are (1) conversion of decarboxylated pyruvic acid into acetyl-CoA before its entry into the citric acid cycle and (2) degradation of fatty acid molecules into multiple molecules of acetyl-CoA. *Thus, lack of pantothenic acid can lead to depressed metabolism of carbohydrates and fats.*

Deficiency of pantothenic acid in experimental animals can cause retarded growth, failure of reproduction, graying of the hair, dermatitis, fatty liver, and hemorrhagic adrenocortical necrosis. In humans, no definite deficiency syndrome has been proved, presumably because of the wide occurrence of this vitamin in almost all foods and because small amounts can probably be synthesized in the body. This situation does not mean that pantothenic acid is not of value in the metabolic systems of the body; indeed, it is perhaps as necessary as any other vitamin.

Pyridoxine (Vitamin B_6)

Pyridoxine exists in the form of *pyridoxal phosphate* in the cells and functions as a coenzyme for many chemical reactions related to amino acid and protein metabolism. *Its most important role is that of coenzyme in the transamination process for the synthesis of amino acids.* As a result, pyridoxine plays many key roles in metabolism, especially protein metabolism. Also, it is believed to act in the transport of some amino acids across cell membranes.

Dietary lack of pyridoxine in experimental animals can cause dermatitis, decreased rate of growth, development of fatty liver, anemia, and evidence of mental deterioration. Rarely, in children, pyridoxine deficiency has been known to cause seizures, dermatitis, and gastrointestinal disturbances such as nausea and vomiting.

Vitamin B_{12}

Several *cobalamin* compounds that possess a common prosthetic group exhibit so-called vitamin B_{12} activity. This prosthetic group contains cobalt, which has bonds similar to those of iron in the hemoglobin molecule. It is likely that the cobalt atom functions in much the same way that the iron atom functions to combine reversibly with other substances.

Vitamin B_{12} Deficiency Causes Pernicious Anemia. Vitamin B_{12} performs several metabolic functions in its role as a hydrogen acceptor coenzyme. Its most important function is to act as a coenzyme for reducing ribonucleotides to deoxyribonucleotides, a step that is necessary in the replication of genes and could explain the major functions of vitamin B_{12}: (1) promotion of growth and (2) promotion of red blood cell formation and maturation. This red blood cell function is described in detail in Chapter 33 in relation to pernicious anemia, a type of anemia caused by failure of red blood cell maturation when vitamin B_{12} is deficient.

Vitamin B_{12} Deficiency Causes Demyelination of the Large Nerve Fibers of the Spinal Cord. The demyelination of nerve fibers in people with vitamin B_{12} deficiency occurs especially in the posterior columns, and occasionally the lateral columns, of the spinal cord. As a result, many people with pernicious anemia have loss of peripheral sensation and, in severe cases, even become paralyzed.

The usual cause of vitamin B_{12} deficiency is not lack of this vitamin in the food but deficiency of formation of *intrinsic factor*, which is normally secreted by the parietal cells of the gastric glands and is essential for absorption of vitamin B_{12} by the ileal mucosa. This topic is discussed in Chapters 33 and 67.

Folic Acid (Pteroylglutamic Acid, Vitamin B_9)

Several pteroylglutamic acids exhibit the "folic acid effect." Folic acid functions as a carrier of hydroxymethyl and formyl groups. *Perhaps its most important use in the body is in the synthesis of purines and thymine, which are required for DNA formation.* Therefore, folic acid, like vitamin B_{12}, is required for replication of the cellular genes and may explain one of the most important functions of folic acid—to promote growth. Indeed, when it is absent from the diet, an animal grows very little.

Folic acid is an even more potent growth promoter than vitamin B_{12} and, like vitamin B_{12}, it is important for the maturation of red blood cells, as discussed in Chapter 33. However, vitamin B_{12} and folic acid each perform specific and different chemical functions in promoting growth and maturation of red blood cells. One of the significant effects of folic acid deficiency is the development of *macrocytic anemia,* almost identical to that which occurs in pernicious anemia. This often can be treated effectively with folic acid alone.

Ascorbic Acid (Vitamin C)

Ascorbic Acid Deficiency Weakens Collagen Fibers Throughout the Body. Ascorbic acid is essential for activating the enzyme *prolyl hydroxylase,* which promotes the hydroxylation step in the formation of hydroxyproline, an integral constituent of collagen. Without ascorbic acid, collagen fibers that are formed in virtually all tissues of the body are defective and weak. Therefore, this vitamin is essential for growth and strength of the fibers in subcutaneous tissue, cartilage, bone, and teeth.

Ascorbic Acid Deficiency Causes Scurvy. Deficiency of ascorbic acid for 20 to 30 weeks causes *scurvy*. One of the most important effects of scurvy is *failure of wounds to heal.* This condition is caused by failure of the cells to deposit collagen fibrils and intercellular cement substances. As a result, healing of a wound may require several months instead of the several days ordinarily necessary.

Lack of ascorbic acid also causes *cessation of bone growth.* The cells of the growing epiphyses continue to proliferate, but no new collagen is laid down between the cells, and the bones fracture easily at the point of growth because of failure to ossify. Also, when an already ossified bone fractures in a person with ascorbic acid deficiency, the osteoblasts cannot form new bone matrix. Consequently, the fractured bone does not heal.

The *blood vessel walls become extremely fragile* in persons with scurvy because of (1) failure of the endothelial cells to be cemented together properly and (2) failure to form the collagen fibrils normally present in vessel walls. The capillaries are especially likely to rupture, and as a result, many small petechial hemorrhages occur throughout the body. The hemorrhages beneath the skin cause purpuric blotches, sometimes over the entire body. In extreme cases of scurvy, the muscle cells sometimes fragment; lesions of the gums occur, with loosening of the teeth; infections of the mouth develop; and vomiting of blood, bloody stools, and cerebral hemorrhage can all occur. Finally, high fever often develops before death.

Vitamin D

Vitamin D (calciferol) increases calcium absorption from the gastrointestinal tract and helps control calcium deposition in the bone. The mechanism by which vitamin D increases calcium absorption is mainly to promote active transport of calcium through the epithelium of the ileum. In particular, it increases the formation of a calcium-binding protein in the intestinal epithelial cells that aids in calcium absorption. The specific functions of vitamin D in relation to overall body calcium metabolism and bone formation are presented in Chapter 80.

Vitamin E (Alpha-Tocopherol)

Several related compounds exhibit so-called vitamin E activity. Only rare cases of proved vitamin E deficiency have occurred in human beings. In animal studies, lack of vitamin E can cause degeneration of the germinal epithelium in the testis and, therefore, can cause male sterility. Lack of vitamin E can also cause resorption of a fetus after conception in the female. Because of these effects of vitamin E deficiency, vitamin E is sometimes called the "antisterility vitamin." Deficiency of vitamin E prevents normal growth and sometimes causes degeneration of the renal tubular cells and the muscle cells.

Vitamin E is believed to play a protective role in the prevention of oxidation of unsaturated fats. In the absence of vitamin E, the quantity of unsaturated fats in the cells becomes diminished, causing abnormal structure and function of such cellular organelles as the mitochondria, the lysosomes, and even the cell membrane.

Vitamin K

Vitamin K is an essential co-factor to a liver enzyme that adds a carboxyl group to factors II (prothrombin), VII (proconvertin), IX, and X, all of which are important in blood coagulation. Without this carboxylation, these coagulation factors are inactive. Therefore, when vitamin K deficiency occurs, blood clotting is retarded. The function of this vitamin and its relation to some of the anticoagulants, such as dicumarol, are presented in greater detail in Chapter 37.

Several natural and synthetic compounds exhibit vitamin K activity. Because vitamin K is synthesized by bacteria in the colon, it is rare for a person to have a bleeding tendency because of vitamin K deficiency in the diet. However, when the bacteria of the colon are destroyed by administration of large quantities of antibiotic drugs, vitamin K deficiency occurs rapidly because of the paucity of this compound in the normal diet.

Mineral Metabolism

The functions of many minerals, such as sodium, potassium, and chloride, are presented at appropriate points in the text. Only specific functions of minerals not covered elsewhere are mentioned here. The average recommended or adequate daily dietary intakes of these minerals for adult men and women are provided in **Table 72-4**.

Magnesium. Magnesium is about one sixth as plentiful in cells as potassium. Magnesium is required as a catalyst for many intracellular enzymatic reactions, particularly those related to carbohydrate metabolism.

The extracellular fluid magnesium concentration is slight, only 1.8 to 2.5 mEq/L. Increased extracellular concentration of magnesium depresses nervous system activity, as well as skeletal muscle contraction. This latter effect can be blocked by the administration of calcium. Low magnesium concentration causes increased irritability of the nervous system, peripheral vasodilation, and cardiac arrhythmias, especially after acute myocardial infarction.

Calcium. Calcium is present in the body mainly in the form of calcium phosphate in the bone. This subject is discussed in detail in Chapter 80, as is the calcium content of extracellular fluid. Excess quantities of calcium ions in extracellular fluid can cause the heart to stop in systole and can act as a mental depressant. At the other extreme, low levels of calcium can cause spontaneous discharge of nerve fibers, resulting in tetany, as discussed in Chapter 80.

Phosphorus. *Phosphate is the major anion of intracellular fluid.* Phosphates have the ability to combine reversibly with many coenzyme systems and with multiple other compounds that are necessary for the operation of metabolic processes. Many important reactions of phosphates have been catalogued at other points in this text, especially in relation to the functions of adenosine triphosphate, adenosine diphosphate, phosphocreatine, and so forth.

Table 72-4 Recommended or Adequate Daily Dietary Intakes of Minerals for Adult Men and Women

	Amount	
Mineral	**Men**	**Women**
Sodium	1500 mg	1500 mg
Potassium	3400 mg	2600 mg
Chloride	2300 mg	2300 mg
Calcium	**1000 mg**[a]	**1000 mg**[b]
Phosphorus	**700 mg**	**700 mg**
Iron	**8 mg**	**18 mg**[c]
Iodine	**150 µg**	**150 µg**
Fluoride	4 mg	3 mg
Magnesium	**420 mg**	**320 mg**
Molybdenum	**45 mg**	**45 mg**
Selenium	**55 µg**	**55 µg**
Copper	**900 µg**	**900 µg**
Manganese	2.3 mg	1.8 mg
Zinc	**11 mg**	**8 mg**

Recommended daily allowances are in bold type and adequate intakes are in regular type.
[a]Increase to 1200 mg/day after age 70.
[b]Increase to 1200 mg/day after age 51.
[c]Decrease to 8 mg/day after age 51.

Also, bone contains a large amount of calcium phosphate, which is discussed in Chapter 80.

Iron. The function of iron in the body, especially in relation to the formation of hemoglobin, is discussed in Chapter 33. *Two thirds of the iron in the body is in the form of hemoglobin*, although smaller quantities are present in other forms, especially in the liver and bone marrow. Electron carriers containing iron (especially the cytochromes) are present in the mitochondria of all cells of the body and are essential for most of the oxidation that occurs in the cells. Therefore, iron is absolutely essential for transport of oxygen to the tissues and operation of oxidative systems within the tissue cells, without which life would cease within a few seconds.

Important Trace Elements in the Body

A few elements are present in the body in such small quantities that they are called *trace elements*. The amounts of these elements in foods are also usually minute. Yet, without any one of them, a specific deficiency syndrome is likely to develop. Three of the most important trace elements are iodine, zinc, and fluorine.

Iodine. The best known of the trace elements is iodine. This element is discussed in Chapter 77 in connection with the formation and function of thyroid hormone; as shown in **Table 72-4,** the entire body contains an average of only 14 milligrams. Iodine is essential for the formation of *thyroxine* and *triiodothyronine*, the two thyroid hormones that are essential for maintenance of normal metabolic rates in all cells of the body.

Zinc. Zinc is an integral part of many enzymes, one of the most important of which is *carbonic anhydrase*, which is present in especially high concentration in the red blood cells. This enzyme is responsible for rapid combination of carbon dioxide with water in red blood cells of peripheral capillary blood and for rapid release of carbon dioxide from pulmonary capillary blood into the alveoli. Carbonic anhydrase is also present to a major extent in the gastrointestinal mucosa, the tubules of the kidney, and the epithelial cells of many glands of the body. Consequently, zinc in small quantities is essential for the performance of many reactions related to carbon dioxide metabolism.

Zinc is also a component of *lactic dehydrogenase* and is therefore important for the interconversions between pyruvic acid and lactic acid. Finally, zinc is a component of some *peptidases* and is important for the digestion of proteins in the gastrointestinal tract.

Fluorine. Fluorine does not seem to be a necessary element for metabolism, but the presence of a small quantity of fluorine in the body during the period of life when the teeth are being formed subsequently protects against caries. Fluorine does not make the teeth stronger but suppresses the cariogenic process. It has been suggested that fluorine is deposited in the hydroxyapatite crystals of the tooth enamel and combines with and therefore blocks the functions of various trace metals that are necessary for activation of the bacterial enzymes that cause caries. Therefore, when fluorine is present, the enzymes remain inactive and cause no caries.

Excessive intake of fluorine causes *fluorosis*, which manifests in its mild state by mottled teeth and in its more severe state by enlarged bones. It has been postulated that in this condition, fluorine combines with trace metals in some of the metabolic enzymes, including the phosphatases, so that various metabolic systems become partially inactivated. According to this theory, the mottled teeth and enlarged bones are due to abnormal enzyme systems in the odontoblasts and osteoblasts. Even though the mottled teeth are highly resistant to the development of caries, the structural strength of these teeth may be lessened by the mottling process.

CHAPTER 73

UNIT XIII

Energetics and Metabolic Rate

Adenosine Triphosphate Functions as an "Energy Currency" in Metabolism

Carbohydrates, fats, and proteins can all be used by cells to synthesize large quantities of adenosine triphosphate (ATP), which is used as an energy source for almost all other cellular functions. For this reason, ATP has been called an energy "currency" in cell metabolism. Indeed, the transfer of energy from foodstuffs to most functional systems of the cells can be performed only through this medium of ATP (or the similar nucleotide guanosine triphosphate [GTP]). Many of the attributes of ATP are presented in Chapter 2.

An attribute of ATP that makes it highly valuable as an energy currency is the large quantity of free energy (≈7300 calories—or 7.3 Calories [kilocalories]—per mole under standard conditions, but as much as 12,000 calories under physiological conditions) vested in each of its two high-energy phosphate bonds. The amount of energy in each bond, when liberated by decomposition of ATP, is enough to cause almost any step of any chemical reaction in the body to take place if appropriate energy transfer is achieved. Some chemical reactions that require ATP energy use only a few hundred of the available 12,000 calories, and the remainder of this energy is lost in the form of heat.

ATP Is Generated by Combustion of Carbohydrates, Fats, and Proteins. In previous chapters, we discussed the transfer of energy from various foods to ATP. To summarize, ATP is produced through the following processes:

1. *Combustion of carbohydrates*—mainly glucose, but also smaller amounts of other sugars such as fructose; this combustion occurs in the cell cytoplasm through the anaerobic process of *glycolysis* and in the cell mitochondria through the aerobic *citric acid (Krebs) cycle.*
2. *Combustion of fatty acids* in the cell mitochondria by *beta-oxidation.*
3. *Combustion of proteins*, which requires hydrolysis to their component amino acids and degradation of the amino acids to intermediate compounds of the citric acid cycle and then to acetyl coenzyme A and carbon dioxide.

ATP Energizes the Synthesis of Cellular Components. Among the most important intracellular processes that require ATP energy is the formation of peptide linkages between amino acids during synthesis of proteins. The different peptide linkages, depending on which types of amino acids are linked, require from 500 to 5000 calories of energy per mole. Recall from Chapter 3 that four high-energy phosphate bonds are expended during the cascade of reactions required to form each peptide linkage. This expenditure provides a total of 48,000 calories of energy, far more than the 500 to 5000 calories eventually stored in each of the peptide linkages.

ATP energy is also used for synthesizing glucose from lactic acid and for synthesizing fatty acids from acetyl coenzyme A. In addition, ATP energy is used for the synthesis of cholesterol, phospholipids, the hormones, and almost all other substances of the body. Even the urea excreted by the kidneys requires ATP for its formation from ammonia. One might wonder why energy is expended to form urea, which is simply discarded by the body. However, remembering the extreme toxicity of ammonia in the body fluids, one can see the value of this reaction, which keeps the ammonia concentration of the body fluids at a low level.

ATP Energizes Muscle Contraction. Muscle contraction will not occur without energy from ATP. Myosin, one of the important contractile proteins of the muscle fiber, acts as an enzyme to cause breakdown of ATP into adenosine diphosphate (ADP), thus releasing the energy required to cause contraction. Only a small amount of ATP is normally degraded in muscles when muscle contraction is not occurring, but this rate of ATP usage can rise to at least 150 times the resting level during short bursts of maximal contraction. The mechanism by which ATP energy is used to cause muscle contraction is discussed in Chapter 6.

ATP Energizes Active Transport Across Membranes. In Chapters 4, 28, and 66, active transport of electrolytes and various nutrients across cell membranes and from the renal tubules and gastrointestinal tract into the blood is discussed. We noted that active transport of most electrolytes and substances such as glucose, amino acids, and acetoacetate can occur against an electrochemical gradient, even though the natural diffusion of the substances would be in the opposite direction. Energy provided by ATP is required to oppose the electrochemical gradient.

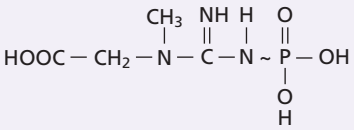
ATP Energizes Glandular Secretion. The same principles apply to glandular secretion as to the absorption of substances against concentration gradients because energy is required to concentrate substances as they are secreted by the glandular cells. In addition, energy is required to synthesize the organic compounds to be secreted.

ATP Energizes Nerve Conduction. The energy used during propagation of nerve impulses is derived from the potential energy stored in the form of concentration differences of ions across the neuronal cell membranes. That is, a high concentration of potassium inside the neuron

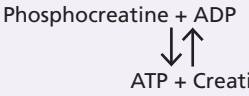
and a low concentration outside the neuron constitute a type of energy storage. Likewise, a high concentration of sodium on the outside of the membrane and a low concentration on the inside represent another store of energy. The energy needed to pass each action potential along the fiber membrane is derived from this energy storage, with small amounts of potassium transferring out of the cell and sodium into the cell during each of the action potentials. However, active transport systems energized by ATP then retransport the ions back through the membrane to their former positions.

Phosphocreatine Functions as an Accessory Storage Depot for Energy and as an "ATP Buffer"

Despite the paramount importance of ATP as a coupling agent for energy transfer, this substance is not the most abundant store of high-energy phosphate bonds in the cells. *Phosphocreatine*, which also contains high-energy phosphate bonds, is three to eight times more abundant than ATP. Also, the high-energy bond (~) of phosphocreatine contains about 8500 calories per mole under standard conditions and as many as 13,000 calories per mole under conditions in the body (37°C and low concentrations of the reactants). This amount is slightly greater than the 12,000 calories per mole in each of the two high-energy phosphate bonds of ATP. The formula for creatinine phosphate is the following:



Unlike ATP, phosphocreatine cannot act as a direct coupling agent for energy transfer between the foods and the functional cellular systems, but it can transfer energy interchangeably with ATP. When extra amounts of ATP are available in the cell, much of its energy is used to synthesize phosphocreatine, thus building up this storehouse of energy. Then, when the ATP begins to be used up, the energy in the phosphocreatine is transferred rapidly back to ATP and then to the functional systems of the cells. This reversible interrelation between ATP and phosphocreatine is demonstrated by the following equation:



The higher energy level of the high-energy phosphate bond in phosphocreatine (1000–1500 calories per mole greater than that in ATP) causes the reaction between phosphocreatine and ADP to proceed rapidly toward the formation of new ATP whenever the slightest amount of ATP expends its energy elsewhere. Therefore, the slightest usage of ATP by the cells calls forth the energy from the phosphocreatine to synthesize new ATP. This effect keeps the concentration of ATP at an almost constant high level as long as any phosphocreatine remains. For this reason, we can call the ATP-phosphocreatine system an ATP "buffer" system. One can readily understand the importance of keeping the concentration of ATP nearly constant because the rates of almost all the metabolic reactions in the body depend on this constancy.

Anaerobic Versus Aerobic Energy

Anaerobic energy means energy that can be derived from foods without the simultaneous utilization of oxygen; *aerobic energy* means energy that can be derived from foods only by oxidative metabolism. In Chapters 68 through 70, we noted that carbohydrates, fats, and proteins can all be oxidized to cause synthesis of ATP. However, *carbohydrates are the only significant foods that can be used to provide energy without utilization of oxygen*; this energy release occurs during glycolytic breakdown of glucose or glycogen to pyruvic acid. For each mole of glucose that is split into pyruvic acid, 2 moles of ATP are formed. However, when stored glycogen in a cell is split to pyruvic acid, each mole of glucose in the glycogen gives rise to 3 moles of ATP. The reason for this difference is that free glucose entering the cell must be phosphorylated by using 1 mole of ATP before it can begin to be split; this is not true of glucose derived from glycogen because it comes from the glycogen already in the phosphorylated state, without the additional expenditure of ATP. *Thus, the best source of energy under anaerobic conditions is the stored glycogen of the cells.*

Anaerobic Energy Utilization During Hypoxia. One of the prime examples of anaerobic energy utilization occurs in acute hypoxia. When a person stops breathing, a small amount of oxygen is already stored in the lungs and an additional amount is stored in the hemoglobin of the blood. This oxygen is sufficient to keep the metabolic processes functioning for only about 2 minutes. Continued life beyond this time requires an additional source of energy. This energy can be derived for another minute or so from glycolysis—that is, the glycogen of the cells splitting into pyruvic acid, and the pyruvic acid becoming lactic acid, which diffuses out of the cells, as described in Chapter 68.

Anaerobic Energy Utilization During Strenuous Bursts of Activity Is Derived Mainly From Glycolysis. Skeletal muscles can perform extreme feats of strength for a few seconds but are much less capable during prolonged activity. Most of the extra energy required during these bursts of activity cannot come from the oxidative processes because they are too slow to respond. Instead, the extra energy comes from anaerobic sources: (1) ATP already present in the muscle cells, (2) phosphocreatine in the cells, and (3) anaerobic energy released by glycolytic breakdown of glycogen to lactic acid.

The maximum amount of ATP in muscle is only about 5 mmol/L of intracellular fluid, and this amount can maintain maximum muscle contraction for no more than a second or so. The amount of phosphocreatine in the cells is three to eight times this amount, but even by using all the phosphocreatine, maximum contraction can be maintained for only 5 to 10 seconds.

Release of energy by glycolysis can occur much more rapidly than can oxidative release of energy. Consequently, most of the extra energy required during strenuous activity that lasts for more than 5 to 10 seconds but less than 1 to 2 minutes is derived from anaerobic glycolysis. As a result, the glycogen content of muscles during strenuous bouts of exercise is reduced, whereas the lactic acid concentration of the blood rises. After the exercise is over, oxidative metabolism is used to reconvert about four fifths of the lactic acid into glucose; the remainder becomes pyruvic acid and is de-

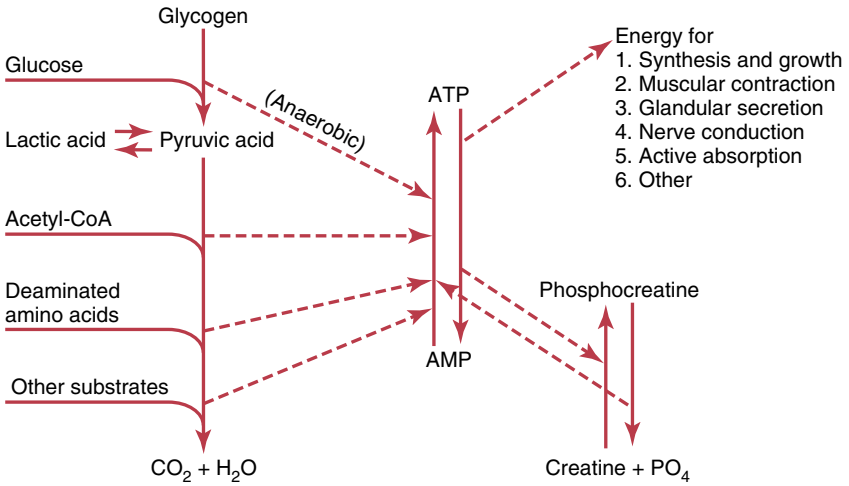


Figure 73-1. Overall schema of energy transfer from foods to the adenylic acid system and then to the functional elements of the cells. Acetyl-CoA, Acetyl coenzyme A; AMP, adenosine monophosphate; ATP, adenosine triphosphate. *(Modified from Soskin S, Levine R: Carbohydrate Metabolism. Chicago: University of Chicago Press, 1952.)*

graded and oxidized in the citric acid cycle. The reconversion to glucose occurs principally in the liver cells, and the glucose is then transported in the blood back to the muscles, where it is stored once more in the form of glycogen.

Extra Consumption of Oxygen Repays the Oxygen Debt After Completion of Strenuous Exercise. After a period of strenuous exercise, a person continues to breathe hard and to consume large amounts of oxygen for at least a few minutes and sometimes for as long as 1 hour thereafter. This additional oxygen is used to (1) reconvert the lactic acid that has accumulated during exercise back into glucose, (2) reconvert adenosine monophosphate and ADP to ATP, (3) reconvert creatine and phosphate to phosphocreatine, (4) re-establish normal concentrations of oxygen bound with hemoglobin and myoglobin, and (5) raise the concentration of oxygen in the lungs to its normal level. This extra consumption of oxygen after exercise is called *repaying the oxygen debt*.

The principle of oxygen debt is discussed further in Chapter 85 in relation to sports physiology. The ability of a person to build up an oxygen debt is especially important in many types of athletics.

Summary of Energy Utilization by the Cells

With the background of the past few chapters and of the preceding discussion, we can now synthesize a composite picture of overall energy utilization by the cells, as shown in **Figure 73-1**. This figure demonstrates the anaerobic utilization of glycogen and glucose to form ATP and the aerobic utilization of compounds derived from carbohydrates, fats, proteins, and other substances to form additional ATP. In turn, ATP is in reversible equilibrium with phosphocreatine in the cells, and because larger quantities of phosphocreatine than of ATP are present in the cells, much of the cells' stored energy is in this energy storehouse.

Energy from ATP can be used by the different functioning systems of the cells to provide for synthesis and growth, muscle contraction, glandular secretion, nerve impulse conduction, active absorption, and other cellular activities. If greater amounts of energy are demanded for cellular activities than can be provided by oxidative metabolism, the phosphocreatine storehouse is used first, followed rapidly by anaerobic breakdown of glycogen. Thus, oxidative metabolism cannot deliver bursts of extreme energy to the cells nearly as rapidly as the anaerobic processes can, but at slower rates of usage, the oxidative processes can continue as long as energy stores (mainly fat) exist.

Control of Energy Release in the Cell

Rate Control of Enzyme-Catalyzed Reactions. Before discussing the control of energy release in the cell, it is necessary to consider the basic principles of *rate control* of enzymatically catalyzed chemical reactions, which are the types of reactions that occur almost universally throughout the body.

The mechanism by which an enzyme catalyzes a chemical reaction is, first, for the enzyme to combine loosely with one of the substrates of the reaction. This loose combination alters the bonding forces on the substrate sufficiently so that it can react with other substances. Therefore, the rate of the overall chemical reaction is determined by the concentration of the enzyme and the concentration of the substrate that binds with the enzyme. The basic equation expressing this concept is as follows:

$$\text{Rate of reaction} = \frac{K_1 \times [\text{Enzyme}] \times [\text{Substrate}]}{K_2 + [\text{Substrate}]}$$

This equation is called the *Michaelis-Menten equation*. **Figure 73-2** shows the application of this equation.

Role of Enzyme Concentration in Regulation of Metabolic Reactions. **Figure 73-2** shows that *when the substrate concentration is high*, as shown in the right half of the figure, the rate of a chemical reaction is determined almost entirely by the concentration of the enzyme. Thus, as the enzyme concentration increases from an arbitrary value of 1 up to 2, 4, or 8, the rate of the reaction increases proportionately, as demonstrated by the rising levels of the curves. For example, when large quantities of glucose enter the renal tubules in a person with diabetes mellitus—that is, the substrate glucose is in great excess in the tubules—further increases in tubular glucose have little effect on glucose reabsorption, because the transport enzymes are saturated. Under these conditions, the rate of reabsorption of the glucose is limited by the concentration of the transport enzymes in the proximal tubular cells, not by the concentration of the glucose.

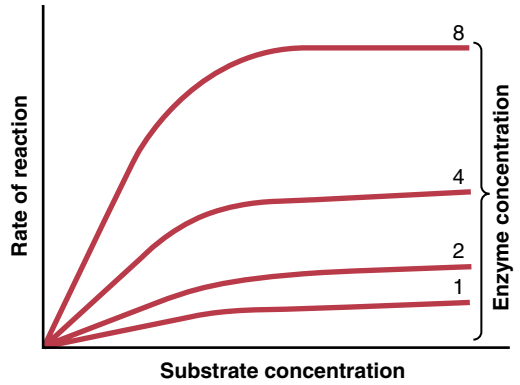

Figure 73-2. Effect of substrate and enzyme concentrations on the rate of enzyme-catalyzed reaction.

Role of Substrate Concentration in Regulation of Metabolic Reactions. Note also in Figure 73-2 that when the substrate concentration becomes low enough that only a small portion of the enzyme is required in the reaction, the rate of the reaction becomes directly proportional to the substrate concentration, as well as the enzyme concentration. This is the relationship seen in the absorption of substances from the intestinal tract and renal tubules when their concentrations are low.

Rate Limitation in a Series of Reactions. Almost all chemical reactions of the body occur in series, with the product of one reaction acting as a substrate for the next reaction, and so on. Therefore, the overall rate of a complex series of chemical reactions is determined mainly by the rate of reaction of the slowest step in the series, which is called the *rate-limiting step* in the entire series.

ADP Concentration as a Rate-Controlling Factor in Energy Release. Under *resting* conditions, the concentration of ADP in the cells is extremely slight, and thus the chemical reactions that depend on ADP as one of the substrates are quite slow. They include all the oxidative metabolic pathways that release energy from food, as well as essentially all other pathways for the release of energy in the body. Thus, *ADP is a major rate-limiting factor* for almost all energy metabolism of the body.

When the cells become active, regardless of the type of activity, ATP is converted into ADP, increasing the concentration of ADP in direct proportion to the degree of activity of the cell. This ADP then automatically increases the rates of all the reactions for the metabolic release of energy from food. Thus, by this simple process, the amount of energy released in the cell is controlled by the degree of activity of the cell. In the absence of cellular activity, the release of energy stops because all the ADP soon becomes ATP.

Metabolic Rate

The *metabolism* of the body simply means all the chemical reactions in all the cells of the body, and the *metabolic rate* is normally expressed in terms of the rate of heat liberation during chemical reactions.

Heat Is the End Product of Almost All the Energy Released in the Body. In discussing many of the metabolic reactions in the preceding chapters, we noted that not all the energy in foods is transferred to ATP; instead, a large portion of this energy becomes heat. On average, 35% of the energy in foods becomes heat during ATP formation. Additional energy becomes heat as it is transferred from ATP to the functional systems of the cells, so even under optimal conditions, no more than 27% of all the energy from food is finally used by the functional systems.

Even when 27% of the energy reaches the functional systems of the cells, most of this energy eventually becomes heat. For example, when proteins are synthesized, large portions of ATP are used to form the peptide linkages, and this action stores energy in these linkages. However, continuous turnover of proteins also occurs—some are being degraded while others are being formed. When proteins are degraded, the energy stored in the peptide linkages is released in the form of heat into the body.

Another example is the energy used for muscle activity. Much of this energy simply overcomes the viscosity of the muscles or of the tissues so that the limbs can move. This viscous movement causes friction within the tissues, which generates heat.

Consider also the energy expended by the heart in pumping blood. The blood distends the arterial system, and this distention represents a reservoir of potential energy. As the blood flows through peripheral vessels, the friction of different layers of blood flowing over one another and the friction of blood against the walls of the vessels turn all this energy into heat.

Essentially all the energy expended by the body is eventually converted into heat. The only significant exception occurs when the muscles are used to perform some form of work outside the body. For example, when the muscles elevate an object to a height or propel the body up steps, a type of potential energy is created by raising a mass against gravity. However, when external expenditure of energy is not taking place, all the energy released by the metabolic processes eventually becomes body heat.

The Calorie. To discuss the metabolic rate of the body and related subjects quantitatively, it is necessary to use some unit for expressing the quantity of energy released from different foods or expended by different functional processes of the body. Most often, the *Calorie* is the unit used for this purpose. Recall that 1 *calorie*—spelled with a small "c" and often called a *gram calorie*—is the quantity of heat required to raise the temperature of 1 gram of water 1°C. The calorie is much too small a unit to use when referring to energy in the body. Consequently, the Calorie—spelled with a capital "C" and often called a *kilocalorie*, which is equivalent to 1000 calories—is the unit ordinarily used when discussing energy metabolism.

Measurement of the Whole-Body Metabolic Rate

Direct Calorimetry Measures Heat Liberated From the Body. If a person is not performing any external work, the whole-body metabolic rate can be determined by simply measuring the total quantity of heat liberated from the body in a given time.

In determining the metabolic rate by direct calorimetry, one measures the quantity of heat liberated from the body in a large, specially constructed *calorimeter*. The subject is placed in an air chamber that is so well insulated that no heat can leak through the walls of the chamber. Heat formed by the subject's body warms the air of the chamber. However, the air temperature within the chamber is maintained at a

constant level by forcing the air through pipes in a cool water bath. The rate of heat gain by the water bath, which can be measured with an accurate thermometer, is equal to the rate at which heat is liberated by the subject's body.

Direct calorimetry is physically difficult to perform and is used only for research purposes.

Indirect Calorimetry—The "Energy Equivalent" of Oxygen. Because more than 95% of the energy expended in the body is derived from reactions of oxygen with the different foods, the whole-body metabolic rate can also be calculated with a high degree of accuracy from the rate of oxygen utilization. When 1 liter of oxygen is metabolized with glucose, 5.01 Calories of energy are released; when metabolized with starches, 5.06 Calories are released; with fat, 4.70 Calories; and with protein, 4.60 Calories.

These figures clearly demonstrate that the quantities of energy liberated per liter of oxygen consumed are nearly equivalent when different types of food are metabolized. For the average diet, the *quantity of energy liberated per liter of oxygen used in the body averages about 4.825 Calories*, which is called the *energy equivalent* of oxygen. By using this energy equivalent, one can calculate with a high degree of precision the rate of heat liberation in the body from the quantity of oxygen used in a given period.

If a person metabolizes only carbohydrates during the period of the metabolic rate determination, the calculated quantity of energy liberated, based on the value for the average energy equivalent of oxygen (4.825 Calories/L), would be about 4% too little. Conversely, if the person obtains most energy from fat, the calculated value would be about 4% too great.

Energy Metabolism—Factors That Influence Energy Output

As discussed in Chapter 72, energy intake is balanced with energy output in healthy adults who maintain a stable body weight. In the average American diet, about 45% of daily energy intake is derived from carbohydrates, 40% from fats, and 15% from proteins. Energy output can also be partitioned into several measurable components, including energy used for (1) performing essential metabolic functions of the body (the "basal" metabolic rate); (2) performing various physical activities, including nonexercise physical activity and physical activity associated with volitional exercise; (3) digesting, absorbing, and processing food; and (4) maintaining body temperature.

Overall Energy Requirements for Daily Activities

An average man who weighs 70 kilograms and lies in bed all day uses about 1650 Calories of energy. The process of eating and digesting food increases the amount of energy used each day by an additional 200 or more Calories, so the same man lying in bed and eating a reasonable diet requires a dietary intake of about 1850 Calories per day. If he sits in a chair all day without exercising, his total energy requirement reaches 2000 to 2250 Calories. Therefore, the daily energy requirement for a very sedentary man performing only essential functions is about 2000 Calories.

The amount of energy used to perform daily physical activities is normally about 25% of the total energy expenditure, but it can vary markedly in different individuals, depending on the type and amount of physical activity

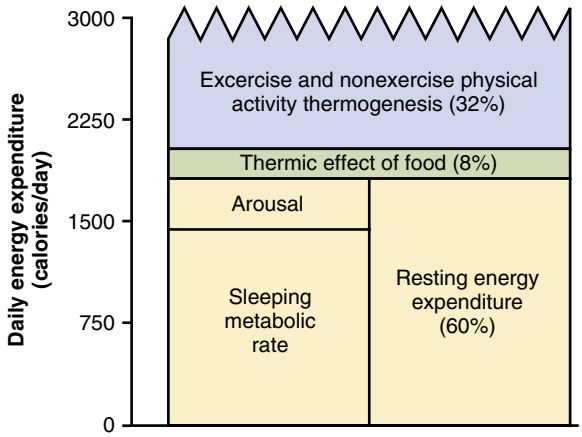

Figure 73-3. Average daily energy expenditure and components of energy usage in a 70-kg person in energy balance and ingesting approximately 3000 Calories per day.

performed. For example, walking up stairs requires about 17 times as much energy as lying in bed asleep. In general, over a 24-hour period, a person performing heavy labor can achieve a maximal rate of energy utilization as great as 6000 to 7000 Calories, or as much as 3.5 times the energy used under conditions of no physical activity.

Basal Metabolic Rate—The Minimum Energy Expenditure for the Body to Exist

Even when a person is at complete rest, considerable energy is required to perform all the chemical reactions of the body. This minimum level of energy required to exist is called the *basal metabolic rate* (BMR) and accounts for about 50% to 70% of the daily energy expenditure in most sedentary persons (**Figure 73-3**).

Because the level of physical activity is highly variable among different persons, measurement of the BMR provides a useful means of comparing one person's metabolic rate with that of another. The usual method for determining BMR is to measure the rate of oxygen utilization over a given period under the following conditions:

1. The person must not have eaten food for at least 12 hours.
2. The BMR is determined after a night of restful sleep.
3. No strenuous activity is performed for at least 1 hour before the test.
4. All psychic and physical factors that cause excitement must be eliminated.
5. The temperature of the air must be comfortable and between 68°F and 80°F.
6. No physical activity is permitted during the test.

The BMR normally averages about 65 to 70 Calories per hour in an average 70-kilogram man. Although much of the BMR is accounted for by essential activities of the central nervous system, heart, kidneys, and other organs, *variations* in BMR among different persons are related mainly to differences in the amount of skeletal muscle and body size.

Skeletal muscle, even under resting conditions, accounts for 20% to 30% of the BMR. For this reason, BMR is usually corrected for differences in body size by expressing it as Calories per hour per square meter of body surface area, calculated from height and weight. The average

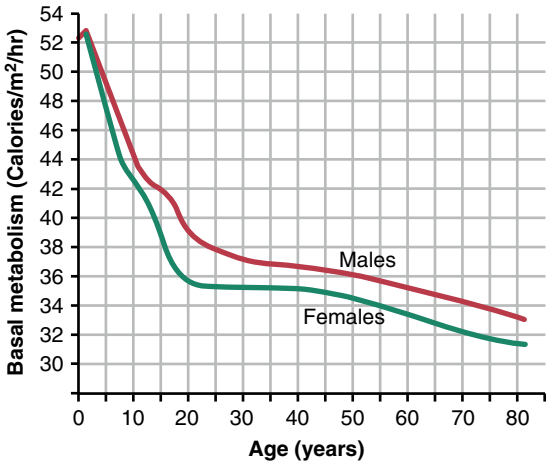

Figure 73-4. Normal basal metabolic rates at different ages for each sex.

values for males and females of different ages are shown in Figure 73-4.

Much of the decline in BMR with increasing age is probably related to loss of muscle mass and replacement of muscle with adipose tissue, which has a lower rate of metabolism. Likewise, slightly lower BMRs in women, compared with men, are due partly to the lower percentage of muscle mass and higher percentage of adipose tissue in women. However, other factors can influence the BMR, as is discussed next.

Thyroid Hormone Increases Metabolic Rate. When the thyroid gland secretes maximal amounts of thyroxine, the metabolic rate sometimes rises 50% to 100% above normal. Conversely, total loss of thyroid secretion decreases the metabolic rate to 40% to 60% of normal. As discussed in Chapter 77, thyroxine increases the chemical reaction rates of many cells in the body and therefore increases metabolic rate. Adaptation of the thyroid gland—with increased secretion in cold climates and decreased secretion in hot climates—contributes to the differences in BMRs among people living in different geographical zones. For example, people living in arctic regions have BMRs that are 10% to 20% higher than those of persons living in tropical regions.

Male Sex Hormone Increases Metabolic Rate. The male sex hormone testosterone can increase the metabolic rate about 10% to 15%. The female sex hormones may increase the BMR a small amount, but usually not enough to be significant. Much of this effect of the male sex hormone is related to its anabolic effect to increase skeletal muscle mass.

Growth Hormone Increases Metabolic Rate. Growth hormone can increase the metabolic rate by stimulating cellular metabolism and by increasing skeletal muscle mass. In adults with growth hormone deficiency, replacement therapy with recombinant growth hormone increases the basal metabolic rate by about 20%.

Fever Increases Metabolic Rate. Fever, regardless of its cause, increases the chemical reactions of the body by an average of about 120% for every 10°C rise in temperature. This is discussed in more detail in Chapter 74.

Sleep Decreases Metabolic Rate. The metabolic rate decreases 10% to 15% below normal during sleep. This decrease is due to two principal factors: (1) decreased tone of the skeletal musculature during sleep; and (2) decreased activity of the central nervous system.

Malnutrition Decreases Metabolic Rate. Prolonged malnutrition can decrease the metabolic rate 20% to 30%, presumably because of the paucity of food substances in the cells. In the final stages of many disease conditions, the inanition that accompanies the disease causes a marked decrease in metabolic rate to the extent that the body temperature may fall several degrees shortly before death.

Energy Used for Physical Activities

The factor that most dramatically increases metabolic rate is strenuous exercise. Short bursts of maximal muscle contraction in a single muscle can liberate as much as 100 times its normal resting amount of heat for a few seconds. For the entire body, maximal muscle exercise can increase the overall heat production of the body for a few seconds to about 50 times normal, or to about 20 times normal for more sustained exercise in a well-trained individual.

Table 73-1 shows the energy expenditure during different types of physical activity for a 70-kilogram man. Because of the great variation in the amount of physical activity among individuals, this component of energy expenditure is the most important reason for the differences in caloric intake required to maintain energy balance. However, in industrialized countries where food supplies are generally plentiful and the level of physical activity is often low, caloric intake often periodically exceeds energy expenditure, and the excess energy is stored mainly as fat. This underscores the importance of maintaining a proper level of physical activity to prevent excess fat stores and obesity.

Even in sedentary individuals who perform little or no daily exercise or physical work, significant energy is spent on spontaneous physical activity required to maintain muscle tone and body posture and on other nonexercise activities. Together, these nonexercise activities typically account for about 7% of a sedentary person's daily energy usage. However, this percentage can vary markedly among different people depending on their occupation, habits (e.g. walking to work, using the stairs rather than elevators, fidgeting), and leisure time activities.

Energy Used for Processing Food—Thermogenic Effect of Food

After a meal is ingested, the metabolic rate increases as a result of the different chemical reactions associated with digestion, absorption, and storage of food in the body. This increase is called the *thermogenic effect of food* because these processes require energy and generate heat.

After a meal that contains a large quantity of carbohydrates or fats, the metabolic rate usually increases about 4%. However, after a meal high in protein, the metabolic rate usually begins rising within an hour, reaching a maximum of about 30% above normal, and this rate lasts for 3 to 12 hours. This effect of protein on the metabolic rate is called the *specific dynamic action of protein*. The thermogenic effect of food accounts for about 8% of the total daily energy expenditure in many persons.

Energy Used for Nonshivering Thermogenesis—Role of Sympathetic Stimulation

Although physical work and the thermogenic effect of food cause liberation of heat, these mechanisms are not aimed primarily at regulation of body temperature. Shivering

Table 73-1 Energy Expenditure During Different Types of Activity for a 70-Kilogram Person

Form of Activity	Calories per Hour
Sleeping	65
Awake lying still	77
Sitting at rest	100
Standing relaxed	105
Dressing and undressing	118
Typing rapidly	140
Walking slowly (2.6 miles per hour)	200
Carpentry, metalworking, industrial painting	240
Sawing wood	480
Swimming	500
Running (5.3 miles per hour)	570
Walking up stairs rapidly	1100

Extracted from data compiled by Professor M.S. Rose.

provides a regulated means of producing heat by increasing muscle activity in response to cold stress, as discussed in Chapter 74. Another mechanism, *nonshivering thermogenesis*, can also produce heat in response to cold stress. This type of thermogenesis is stimulated by sympathetic nervous system activation, which releases norepinephrine and epinephrine, which in turn increase metabolic activity and heat generation.

In certain types of fat tissue, called *brown fat*, sympathetic nervous stimulation causes liberation of large amounts of heat. This type of fat contains large numbers of mitochondria and many small globules of fat instead of one large fat globule. In these cells, the process of oxidative phosphorylation in the mitochondria is mainly "uncoupled." That is, when the cells are stimulated by the sympathetic nerves, the mitochondria produce a large amount of heat but almost no ATP, so almost all the released oxidative energy immediately becomes heat.

A neonate has a considerable amount of brown fat, and maximal sympathetic stimulation can increase the child's metabolism more than 100%. The magnitude of this type of thermogenesis in an adult human, who has virtually no brown fat, is probably less than 15%, although this might increase significantly after cold adaptation.

Nonshivering thermogenesis may also serve as a buffer against obesity. Recent studies indicate that sympathetic nervous system activity is increased in obese persons who have a persistent excess caloric intake. The mechanism responsible for sympathetic activation in obese persons is uncertain, but it may be mediated partly through the effects of increased leptin, which activates pro-opiomelanocortin neurons in the hypothalamus. Sympathetic stimulation, by increasing thermogenesis, helps to limit excess weight gain.

CHAPTER 74

UNIT XIII

Body Temperature Regulation and Fever

NORMAL BODY TEMPERATURES

Body Core Temperature and Skin Temperature. The temperature of the deep tissues of the body—the "core" of the body—usually remains very constant, within ±1°F (±0.6°C), except when a person has a febrile illness. Indeed, a nude person can be exposed to temperatures as low as 55°F or as high as 130°F in *dry* air and still maintain an almost constant core temperature. The mechanisms for regulating body temperature represent a beautifully designed control system. In this chapter we discuss this system as it operates in health and in disease.

The *skin temperature,* in contrast to the *core temperature,* rises and falls with the temperature of the surroundings. The skin temperature is important when we refer to the skin's ability to lose heat to the surroundings.

Normal Core Temperature. No single core temperature can be considered normal because measurements in many healthy people have shown a *range* of normal temperatures measured orally, as shown in **Figure 74-1**, from less than 97°F (36°C) to greater than 99.5°F (37.5°C). The average normal core temperature is generally considered to be between 98.0°F and 98.6°F when measured orally and about 1°F higher when measured rectally.

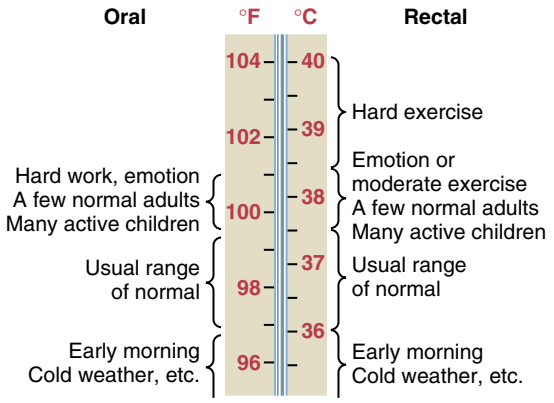

Figure 74-1. Estimated normal range of body "core" temperature. *(Modified from DuBois EF: Fever. Springfield, IL: Charles C. Thomas, 1948.)*

The body temperature increases during exercise and varies with temperature extremes of the surroundings because the temperature regulatory mechanisms are not perfect. When excessive heat is produced in the body by strenuous exercise, the temperature can rise temporarily to as high as 101°F to 104°F. Conversely, when the body is exposed to extreme cold, the temperature can fall below 96°F.

BODY TEMPERATURE IS CONTROLLED BY BALANCING HEAT PRODUCTION AND HEAT LOSS

When the rate of heat production in the body is greater than the rate at which heat is being lost, heat builds up in the body, and the body temperature rises. Conversely, when heat loss is greater, both body heat and body temperature decrease. Most of the remainder of this chapter is concerned with this balance between heat production and heat loss and the mechanisms by which the body controls this production and loss.

HEAT PRODUCTION

Heat production is a principal by-product of metabolism. In Chapter 73, which summarizes body energetics, we discuss the different factors that determine the rate of heat production, called the *metabolic rate of the body*. The most important of these factors are listed again here: (1) basal rate of metabolism of all the cells of the body; (2) extra rate of metabolism caused by muscle activity, including muscle contractions caused by shivering; (3) extra metabolism caused by the effect of thyroxine (and, to a lesser extent, other hormones, such as growth hormone and testosterone) on the cells; (4) extra metabolism caused by the effect of epinephrine, norepinephrine, and sympathetic stimulation on the cells; (5) extra metabolism caused by increased chemical activity in the cells, especially when the cell temperature increases; and (6) extra metabolism needed for digestion, absorption, and storage of food (thermogenic effect of food).

HEAT LOSS

Most of the heat produced in the body is generated in the deep organs, especially the liver, brain, and heart, and in the skeletal muscles during physical activity. This heat is then transferred from the deeper organs and tissues to the skin, where it is lost to the air and other surroundings. Therefore, the rate at which heat is lost is determined almost entirely by two factors: (1) how rapidly heat can be conducted from where it is produced in the body core to the skin and (2) how rapidly heat can then be transferred from the skin to the surroundings. Let us begin by discussing the system that insulates the core from the skin surface.

Insulator System of the Body

The skin, the subcutaneous tissues, and especially the fat of the subcutaneous tissues act together as a heat insulator for the body. The fat is important because it conducts heat only *one-third* as readily as other tissues. When no blood is flowing from the heated internal organs to the skin, the insulating properties of the normal male body are about equal to three-quarters the insulating properties of a usual suit of clothes. In women, this insulation is even better.

The insulation beneath the skin is an effective means of maintaining normal internal core temperature, even though it allows the temperature of the skin to approach the temperature of the surroundings.

Blood Flow to the Skin From the Body Core Provides Heat Transfer

Blood vessels are distributed profusely beneath the skin. Especially important is a continuous venous plexus that is supplied by inflow of blood from the skin capillaries, shown in **Figure 74-2**. In the most exposed areas of the body—the hands, feet, and ears—blood is also supplied to the plexus directly from the small arteries through highly muscular *arteriovenous anastomoses*.

The rate of blood flow into the skin venous plexus can vary tremendously, from barely above zero to as great as 30% of the total cardiac output. A high rate of skin flow causes heat to be conducted from the body core to the skin with great efficiency, whereas reduction in the rate of skin flow can decrease heat conduction from the core to very little.

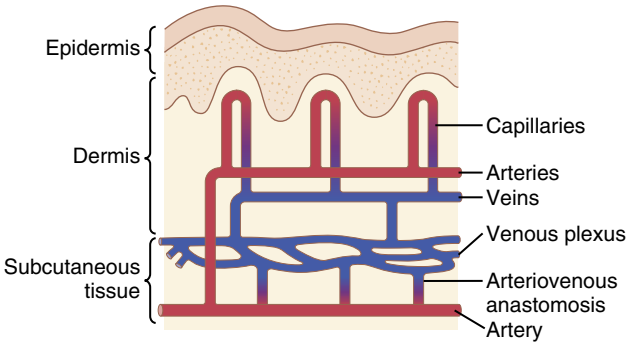

Figure 74-2. Skin circulation.

Figure 74-3 shows quantitatively the effect of environmental air temperature on conductance of heat from the core to the skin surface and then conductance into the air, demonstrating an approximate eightfold increase in heat conductance between the fully vasoconstricted state and the fully vasodilated state.

Therefore, the skin is an effective *controlled "heat radiator" system*, and the flow of blood to the skin is a most effective mechanism for heat transfer from the body core to the skin.

Control of Heat Conduction to the Skin by the Sympathetic Nervous System. Heat conduction to the skin by the blood is controlled by the degree of vasoconstriction of the arterioles and the arteriovenous anastomoses that supply blood to the venous plexus of the skin. This vasoconstriction is controlled almost entirely by the sympathetic nervous system in response to changes in body core temperature and changes in environmental temperature. This is discussed later in the chapter in connection with control of body temperature by the hypothalamus.

Basic Physics of Heat Loss From the Skin Surface

The various methods by which heat is lost from the skin to the surroundings are shown in **Figure 74-4**. They include *radiation, conduction*, and *evaporation*, which are explained next.

Radiation Causes Heat Loss in the Form of Infrared Rays. As shown in **Figure 74-4**, in a nude person sitting inside at normal room temperature, about 60% of total heat loss is by radiation.

Most infrared heat rays (a type of electromagnetic ray) that radiate from the body have wavelengths of 5 to

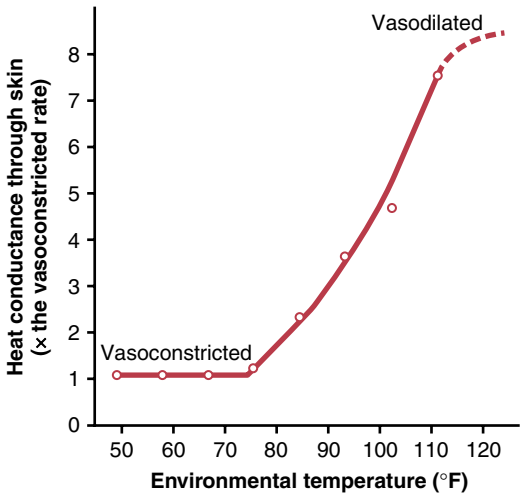

Figure 74-3. Effect of changes in the environmental temperature on heat conductance from the body core to the skin surface (in °F). *(Modified from Benzinger TH: Heat and Temperature Fundamentals of Medical Physiology. New York: Dowden, Hutchinson & Ross, 1980.)*

20 micrometers, 10 to 30 times the wavelengths of light rays. All objects that are not at absolute zero temperature radiate such rays. The human body radiates heat rays in all directions. Heat rays are also being radiated from the walls of rooms and other objects toward the body. If the temperature of the body is greater than the temperature of the surroundings, a greater quantity of heat is radiated from the body than is radiated to the body.

Conductive Heat Loss Occurs by Direct Contact With an Object. As shown in Figure 74-4, only minute quantities of heat, about 3%, are normally lost from the body by direct conduction from the surface of the body to *solid objects,* such as a chair or a bed. Loss of heat by *conduction to air*, however, represents a sizable proportion of the body's heat loss (≈15%), even under normal conditions.

Heat is actually the kinetic energy of molecular motion, and the molecules of the skin are continually undergoing vibratory motion. Much of the energy of this motion can be transferred to the air if the air is colder than the skin, thus increasing the velocity of the air molecules' motion. Once the temperature of the air adjacent to the skin equals the temperature of the skin, no further loss of heat occurs in this way because now an equal amount of heat is conducted from the air to the body. Therefore, conduction of heat from the body to the air is self-limited *unless the heated air moves away from the skin*, so new, unheated air is continually brought in contact with the skin, a phenomenon called *air convection*.

Convective Heat Loss Results From Air Movement. Heat from the skin is first *conducted* to the air and then carried away by the convection air currents.

A small amount of convection almost always occurs around the body because of the tendency for air adjacent to the skin to rise as it becomes heated. Therefore, in a nude person seated in a comfortable room without gross air movement, about 15% of his or her total heat loss occurs by conduction to the air and then by air convection away from the body.

Cooling Effect of Wind. When the body is exposed to wind, the layer of air immediately adjacent to the skin is replaced by new air much more rapidly than is normal, and heat loss by convection increases accordingly. The cooling effect of wind at low velocities is about proportional to the *square root of the wind velocity*. For example, a wind of 4 miles per hour is about twice as effective for cooling as a wind of 1 mile per hour.

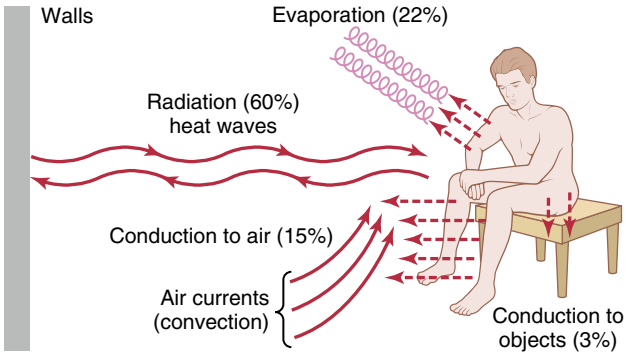

Figure 74-4. Mechanisms of heat loss from the body.

Conduction and Convection of Heat From a Person Suspended in Water. Water has a specific heat several thousand times as great as that of air, so each unit portion of water adjacent to the skin can absorb far greater quantities of heat than can be absorbed by air. Also, heat conductivity in water is very great in comparison with that in air. Consequently, it is impossible for the body to heat a thin layer of water next to the body to form an "insulator zone" as occurs in air. Therefore, if the temperature of the water is below body temperature the rate of heat loss to water is usually many times greater than the rate of heat loss to air.

Evaporation

When water evaporates from the body surface, 0.58 Calorie (kilocalorie) of heat is lost for each gram of water that evaporates. Even when a person is not sweating, water still evaporates *insensibly* from the skin and lungs at a rate of about 600 to 700 ml/day. This insensible evaporation causes continual heat loss at a rate of 16 to 19 Calories per hour. Insensible evaporation through the skin and lungs cannot be controlled for purposes of temperature regulation because it results from continual diffusion of water molecules through the skin and respiratory surfaces. However, loss of heat by *evaporation of sweat* can be controlled by regulating the rate of sweating, which is discussed later in this chapter.

Evaporation is a Necessary Cooling Mechanism at Very High Air Temperatures. As long as skin temperature is greater than the temperature of the surroundings, heat can be lost by radiation and conduction. However, when the temperature of the surroundings becomes greater than that of the skin, instead of losing heat, the body gains heat by both radiation and conduction. Under these conditions, *the only means by which the body can rid itself of heat is by evaporation.*

Therefore, anything that prevents adequate evaporation when the surrounding temperature is higher than the skin temperature will cause the internal body temperature to rise. This phenomenon occurs occasionally in human beings who are born with congenital absence of sweat glands. These people can tolerate cold temperatures as well as normal people can, but they can become severely stressed and die of heatstroke in tropical zones because, without the evaporative refrigeration system, they cannot prevent a rise in body temperature when the air temperature is greater than that of the body.

Clothing Reduces Conductive and Convective Heat Loss. Clothing entraps air next to the skin in the weave of the cloth, thereby increasing the thickness of the so-called

private zone of air adjacent to the skin and decreasing the flow of convection air currents. Consequently, the rate of heat loss from the body by conduction and convection is greatly depressed. A usual suit of clothes decreases the rate of heat loss to about half that from the nude body, but arctic-type clothing can decrease this heat loss to as little as one sixth.

About half the heat transmitted from the skin to the clothing is radiated to the clothing instead of being conducted across the small intervening space. Therefore, coating the inside of clothing with a thin layer of metal, such as silver or gold, which reflects radiant heat back to the body, makes the insulating properties of clothing far more effective than otherwise. By using this technique, clothing for use in the arctic can be decreased in weight by about half.

The effectiveness of clothing in maintaining body temperature is almost completely lost when the clothing becomes wet because the high conductivity of water increases the rate of heat transmission through cloth 20-fold or more. Therefore, one of the most important factors for protecting the body against cold in arctic regions is extreme caution against allowing the clothing to become wet. Indeed, one must be careful not to become overheated even temporarily because sweating in one's clothes makes them much less effective thereafter as an insulator.

Sweating and Its Regulation by the Autonomic Nervous System

Stimulation of the anterior hypothalamus-preoptic area in the brain either electrically or by excess heat causes sweating. The nerve impulses from this area that cause sweating are transmitted in the autonomic pathways to the spinal cord and then through sympathetic outflow to the skin.

It should be recalled from the discussion of the autonomic nervous system in Chapter 61 that the sweat glands are innervated by *cholinergic* nerve fibers (fibers that secrete acetylcholine but that run in the sympathetic nerves along with the adrenergic fibers). These glands can also be stimulated to some extent by epinephrine or norepinephrine circulating in the blood, even though the glands themselves do not have adrenergic innervation. This mechanism is important during exercise, when these hormones are secreted by the adrenal medullae and the body needs to lose excessive amounts of heat produced by the active muscles.

Mechanism of Sweat Secretion. In Figure 74-5, the sweat gland is shown to be a tubular structure consisting of two parts: (1) a deep subdermal *coiled portion* that secretes the sweat, and (2) a *duct portion* that passes outward through the dermis and epidermis of the skin. As is true of so many other glands, the secretory portion of the sweat gland secretes a fluid called the *primary secretion* or *precursor secretion*; the concentrations of constituents in the fluid are then modified as the fluid flows through the duct.

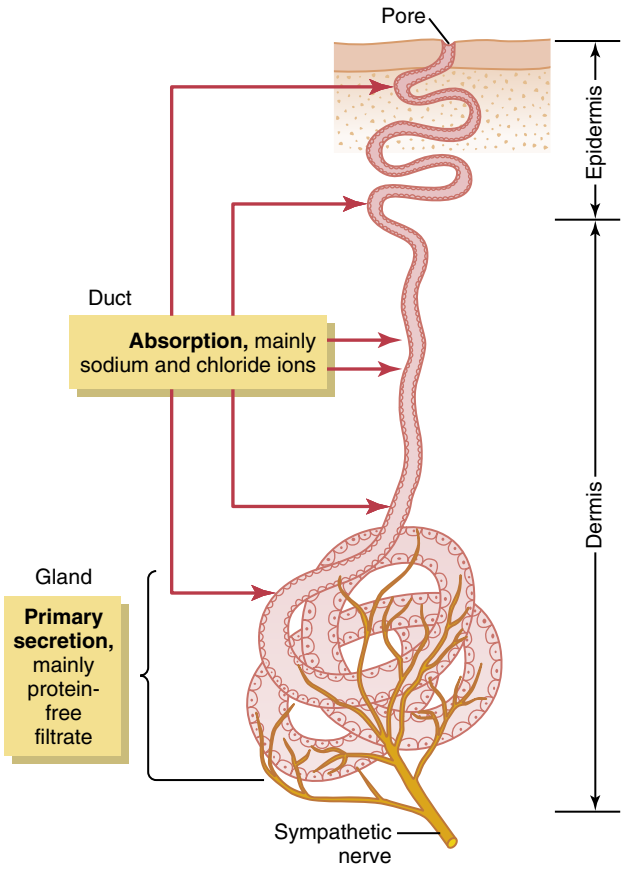

Figure 74-5. Sweat gland innervated by an acetylcholine-secreting sympathetic nerve. A *primary protein-free secretion* is formed by the glandular portion, but most of the electrolytes are reabsorbed in the duct, leaving a dilute, watery secretion.

The precursor secretion is an active secretory product of the epithelial cells lining the coiled portion of the sweat gland. Cholinergic sympathetic nerve fibers ending on or near the glandular cells elicit the secretion.

The composition of the precursor secretion is similar to that of plasma, except that it does not contain plasma proteins. The concentration of sodium is about 142 mEq/L, and that of chloride is about 104 mEq/L, with much smaller concentrations of the other solutes of plasma. As this precursor solution flows through the duct portion of the gland, it is modified by reabsorption of most of the sodium and chloride ions. The degree of this reabsorption depends on the rate of sweating.

When the sweat glands are stimulated only slightly, the precursor fluid passes through the duct slowly. In this case, essentially all the sodium and chloride ions are reabsorbed, and the concentration of each falls to as low as 5 mEq/L. This process reduces the osmotic pressure of the sweat fluid to such a low level that most of the water is also reabsorbed, which concentrates most of the other constituents. Therefore, at low rates of sweating, such constituents as urea, lactic acid, and potassium ions are usually very concentrated.

Conversely, when the sweat glands are strongly stimulated by the sympathetic nervous system, large amounts of precursor secretion are formed, and the duct may reabsorb only slightly more than half the sodium chloride; the concentrations of sodium and chloride ions are then (in an *unacclimatized* person) a maximum of about 50 to 60 mEq/L, slightly less than half the concentrations in plasma. Furthermore, the sweat flows through the glandular tubules so rapidly that little of the water is reabsorbed. Therefore, the other dissolved constituents of sweat are only moderately increased in concentration; urea is about twice that in the plasma, lactic acid about 4 times, and potassium about 1.2 times.

A significant loss of sodium chloride occurs in the sweat when a person is unacclimatized to heat. Much less electrolyte loss occurs, despite increased sweating capacity, once a person has become acclimatized.

Acclimatization of the Sweating Mechanism to Heat—The Role of Aldosterone. Although a normal, unacclimatized person seldom produces more than about 1 liter of sweat per hour, when this person is exposed to hot weather for 1 to 6 weeks, he or she begins to sweat more profusely, often increasing maximum sweat production to as much as 2 to 3 L/hr. Evaporation of this much sweat can remove heat from the body at a rate *more than 10 times* the normal basal rate of heat production. This increased effectiveness of the sweating mechanism is caused by a change in the internal sweat gland cells to increase their sweating capability.

Also associated with acclimatization is a further decrease in the concentration of sodium chloride in the sweat, which allows progressively better conservation of body salt. Most of this effect is caused by *increased secretion of aldosterone* by the adrenocortical glands, which results from a slight decrease in sodium chloride concentration in the extracellular fluid and plasma. An *unacclimatized* person who sweats profusely often loses 15 to 30 grams of salt each day for the first few days. After 4 to 6 weeks of acclimatization, the loss is usually 3 to 5 g/day.

Loss of Heat by Panting

Many animals have little ability to lose heat from the surfaces of their bodies, for two reasons: (1) the surfaces are often covered with fur, and (2) the skin of most animals is not supplied with sweat glands, which prevents most of the evaporative loss of heat from the skin. A substitute mechanism, the *panting* mechanism, is used by many animals as a means of dissipating heat.

The phenomenon of panting is "turned on" by the thermoregulator centers of the brain. That is, when the blood becomes overheated, the hypothalamus initiates neurogenic signals to decrease the body temperature. One of these signals initiates panting. The actual panting process is controlled by a *panting center* that is associated with the pneumotaxic respiratory center located in the pons.

When an animal pants, it breathes in and out rapidly, and thus large quantities of new air from the exterior come in contact with the upper portions of the respiratory passages. This mechanism cools the blood in the respiratory passage mucosa as a result of water evaporation from the mucosal surfaces, especially evaporation of saliva from the tongue. Yet, panting does not increase the alveolar ventilation more than is required for proper control of the blood gases because each breath is extremely shallow; therefore, most of the air that enters the alveoli is dead-space air mainly from the trachea and not from the atmosphere.

REGULATION OF BODY TEMPERATURE—ROLE OF THE HYPOTHALAMUS

Figure 74-6 shows what happens to the body "core" temperature of a nude person after a few hours' exposure to *dry* air ranging from 30°F to 160°F. The precise dimensions of this curve depend on the wind movement of the air, the amount of moisture in the air, and even the nature of the surroundings. In general, a nude person in dry air between 55°F and 130°F is capable of maintaining a normal body core temperature somewhere between 97°F and 100°F.

The temperature of the body is regulated almost entirely by nervous feedback mechanisms, and almost all these mechanisms operate through *temperature-regulating centers* located in the *hypothalamus*. For these feedback mechanisms to operate, there must also be temperature detectors to determine when body temperature becomes either too high or too low.

ROLE OF THE ANTERIOR HYPOTHALAMIC-PREOPTIC AREA IN THERMOSTATIC DETECTION OF TEMPERATURE

The anterior hypothalamic-preoptic area contains large numbers of heat-sensitive neurons, as well as about one-third as many cold-sensitive neurons. These neurons are believed to function as temperature sensors for controlling body temperature. The heat-sensitive neurons increase their firing rate 2- to 10-fold in response to a 10°-C increase in body temperature. The cold-sensitive neurons, by contrast, increase their firing rate when body temperature falls.

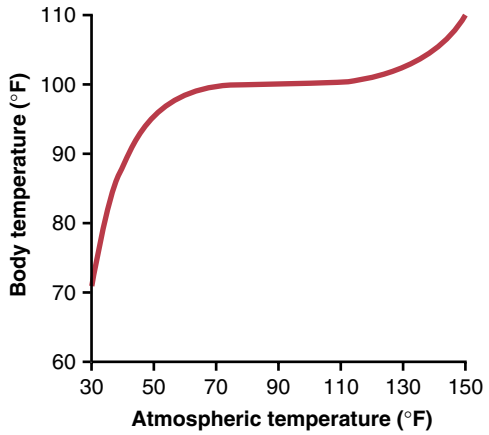

Figure 74-6. Effect of high and low atmospheric temperatures of several hours' duration, under dry conditions, on the internal body core temperature (in °F). Note that the internal body temperature remains stable, despite wide changes in atmospheric temperature.

When the preoptic area is heated, the skin all over the body immediately breaks out in a profuse sweat, whereas the skin blood vessels over the entire body become greatly dilated. This response is an immediate reaction to cause the body to lose heat, thereby helping to return the body temperature toward the normal level. In addition, any excess body heat production is inhibited. Therefore, it is clear that the hypothalamic-preoptic area has the capability to serve as a thermostatic body temperature control center.

DETECTION OF TEMPERATURE BY RECEPTORS IN THE SKIN AND DEEP BODY TISSUES

Although the signals generated by the temperature receptors of the hypothalamus are extremely powerful in controlling body temperature, receptors in other parts of the body play additional roles in temperature regulation. This is especially true of temperature receptors in the skin and in a few specific deep tissues of the body.

Recall from the discussion of sensory receptors in Chapter 49 that the skin is endowed with both *cold* and *warmth* receptors. The skin has far more cold receptors than warmth receptors—in fact, 10 times as many in many parts of the skin. Therefore, peripheral detection of temperature mainly concerns detecting cool and cold instead of warm temperatures.

Although the molecular mechanisms for sensing changes in temperature are not well understood, experimental studies suggest that the *transient receptor potential family of cation channels,* found in somatosensory neurons and epidermal cells, may mediate thermal sensation over a wide range of skin temperatures.

When the skin is chilled over the entire body, immediate reflex effects are invoked and begin to increase the temperature of the body in several ways: (1) by providing a strong stimulus to cause shivering, with a resultant increase in the rate of body heat production; (2) by inhibiting sweating, if this is already occurring; and (3) by promoting skin vasoconstriction to diminish loss of body heat from the skin.

Deep body temperature receptors are found mainly in the *spinal cord*, in the *abdominal viscera*, and in or around the *great veins* in the upper abdomen and thorax. These deep receptors function differently from the skin receptors because they are exposed to the body core temperature rather than the body surface temperature. Yet, like the skin temperature receptors, they detect mainly cold rather than warmth. It is probable that both the skin and the deep body receptors are concerned with preventing *hypothermia*—that is, preventing low body temperature.

POSTERIOR HYPOTHALAMUS INTEGRATES CENTRAL AND PERIPHERAL TEMPERATURE SENSORY SIGNALS

Even though many temperature sensory signals arise in peripheral receptors, these signals contribute to body temperature control mainly through the hypothalamus. The area of the hypothalamus that they stimulate is located bilaterally in the posterior hypothalamus approximately at the level of the mammillary bodies. The temperature sensory signals from the anterior hypothalamic-preoptic area are also transmitted into this posterior hypothalamic area. Here the signals from the preoptic area and the signals from elsewhere in the body are combined and integrated to control the heat-producing and heat-conserving reactions of the body.

NEURONAL EFFECTOR MECHANISMS THAT DECREASE OR INCREASE BODY TEMPERATURE

When the hypothalamic temperature centers detect that the body temperature is either too high or too low, they institute appropriate temperature-decreasing or temperature-increasing procedures. The reader is probably familiar with most of these procedures from personal experience, but special features are described in the following sections.

Temperature-Decreasing Mechanisms When the Body Is Too Hot

The temperature control system uses three important mechanisms to reduce body heat when the body temperature becomes too great:

1. *Vasodilation of skin blood vessels.* In almost all areas of the body, the skin blood vessels become intensely dilated. This dilation is caused by inhibition of the sympathetic centers in the posterior hypothalamus that cause vasoconstriction. Full vasodilation can increase the rate of heat transfer to the skin as much as eightfold.
2. *Sweating.* The effect of increased body temperature to cause sweating is demonstrated by the blue curve in **Figure 74-7**, which shows a sharp increase in the rate of evaporative heat loss resulting from sweating when the body core temperature rises above the critical level of 37.1°C (98.8°F). An additional 1°C increase in body temperature causes enough sweating to remove 10 times the basal rate of body heat production.
3. *Decrease in heat production.* The mechanisms that cause excess heat production, such as shivering and chemical thermogenesis, are strongly inhibited.

Temperature-Increasing Mechanisms When the Body Is Too Cold

When the body is too cold, the temperature control system institutes procedures opposite of those when the body is too hot:

1. *Skin vasoconstriction throughout the body.* This vasoconstriction is caused by stimulation of the posterior hypothalamic sympathetic centers.
2. *Piloerection.* Piloerection means hairs "standing on end." Sympathetic stimulation causes the arrector

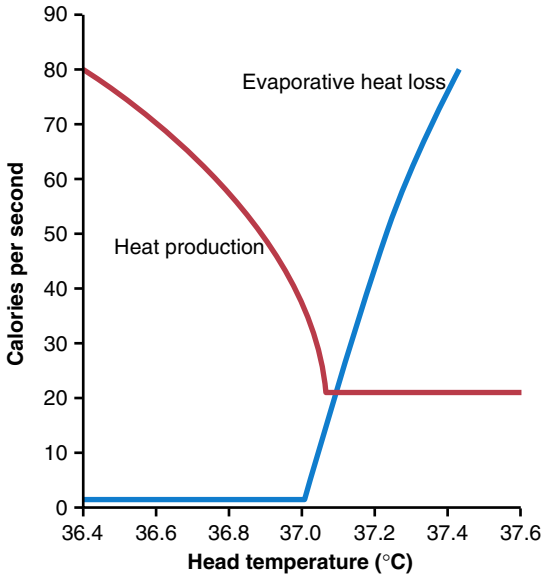

Figure 74-7. Effect of hypothalamic temperature on evaporative heat loss from the body and on heat production caused primarily by muscle activity and shivering (in °C). This figure demonstrates the extremely critical temperature level at which increased heat loss begins and heat production reaches a minimum stable level.

pili muscles attached to the hair follicles to contract, which brings the hairs to an upright stance and produces "*goose bumps*" on the skin at the base of the hairs. This mechanism is not important in human beings, but in many animals, upright projection of the hairs allows them to entrap a thick layer of "insulator air" next to the skin, so transfer of heat to the surroundings is greatly depressed.

3. *Increase in thermogenesis (heat production).* Heat production by the metabolic systems is increased by promoting shivering, sympathetic excitation of heat production, and thyroxine secretion. These methods of increasing heat require additional explanation, which is provided in the following sections.

Hypothalamic Stimulation of Shivering. Located in the dorsomedial portion of the posterior hypothalamus near the wall of the third ventricle is an area called the *primary motor center for shivering*. This area is normally inhibited by signals from the heat center in the anterior hypothalamic-preoptic area but is excited by cold signals from the skin and spinal cord. Therefore, as shown by the sudden increase in "heat production" (see the red curve in **Figure 74-7**), this center becomes activated when the body temperature falls even a fraction of a degree below a critical temperature level. It then transmits signals that cause shivering through bilateral tracts down the brain stem, into the lateral columns of the spinal cord, and finally to the anterior motor neurons. These signals are nonrhythmic and do not cause the actual muscle shaking. Instead, they increase the tone of the skeletal muscles throughout the body by facilitating the activity of the anterior motor neurons. When the tone rises above a certain critical level, shivering begins. This reaction probably results from feedback oscillation of the muscle spindle stretch reflex mechanism, which is discussed in Chapter 55. *During maximum shivering, body heat production can rise to four to five times normal.*

Sympathetic "Chemical" Excitation of Heat Production. As noted in Chapter 73, an increase in either sympathetic stimulation or circulating norepinephrine and epinephrine in the blood can rapidly increase the rate of cellular metabolism. This effect is called *chemical thermogenesis*, or *nonshivering thermogenesis*. It results at least partially from the ability of norepinephrine and epinephrine to *uncouple* oxidative phosphorylation, which means that excess foodstuffs are oxidized and thereby release energy in the form of heat but do not cause adenosine triphosphate to be formed.

The degree of chemical thermogenesis that occurs in an animal is almost directly proportional to the amount of *brown fat* in the animal's tissues. This type of fat contains large numbers of special mitochondria where uncoupled oxidation occurs, as described in Chapter 73. Brown fat is richly supplied with sympathetic nerves that release norepinephrine, which stimulates tissue expression of *mitochondrial uncoupling protein 1* (*UCP1,* also called *thermogenin*) and increases thermogenesis.

Acclimatization greatly affects the intensity of chemical thermogenesis; some animals, such as rats, that have been exposed to a cold environment for several weeks exhibit a 100% to 500% increase in heat production when acutely exposed to cold, in contrast to the unacclimatized animal, which responds with an increase of perhaps one-third as much. This increased thermogenesis also leads to a corresponding increase in food intake.

In adult human beings, who have almost no brown fat, it is rare for chemical thermogenesis to increase the rate of heat production more than 10% to 15%. However, in infants, who *do* have a small amount of brown fat in their interscapular space, chemical thermogenesis can increase the rate of heat production 100%, which is probably an important factor in maintaining normal body temperature in neonates.

Increased Thyroxine Output as a Long-Term Cause of Increased Heat Production. Cooling the anterior hypothalamic-preoptic area also increases production of the neurosecretory hormone *thyrotropin-releasing hormone* by the hypothalamus. This hormone is carried by way of the hypothalamic portal veins to the anterior pituitary gland, where it stimulates secretion of *thyroid-stimulating hormone*.

Thyroid-stimulating hormone in turn stimulates increased output of *thyroxine* by the thyroid gland, as explained in Chapter 77. The increased thyroxine activates uncoupling protein and increases the rate of cellular metabolism throughout the body, which is yet another mechanism of *chemical thermogenesis*. This increase in metabolism does not occur immediately but requires several weeks' exposure to cold to make the thyroid gland hypertrophy and reach its new level of thyroxine secretion.

Exposure of animals to extreme cold for several weeks can cause their thyroid glands to increase in size 20% to 40%. However, human beings seldom allow themselves to be exposed to the same degree of cold as that to which many animals are often subjected. Therefore, we still do not know, quantitatively, how important the thyroid mechanism of adaptation to cold is in the human being.

Isolated measurements have shown that metabolic rates increase in military personnel residing for several months in the arctic; some of the Inuit, the indigenous people who inhabit the Arctic regions of Alaska, Canada, or Greenland, also have abnormally high basal metabolic rates. Further, the continuous stimulatory effect of cold on the thyroid gland may explain the much higher incidence of toxic thyroid goiters in people who live in cold climates than in those who live in warm climates.

"SET POINT" FOR TEMPERATURE CONTROL

In the example of **Figure 74-7**, it is clear that at a critical body core temperature of about 37.1°C (98.8°F), drastic changes occur in the rates of both heat loss and heat production. At temperatures above this level, the rate of heat loss is greater than that of heat production, so the body temperature falls and approaches the 37.1°C level. At temperatures below this level, the rate of heat production is greater than that of heat loss, so the body temperature rises and again approaches the 37.1°C level. This crucial temperature level is called the "set point" of the temperature control mechanism—that is, all the temperature control mechanisms continually attempt to bring the body temperature back to this set point level.

Feedback Gain for Body Temperature Control. As discussed in Chapter 1, feedback gain is a measure of the effectiveness of a control system. In the case of body temperature control, it is important for the internal core temperature to change as little as possible, even though the environmental temperature might change greatly from day to day or even hour to hour. The *feedback gain* of the temperature control system is equal to the ratio of the change in environmental temperature to the change in body core temperature minus 1.0 (see Chapter 1 for this formula). Experiments have shown that the body temperature of humans changes about 1°C for each 25°- to 30°C-change in environmental temperature. Therefore, the feedback gain of the total mechanism for body temperature control averages about 27 (28/1.0 – 1.0 = 27), which is an extremely high gain for a biological control system (the baroreceptor arterial pressure control system, by comparison, has a feedback gain of <2).

Skin Temperature Can Slightly Alter the Set Point for Core Temperature Control

The critical temperature set point in the hypothalamus above which sweating begins and below which shivering begins is determined mainly by the degree of activity of the heat temperature receptors in the anterior hypothalamic-preoptic area. However, temperature signals from the peripheral areas of the body, especially from the skin and certain deep body tissues (e.g., spinal cord and abdominal viscera), also contribute slightly to body temperature regulation by altering the set point of the hypothalamic temperature control center. This effect is shown in **Figures 74-8** and **74-9**.

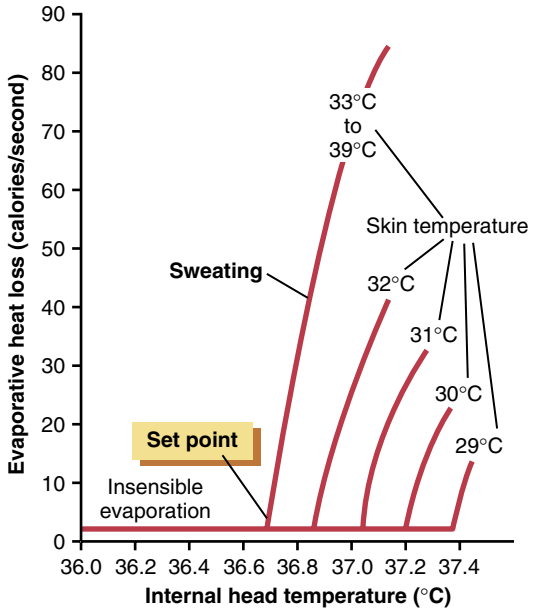

Figure 74-8. Effect of changes in the internal head temperature on the rate of evaporative heat loss from the body (in °C). Note that the skin temperature determines the set point level at which sweating begins. *(Courtesy Dr. T.H. Benzinger.)*

Figure 74-8 demonstrates the effect of different skin temperatures on the set point for sweating, showing that the set point increases as skin temperature decreases. Thus, for the person represented in this figure, the hypothalamic set point increased from 36.7°C when the skin temperature was higher than 33°C to a set point of 37.4°C when the skin temperature had fallen to 29°C. Therefore, when the skin temperature was high, sweating began at a lower hypothalamic temperature than when the skin temperature was low. One can readily understand the value of such a system because it is important that sweating be inhibited when the skin temperature is low; otherwise, the combined effect of low skin temperature and sweating could cause far too much loss of body heat.

A similar effect occurs in shivering, as shown in **Figure 74-9**. That is, when the skin becomes cold, it drives the hypothalamic centers to the shivering threshold even when the hypothalamic temperature is still on the hot side of normal. Here again, one can understand the value of the control system because a cold skin temperature would soon lead to a deeply depressed body temperature unless heat production were increased. Thus, a cold skin temperature actually "anticipates" a fall in internal body temperature and prevents it.

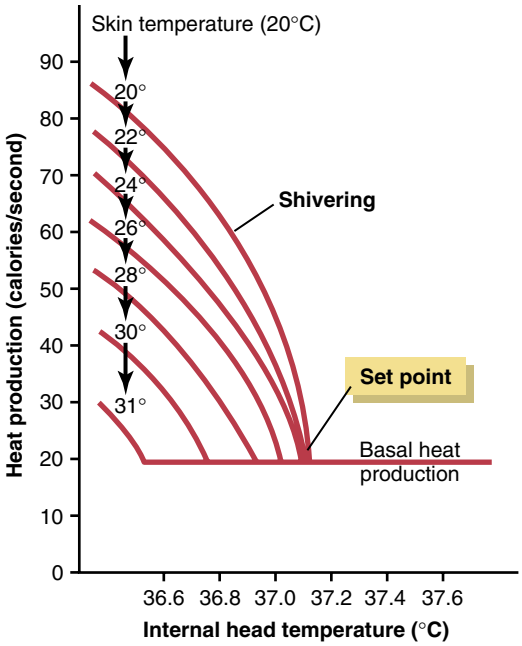

Figure 74-9. Effect of changes in the internal head temperature on the rate of heat production by the body (in °C). Note that the skin temperature determines the set point level at which shivering begins. *(Courtesy Dr. T.H. Benzinger.)*

BEHAVIORAL CONTROL OF BODY TEMPERATURE

Aside from the subconscious mechanisms for body temperature control, the body has another temperature-control mechanism that is even more potent—*behavioral control of temperature*.

Whenever the internal body temperature becomes too high, signals from the temperature-controlling areas in the brain give the person a psychic sensation of being overheated. Conversely, whenever the body becomes too cold, signals from the skin and probably also from some deep body receptors elicit the feeling of cold discomfort. Therefore, the person makes appropriate environmental adjustments to re-establish comfort, such as moving into a heated room or wearing well-insulated clothing in freezing weather. Behavioral control of temperature is the only really effective mechanism to maintain body heat control in severely cold environments.

Local Skin Temperature Reflexes

When a person places a foot under a hot lamp and leaves it there for a short time, *local vasodilation* and mild *local sweating* occur. Conversely, placing the foot in cold water causes local vasoconstriction and local cessation of sweating. These reactions are caused by local effects of temperature directly on the blood vessels and also by local cord reflexes conducted from skin receptors to the spinal cord and back to the same skin area and the sweat glands. The intensity of these local effects is, in addition, controlled by the central brain temperature controller, so their overall effect is proportional to the hypothalamic heat control signal *times* the local signal. Such reflexes can help prevent excessive heat exchange from locally cooled or heated portions of the body.

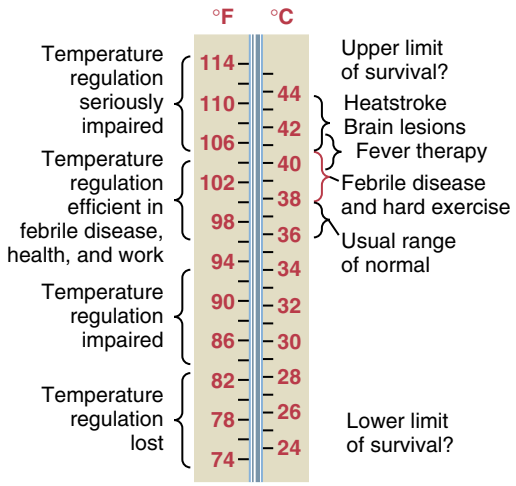

Figure 74-10. Body temperatures under different conditions. *(Modified from DuBois EF: Fever. Springfield, IL: Charles C. Thomas, 1948.)*

Regulation of Internal Body Temperature Is Impaired by Cutting the Spinal Cord. If the spinal cord is severed in the neck above the sympathetic outflow from the cord, regulation of body temperature becomes extremely poor because the hypothalamus can no longer control either skin blood flow or the degree of sweating anywhere in the body. This is true even though the local temperature reflexes originating in the skin, spinal cord, and intra-abdominal receptors still exist. These reflexes are extremely weak in comparison with hypothalamic control of body temperature.

In people with this condition, body temperature must be regulated principally by the patient's psychic response to cold and hot sensations in the head region—that is, by behavioral control of clothing and by moving into an appropriate warm or cold environment.

ABNORMALITIES OF BODY TEMPERATURE REGULATION

FEVER

Fever, which means a body temperature above the usual range of normal, can be caused by abnormalities in the brain or by toxic substances that affect the temperature-regulating centers. Some causes of fever (and also of subnormal body temperatures) are presented in **Figure 74-10**. They include bacterial or viral infections, brain tumors, and environmental conditions that may terminate in heatstroke.

Resetting the Hypothalamic Temperature-Regulating Center in Febrile Diseases—Effect of Pyrogens

Many proteins, breakdown products of proteins, and certain other substances, especially lipopolysaccharide toxins released from bacterial cell membranes, can cause the set point of the hypothalamic thermostat to rise. Substances that cause this effect are called *pyrogens*.

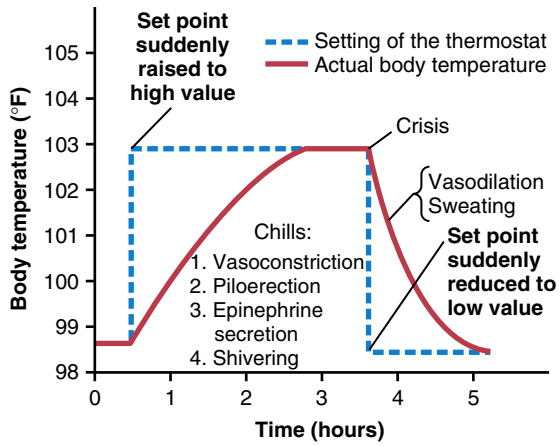

Figure 74-11. Effects of changing the set point of the hypothalamic temperature controller.

Pyrogens released from toxic bacteria or those released from degenerating body tissues cause fever during disease conditions. When the set point of the hypothalamic temperature-regulating center becomes higher than normal, all the mechanisms for raising the body temperature are brought into play, including heat conservation and increased heat production. Within a few hours after the set point has been increased, the body temperature also approaches this level, as shown in **Figure 74-11**.

Mechanism of Action of Pyrogens in Causing Fever—Role of Cytokines. Experiments in animals have shown that some pyrogens, when injected into the hypothalamus, can act directly and immediately on the hypothalamic temperature-regulating center to increase its set point. Other pyrogens function indirectly and may require several hours of latency before causing their effects. This is true of many of the bacterial pyrogens, especially the *endotoxins* from gram-negative bacteria.

When bacteria or breakdown products of bacteria are present in the tissues or in the blood, they are *phagocytized by the blood leukocytes, by tissue macrophages*, and *by large granular killer lymphocytes*, as discussed in Chapter 34. All these cells digest the bacterial products and then release cytokines, a diverse group of peptide-signaling molecules involved in the innate and adaptive immune responses. One of the most important of these cytokines in causing fever is *interleukin-1 (IL-1),* also called *leukocyte pyrogen* or *endogenous pyrogen*. IL-1 is released from macrophages into the body fluids and, upon reaching the hypothalamus, almost immediately activates the processes to produce fever, sometimes increasing the body temperature a noticeable amount in only 8 to 10 minutes. *As little as one ten-millionth of a gram of endotoxin lipopolysaccharide* from bacteria, acting in concert with the blood leukocytes, tissue macrophages, and killer lymphocytes, can cause fever. The amount of IL-1 that is formed in response to lipopolysaccharide to cause fever is only a few nanograms.

Several experiments have suggested that IL-1 causes fever by first inducing formation of one of the prostaglandins, mainly prostaglandin E_2, or a similar substance, which acts in the hypothalamus to elicit the fever reaction. When prostaglandin formation is blocked by drugs, the fever is either completely abrogated or at least reduced. In fact, this may be the explanation for the manner in which aspirin reduces fever because aspirin impedes the formation of prostaglandins from arachidonic acid. Drugs such as aspirin that reduce fever are called *antipyretics*.

Fever Caused by Brain Lesions. When a brain surgeon operates in the region of the hypothalamus, severe fever almost always occurs; rarely, the opposite effect, hypothermia, occurs, demonstrating both the potency of the hypothalamic mechanisms for body temperature control and the ease with which abnormalities of the hypothalamus can alter the set point of temperature control. Another condition that frequently causes prolonged high temperature is compression of the hypothalamus by a brain tumor.

Characteristics of Febrile Conditions

Chills. When the set point of the hypothalamic temperature-control center is suddenly changed from the normal level to higher than normal (as a result of tissue destruction, pyrogenic substances, or dehydration), the body temperature usually takes several hours to reach the new temperature set point.

Figure 74-11 demonstrates the effect of suddenly increasing the temperature set point to a level of 103°F. Because the blood temperature is now less than the set point of the hypothalamic temperature controller, the usual responses that cause elevation of body temperature occur. During this period, the person experiences chills and feels extremely cold, even though his or her body temperature may already be above normal. Also, the skin becomes cold because of vasoconstriction and the person shivers. Chills can continue until the body temperature reaches the hypothalamic set point of 103°F. Then the person no longer experiences chills but instead feels neither cold nor hot. As long as the factor that is causing the higher set point of the hypothalamic temperature controller is present, the body temperature is regulated more or less in the normal manner, but at the high temperature set point level.

Crisis, or "Flush." If the factor that is causing the high temperature is removed, the set point of the hypothalamic temperature controller will be reduced to a lower value—perhaps even back to the normal level, as shown in **Figure 74-11**. In this case, the body temperature is still 103°F, but the hypothalamus is attempting to regulate the temperature to 98.6°F. This situation is analogous to excessive heating of the anterior hypothalamic-preoptic area, which causes intense sweating and the sudden development of hot skin because of vasodilation everywhere. This sudden change of events in a febrile state is known as the "crisis" or, more appropriately, the "flush." In the days before the advent of antibiotics, the crisis was always anxiously awaited because once this occurred, the doctor assumed that the patient's temperature would soon begin falling.

Heatstroke

The upper limit of air temperature that one can stand depends to a great extent on whether the air is dry or wet. If the air is dry and sufficient convection air currents are flowing to promote rapid evaporation from the body, a person can withstand several hours of air temperature at 130°F. Conversely, if the air is 100% humidified or if the body is in water, the body temperature begins to rise whenever the environmental temperature rises above about 94°F. If the person is performing heavy work, the critical *environmental temperature* above which heatstroke is likely to occur may be as low as 85°F to 90°F.

When the body temperature rises beyond a critical temperature, into the range of 105°F to 108°F, *heatstroke* is likely to develop. The symptoms include dizziness, abdominal distress, sometimes accompanied by vomiting, sometimes delirium, and eventually loss of consciousness if the body temperature is not soon decreased. These symptoms are often exacerbated by a degree of *circulatory shock* brought on by excessive loss of fluid and electrolytes in the sweat.

The hyperpyrexia is also exceedingly damaging to the body tissues, especially the brain, and is responsible for many of the effects. In fact, even a few minutes of very high body temperature can sometimes be fatal. For this reason, some authorities recommend immediate treatment of heatstroke by placing the person in a cold-water bath. Because a cold-water bath often induces uncontrollable shivering, with a considerable increase in the rate of heat production, a muscle relaxant may be administered in some cases. Others have suggested that sponge or spray cooling of the skin along with blowing cool air over the moist skin may be more effective and more practical for rapidly decreasing the body core temperature.

Harmful Effects of High Temperature. The pathological findings in a person who dies of hyperpyrexia are local hemorrhages and parenchymatous degeneration of cells throughout the entire body, but especially in the brain. Once neuronal cells are destroyed, they can never be replaced. Also, damage to the liver, kidneys, and other organs can often be severe enough that failure of one or more of these organs eventually causes death, but sometimes not until several days after the heatstroke occurs.

Acclimatization to Heat. It can be extremely important to acclimatize people to extreme heat. Examples of people requiring acclimatization are soldiers on duty in the tropics and miners working in the 2-mile-deep gold mines of South Africa, where the temperature approaches body temperature and the humidity approaches 100%. A person exposed to heat for several hours each day while performing a reasonably heavy workload will develop increased tolerance to hot and humid conditions in 1 to 3 weeks.

Among the most important physiological changes that occur during this acclimatization process are an approximately twofold increase in the maximum rate of sweating, an increase in plasma volume, and diminished loss of salt in the sweat and urine to almost none; the last two effects result from increased secretion of aldosterone by the adrenal glands.

Exposure of the Body to Extreme Cold

Unless treated immediately, a person exposed to ice water for 20 to 30 minutes ordinarily dies because of heart standstill or heart fibrillation. By that time, the internal body temperature will have fallen to about 77°F. If warmed rapidly by the application of external heat, the person's life can often be saved.

Loss of Temperature Regulation at Low Temperatures. As noted in **Figure 74-10**, once the body temperature has fallen below about 85°F, the ability of the hypothalamus to regulate temperature is lost; it is greatly impaired even when the body temperature falls below about 94°F. Part of the reason for this diminished temperature regulation is that the rate of chemical heat production in each cell is depressed almost twofold for each 10°F decrease in body temperature. Also, sleepiness develops (later followed by coma), which depresses the activity of the central nervous system heat control mechanisms and prevents shivering.

Frostbite. When the body is exposed to extremely low temperatures, surface areas can freeze, which is a phenomenon called *frostbite*. Frostbite occurs especially in the lobes of the ears and in the digits of the hands and feet. If the freeze has been sufficient to cause extensive formation of ice crystals in the cells, permanent damage usually results, such as permanent circulatory impairment and local tissue damage. Gangrene often follows thawing, and the frostbitten areas must be removed surgically.

Cold-Induced Vasodilation Is a Final Protection Against Frostbite at Almost Freezing Temperatures. When the temperature of tissues falls almost to freezing, the smooth muscle in the vascular wall becomes paralyzed because of the cold, and sudden vasodilation occurs, often manifested by a flush of the skin. This mechanism helps prevent frostbite by delivering warm blood to the skin. This mechanism is far less developed in humans than in most animals that live in the cold all the time.

Artificial Hypothermia. It is easy to decrease the temperature of a person by first administering a strong sedative to depress the reactivity of the hypothalamic temperature controller and then cooling the person with ice or cooling blankets until the temperature falls. The temperature can then be maintained below 90°F for several days to a week or more by continual sprinkling of cool water or alcohol on the body. Such artificial cooling has been used during heart surgery so that the heart can be stopped artificially for many minutes at a time. Cooling to this extent does not cause tissue damage, but it does slow the heart and greatly depresses cell metabolism so that the body's cells can survive 30 minutes to more than 1 hour without blood flow during the surgical procedure.

CHAPTER 75

UNIT XIV

Introduction to Endocrinology

COORDINATION OF BODY FUNCTIONS BY CHEMICAL MESSENGERS

The multiple activities of the cells, tissues, and organs of the body are coordinated by the interplay of several types of chemical messenger systems:

1. *Neurotransmitters* are released by axon terminals of neurons into the synaptic junctions and act locally to control nerve cell functions.
2. *Endocrine hormones* are released by glands or specialized cells into the circulating blood and influence the function of target cells at another location in the body.
3. *Neuroendocrine hormones* are secreted by neurons into the circulating blood and influence the function of target cells at another location in the body.
4. *Paracrines* are secreted by cells into the extracellular fluid and affect neighboring target cells of a different type.
5. *Autocrines* are secreted by cells into the extracellular fluid and affect the function of the same cells that produced them.
6. *Cytokines* are peptides secreted by cells into the extracellular fluid and can function as autocrines, paracrines, or endocrine hormones. Examples of cytokines include the *interleukins* and other *lymphokines* that are secreted by helper cells and act on other cells of the immune system (see Chapter 35). Cytokine hormones (e.g., *leptin*) produced by adipocytes are sometimes called *adipokines.*

In the next few chapters, we discuss mainly the endocrine and neuroendocrine hormone systems, keeping in mind that many of the body's chemical messenger systems interact with one another to maintain homeostasis. For example, the adrenal medullae and the pituitary gland secrete their hormones primarily in response to neural stimuli. The neuroendocrine cells, located in the hypothalamus, have axons that terminate in the posterior pituitary gland and median eminence and secrete several neurohormones, including *antidiuretic hormone*, *oxytocin,* and *hypophysiotropic hormones,* which control the secretion of anterior pituitary hormones.

The *endocrine hormones* are carried by the circulatory system to cells throughout the body, including the nervous system in some cases, where they bind with receptors and initiate many cell reactions. Some endocrine hormones affect many different types of cells of the body; for example, *growth hormone* from the anterior pituitary gland causes growth in most parts of the body, and *thyroxine* from the thyroid gland increases the rate of many chemical reactions in almost all the body's cells.

Other hormones affect mainly specific *target tissues* because these tissues have abundant receptors for the hormone. For example, *adrenocorticotropic hormone* from the anterior pituitary gland specifically stimulates the adrenal cortex, causing it to secrete adrenocortical hormones, and the *ovarian hormones* have their main effects on the female sex organs and the secondary sexual characteristics of the female body.

Figure 75-1 shows the anatomical loci of the major endocrine glands and endocrine tissues of the body, except for the placenta, which is an additional source of the sex hormones. **Table 75-1** provides an overview of the different hormone systems and their major actions.

The multiple hormone systems play a key role in regulating almost all body functions, including metabolism, growth and development, water and electrolyte balance, reproduction, and behavior. For example, without growth hormone, a person would have very short stature. Without thyroxine and triiodothyronine from the thyroid gland, almost all the chemical reactions of the body would become sluggish and the person would become sluggish as well. Without insulin from the pancreas, the body's cells could use little of the food carbohydrates for energy. And without the sex hormones, sexual development and sexual functions would be absent.

CHEMICAL STRUCTURE AND SYNTHESIS OF HORMONES

Three general classes of hormones exist:

1. *Proteins and polypeptides,* including hormones secreted by the anterior and posterior pituitary gland, the pancreas (insulin and glucagon), the parathyroid

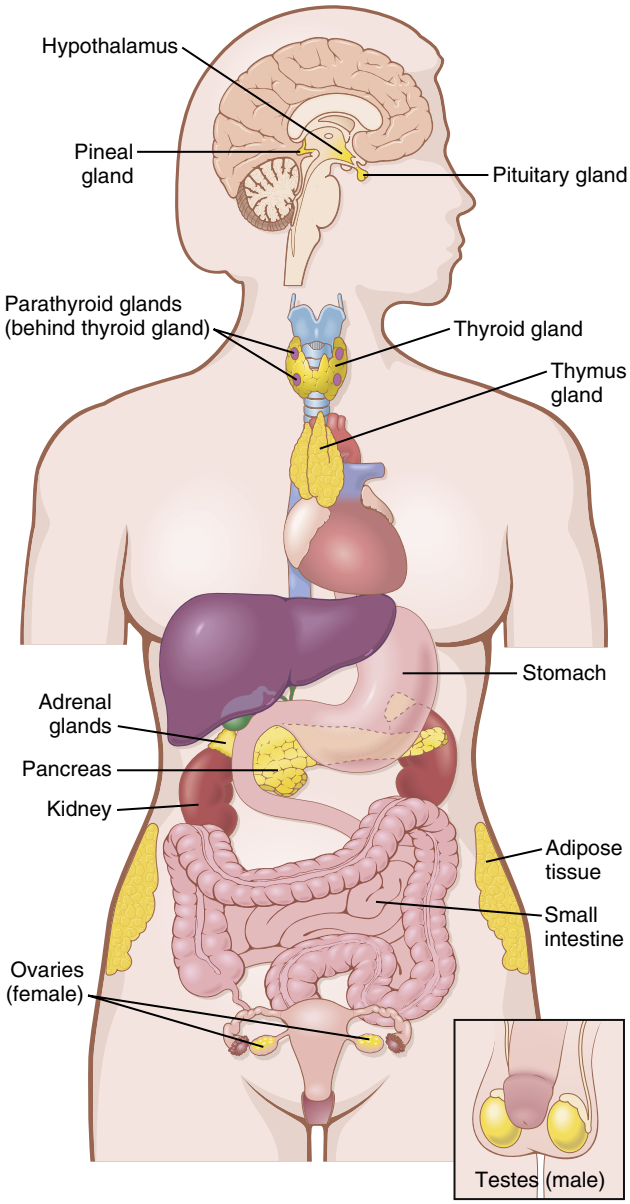

Figure 75-1. Anatomical loci of the principal endocrine glands and tissues of the body.

gland (parathyroid hormone), and many others (see Table 75-1).

2. *Steroids* secreted by the adrenal cortex (cortisol and aldosterone), the ovaries (estrogen and progesterone), the testes (testosterone), and the placenta (estrogen and progesterone).
3. *Derivatives of the amino acid tyrosine,* secreted by the thyroid (thyroxine and triiodothyronine) and the adrenal medullae (epinephrine and norepinephrine). There are no known polysaccharides or nucleic acid hormones.

Polypeptide and Protein Hormones Are Stored in Secretory Vesicles Until Needed. Most of the hormones in the body are polypeptides and proteins. These hormones range in size from small peptides with as few as three amino acids (e.g., thyrotropin-releasing hormone) to proteins with almost 200 amino acids (e.g., growth hormone and prolactin). In general, polypeptides with 100 or more amino acids are called *proteins,* and those with fewer than 100 amino acids are referred to as *peptides.*

Protein and peptide hormones are synthesized on the rough end of the endoplasmic reticulum of the different endocrine cells, in the same fashion as most other proteins (Figure 75-2). They are usually synthesized first as larger proteins that are not biologically active *(preprohormones)* and are cleaved to form smaller *prohormones* in the endoplasmic reticulum. These prohormones are then transferred to the Golgi apparatus for packaging into secretory vesicles. In this process, enzymes in the vesicles cleave the prohormones to produce smaller, biologically active hormones and inactive fragments. The vesicles are stored within the cytoplasm, and many are bound to the cell membrane until their secretion is needed. Secretion of the hormones (as well as the inactive fragments) occurs when the secretory vesicles fuse with the cell membrane and the granular contents are extruded into the interstitial fluid or directly into the blood stream by *exocytosis.*

In many cases, the stimulus for exocytosis is increased cytosolic calcium concentration caused by depolarization of the plasma membrane. In other cases, stimulation of an endocrine cell surface receptor causes increased cyclic adenosine monophosphate (cAMP) and subsequently activation of protein kinases that initiate secretion of the hormone. The peptide hormones are water soluble, allowing them to enter the circulatory system easily, where they are carried to their target tissues.

Steroid Hormones Are Usually Synthesized From Cholesterol and Are Not Stored. Steroid hormones have a chemical structure that is similar to cholesterol, and in most cases are synthesized from cholesterol. They are lipid soluble and consist of three cyclohexyl rings and one cyclopentyl ring combined into a single structure (Figure 75-3).

Although there is usually very little hormone storage in steroid-producing endocrine cells, large stores of cholesterol esters in cytoplasm vacuoles can be rapidly mobilized for steroid synthesis after a stimulus. Much of the cholesterol in steroid-producing cells comes from the plasma, but there is also de novo synthesis of cholesterol in steroid-producing cells. Because steroids are highly lipid soluble, once they are synthesized, they can simply diffuse across the cell membrane and enter the interstitial fluid and then the blood.

Amine Hormones Are Derived From Tyrosine. The two groups of hormones derived from tyrosine, the thyroid and the adrenal medullary hormones, are formed by the actions of enzymes in the cytoplasmic compartments of glandular cells. The thyroid hormones are synthesized and stored in the thyroid gland and incorporated into macromolecules of the protein *thyroglobulin,* which is stored in large follicles within the thyroid gland. Hormone secretion occurs when the amines are split from

Table 75-1 Endocrine Glands, Hormones, and Their Functions and Structure

Gland/Tissue	Hormones	Major Functions	Chemical Structure
Hypothalamus (Chapter 76)	Thyrotropin-releasing hormone	Stimulates secretion of thyroid-stimulating hormone and prolactin	Peptide
	Corticotropin-releasing hormone	Causes release of adrenocorticotropic hormone	Peptide
	Growth hormone–releasing hormone	Causes release of growth hormone	Peptide
	Growth hormone inhibitory hormone (somatostatin)	Inhibits release of growth hormone	Peptide
	Gonadotropin-releasing hormone	Causes release of luteinizing hormone and follicle-stimulating hormone	Peptide
	Dopamine or prolactin-inhibiting factor	Inhibits release of prolactin	Amine
Anterior pituitary (Chapter 76)	Growth hormone	Stimulates protein synthesis and overall growth of most cells and tissues	Peptide
	Thyroid-stimulating hormone	Stimulates synthesis and secretion of thyroid hormones (thyroxine and triiodothyronine)	Peptide
	Adrenocorticotropic hormone	Stimulates synthesis and secretion of adrenocortical hormones (cortisol, androgens, and aldosterone)	Peptide
	Prolactin	Promotes development of the female breasts and secretion of milk	Peptide
	Follicle-stimulating hormone	Causes growth of follicles in the ovaries and sperm maturation in Sertoli cells of testes	Peptide
	Luteinizing hormone	Stimulates testosterone synthesis in Leydig cells of testes; stimulates ovulation, formation of corpus luteum, and estrogen and progesterone synthesis in ovaries	Peptide
Posterior pituitary (Chapter 76)	Antidiuretic hormone (also called *vasopressin*)	Increases water reabsorption by the kidneys and causes vasoconstriction and increased blood pressure	Peptide
	Oxytocin	Stimulates milk ejection from breasts and uterine contractions	Peptide
Thyroid (Chapter 77)	Thyroxine (T_4) and triiodothyronine (T_3)	Increases the rates of chemical reactions in most cells, thus increasing body metabolic rate	Amine
	Calcitonin	Promotes deposition of calcium in the bones and decreases extracellular fluid calcium ion concentration	Peptide
Adrenal cortex (Chapter 78)	Cortisol	Has multiple metabolic functions for controlling metabolism of proteins, carbohydrates, and fats; also has anti-inflammatory effects	Steroid
	Aldosterone	Increases renal sodium reabsorption, potassium secretion, and hydrogen ion secretion	Steroid
Adrenal medulla (Chapter 61)	Norepinephrine, epinephrine	Same effects as sympathetic stimulation	Amine
Pancreas (Chapter 79)	Insulin (beta cells)	Promotes glucose entry in many cells, and in this way controls carbohydrate metabolism	Peptide
	Glucagon (α cells)	Increases synthesis and release of glucose from the liver into the body fluids	Peptide
Parathyroid (Chapter 80)	Parathyroid hormone	Controls serum calcium ion concentration by increasing calcium absorption by the gut and kidneys and releasing calcium from bones	Peptide
Testes (Chapter 81)	Testosterone	Promotes development of male reproductive system and male secondary sexual characteristics	Steroid
Ovaries (Chapter 82)	Estrogens	Promotes growth and development of female reproductive system, female breasts, and female secondary sexual characteristics	Steroid
	Progesterone	Stimulates secretion of "uterine milk" by the uterine endometrial glands and promotes development of secretory apparatus of breasts	Steroid

Continued

Table 75-1 Endocrine Glands, Hormones, and Their Functions and Structure—cont'd

Gland/Tissue	Hormones	Major Functions	Chemical Structure
Placenta (Chapter 83)	Human chorionic gonadotropin	Promotes growth of corpus luteum and secretion of estrogens and progesterone by corpus luteum	Peptide
	Human somatomammotropin	Probably helps promote development of some fetal tissues, as well as the mother's breasts	Peptide
	Estrogens	See actions of estrogens from ovaries.	Steroid
	Progesterone	See actions of progesterone from ovaries.	Steroid
Kidney (Chapter 26)	Renin	Catalyzes conversion of angiotensinogen to angiotensin I (acts as an enzyme)	Peptide
	1,25-Dihydroxycholecalciferol	Increases intestinal absorption of calcium and bone mineralization	Steroid
	Erythropoietin	Increases erythrocyte production	Peptide
Heart (Chapter 22)	Atrial natriuretic peptide	Increases sodium excretion by kidneys, reduces blood pressure	Peptide
Stomach (Chapter 65)	Gastrin	Stimulates hydrogen chloride secretion by parietal cells	Peptide
Small intestine (Chapter 65)	Secretin	Stimulates pancreatic acinar cells to release bicarbonate and water	Peptide
	Cholecystokinin	Stimulates gallbladder contraction and release of pancreatic enzymes	Peptide
Adipocytes (Chapter 72)	Leptin	Inhibits appetite, stimulates thermogenesis	Peptide

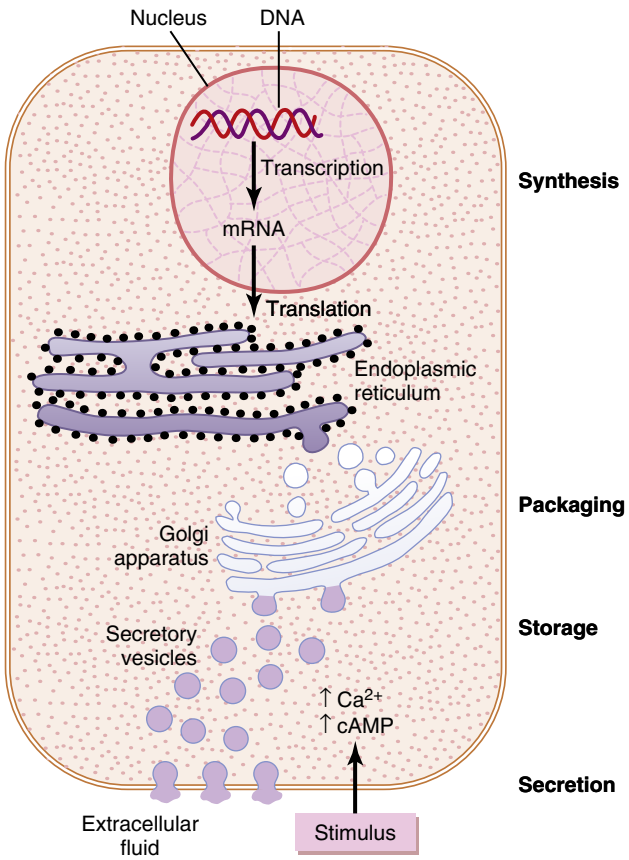

Figure 75-2. Synthesis and secretion of peptide hormones. The stimulus for hormone secretion often involves changes in intracellular calcium or changes in cyclic adenosine monophosphate *(cAMP)* in the cell.

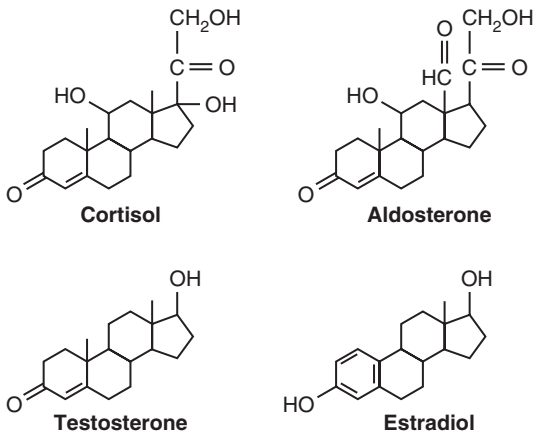

Figure 75-3. Chemical structures of several steroid hormones.

thyroglobulin, and the free hormones are then released into the blood stream. After entering the blood, most of the thyroid hormones combine with plasma proteins, especially *thyroxine-binding globulin,* which slowly releases the hormones to the target tissues.

Epinephrine and norepinephrine are formed in the adrenal medulla, which normally secretes about four times more epinephrine than norepinephrine. Catecholamines are taken up into preformed vesicles and stored until secreted. Similar to the protein hormones stored in secretory granules, catecholamines are also released from adrenal medullary cells by exocytosis. Once the catecholamines enter the circulation, they can exist in the plasma in free form or in conjugation with other substances.

HORMONE SECRETION, TRANSPORT, AND CLEARANCE FROM THE BLOOD

Hormone Secretion After a Stimulus and Duration of Action of Different Hormones. Some hormones, such as norepinephrine and epinephrine, are secreted within seconds after the gland is stimulated and may develop full action within another few seconds to minutes; the actions of other hormones, such as thyroxine or growth hormone, may require months for full effect. Thus, each of the different hormones has its own characteristic onset and duration of action—each tailored to perform its specific control function.

Concentrations of Hormones in the Circulating Blood and Hormonal Secretion Rates. The concentrations of hormones required to control most metabolic and endocrine functions are incredibly small. Their concentrations in the blood range from as little as 1 picogram (which is one millionth of one millionth of a gram) in each milliliter of blood up to at most a few micrograms (a few millionths of a gram) per milliliter of blood. Similarly, the rates of secretion of the various hormones are extremely small, usually measured in micrograms or milligrams per day. We shall see later in this chapter that highly specialized mechanisms are available in the target tissues that allow even these minute quantities of hormones to exert powerful control over the physiological systems.

FEEDBACK CONTROL OF HORMONE SECRETION

Negative Feedback Prevents Overactivity of Hormone Systems. Although the plasma concentrations of many hormones fluctuate in response to various stimuli that occur throughout the day, all hormones studied thus far appear to be closely controlled. In most cases, this control is exerted through *negative feedback mechanisms* (described in Chapter 1) that ensure a proper level of hormone activity at the target tissue. After a stimulus causes release of the hormone, conditions or products resulting from the action of the hormone tend to suppress its further release. In other words, the hormone (or one of its products) has a negative feedback effect to prevent oversecretion of the hormone or overactivity at the target tissue. Feedback regulation of hormones can occur at all levels, including gene transcription and translation steps involved in the synthesis of hormones and steps involved in processing hormones or releasing stored hormones.

The controlled variable is sometimes the degree of activity of the target tissue rather than the synthesis or secretory rates of the hormone. Therefore, only when the target tissue activity rises to an appropriate level will feedback signals to the endocrine gland become powerful enough to slow further synthesis and secretion of the hormone.

Surges of Hormones Can Occur With Positive Feedback. In a few cases, *positive feedback* occurs when the biological action of the hormone causes additional secretion of the hormone. One example of positive feedback is the surge of *luteinizing hormone* (LH) that occurs as a result of the stimulatory effect of estrogen on the anterior pituitary before ovulation. The secreted LH then acts on the ovaries to stimulate additional secretion of estrogen, which in turn causes more secretion of LH. Eventually, LH reaches an appropriate concentration and typical negative feedback control of hormone secretion is then exerted.

Cyclical Variations Occur in Hormone Release. Superimposed on the negative and positive feedback control of hormone secretion are periodic variations in hormone release that are influenced by seasonal changes, various stages of development and aging, the diurnal (daily) cycle, and sleep. For example, the secretion of growth hormone is markedly increased during the early period of sleep but is reduced during the later stages of sleep. In many cases, these cyclical variations in hormone secretion are due to changes in activity of neural pathways involved in controlling hormone release.

Oscillations of endocrine signaling are driven, in part by *circadian clocks*. As discussed in Chapter 59 (see **Figure 59-8**), the suprachiasmatic nucleus (SCN) of the hypothalamus serves as a "*master clock*" that controls rhythmic patterns of biological clocks in many parts of the body, including neuroendocrine cells and endocrine glands. There is also evidence for *local clock control* in peripheral endocrine tissues, such as the adrenal gland and pancreas, which have cyclical changes in their sensitivity to various signals.

Cyclical changes in tissue responsiveness and fluctuations in hormone concentrations provide important mechanisms for the body to anticipate and adapt to the dramatic changes in stresses and demands that normally occur over the course of a day— ranging from restful sleep to eating meals and high levels of mental and physical activity. Rhythmic changes in female sex hormones that occur with an average 28-day cycle are also essential for reproduction, as discussed in Chapter 82.

TRANSPORT OF HORMONES IN THE BLOOD

Water-soluble hormones (peptides and catecholamines) are dissolved in the plasma and transported from their sites of synthesis to target tissues, where they diffuse out

of the capillaries, into the interstitial fluid, and ultimately to target cells.

Steroid and thyroid hormones, in contrast, circulate in the blood while being mainly bound to plasma proteins. Usually less than 10% of steroid or thyroid hormones in the plasma exist free in solution. For example, more than 99% of the thyroxine in the blood is bound to plasma proteins. However, protein-bound hormones cannot easily diffuse across the capillaries and gain access to their target cells and are therefore biologically inactive until they dissociate from plasma proteins.

The relatively large amounts of hormones bound to proteins serve as reservoirs, replenishing the concentration of free hormones when they are bound to target receptors or lost from the circulation. Binding of hormones to plasma proteins greatly slows their clearance from the plasma.

"Clearance" of Hormones From the Blood. Two factors can increase or decrease the concentration of a hormone in the blood: (1) the rate of hormone secretion into the blood; (2) the rate of removal of the hormone from the blood, which is called the *metabolic clearance rate* and is usually expressed in terms of the number of milliliters of plasma cleared of the hormone per minute. To calculate this clearance rate, one measures (1) the rate of disappearance of the hormone from the plasma (e.g., nanograms per minute) and (2) the plasma concentration of the hormone (e.g., nanograms per milliliter of plasma). Then, the metabolic clearance rate is calculated with use of the following formula:

$$\text{Metabolic clearance rate} = \frac{\text{Rate of disappearance of hormone from the plasma}}{\text{Concentration of hormone}}$$

The usual procedure for making this measurement is as follows. A purified solution of the hormone to be measured is tagged with a radioactive substance. Then the radioactive hormone is infused at a constant rate into the blood stream until the radioactive concentration in the plasma becomes steady. At this time, the disappearance rate of the radioactive hormone from the plasma equals the rate at which it is infused, which gives one the rate of disappearance. At the same time, the plasma concentration of the radioactive hormone is measured using a standard radioactive counting procedure. Then, using the formula just cited, the metabolic clearance rate is calculated.

Hormones are "cleared" from the plasma in several ways, including (1) metabolic destruction by the tissues, (2) binding with the tissues, (3) excretion by the liver into the bile, and (4) excretion by the kidneys into the urine. For certain hormones, a decreased metabolic clearance rate may cause an excessively high concentration of the hormone in the circulating body fluids. For example, excessive steroid hormones accumulate when the liver is diseased because these hormones are conjugated mainly in the liver and then "cleared" into the bile.

Hormones are sometimes degraded at their target cells by enzymatic processes that cause endocytosis of the cell membrane hormone-receptor complex; the hormone is then metabolized in the cell, and the receptors are usually recycled back to the cell membrane.

Most of the peptide hormones and catecholamines are water soluble and circulate freely in the blood. They are usually degraded by enzymes in the blood and tissues and rapidly excreted by the kidneys and liver, thus remaining in the blood for only a short time. For example, the half-life of angiotensin II circulating in the blood is less than a minute.

Hormones that are bound to plasma proteins are cleared from the blood at much slower rates and may remain in the circulation for several hours or even days. The half-life of adrenal steroids in the circulation, for example, ranges between 20 and 100 minutes, whereas the half-life of the protein-bound thyroid hormones may be as long as 1 to 6 days.

MECHANISMS OF ACTION OF HORMONES

HORMONE RECEPTORS AND THEIR ACTIVATION

The first step of a hormone's action is to bind to specific *receptors* at the target cell. Cells that lack receptors for the hormones do not respond. Receptors for some hormones are located on the target cell membrane, whereas other hormone receptors are located in the cytoplasm or the nucleus. When the hormone combines with its receptor, this action usually initiates a cascade of reactions in the cell, with each stage becoming more powerfully activated so that even small concentrations of the hormone can have a large effect.

Hormone receptors are large proteins, and each cell that is to be stimulated usually has some 2000 to 100,000 receptors. Also, each receptor is usually highly specific for a single hormone, which determines the type of hormone that will act on a particular tissue. The target tissues that are affected by a hormone are those that contain its specific receptors.

The locations for the different types of hormone receptors are generally the following:

1. *In or on the surface of the cell membrane.* The membrane receptors are specific mostly for the protein, peptide, and catecholamine hormones.
2. *In the cell cytoplasm.* The primary receptors for the different steroid hormones are found mainly in the cytoplasm.
3. *In the cell nucleus.* The receptors for the thyroid hormones are found in the nucleus and are believed to be located in direct association with one or more of the chromosomes.

The Number and Sensitivity of Hormone Receptors Are Regulated. The number of receptors in a target cell usually does not remain constant from day to day or even from minute to minute. Receptor proteins are often inactivated or destroyed during the course of their function, and at other times they are reactivated or new ones are manufactured by the cell. For example, increased hormone concentration and increased binding with its target cell receptors sometimes cause the number of active receptors to decrease. This *down-regulation* of the receptors can occur as a result of (1) inactivation of some of the receptor molecules; (2) inactivation of some of the intracellular protein signaling molecules; (3) temporary sequestration of the receptor to the inside of the cell, away from the site of action of hormones that interact with cell membrane receptors; (4) destruction of the receptors by lysosomes after they are internalized; or (5) decreased production of the receptors. In each case, receptor down-regulation decreases the target tissue's responsiveness to the hormone.

Some hormones cause *up-regulation* of receptors and intracellular signaling proteins; that is, the stimulating hormone induces greater than normal formation of receptor or intracellular signaling molecules by the target cell or greater availability of the receptor for interaction with the hormone. When up-regulation occurs, the target tissue becomes progressively more sensitive to the stimulating effects of the hormone.

INTRACELLULAR SIGNALING AFTER HORMONE RECEPTOR ACTIVATION

Almost without exception, a hormone affects its target tissues by first forming a hormone-receptor complex. Formation of this complex alters the function of the receptor, and the activated receptor initiates the hormonal effects. To explain this process, let us give a few examples of the different types of interactions.

Ion Channel–Linked Receptors. Virtually all the neurotransmitter substances, such as acetylcholine and norepinephrine, combine with receptors in the postsynaptic membrane. This combination almost always causes a change in the structure of the receptor, usually opening or closing a channel for one or more ions. Some of these *ion channel–linked receptors* open (or close) channels for sodium ions, others for potassium ions, others for calcium ions, and so forth. The altered movement of these ions through the channels causes the subsequent effects on the postsynaptic cells. Although a few hormones may exert some of their actions through activation of ion channel receptors, most hormones that open or close ions channels do this indirectly by coupling with G protein–linked or enzyme-linked receptors, as discussed next.

G Protein–Linked Hormone Receptors. Many hormones activate receptors that indirectly regulate the activity of target proteins (e.g., enzymes or ion channels) by coupling with groups of cell membrane proteins called *heterotrimeric guanosine triphosphate (GTP)-binding proteins (G proteins)* (**Figure 75-4**). All of the known G protein–coupled receptors (~1000) have seven transmembrane segments that loop in and out of the cell membrane. Some parts of the receptor that protrude into the cell cytoplasm (especially the cytoplasmic tail of the receptor) are coupled to G proteins that include three (i.e., trimeric) parts—the α, β, and γ subunits. When the ligand (hormone) binds to the extracellular part of the receptor, a conformational change occurs in the receptor that activates the G proteins and induces intracellular signals that either (1) open or close cell membrane ion channels, (2) change the activity of an enzyme in the cytoplasm of the cell, or (3) activate gene transcription.

The trimeric G proteins are named for their ability to bind *guanosine nucleotides.* In their inactive state, the α, β, and γ subunits of G proteins form a complex that binds *guanosine diphosphate* (GDP) on the α subunit.

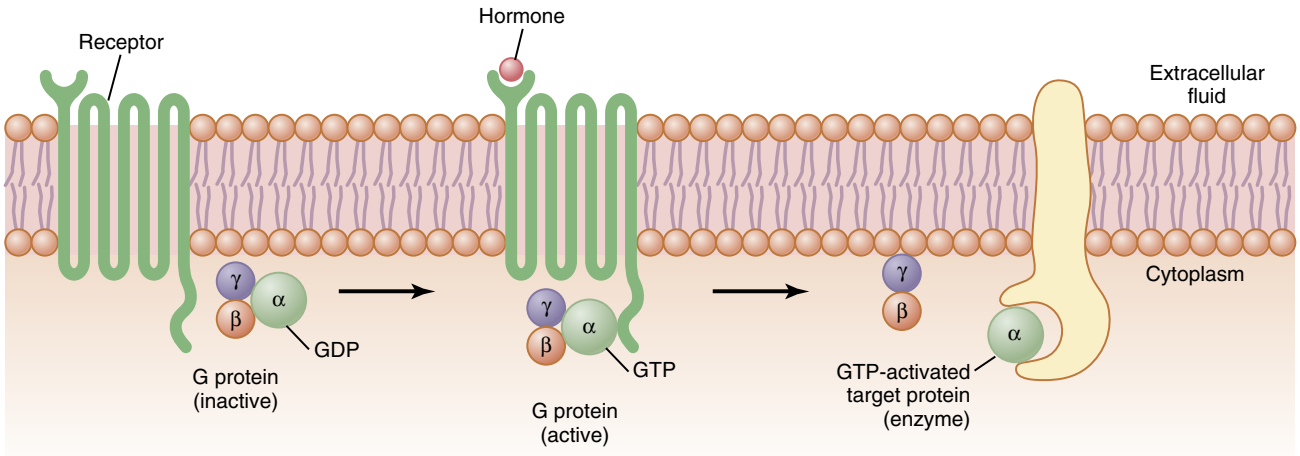

Figure 75-4. Mechanism of activation of a G protein–coupled receptor. When the hormone activates the receptor, the inactive α, β, and γ G protein complex associates with the receptor and is activated, with an exchange of guanosine triphosphate *(GTP)* for guanosine diphosphate *(GDP)*. This process causes the α subunit (to which the GTP is bound) to dissociate from the β and γ subunits of the G protein and to interact with membrane-bound target proteins (enzymes) that initiate intracellular signals.

When the receptor is activated, it undergoes a conformational change that causes the GDP-bound trimeric G protein to associate with the cytoplasmic part of the receptor and to exchange GDP for GTP. Displacement of GDP by GTP causes the α subunit to dissociate from the trimeric complex and to associate with other intracellular signaling proteins; these proteins, in turn, alter the activity of ion channels or intracellular enzymes such as *adenylyl cyclase* or *phospholipase C,* which alter cell function.

The signaling event is terminated when the hormone is removed and the α subunit inactivates itself by converting its bound GTP to GDP; then the α subunit once again combines with the β and γ subunits to form an inactive, membrane-bound trimeric G protein. Additional details of G protein signaling are discussed in Chapter 46 and shown in **Figure 46-7**.

Some hormones are coupled to *inhibitory G proteins* (denoted as G_i proteins), whereas others are coupled to *stimulatory G proteins* (denoted as G_s proteins). Thus, depending on the coupling of a hormone receptor to an inhibitory or stimulatory G protein, a hormone can either increase or decrease the activity of intracellular enzymes. This complex system of cell membrane G proteins provides a vast array of potential cell responses to different hormones in the various target tissues of the body.

Enzyme-Linked Hormone Receptors. Some receptors, when activated, function directly as enzymes or are closely associated with enzymes that they activate. These *enzyme-linked receptors* are proteins that pass through the membrane only once, in contrast to the seven-transmembrane G protein–coupled receptors. Enzyme-linked receptors have their hormone-binding site on the outside of the cell membrane and their catalytic or enzyme-binding site on the inside. When the hormone binds to the extracellular part of the receptor, an enzyme immediately inside the cell membrane is activated (or occasionally inactivated). Although many enzyme-linked receptors have intrinsic enzyme activity, others rely on enzymes that are closely associated with the receptor to produce changes in cell function.

Table 75-2 lists a few of the many peptide growth factors, cytokines, and hormones that use the enzyme-linked receptor *tyrosine kinases* for cell signaling. One example of an enzyme-linked receptor is the *leptin receptor* (**Figure 75-5**). Leptin is a hormone secreted by fat cells and has many physiological effects, but it is especially important in regulating appetite and energy balance, as discussed in Chapter 72. The leptin receptor is a member of a large family of *cytokine receptors* that do not themselves contain enzymatic activity but signal through associated enzymes. In the case of the leptin receptor, one of the signaling pathways occurs through a tyrosine kinase of the *janus kinase* (JAK) family, *JAK2.* The leptin receptor exists as a dimer (i.e., in two parts), and binding of leptin to the extracellular part of the receptor alters its conformation, enabling phosphorylation and activation of the intracellular associated JAK2 molecules. The activated JAK2 molecules then phosphorylate other tyrosine residues within the leptin receptor–JAK2 complex to mediate intracellular signaling. The intracellular signals include phosphorylation of *signal transducer and activator of transcription* (STAT) proteins, which activates transcription by leptin target genes to initiate protein synthesis. Phosphorylation of JAK2 also leads to activation of other intracellular enzyme pathways such as *mitogen-activated protein kinases* (MAPK) and *phosphatidylinositol 3-kinase* (PI3K). Some of the effects of leptin occur rapidly as a result of activation of these intracellular enzymes, whereas other actions occur more slowly and require synthesis of new proteins.

Another example, one widely used in hormonal control of cell function, is for the hormone to bind with a

Table 75-2 Hormones That Use Receptor Tyrosine Kinase Signaling

Vascular endothelial growth factor

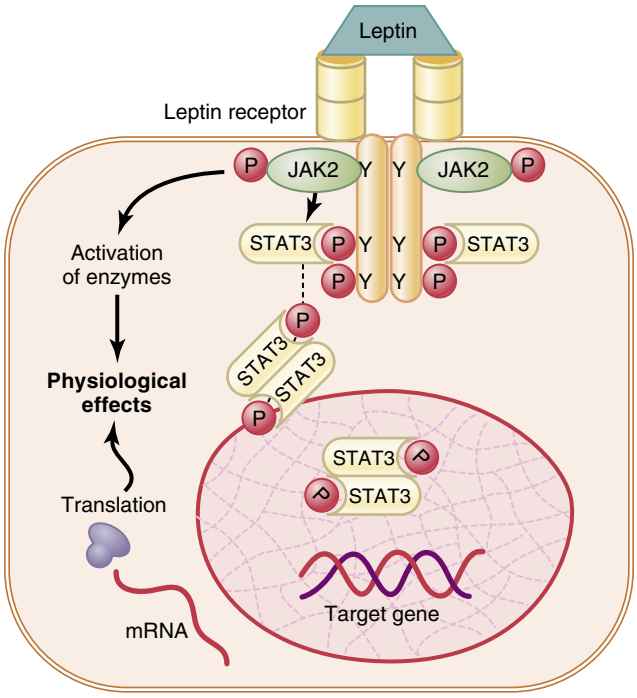

Figure 75-5. An enzyme-linked receptor—the leptin receptor. The receptor exists as a homodimer (two identical parts), and leptin binds to the extracellular part of the receptor, causing phosphorylation *(P)* and activation of the intracellular associated janus kinase 2 *(JAK2)*. This mechanism causes phosphorylation of signal transducer and activator of transcription *(STAT)* proteins, which then activates the transcription of target genes and the synthesis of proteins. JAK2 phosphorylation also activates several other enzyme systems that mediate some of the more rapid effects of leptin. Y, Specific tyrosine phosphorylation sites.

special transmembrane receptor, which then becomes the activated enzyme *adenylyl cyclase* at the end that protrudes to the interior of the cell. This cyclase catalyzes the formation of cAMP, which has a multitude of effects inside the cell to control cell activity, as discussed later. cAMP is called a *second messenger* because it is not the hormone itself that directly institutes the intracellular changes; instead, the cAMP serves as a second messenger to cause these effects.

For a few peptide hormones, such as atrial natriuretic peptide, *cyclic guanosine monophosphate*, which is only slightly different from cAMP, serves in a similar manner as a second messenger.

Intracellular Hormone Receptors and Activation of Genes. Several hormones, including adrenal and gonadal steroid hormones, thyroid hormones, retinoid hormones, and vitamin D, bind with protein receptors inside the cell rather than in the cell membrane. Because these hormones are lipid soluble, they readily cross the cell membrane and interact with receptors in the cytoplasm or nucleus. The activated hormone-receptor complex then binds with a specific regulatory (promoter) sequence of the DNA called the *hormone response element,* and in this manner either activates or represses transcription of specific genes and formation of messenger RNA (mRNA; Figure 75-6). Therefore, minutes, hours, or even days after the hormone has entered the cell, newly formed proteins appear in the cell and become the controllers of new or altered cellular functions.

Many different tissues have identical intracellular hormone receptors, but the genes that the receptors regulate are different in the various tissues. An intracellular receptor can activate a gene response only if the appropriate combination of gene regulatory proteins is present, and many of these regulatory proteins are tissue specific. *Thus, the responses of different tissues to a hormone are determined not only by the specificity of the receptors but also by the expression of genes that the receptor regulates.*

SECOND MESSENGER MECHANISMS FOR MEDIATING INTRACELLULAR HORMONAL FUNCTIONS

We noted earlier that one way that hormones exert intracellular actions is to stimulate formation of the second messenger cAMP inside the cell membrane. The cAMP then causes subsequent intracellular effects of the hormone. Thus, the only direct effect that the hormone has on the cell is to activate a single type of membrane receptor. The second messenger does the rest.

cAMP is not the only second messenger used by the different hormones. Two other especially important ones are (1) calcium ions and associated *calmodulin* and (2) products of membrane phospholipid breakdown. In some cases, a hormone may stimulate more than one second messenger system in the same target tissue.

Adenylyl Cyclase–cAMP Second Messenger System

Table 75-3 shows a few of the many hormones that use the adenylyl cyclase–cAMP mechanism to stimulate their target tissues, and Figure 75-7 shows the adenylyl cyclase–cAMP second messenger system. Binding of the

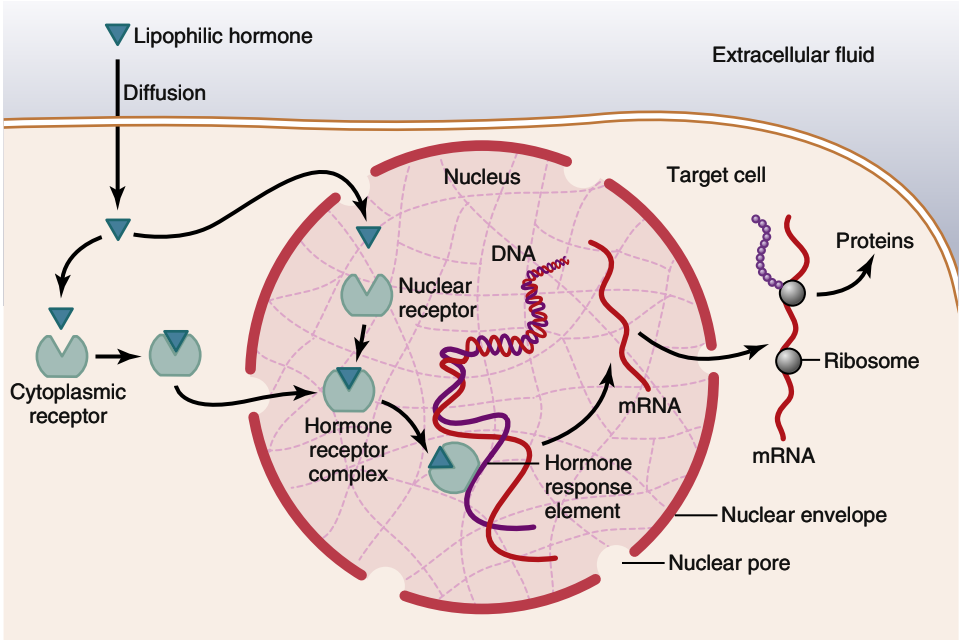

Figure 75-6. Mechanisms of interaction of lipophilic hormones, such as steroids, with intracellular receptors in target cells. After the hormone binds to the receptor in the cytoplasm or in the nucleus, the hormone-receptor complex binds to the hormone response element (promoter) on the DNA. This action either activates or inhibits gene transcription, formation of messenger RNA *(mRNA)*, and protein synthesis.

Table 75-3 Hormones That Use the Adenylyl Cyclase–cAMP Second Messenger System

Adrenocorticotropic hormone (ACTH)
Angiotensin II (epithelial cells)
Calcitonin
Catecholamines (beta receptors)
Corticotropin-releasing hormone (CRH)
Follicle-stimulating hormone (FSH)
Glucagon
Growth hormone–releasing hormone (GHRH)
Human chorionic gonadotropin (hCG)
Luteinizing hormone (LH)
Parathyroid hormone (PTH)
Secretin
Somatostatin
Thyroid-stimulating hormone (TSH)
Vasopressin (V_2 receptor, epithelial cells)

cAMP, Cyclic adenosine monophosphate.

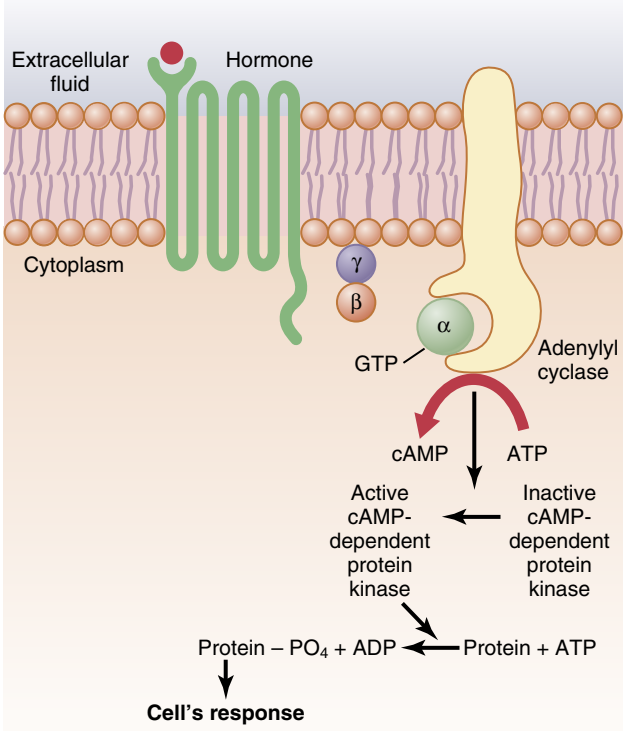

Figure 75-7. The cyclic adenosine monophosphate *(cAMP)* mechanism by which many hormones exert their control of cell function. ADP, Adenosine diphosphate; ATP, adenosine triphosphate; GTP, guanosine triphosphate.

hormones with the receptor allows coupling of the receptor to a *G protein.* If the G protein stimulates the adenylyl cyclase–cAMP system, it is called a *G_s protein,* denoting a stimulatory G protein. Stimulation of adenylyl cyclase, a membrane-bound enzyme, by the G_s protein then catalyzes the conversion of a small amount of cytoplasmic *adenosine triphosphate* into cAMP inside the cell. This then activates *cAMP-dependent protein kinase,* which phosphorylates specific cell proteins, triggering biochemical reactions that ultimately lead to the cell's response to the hormone.

Table 75-4 Hormones That Use the Phospholipase C Second Messenger System

Angiotensin II (vascular smooth muscle)
Catecholamines (α receptors)
Gonadotropin-releasing hormone (GnRH)
Growth hormone–releasing hormone (GHRH)
Parathyroid hormone (PTH)
Oxytocin
Thyrotropin-releasing hormone (TRH)
Vasopressin (V_1 receptor, vascular smooth muscle)

Once cAMP is formed inside the cell, it usually activates a *cascade of enzymes.* That is, first one enzyme is activated, which activates a second enzyme, which activates a third, and so forth. The importance of this mechanism is that only a few molecules of activated adenylyl cyclase immediately inside the cell membrane can cause many more molecules of the next enzyme to be activated, which can cause still more molecules of the third enzyme to be activated, and so forth. In this way, even the slightest amount of hormone acting on the cell surface can initiate a powerful cascading activating force for the entire cell.

If binding of the hormone to its receptors is coupled to an inhibitory G protein (denoted G_i protein), adenylyl cyclase will be inhibited, reducing formation of cAMP and ultimately leading to an inhibitory action in the cell. Thus, depending on the coupling of the hormone receptor to an inhibitory or a stimulatory G protein, a hormone can either increase or decrease the concentration of cAMP and phosphorylation of key proteins inside the cell.

The specific action that occurs in response to increases or decreases of cAMP in each type of target cell depends on the nature of the intracellular machinery; some cells have one set of enzymes, and other cells have other enzymes. Therefore, different functions are elicited in different target cells, such as initiating synthesis of specific intracellular chemicals, causing muscle contraction or relaxation, initiating secretion by the cells, and altering cell permeability.

Thus, a thyroid cell stimulated by cAMP forms the metabolic hormones thyroxine and triiodothyronine, whereas the same cAMP in an adrenocortical cell causes secretion of the adrenocortical steroid hormones. In some epithelial cells of the distal and collecting tubules of the kidney, cAMP increases their permeability to water.

Cell Membrane Phospholipid Second Messenger System

Some hormones activate transmembrane receptors that activate the enzyme *phospholipase C* attached to the inside projections of the receptors (**Table 75-4**). This enzyme catalyzes the breakdown of some phospholipids in the cell membrane, especially *phosphatidylinositol biphosphate* (PIP_2), into two different second messenger products: *inositol triphosphate* (IP_3) and *diacylglycerol* (DAG). The IP_3 mobilizes calcium ions from mitochondria and the endoplasmic reticulum, and the calcium ions

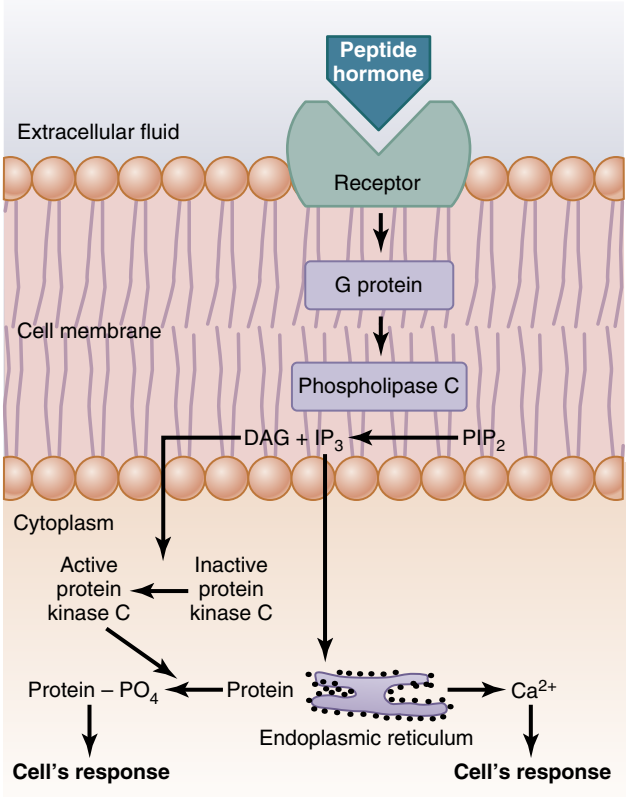

Figure 75-8. The cell membrane phospholipid second messenger system by which some hormones exert their control of cell function. DAG, Diacylglycerol; IP_3, inositol triphosphate; PIP_2, phosphatidylinositol biphosphate.

then have their own second messenger effects, such as smooth muscle contraction and changes in cell secretion.

DAG, the other lipid second messenger, activates the enzyme *protein kinase C*, which then phosphorylates a large number of proteins, leading to the cell's response (**Figure 75-8**). In addition to these effects, the lipid portion of DAG is *arachidonic acid,* which is the precursor for the *prostaglandins* and other local hormones that cause multiple effects in tissues throughout the body.

Calcium-Calmodulin Second Messenger System

Another second messenger system operates in response to entry of calcium into the cells. Calcium entry may be initiated by (1) changes in membrane potential that open calcium channels or (2) a hormone interacting with membrane receptors that open calcium channels.

Upon entering a cell, calcium ions bind with the protein *calmodulin.* This protein has four calcium sites, and when three or four of these sites have become bound with calcium, the calmodulin changes its shape and initiates multiple effects inside the cell, including activation or inhibition of protein kinases. Activation of calmodulin-dependent protein kinases causes, via phosphorylation, activation or inhibition of proteins involved in the cell's response to the hormone. For example, one specific function of calmodulin is to activate *myosin light chain kinase,* which acts directly on the myosin of smooth muscle to cause smooth muscle contraction (see **Figure 8-3**).

The normal calcium ion concentration in most cells of the body is 10^{-8} to 10^{-7} mol/L, which is not enough to activate the calmodulin system. However, when the calcium ion concentration rises to 10^{-6} to 10^{-5} mol/L, enough binding occurs to cause all the intracellular actions of calmodulin. This is almost exactly the same amount of calcium ion change in skeletal muscle that is required to activate troponin C, which causes skeletal muscle contraction, as explained in Chapter 7. It is interesting that troponin C is similar to calmodulin in both function and protein structure.

HORMONES THAT ACT MAINLY ON THE GENETIC MACHINERY OF THE CELL

Steroid Hormones Increase Protein Synthesis

Another means by which hormones act, especially steroid hormones, is to cause protein synthesis in target cells. These proteins then function as enzymes, transport proteins, or structural proteins, which in turn provide other functions of the cells.

The sequence of events in steroid function is essentially the following (see **Figure 75-6**):

1. The steroid hormone diffuses across the cell membrane and enters the cytoplasm of the cell, where it binds with a specific *receptor protein.*
2. The combined receptor protein–hormone then diffuses into or is transported into the nucleus.
3. The combination binds at specific points on the DNA strands in the chromosomes, which activates the transcription process of specific genes to form mRNA.
4. The mRNA diffuses into the cytoplasm, where it promotes the translation process at the ribosomes to form new proteins.

To give an example, *aldosterone,* one of the hormones secreted by the adrenal cortex, enters the cytoplasm of renal tubular cells, which contain a specific receptor protein often called the *mineralocorticoid receptor*. Therefore, in these cells, the sequence of events cited earlier ensues. After about 45 minutes, proteins begin to appear in the renal tubular cells and promote sodium reabsorption from the tubules and potassium secretion into the tubules. Thus, the full action of the steroid hormone is characteristically delayed for at least 45 minutes—up to several hours or even days. This action is in marked contrast to the rapid actions of some of the peptide and amino acid–derived hormones, such as vasopressin and norepinephrine.

Thyroid Hormones Increase Gene Transcription in the Cell Nucleus

The thyroid hormones *thyroxine* and *triiodothyronine* cause increased transcription by specific genes in the nucleus. To

accomplish this increased transcription, these hormones first bind directly with receptor proteins in the nucleus, as discussed in more detail in Chapter 77 (see **Figure 77-5**); these receptors are *activated transcription factors* located within the chromosomal complex, and they control the function of the gene promoters, as explained in Chapter 3.

The following two features of thyroid hormone function in the nucleus are important:

1. They activate the genetic mechanisms for synthesizing many types of intracellular proteins—probably 100 or more. Many of these intracellular proteins are enzymes that promote enhanced intracellular metabolic activity in virtually all cells of the body.
2. Once bound to the intranuclear receptors, the thyroid hormones can continue to express their control functions for days or even weeks.

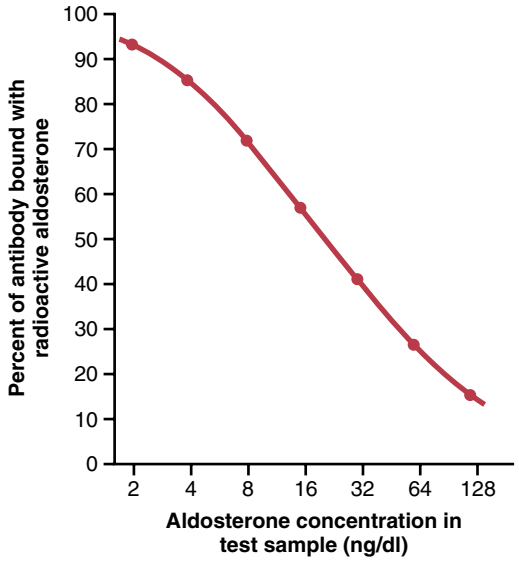

Figure 75-9. Standard curve for radioimmunoassay of aldosterone. *(Courtesy Dr. Manis Smith.)*

Measurement of Hormone Concentrations in the Blood

Most hormones are present in the blood in extremely minute quantities; some concentrations are as low as one billionth of a milligram (1 picogram) per milliliter. Therefore, it was difficult to measure these concentrations by the usual chemical means. However, an extremely sensitive method, called *radioimmunoassay,* was developed by Rosalyn Yalow and Solomon Berson in 1959 and revolutionized the measurement of hormones, their precursors, and their metabolic end products. More recently, additional methods, such as *enzyme-linked immunosorbent assays*, have been developed for accurate, high-throughput measurements of hormones.

Radioimmunoassay

The method of performing radioimmunoassay is as follows. First, an antibody that is highly specific for the hormone to be measured is produced.

Second, a small quantity of this antibody is (1) mixed with a quantity of fluid from the animal containing the hormone to be measured and (2) mixed simultaneously with an appropriate amount of purified standard hormone that has been tagged with a radioactive isotope. However, one specific condition must be met. There must be too little antibody to bind completely both the radioactively tagged hormone and the hormone in the fluid to be assayed. Therefore, the natural hormone in the assay fluid and the radioactive standard hormone *compete for binding sites* of the antibody. In the process of competing, the quantity of each of the two hormones, the natural and the radioactive, that binds is proportional to its concentration in the assay fluid.

Third, after binding has reached equilibrium, the antibody-hormone complex is separated from the remainder of the solution, and the quantity of radioactive hormone bound in this complex is measured by radioactive counting techniques. If a large amount of radioactive hormone has bound with the antibody, it is clear that there was only a small amount of natural hormone to compete with the radioactive hormone, and therefore the concentration of the natural hormone in the assayed fluid was small. Conversely, if only a small amount of radioactive hormone has bound, it is clear that there was a large amount of natural hormone to compete for the binding sites.

Fourth, to make the assay highly quantitative, the radioimmunoassay procedure is also performed for "standard" solutions of untagged hormone at several concentration levels. Then a "standard curve" is plotted, as shown in **Figure 75-9**. By comparing the radioactive counts recorded from the "unknown" assay procedures with the standard curve, one can determine within an error of 10% to 15%, the concentration of the hormone in the "unknown" assayed fluid. As little as billionths or even trillionths of a gram of hormone can often be assayed in this way.

Enzyme-Linked Immunosorbent Assay

Enzyme-linked immunosorbent assays (ELISAs) can be used to measure almost any protein, including hormones. This test combines the specificity of antibodies with the sensitivity of simple enzyme assays. **Figure 75-10** shows the basic elements of this method, which is often performed on plastic plates that each have 96 small wells. Each well is coated with an antibody (AB_1) that is specific for the hormone being assayed. Samples or standards are added to each of the wells, followed by a second antibody (AB_2) that is also specific for the hormone but binds to a different site of the hormone molecule. A third antibody (AB_3) that is added recognizes AB_2 and is coupled to an enzyme that converts a suitable substrate to a product that can be easily detected by colorimetric or fluorescent optical methods.

Because each molecule of enzyme catalyzes the formation of many thousands of product molecules, even small amounts of hormone molecules can be detected. In contrast to competitive radioimmunoassay methods, ELISA methods use excess antibodies so that all hormone molecules are captured in antibody-hormone complexes. Therefore, the amount of hormone present in the sample or in the standard is proportional to the amount of product formed.

The ELISA method has become widely used in clinical and research laboratories because (1) it does not use radioactive isotopes, (2) much of the assay can be automated using 96-well plates, and (3) it has proved to be a cost-effective and accurate method for assessing hormone levels.

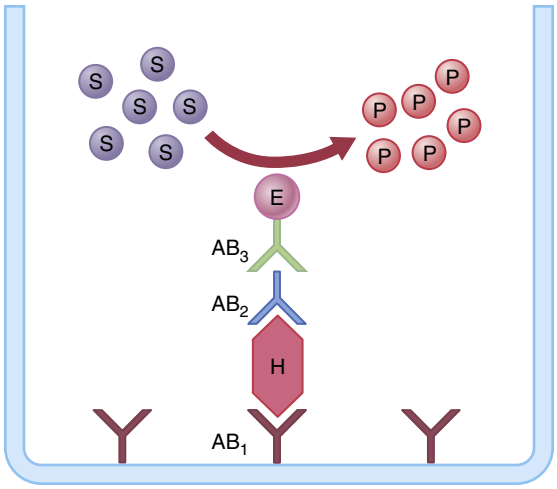

Figure 75-10. Basic principles of the enzyme-linked immunosorbent assay for measuring the concentration of a hormone *(H)*. AB_1 and AB_2 are antibodies that recognize the hormone at different binding sites, and AB_3 is an antibody that recognizes AB_2. *E* is an enzyme linked to AB_3 that catalyzes the formation of a colored fluorescent product *(P)* from a substrate *(S)*. The amount of the product is measured using optical methods and is proportional to the amount of hormone in the well if there are excess antibodies in the well.

CHAPTER 76

UNIT XIV

Pituitary Hormones and Their Control by the Hypothalamus

PITUITARY GLAND AND ITS RELATION TO THE HYPOTHALAMUS

ANTERIOR AND POSTERIOR LOBES OF THE PITUITARY GLAND

The *pituitary gland* (**Figure 76-1**), also called the *hypophysis,* is a small gland—about 1 centimeter in diameter and 0.5 to 1 gram in weight—that lies in the *sella turcica,* a bony cavity at the base of the brain—and is connected to the hypothalamus by the *pituitary* (or *hypophysial*) *stalk*. Physiologically, the pituitary gland is divisible into two distinct portions: the *anterior pituitary,* also known as the *adenohypophysis,* and the *posterior pituitary,* also known as the *neurohypophysis.* Between these portions is a small, relatively avascular zone called the *pars intermedia,* which is much less developed in humans but is larger and much more functional in some animals.

Embryologically, the two portions of the pituitary originate from different sources—the anterior pituitary from *Rathke's pouch,* which is an embryonic invagination of the pharyngeal epithelium, and the posterior pituitary from a neural tissue outgrowth from the hypothalamus. The origin of the anterior pituitary from the pharyngeal epithelium explains the epithelioid nature of its cells, and the origin of the posterior pituitary from neural tissue explains the presence of large numbers of glial-type cells in this gland.

Six major peptide hormones plus several other hormones of lesser known importance are secreted by the *anterior* pituitary, and two important peptide hormones are secreted by the *posterior* pituitary.

The hormones of the anterior pituitary play major roles in the control of metabolic functions throughout the body, as shown in **Figure 76-2**.

- *Growth hormone* promotes growth of the entire body by affecting protein formation, cell multiplication, and cell differentiation.
- *Adrenocorticotropic hormone (corticotropin)* controls the secretion of some of the adrenocortical hormones, which affect metabolism of glucose, proteins, and fats.
- *Thyroid-stimulating hormone (thyrotropin)* controls the secretion rate of thyroxine and triiodothyronine by the thyroid gland, and these hormones control the rates of most intracellular chemical reactions in the body.
- *Prolactin* promotes mammary gland development and milk production.
- Two separate gonadotropic hormones, *follicle-stimulating hormone* and *luteinizing hormone,* control growth of the ovaries and testes, as well as their hormonal and reproductive activities.

The two hormones secreted by the posterior pituitary play other roles.

- *Antidiuretic hormone* (also called *vasopressin*) controls the rate of water excretion into the urine, thus helping to control water concentration in the body fluids.
- *Oxytocin* helps express milk from the glands of the breast to the nipples during suckling and helps in delivery of the baby at the end of gestation.

The Anterior Pituitary Gland Contains Several Different Cell Types That Synthesize and Secrete Hormones. Usually, there is one cell type for each major hormone formed in the anterior pituitary gland. With

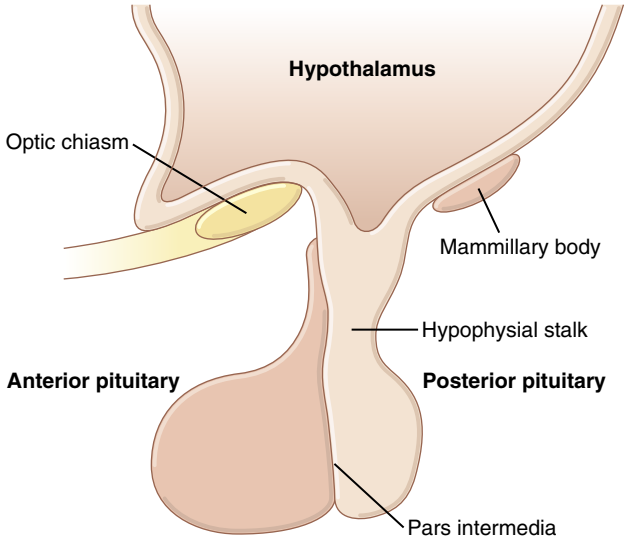

Figure 76-1. Pituitary gland.

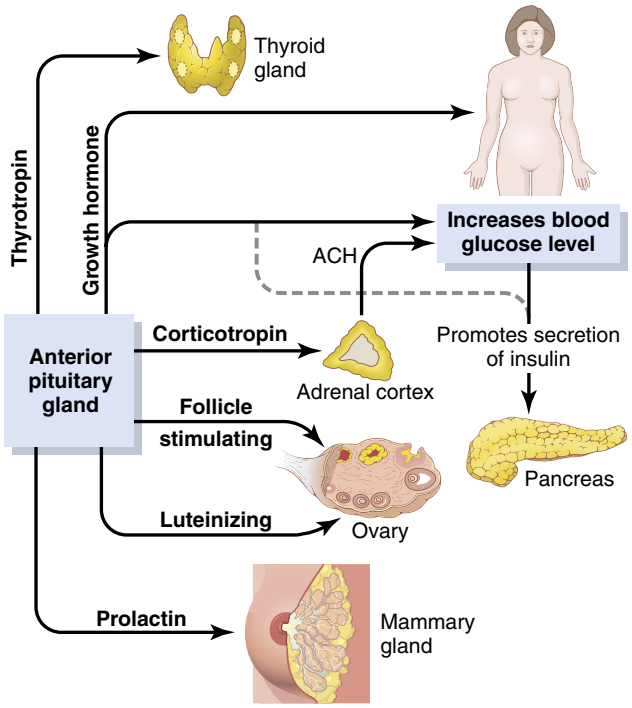

Figure 76-2. Metabolic functions of the anterior pituitary hormones. ACH, Adrenal corticosteroid hormones.

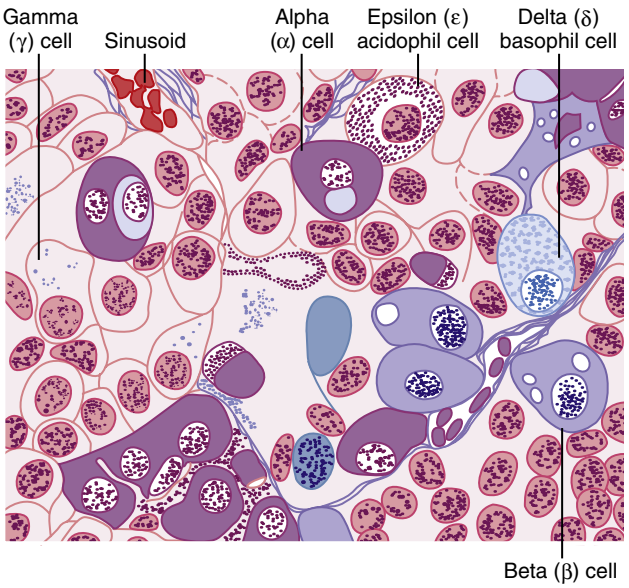

Figure 76-3. Cellular structure of the anterior pituitary gland. *(Modified from Guyton AC: Physiology of the Human Body, 6th ed. Philadelphia: Saunders College Publishing, 1984.)*

special stains attached to high-affinity antibodies that bind with the distinctive hormones, at least five cell types can be differentiated (Figure 76-3). Table 76-1 provides a summary of these cell types, the hormones they produce, and their physiological actions. These five cell types are as follows:

1. *Somatotropes*—human growth hormone (hGH)
2. *Corticotropes*—adrenocorticotropic hormone (ACTH)
3. *Thyrotropes*—thyroid-stimulating hormone (TSH)
4. *Gonadotropes*—gonadotropic hormones, which include both luteinizing hormone (LH) and follicle-stimulating hormone (FSH)
5. *Lactotropes*—prolactin (PRL)

About 30% to 40% of the anterior pituitary cells are somatotropes that secrete growth hormone (GH), and about 20% are corticotropes that secrete ACTH. Each of the other cell types accounts for only 3% to 5% of the total; nevertheless, they secrete powerful hormones for controlling thyroid function, sexual functions, and milk secretion by the breasts.

Somatotropes stain strongly with acid dyes and are therefore called *acidophils.* Thus, pituitary tumors that secrete large quantities of hGH are called *acidophilic tumors.*

Posterior Pituitary Hormones Are Synthesized by Cell Bodies in the Hypothalamus. The bodies of the cells that secrete the *posterior* pituitary hormones are not located in the pituitary gland but are large neurons, called *magnocellular neurons,* located in the *supraoptic* and *paraventricular nuclei* of the hypothalamus. The hormones are then transported in the axoplasm of the neuron's nerve fibers passing from the hypothalamus to the posterior pituitary gland. This mechanism is discussed later in the chapter.

HYPOTHALAMUS CONTROLS PITUITARY SECRETION

Almost all pituitary secretion is controlled by hormonal or nervous signals from the hypothalamus. Indeed, when the pituitary gland is removed from its normal position beneath the hypothalamus and transplanted to some other part of the body, its secretion rates of the different hormones (except for prolactin) fall to very low levels.

Secretion from the posterior pituitary is controlled by nerve signals that originate in the hypothalamus and terminate in the posterior pituitary. In contrast, secretion by the anterior pituitary is controlled by hormones called *hypothalamic releasing* and *hypothalamic inhibitory hormones* (or *factors*) secreted within the hypothalamus and then conducted, as shown in Figure 76-4, to the anterior pituitary through minute blood vessels called *hypothalamic-hypophysial portal vessels.* In the anterior pituitary, these releasing and inhibitory hormones act on the glandular cells to control their secretion. This system of control is discussed in the next section of this chapter.

The hypothalamus receives signals from many sources in the nervous system. Thus, when a person is exposed to pain, a portion of the pain signal is transmitted into the hypothalamus. Likewise, when a person experiences some powerful depressing or exciting thought, a portion of the signal is transmitted into the hypothalamus. Olfactory stimuli denoting pleasant or unpleasant smells transmit strong signals directly and through the amygdaloid nuclei

Table 76-1 Cells and Hormones of the Anterior Pituitary Gland and Their Physiological Functions

Cell	Hormone	Chemistry	Physiological Action
Somatotropes	Growth hormone (GH) (somatotropin)	Single chain of 191 amino acids	Stimulates body growth; stimulates secretion of insulin-like growth factor-1; stimulates lipolysis; inhibits actions of insulin on carbohydrate and lipid metabolism
Corticotropes	Adrenocorticotropic hormone (ACTH) (corticotropin)	Single chain of 39 amino acids	Stimulates production of glucocorticoids and androgens by the adrenal cortex; maintains size of zona fasciculata and zona reticularis of cortex
Thyrotropes	Thyroid-stimulating hormone (TSH) (thyrotropin)	Glycoprotein of two subunits, α (89 amino acids) and β (112 amino acids)	Stimulates production of thyroid hormones by thyroid follicular cells; maintains size of follicular cells
Gonadotropes	Follicle-stimulating hormone (FSH)	Glycoprotein of two subunits, α (89 amino acids) and β (112 amino acids)	Stimulates development of ovarian follicles; regulates spermatogenesis in the testis
	Luteinizing (LH) hormone	Glycoprotein of two subunits, α (89 amino acids) and β (115 amino acids)	Causes ovulation and formation of the corpus luteum in the ovary; stimulates production of estrogen and progesterone by the ovary; stimulates testosterone production by the testis
Lactotropes-mammotropes	Prolactin (PRL)	Single chain of 198 amino acids	Stimulates milk secretion and production

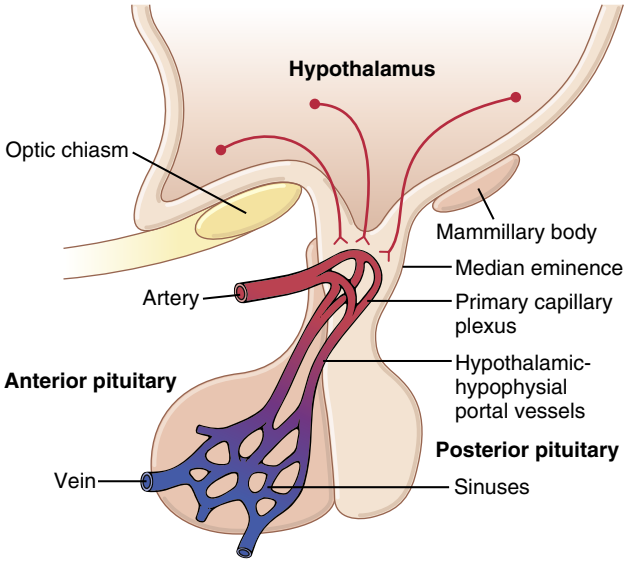

Figure 76-4. Hypothalamic-hypophysial portal system.

into the hypothalamus. Even the concentrations of nutrients, electrolytes, water, and various hormones in the blood excite or inhibit various portions of the hypothalamus. Thus, the hypothalamus is a center for integrating information concerning the internal well-being of the body, and much of this information is used to control secretions of the many globally important pituitary hormones.

HYPOTHALAMIC-HYPOPHYSIAL PORTAL BLOOD VESSELS OF THE ANTERIOR PITUITARY GLAND

The anterior pituitary is a highly vascular gland with extensive capillary sinuses among the glandular cells. Almost all the blood that enters these sinuses passes first through another capillary bed in the lower hypothalamus. The blood then flows through small *hypothalamic-hypophysial portal blood vessels* into the anterior pituitary sinuses. **Figure 76-4** shows the lowermost portion of the hypothalamus, called the *median eminence,* which connects inferiorly with the pituitary stalk. The median eminence is the functional link between the hypothalamus and the anterior pituitary gland. Small arteries penetrate into the median eminence and then additional small vessels return to its surface, coalescing to form the hypothalamic-hypophysial portal blood vessels. These vessels pass downward along the pituitary stalk to supply blood to the anterior pituitary sinuses.

Hypothalamic Releasing and Inhibitory Hormones Are Secreted Into the Median Eminence. Special neurons in the hypothalamus synthesize and secrete the *hypothalamic releasing* and *inhibitory hormones* that control secretion of the anterior pituitary hormones. These neurons originate in various parts of the hypothalamus and send their nerve fibers to the median eminence and *tuber cinereum,* an extension of hypothalamic tissue into the pituitary stalk.

The endings of these fibers are different from most endings in the central nervous system in that their function is not to transmit signals from one neuron to another but rather to secrete the hypothalamic releasing and inhibitory hormones into the tissue fluids. These hormones are immediately absorbed into the hypothalamic-hypophysial portal system and carried directly to the sinuses of the anterior pituitary gland.

Table 76-2 Hypothalamic Releasing and Inhibitory Hormones That Control Secretion of the Anterior Pituitary Gland

Hormone	Structure	Primary Action on Anterior Pituitary
Thyrotropin-releasing hormone (TRH)	Peptide of 3 amino acids	Stimulates secretion of TSH by thyrotropes
Gonadotropin-releasing hormone (GnRH)	Single chain of 10 amino acids	Stimulates secretion of FSH and LH by gonadotropes
Corticotropin-releasing hormone (CRH)	Single chain of 41 amino acids	Stimulates secretion of ACTH by corticotropes
Growth hormone–releasing hormone (GHRH)	Single chain of 44 amino acids	Stimulates secretion of growth hormone by somatotropes
Growth hormone inhibitory hormone (somatostatin)	Single chain of 14 amino acids	Inhibits secretion of growth hormone by somatotropes
Prolactin-inhibiting hormone (PIH)	Dopamine (a catecholamine)	Inhibits synthesis and secretion of prolactin by lactotropes

ACTH, Adrenocorticotropic hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone.

Hypothalamic Releasing and Inhibitory Hormones Control Anterior Pituitary Secretion. The function of the releasing and inhibitory hormones is to control secretion of the anterior pituitary hormones. For most of the anterior pituitary hormones, it is the releasing hormones that are important, but for prolactin, a hypothalamic inhibitory hormone probably exerts more control. The major hypothalamic releasing and inhibitory hormones, which are summarized in **Table 76-2,** are the following:

1. *Thyrotropin-releasing hormone* (TRH), which causes release of TSH
2. *Corticotropin-releasing hormone* (CRH), which causes release of ACTH
3. *Growth hormone–releasing hormone* (GHRH), which causes release of GH, and *growth hormone inhibitory hormone* (GHIH), also called *somatostatin,* which inhibits release of GH
4. *Gonadotropin-releasing hormone* (GnRH), which causes release of the two gonadotropic hormones, LH and FSH
5. *Prolactin inhibitory hormone* (PIH), also known as *dopamine,* which causes inhibition of prolactin secretion

Additional hypothalamic hormones include one that stimulates prolactin secretion and perhaps others that inhibit release of the anterior pituitary hormones. Each of the more important hypothalamic hormones is discussed in detail as the specific hormonal systems controlled by them are presented in this and subsequent chapters.

Specific Areas in the Hypothalamus Control Secretion of Specific Hypothalamic Releasing and Inhibitory Hormones. All or most of the hypothalamic hormones are secreted at nerve endings in the median eminence before being transported to the anterior pituitary gland. Electrical stimulation of this region excites these nerve endings and, therefore, causes release of essentially all the hypothalamic hormones. However, the neuronal cell bodies that give rise to these median eminence nerve endings are located in other discrete areas of the hypothalamus or in closely related areas of the basal brain.

PHYSIOLOGICAL FUNCTIONS OF GROWTH HORMONE

All the major anterior pituitary hormones, except for GH, exert their principal effects mainly by stimulating target glands, including thyroid gland, adrenal cortex, ovaries, testicles, and mammary glands. The functions of each of these pituitary hormones are so intimately concerned with the functions of the respective target glands that, except for GH, their functions are discussed in subsequent chapters along with the target glands. GH, however, exerts its effects directly on all or almost all tissues of the body.

GROWTH HORMONE PROMOTES GROWTH OF MANY BODY TISSUES

GH, also called *somatotropic hormone* or *somatotropin,* is a small protein molecule that contains 191 amino acids in a single chain and has a molecular weight of 22,005. It causes growth of almost all tissues of the body that are capable of growing. It promotes increased sizes of the cells and increased mitosis, with development of greater numbers of cells and specific differentiation of certain types of cells such as bone growth cells and early muscle cells.

Figure 76-5 shows typical weight charts of two growing littermate rats; one received daily injections of GH, and the other did not receive GH. This figure shows marked enhancement of growth in the rat given GH, in the early days of life and even after the two rats reached adulthood. In the early stages of development, all organs of the treated rat increased proportionately in size; after adulthood was reached, most of the bones stopped lengthening, but many of the soft tissues continued to grow. Once the epiphyses of the long bones have united with the shafts, further lengthening of bone cannot occur, even though many other tissues of the body can continue to grow throughout life.

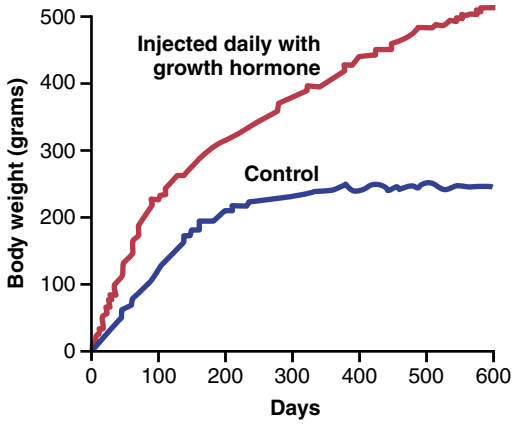

Figure 76-5. Comparison of weight gain of a rat injected daily with growth hormone with that of a normal littermate.

GROWTH HORMONE HAS SEVERAL METABOLIC EFFECTS

Aside from its general effect in causing growth, GH has multiple specific metabolic effects (**Figure 76-6**), including the following: (1) increased rate of protein synthesis in most cells of the body; (2) increased mobilization of fatty acids from adipose tissue, increased free fatty acids in the blood, and increased use of fatty acids for energy; and (3) decreased rate of glucose utilization throughout the body. Thus, in effect, GH enhances body protein, decreases fat stores, and conserves carbohydrates.

Growth Hormone Promotes Protein Deposition in Tissues

Although the precise mechanisms by which growth hormone increases protein deposition are not fully understood, a series of different effects are known, all of which could lead to enhanced protein deposition.

Enhancement of Amino Acid Transport Through the Cell Membranes. GH directly enhances transport of most amino acids through cell membranes to the interior of the cells. This increases amino acid concentrations in the cells and is presumed to be at least partly responsible for the increased protein synthesis. This control of amino acid transport is similar to the effect of insulin in controlling glucose transport through the membrane, as discussed in Chapters 68 and 79.

Enhancement of RNA Translation to Cause Protein Synthesis by the Ribosomes. Even when the amino acid concentrations are not increased in the cells, GH still increases RNA translation, causing protein to be synthesized in greater amounts by the ribosomes in the cytoplasm.

Increased Nuclear Transcription of DNA to Form RNA. Over more prolonged periods (24–48 hours), GH also stimulates transcription of DNA in the nucleus, causing formation of increased quantities of RNA. This promotes more

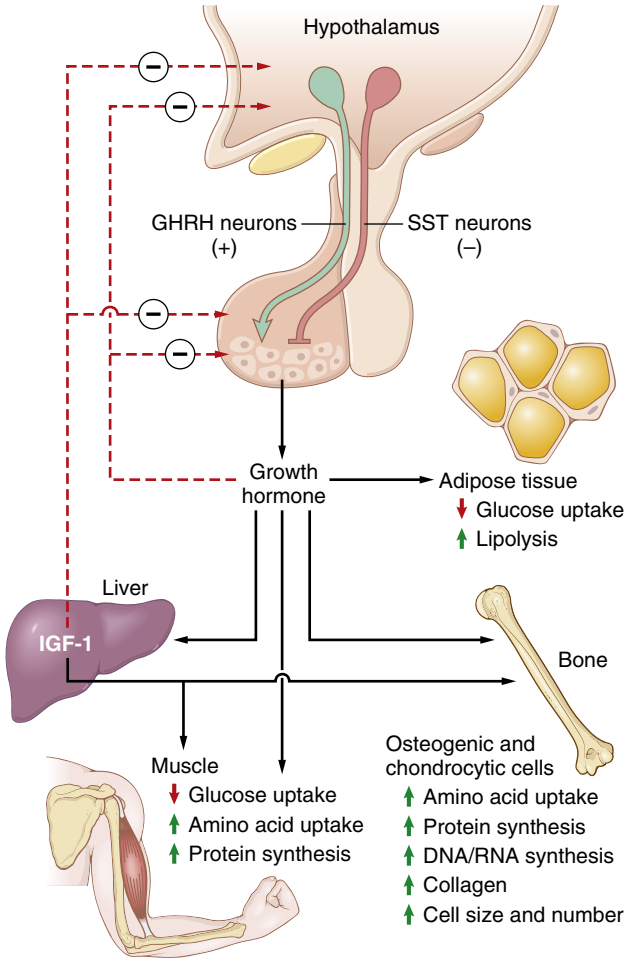

Figure 76-6. Effects of growth hormone and insulin-like growth factor -1 (IGF-1) on growth and metabolism. Growth hormone secretion is stimulated by growth hormone–releasing hormone (GHRH) and inhibited by somatostatin (SST), as well as negative feedback effects of growth hormone and IGF-1 on the anterior pituitary gland and the hypothalamic neurons. Other factors that control growth hormone secretion are described in Table 76-3.

Table 76-3 Factors That Stimulate or Inhibit Secretion of Growth Hormone

Stimulate Growth Hormone Secretion	Inhibit Growth Hormone Secretion
Decreased blood glucose level	Increased blood glucose level
Decreased blood free fatty acid levels	Increased blood free fatty acid levels
Increased blood amino acid levels (arginine)	Aging
Starvation or fasting, protein deficiency	Obesity
Trauma, stress, excitement	Growth hormone inhibitory hormone (somatostatin)
Exercise	Growth hormone (exogenous)
Testosterone, estrogen	Insulin-like growth factors (somatomedins)
Deep sleep (stages 2 and 4)	
Growth hormone–releasing hormone	
Ghrelin	

protein synthesis and growth if sufficient energy, amino acids, vitamins, and other requisites for growth are available. In the long run, this may be the most important function of GH.

Decreased Catabolism of Protein and Amino Acids. In addition to the increase in protein synthesis, GH decreases breakdown of cell protein. A probable reason for this decrease is that GH also mobilizes large quantities of free fatty acids from the adipose tissue, and these are used to supply most of the energy for the body's cells, thus acting as a potent "protein sparer."

Summary. GH enhances almost all facets of amino acid uptake and protein synthesis by cells, while at the same time reducing the breakdown of proteins.

Growth Hormone Enhances Fat Utilization for Energy

GH has a specific effect to cause release of fatty acids from adipose tissue and, therefore, increases the concentration of fatty acids in body fluids. Also, in tissues throughout the body, GH enhances conversion of fatty acids to acetyl coenzyme A (acetyl-CoA) and its subsequent utilization for energy. Therefore, under the influence of GH, fat is used for energy in preference to use of carbohydrates and proteins.

The ability of GH to promote fat utilization, together with its protein anabolic effect, causes an increase in lean body mass. However, mobilization of fat by GH requires several hours to occur, whereas enhancement of protein synthesis can begin in minutes under the influence of GH.

"Ketogenic" Effect of Excessive Growth Hormone. Under the influence of excessive amounts of GH, fat mobilization from adipose tissue sometimes becomes so great that large quantities of acetoacetic acid are formed by the liver and released into the body fluids, thus causing *ketosis.* This excessive mobilization of fat from the adipose tissue also frequently causes a fatty liver.

Growth Hormone Decreases Carbohydrate Utilization

GH has multiple effects that influence carbohydrate metabolism, including (1) decreased glucose uptake in tissues such as skeletal muscle and fat, (2) increased glucose production by the liver, and (3) increased insulin secretion.

Each of these changes results from GH-induced "insulin resistance," which attenuates insulin's actions to stimulate uptake and utilization of glucose in skeletal muscle and adipose tissue and to inhibit gluconeogenesis (glucose production) by the liver; this leads to increased blood glucose concentration and a compensatory increase in insulin secretion. For these reasons, GH's effects are called *diabetogenic,* and excess secretion of GH can produce metabolic disturbances similar to those found in patients with type 2 (non–insulin-dependent) diabetes, who are also resistant to the metabolic effects of insulin. However, patients with *acromegaly* who have excess GH secretion are usually lean with little visceral fat whereas patients with type 2 diabetes are frequently overweight with excessive visceral fat which drives insulin resistance.

We do not know the precise mechanism by which GH causes insulin resistance and decreased glucose utilization by the cells. However, GH-induced increases in lipolysis and blood concentrations of fatty acids likely contribute to impairment of insulin's actions on tissue glucose utilization. Experimental studies indicate that raising blood levels of fatty acids above normal rapidly decreases the sensitivity of the liver and skeletal muscle to insulin's effects on carbohydrate metabolism.

Necessity of Insulin and Carbohydrate for the Growth-Promoting Action of Growth Hormone

GH fails to cause growth in animals that lack a pancreas; it also fails to cause growth if carbohydrates are excluded from the diet. Thus, adequate insulin activity and adequate availability of carbohydrates are necessary for GH to be effective. Part of this requirement for carbohydrates and insulin is to provide the energy needed for the metabolism of growth, but there seem to be other effects as well. Especially important is the ability of insulin to enhance transport of some amino acids into cells, in the same way that it stimulates glucose transport.

GROWTH HORMONE STIMULATES CARTILAGE AND BONE GROWTH

Although GH stimulates increased deposition of protein and increased growth in almost all tissues of the body, its most obvious effect is to increase growth of the skeletal frame. This results from multiple effects of growth hormone on bone, including (1) increased deposition of protein by the chondrocytic and osteogenic cells that cause bone growth, (2) increased rate of reproduction of these cells, and (3) a specific effect of converting chondrocytes into osteogenic cells, thus causing deposition of new bone.

There are two principal mechanisms of bone growth. First, in response to GH stimulation, the long bones grow in length at the epiphyseal cartilages, where the epiphyses at the ends of the bone are separated from the shaft. This growth first causes deposition of new cartilage, followed by its conversion into new bone, thus elongating the shaft and pushing the epiphyses farther and farther apart. At the same time, the epiphyseal cartilage is progressively used up so, by late adolescence, no additional epiphyseal cartilage remains to provide for further long bone growth. At this time, bony fusion occurs between the shaft and the epiphysis at each end, so no further lengthening of the long bone can occur.

Second, *osteoblasts* in the bone periosteum and in some bone cavities deposit new bone on the surfaces of older bone. Simultaneously, *osteoclasts* in the bone (discussed in detail in Chapter 80) remove old bone. When the rate of

deposition is greater than that of resorption, the thickness of the bone increases. *Growth hormone strongly stimulates osteoblasts.* Therefore, the bones can continue to become thicker throughout life under the influence of GH; this is especially true for the membranous bones. For example, the jaw bones can be stimulated to grow even after adolescence, causing forward protrusion of the chin and lower teeth. Likewise, the bones of the skull can grow in thickness and give rise to bony protrusions over the eyes.

GROWTH HORMONE EXERTS MUCH OF ITS EFFECT THROUGH INSULIN-LIKE GROWTH FACTORS (SOMATOMEDINS)

GH causes the liver (and, to a much less extent, other tissues) to form several small proteins called *insulin-like growth factors* (IGFs, also called *somatomedins*) that mediate some of the growth and metabolic effects of GH (**Figure 76-6**).

At least four IGFs have been isolated, but by far the most important of these is IGF-1 (*somatomedin C*). The molecular weight of IGF-1 is about 7500, and its concentration in the plasma closely follows the rate of GH secretion.

Children with deficiency of IGF fail to grow normally even though they may have normal or elevated secretion of GH. The pygmy peoples of Africa, for example, have very small stature due to a congenital inability to synthesize significant amounts of IGF-1. Although their plasma concentration of GH is either normal or high, they have diminished amounts of IGF-1 in the plasma, which apparently accounts for the small stature of these people. Some other dwarfs (e.g., Laron syndrome) have a similar problem, generally caused by a mutation of the GH receptor and therefore failure of GH to stimulate formation of IGF-1.

It has been postulated that most of the growth effects of GH result from IGF-1 and other IGFs, rather than from direct effects of GH on the bones and other peripheral tissues. Even so, experiments have demonstrated that injection of GH directly into the epiphyseal cartilages of bones of living animals causes growth of these cartilage areas, and the amount of GH required for this growth to occur is minute. One possible explanation for this finding is that GH can cause formation of enough IGF-1 in the local tissue to cause local growth. However, GH also has IGF-independent effects that stimulate growth in some tissues such as chondrocytes of cartilage.

Short Duration of Action of Growth Hormone but Prolonged Action of IGF-1. GH attaches only weakly to the plasma proteins in blood. Therefore, it is released from the blood into the tissues rapidly, having a half-time in blood of less than 20 minutes. By contrast, IGF-1 attaches strongly to a carrier protein in the blood that, like IGF-1, is produced in response to GH. As a result, IGF-1 is released only slowly from the blood to the tissues, with a half-time of about 20 hours. This slow release greatly prolongs the growth-promoting effects of the bursts of GH secretion shown in **Figure 76-7**.

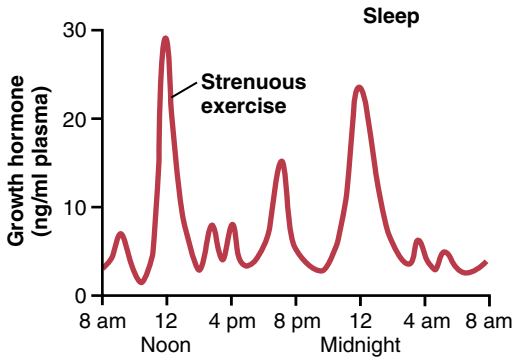

Figure 76-7. Typical variations in growth hormone secretion throughout the day, demonstrating the especially powerful effect of strenuous exercise and also the high rate of growth hormone secretion that occurs during the first few hours of deep sleep.

REGULATION OF GROWTH HORMONE SECRETION

After adolescence, GH secretion decreases slowly with aging, finally falling to about 25% of the adolescent level in very old age.

GH is secreted in a pulsatile pattern, increasing and decreasing. The precise mechanisms that control secretion of GH are not fully understood, but several factors related to a person's state of nutrition or stress are known to stimulate secretion: (1) *starvation,* especially with severe *protein deficiency;* (2) *hypoglycemia* or *low concentration of fatty acids in the blood;* (3) *exercise;* (4) *excitement;* (5) *trauma;* (6) *ghrelin,* a hormone secreted by the stomach before meals; and (7) some *amino acids*, including arginine. GH also characteristically increases during the first 2 hours of *deep sleep,* as shown in **Figure 76-7**. **Table 76-3** summarizes some of the factors that are known to influence growth hormone secretion.

The normal concentration of GH in the plasma of an adult is between 1.6 and 3 ng/ml; in a child or adolescent, it is about 6 ng/ml. These values may increase to as high as 50 ng/ml after depletion of the body stores of proteins or carbohydrates during prolonged starvation.

Under acute conditions, hypoglycemia is a far more potent stimulator of GH secretion than is an acute decrease in protein intake. Conversely, in chronic conditions, GH secretion seems to correlate more with the degree of cellular protein depletion than with the degree of glucose insufficiency. For example, the extremely high levels of GH that occur during starvation are closely related to the amount of protein depletion.

Figure 76-8 demonstrates the effect of protein deficiency on plasma GH and then the effect of adding protein to the diet. The first column shows very high levels of GH in children with extreme protein deficiency during the protein malnutrition condition called *kwashiorkor;* the second column shows the levels in the same children after 3 days of treatment with more than adequate quantities of carbohydrates in their diets, demonstrating that the carbohydrates did not lower the plasma GH concentration.

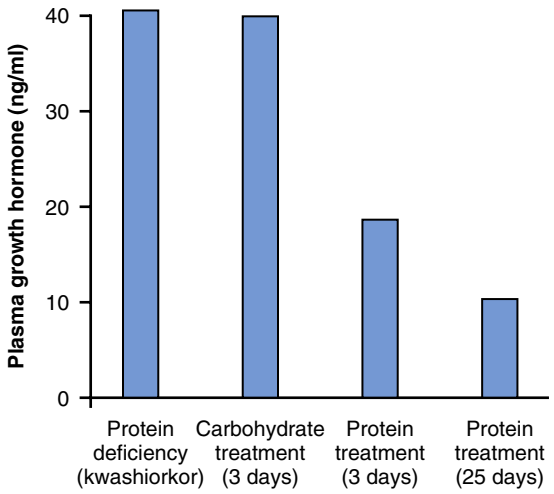

Figure 76-8. Effect of extreme protein deficiency on the plasma concentration of growth hormone in the disease kwashiorkor. Also shown is the failure of carbohydrate treatment but the effectiveness of protein treatment in lowering growth hormone concentration. *(Data from Pimstone BL, Barbezat G, Hansen JD, et al: Studies on growth hormone secretion in protein-calorie malnutrition. Am J Clin Nutr 21:482, 1968.)*

The third and fourth columns show the levels after treatment with protein supplements for 3 and 25 days, respectively, with a concomitant decrease in the hormone.

These results demonstrate that under severe conditions of protein malnutrition, adequate calories alone are not sufficient to correct the excess production of GH. The protein deficiency must also be corrected before the GH concentration will return to normal.

Hypothalamic Growth Hormone–Releasing Hormone Stimulates, and Somatostatin Inhibits Growth Hormone Secretion

From the preceding description of the many factors that can affect GH secretion, one can readily understand the perplexity of physiologists as they attempted to unravel the mysteries of regulation of GH secretion. It is known that GH secretion is controlled by two factors secreted in the hypothalamus and then transported to the anterior pituitary gland through the hypothalamic-hypophysial portal vessels. They are *growth hormone–releasing hormone* (GHRH) and *growth hormone inhibitory hormone* (also called *somatostatin*). Both of these are polypeptides; GHRH is composed of 44 amino acids, and somatostatin is composed of 14 amino acids.

Neurons in the arcuate and ventromedial nuclei of the hypothalamus secrete GHRH; this is the same area of the hypothalamus that is sensitive to blood glucose concentration, causing satiety in hyperglycemic states and hunger in hypoglycemic states. Secretion of somatostatin is controlled by the nearby periventricular neurons of the hypothalamus. Therefore, it is reasonable to expect that some of the same signals that modify a person's behavioral feeding instincts also alter the rate of GH secretion.

In a similar manner, hypothalamic signals depicting emotions, stress, and trauma can all affect hypothalamic control of GH secretion. In fact, experiments have shown that catecholamines, dopamine, and serotonin, each of which is released by a different neuronal system in the hypothalamus, all increase the rate of GH secretion.

Most of the control of GH secretion is probably mediated through GHRH rather than through the inhibitory hormone somatostatin. GHRH stimulates GH secretion by attaching to specific cell membrane receptors on the outer surfaces of the GH cells in the pituitary gland. The receptors activate the adenylyl cyclase system inside the cell membrane, increasing the intracellular level of cyclic adenosine monophosphate (cAMP). This increase has both short-term and long-term effects. The short-term effect is to increase calcium ion transport into the cell; within minutes, this increase causes fusion of the GH secretory vesicles with the cell membrane and release of the hormone into the blood. The long-term effect is to increase transcription in the nucleus by the genes to stimulate synthesis of new GH.

When GH is administered directly into the blood of an animal over several hours, the rate of endogenous GH secretion decreases. This decrease demonstrates that GH secretion is subject to typical negative feedback control, as is true for essentially all hormones. The nature of this feedback mechanism and whether it is mediated mainly through inhibition of GHRH or enhancement of somatostatin, which inhibits growth hormone secretion, are uncertain.

In summary, our knowledge of the regulation of GH secretion is not sufficient to describe a composite picture. Yet, because of the extreme secretion of GH during starvation and its important long-term effect to promote protein synthesis and tissue growth, we can propose the following: the major long-term controller of GH secretion is the long-term state of nutrition of the tissues, especially their level of protein nutrition. That is, nutritional deficiency or excess tissue need for cellular proteins—for example, after a severe bout of exercise when the muscle's nutritional status has been taxed—in some way increases the rate of GH secretion. GH, in turn, promotes synthesis of new proteins while at the same time conserving the proteins already present in the cells.

Abnormalities of Growth Hormone Secretion

Panhypopituitarism—Decreased Secretion of All Anterior Pituitary Hormones. Decreased secretion of all anterior pituitary hormones in patients with panhypopituitarism may be congenital (present from birth), or it may occur suddenly or slowly at any time during life, most often resulting from a pituitary tumor that destroys the pituitary gland.

Panhypopituitarism in the Adult. Panhypopituitarism first occurring in adulthood generally results from one of three abnormalities. Two tumorous conditions, craniopharyngiomas or chromophobe tumors, may compress the pituitary gland until the functioning anterior pituitary cells are totally or almost totally destroyed. The third cause is thrombosis of the pituitary blood vessels. This abnormality occasionally occurs when a new mother experiences circulatory shock after the birth of her baby.

The general effects of adult panhypopituitarism are (1) hypothyroidism, (2) depressed production of glucocorticoids by the adrenal glands, and (3) suppressed secretion of the gonadotropic hormones so that sexual functions are lost. Thus, the picture is that of a lethargic person (from lack of thyroid hormones) who is gaining weight (because of lack of fat mobilization by growth, adrenocorticotropic, adrenocortical, and thyroid hormones) and has lost all sexual functions. Except for the abnormal sexual functions, the patient can usually be treated satisfactorily by administering adrenocortical and thyroid hormones.

Panhypopituitarism During Childhood and Dwarfism. Most cases of dwarfism result from generalized deficiency of anterior pituitary secretion (panhypopituitarism) during childhood. In general, all the physical parts of the body develop in appropriate proportion to one another, but the rate of development is greatly decreased. A child who has reached the age of 10 years may have the bodily development of a child aged 4 to 5 years, and the same person at age 20 years may have the bodily development of a child aged 7 to 10 years.

A person with panhypopituitary dwarfism does not pass through puberty and never secretes sufficient quantities of gonadotropic hormones to develop adult sexual functions. In one-third of such dwarfs, however, only GH is deficient; these persons do mature sexually and occasionally reproduce. In Laron dwarfs and African pygmies, the rate of GH secretion is normal or high, but responsiveness to GH is impaired due to mutations of the GH receptor or a hereditary inability to form IGF-1, a key step for the promotion of growth by GH.

Treatment With Human Growth Hormone. Growth hormones from different species of animals are sufficiently different from one another that they will cause growth only in the one species or, at most, closely related species. For this reason, GH prepared from other animals (except, to some extent, from primates) is not effective in human beings. Therefore, the GH of the human being is called *human growth hormone* (hGH) to distinguish it from the others.

In the past, because GH had to be prepared from human pituitary glands, it was difficult to obtain sufficient quantities to treat patients with GH deficiency, except on an experimental basis. However, hGH can now be synthesized by *Escherichia coli* bacteria as a result of successful application of recombinant DNA technology. Therefore, this hormone is now available in sufficient quantities for treatment purposes. Dwarfs who have pure GH deficiency can be completely cured if treated early in life.

Gigantism and Excess Growth Hormone Before Adolescence. Occasionally, the acidophilic, GH-producing cells of the anterior pituitary gland become excessively active, and sometimes even acidophilic tumors occur in the gland. As a result, large quantities of GH are produced. All body tissues grow rapidly, including the bones. If the condition occurs before adolescence, before the epiphyses of the long bones have become fused with the shafts, height increases so that the person becomes a giant—up to 8 feet tall.

The giant ordinarily has *hyperglycemia,* and the beta cells of the islets of Langerhans in the pancreas are prone to degenerate because they become overactive owing to the hyperglycemia. Consequently, in about 10% of giants, full-blown *diabetes mellitus* eventually develops.

In most giants, panhypopituitarism eventually develops if they remain untreated because the gigantism is usually caused by a tumor of the pituitary gland that grows until the gland is destroyed. This eventual general deficiency of pituitary hormones usually causes death in early adulthood. However, once gigantism is diagnosed, further effects can often be blocked by microsurgical removal of the tumor or by irradiation of the pituitary gland.

Acromegaly and Excess Growth Hormone After Adolescence. If an acidophilic tumor occurs after adolescence—that is, after the epiphyses of the long bones have fused with the shafts—the person cannot grow taller, but the bones can become thicker and the soft tissues can continue to grow. This condition, shown in **Figure 76-9**, is known as *acromegaly.* Enlargement is especially marked in the bones of the hands and feet and in the *membranous bones,* including the cranium, nose, bosses on the forehead, supraorbital ridges, lower jawbone, and portions of the vertebrae, because their growth does not cease at adolescence. Consequently, the lower jaw protrudes forward, sometimes as much as half an inch, the forehead slants forward because of excess development of the supraorbital ridges, the nose increases to as much as twice normal size, the feet require size 14 or larger shoes, and the fingers become extremely thickened so that the hands are almost twice normal size. In addition to these effects, changes in the vertebrae ordinarily cause a hunched back, which is known clinically as *kyphosis.* Finally, many soft tissue organs, such as the tongue, the liver, and especially the kidneys, become greatly enlarged.

Possible Role of Decreased Growth Hormone Secretion in Causing Changes Associated With Aging

In people who have lost the ability to secrete GH, some features of the aging process accelerate. For example, a 50-year-old person who has been without GH for many years may have the appearance of a person aged 65 years or older. The aged appearance seems to result mainly from decreased protein deposition in most tissues of the body and increased fat deposition in its place. The physical and physiological effects are increased wrinkling of the skin, diminished rates of function of some of the organs, and diminished muscle mass and strength.

As one ages, the average plasma concentration of growth hormone in an otherwise normal person changes approximately as follows:

Age (years)	ng/ml
5 to 20	6
20 to 40	3
40 to 70	1.6

Thus, it is possible that some of the normal aging effects result from diminished growth hormone secretion. In fact, some studies of growth hormone therapy in older people have demonstrated three important beneficial effects: (1) increased protein deposition in the body, especially in the muscles; (2) decreased fat deposits; and (3) a feeling of increased energy. Other studies, however, have shown that treatment of elderly patients with recombinant GH may produce several undesirable adverse effects including insulin resistance and diabetes, edema, carpal tunnel syndrome, and arthralgias (joint pain). Therefore, recombinant GH therapy is generally not recommended for use in healthy elderly patients with normal endocrine function.

POSTERIOR PITUITARY GLAND AND ITS RELATION TO THE HYPOTHALAMUS

The *posterior pituitary gland,* also called the *neurohypophysis,* is composed mainly of glial-like cells called *pituicytes.* The pituicytes do not secrete hormones; they act simply as a supporting structure for large numbers of *terminal nerve fibers* and *terminal nerve endings* from nerve tracts that originate in the *supraoptic* and *paraventricular nuclei* of the hypothalamus, as shown in **Figure 76-10**. These tracts pass to the neurohypophysis through the *pituitary stalk* (hypophysial stalk). The nerve endings are bulbous knobs that contain many secretory granules. These endings lie on the surfaces of capillaries, where they secrete two posterior pituitary hormones: (1) *antidiuretic hormone* (ADH), also called *vasopressin,* and (2) *oxytocin.*

If the pituitary stalk is cut above the pituitary gland but the entire hypothalamus is left intact, the posterior pituitary hormones continue to be secreted normally, after a transient decrease for a few days; they are then secreted by the cut ends of the fibers within the hypothalamus and not by the nerve endings in the posterior pituitary. The reason for this is that the hormones are initially synthesized in the cell bodies of the supraoptic and paraventricular nuclei and are then transported in combination with "carrier" proteins called *neurophysins* down to the nerve endings in the posterior pituitary gland, requiring several days to reach the gland.

ADH is formed primarily in the supraoptic nuclei, whereas oxytocin is formed primarily in the paraventricular nuclei. Each of these nuclei can synthesize about one sixth as much of the second hormone as of its primary hormone.

When nerve impulses are transmitted downward along the fibers from the supraoptic or paraventricular nuclei, the hormone is immediately released from the secretory granules in the nerve endings by the usual secretory mechanism of *exocytosis* and is absorbed into adjacent capillaries. Both the neurophysin and the hormone are secreted together, but because they are only loosely bound to each other, the hormone separates almost immediately. The neurophysin has no known function after leaving the nerve terminals.

Chemical Structures of Antidiuretic Hormone and Oxytocin

Both oxytocin and ADH (vasopressin) are polypeptides, each containing nine amino acids. Their amino acid sequences are the following:

Vasopressin: Cys-Tyr-Phe-Gln-Asn-Cys-Pro-Arg-$GlyNH_2$

Oxytocin: Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Leu-$GlyNH_2$

Note that these two hormones are almost identical except that in vasopressin, phenylalanine and arginine replace isoleucine and leucine of the oxytocin molecule. The similarity of the molecules explains their partial functional similarities.

PHYSIOLOGICAL FUNCTIONS OF ANTIDIURETIC HORMONE

Injection of extremely minute quantities of ADH—as small as 2 nanograms—can cause decreased excretion of water by the kidneys (antidiuresis). This antidiuretic effect is discussed in Chapters 28 and 29. Briefly, in the absence of ADH, the collecting tubules and ducts become almost impermeable to water, which prevents significant reabsorption of water and therefore allows extreme loss

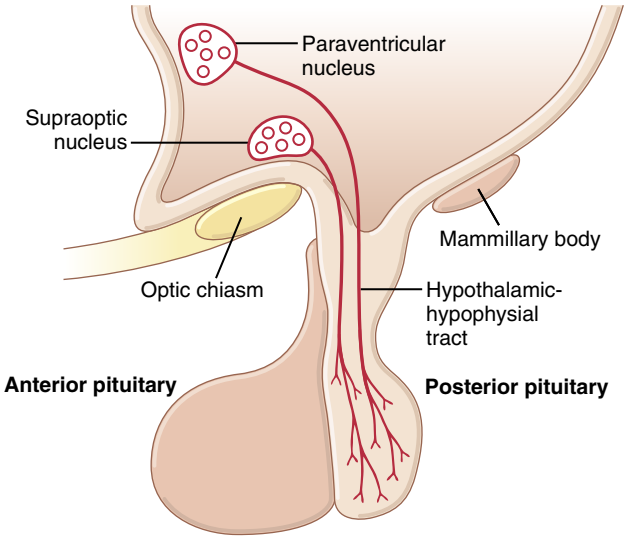

Figure 76-10. Hypothalamic control of the posterior pituitary.

of water into the urine, also causing extreme dilution of the urine, a condition called *central diabetes insipidus*. Conversely, in the presence of high levels of ADH, the permeability of the collecting ducts and tubules to water increases greatly and allows most of the water to be reabsorbed as the tubular fluid passes through these ducts, thereby conserving water in the body and producing very concentrated urine.

Without ADH, the luminal membranes of the tubular epithelial cells of the collecting ducts are almost impermeable to water. However, immediately inside the cell membrane are a large number of special vesicles that have highly water-permeable pores called *aquaporins* (see **Figure 28-19**). When ADH acts on the cell, it first combines with membrane receptors that activate adenylyl cyclase and cause the formation of cAMP inside the tubular cell cytoplasm. This formation causes phosphorylation of elements in the special vesicles, which then causes the vesicles to insert into the apical cell membranes, thus providing many areas of high water permeability. All this occurs within 5 to 10 minutes. Then, in the absence of ADH, the entire process reverses in another 5 to 10 minutes. Thus, this process temporarily provides many new pores that allow free diffusion of water from the tubular fluid through the tubular epithelial cells and into the renal interstitial fluid. Water is then absorbed from the collecting tubules and ducts by osmosis, as explained in Chapter 29 in relation to the urine-concentrating mechanism of the kidneys.

REGULATION OF ANTIDIURETIC HORMONE PRODUCTION

Increased Extracellular Fluid Osmolarity Stimulates ADH Secretion. When a concentrated electrolyte solution is injected into the artery that supplies the hypothalamus, the ADH neurons in the supraoptic and paraventricular nuclei immediately transmit impulses into the posterior pituitary to release large quantities of ADH into the circulating blood, sometimes increasing the ADH secretion to as high as 20 times normal. Conversely, injection of a dilute solution into this artery causes cessation of these impulses and therefore almost total cessation of ADH secretion. Thus, the concentration of ADH in the body fluids can change from small amounts to large amounts, or vice versa, in only a few minutes.

In or near the hypothalamus are modified neuron receptors called *osmoreceptors.* When the extracellular fluid becomes too concentrated, fluid is pulled by osmosis out of the osmoreceptor cell, decreasing its size and initiating appropriate nerve signals in the hypothalamus to cause additional ADH secretion. Conversely, when the extracellular fluid becomes too dilute, water moves by osmosis in the opposite direction, into the cell, which decreases the signal for ADH secretion. Although some researchers place these osmoreceptors in the hypothalamus (in the supraoptic nuclei), others believe that they are located in the *organum vasculosum,* a highly vascular structure in the anteroventral wall of the third ventricle (AV3V region). As discussed in Chapter 29, lesions of the AV3V region greatly impair ADH secretion, whereas electrical stimulation or stimulation by angiotensin II increases ADH secretion.

Regardless of the mechanism, concentrated body fluids stimulate these osmoreceptors and ADH secretion whereas dilute body fluids inhibit them, providing a powerful feedback control system for controlling the total osmotic pressure of the body fluids. Further details on the control of ADH secretion and the role of ADH in controlling renal function and body fluid osmolality are presented in Chapter 29.

Low Blood Volume and Low Blood Pressure Stimulate ADH Secretion—Vasoconstrictor Effects of ADH. Whereas minute concentrations of ADH cause increased water conservation by the kidneys, higher concentrations of ADH have a potent effect of constricting the arterioles throughout the body and therefore increasing the arterial pressure. For this reason, ADH is also called *vasopressin.*

One of the stimuli for causing intense ADH secretion is decreased blood volume. This occurs strongly when the blood volume decreases 15% to 25% or more; the secretory rate then sometimes rises to as high as 50 times normal.

The atria have stretch receptors that are excited by overfilling. When excited, they send signals to the brain to inhibit ADH secretion. Conversely, when the receptors are unexcited as a result of underfilling, the opposite occurs, with greatly increased ADH secretion. Decreased stretch of the baroreceptors of the carotid, aortic, and pulmonary regions also stimulates ADH secretion. For further details about this blood volume–pressure feedback mechanism, refer to Chapter 29.

PHYSIOLOGICAL FUNCTIONS OF OXYTOCIN

Oxytocin Causes Contraction of the Pregnant Uterus. The hormone *oxytocin,* in accordance with its name, powerfully stimulates contraction of the pregnant uterus, especially toward the end of gestation. Therefore, many obstetricians believe that this hormone is at least partially responsible for causing birth of the baby. This belief is supported by the following facts: (1) In a hypophysectomized animal, the duration of labor is prolonged, indicating a possible effect of oxytocin during delivery; (2) the amount of oxytocin in the plasma increases during labor, especially during the last stage; and (3) stimulation of the cervix in a pregnant animal elicits nervous signals that pass to the hypothalamus and cause increased secretion of oxytocin. These effects and this possible mechanism for aiding in the birth process are discussed in more detail in Chapter 83.

Oxytocin Aids in Milk Ejection by the Breasts. Oxytocin also plays an especially important role in lactation—a role that is far better understood than its role in delivery. In lactation, oxytocin causes milk to be expressed from the alveoli into the ducts of the breast so that the baby can obtain it by suckling.

This mechanism works as follows: The suckling stimulus on the nipple of the breast causes signals to be transmitted through sensory nerves to the oxytocin neurons in the paraventricular and supraoptic nuclei in the hypothalamus, which causes release of oxytocin by the posterior pituitary gland. The oxytocin is then carried by the blood to the breasts, where it causes contraction of *myoepithelial cells* that lie outside of and form a latticework surrounding the alveoli of the mammary glands. In less than a minute after the beginning of suckling, milk begins to flow. This mechanism is called *milk letdown* or *milk ejection.* It is discussed further in Chapter 83 in relation to the physiology of lactation.

CHAPTER 77

UNIT XIV

Thyroid Metabolic Hormones

The thyroid gland, located immediately below the larynx on each side of and anterior to the trachea, is one of the largest of the endocrine glands, normally weighing 15 to 20 grams in adults. The thyroid secretes two major metabolic hormones, *thyroxine* and *triiodothyronine,* commonly called T_4 and T_3, respectively. Both of these hormones profoundly increase the metabolic rate of the body. Complete lack of thyroid secretion usually causes the basal metabolic rate to fall 40% to 50% below normal, and extreme excesses of thyroid secretion can increase the basal metabolic rate to 60% to 100% above normal. Thyroid secretion is controlled primarily by *thyroid-stimulating hormone* (TSH) secreted by the anterior pituitary gland.

The thyroid gland also secretes *calcitonin,* a hormone involved in calcium metabolism that is discussed in Chapter 80.

The purpose of this chapter is to discuss the formation and secretion of the thyroid hormones, their metabolic functions, and regulation of their secretion.

SYNTHESIS AND SECRETION OF THE THYROID METABOLIC HORMONES

About 93% of the metabolically active hormones secreted by the thyroid gland is *thyroxine* and 7% is *triiodothyronine*. However, almost all the thyroxine is eventually converted to triiodothyronine in the tissues, so both are functionally important. The functions of these two hormones are qualitatively the same, but they differ in rapidity and intensity of action. Triiodothyronine is about four times as potent as thyroxine, but it is present in the blood in much smaller quantities and persists for a much shorter time compared with thyroxine.

PHYSIOLOGIC ANATOMY OF THE THYROID GLAND

As shown in **Figure 77-1**, the thyroid gland is composed of large numbers of closed *follicles* (100–300 micrometers in diameter) that are filled with a secretory substance called *colloid* and lined with *cuboidal epithelial cells* that secrete into the interior of the follicles. The major constituent of colloid is the large glycoprotein *thyroglobulin,* which contains the thyroid hormones. Once the secretion has entered the follicles, it must be absorbed back through the follicular epithelium into the blood before it can function in the body. The thyroid gland has a blood flow about five times the weight of the gland each minute, which is a blood supply as great as that of any other area of the body, with the possible exception of the adrenal cortex.

The thyroid gland also contains *C cells* that secrete *calcitonin*, a hormone that contributes to regulation of plasma calcium ion concentration, as discussed in Chapter 80.

IODINE IS REQUIRED FOR THYROXINE FORMATION

To form normal quantities of thyroxine, about 50 milligrams of ingested iodine in the form of iodides are required *each year,* or about *1 mg/week*. To prevent iodine deficiency, common table salt is iodized with about 1 part sodium iodide to every 100,000 parts sodium chloride.

Fate of Ingested Iodides. Iodides ingested orally are absorbed from the gastrointestinal tract into the blood in about the same manner as chlorides. Normally, most of the iodides are rapidly excreted by the kidneys, but only after about one fifth are selectively removed from the circulating blood by the cells of the thyroid gland and used for synthesis of the thyroid hormones.

IODIDE PUMP—THE SODIUM-IODIDE SYMPORTER (IODIDE TRAPPING)

The first stage in formation of thyroid hormones, shown in **Figure 77-2**, is transport of iodides from the blood into the thyroid glandular cells and follicles. The basal membrane of the thyroid cell has the specific ability to pump the iodide actively to the interior of the cell. This pumping is achieved by the action of a *sodium-iodide symporter*, which co-transports one iodide ion along with two sodium ions across the basolateral (plasma) membrane into the cell. The energy for transporting iodide against a concentration gradient comes from the sodium-potassium adenosine triphosphatase (Na^+-K^+ ATPase) pump, which pumps sodium out of the cell,

thereby establishing a low intracellular sodium concentration and a gradient for facilitated diffusion of sodium into the cell.

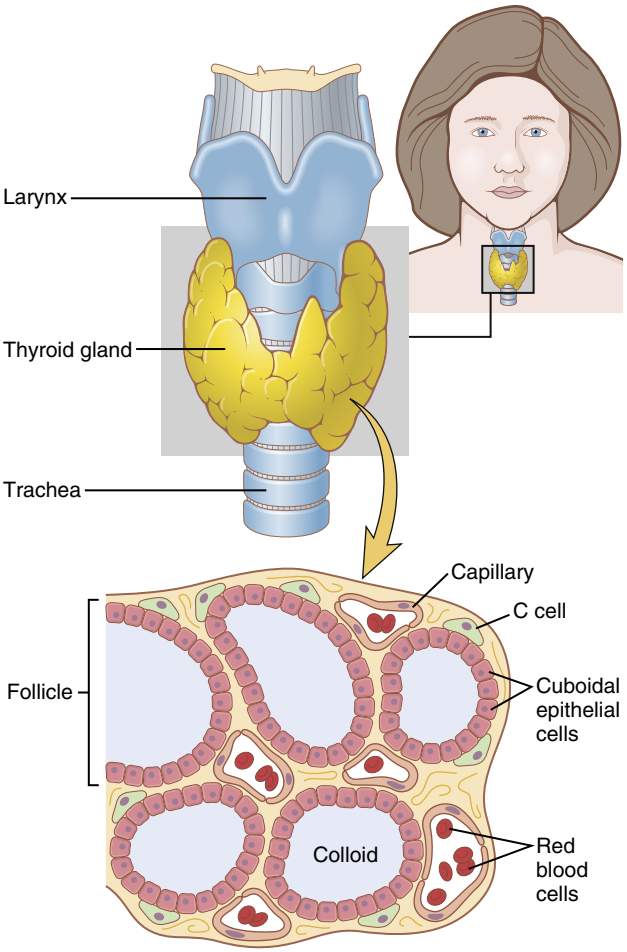

Figure 77-1 Anatomy and microscopic appearance of the thyroid gland, showing secretion of thyroglobulin into the follicles.

This process of concentrating the iodide in the cell is called *iodide trapping.* In a normal gland, the iodide pump concentrates the iodide to about 30 times its concentration in the blood. When the thyroid gland becomes maximally active, this concentration ratio can rise to as high as 250 times. The rate of iodide trapping by the thyroid is influenced by several factors, the most important being the concentration of TSH; TSH stimulates and hypophysectomy greatly diminishes the activity of the iodide pump in thyroid cells.

Iodide is transported out of the thyroid cells across the apical membrane into the follicle by a chloride-iodide ion counter-transporter molecule called *pendrin.* The thyroid epithelial cells also secrete into the follicle thyroglobulin that contains tyrosine amino acids to which the iodine will bind, as discussed in the next section.

THYROGLOBULIN AND FORMATION OF THYROXINE AND TRIIODOTHYRONINE

Formation and Secretion of Thyroglobulin by the Thyroid Cells. The thyroid cells are typical protein-secreting glandular cells, as shown in **Figure 77-2**. The endoplasmic reticulum and Golgi apparatus synthesize and secrete into the follicles a large glycoprotein molecule called *thyroglobulin,* with a molecular weight of about 335,000.

Each molecule of thyroglobulin contains about 70 tyrosine amino acids, and they are the major substrates that combine with iodine to form the thyroid hormones. Thus, the thyroid hormones form *within* the thyroglobulin molecule. That is, the thyroxine and triiodothyronine hormones formed from the tyrosine amino acids remain part of the thyroglobulin molecule during synthesis of the thyroid hormones and even afterward as stored hormones in the follicular colloid.

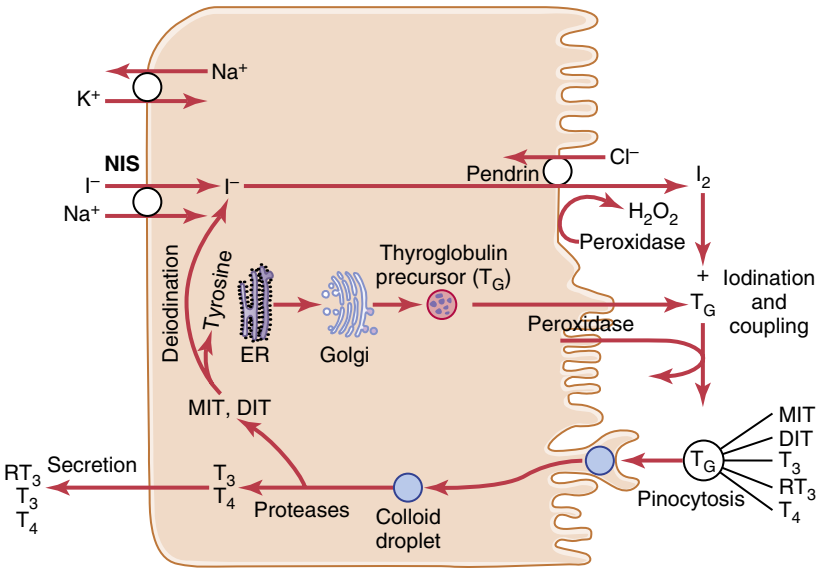

Figure 77-2 Thyroid cellular mechanisms for iodine transport, thyroxine and triiodothyronine formation, and thyroxine and triiodothyronine release into the blood. DIT, Diiodotyrosine; ER, endoplasmic reticulum; I^-, iodide ion; I_2, iodine; MIT, monoiodotyrosine; NIS, sodium-iodide symporter; RT_3, reverse triiodothyronine; T_3, triiodothyronine; T_4, thyroxine; T_G, thyroglobulin.

Oxidation of the Iodide Ion. The first essential step in thyroid hormone formation is conversion of iodide ions to an *oxidized form of iodine,* either nascent iodine (I^0) or I_3^-, which is then capable of combining directly with the amino acid tyrosine. This oxidation of iodine is promoted by the enzyme *peroxidase* and its accompanying *hydrogen peroxide,* which provide a potent system capable of oxidizing iodides. The peroxidase is either located in the apical membrane of the cell or attached to it, thus providing the oxidized iodine at exactly the point in the cell where the thyroglobulin molecule issues forth from the Golgi apparatus and through the cell membrane into the stored thyroid gland colloid. When the peroxidase system is blocked or when it is hereditarily absent from the cells, the rate of formation of thyroid hormones falls to zero.

Iodination of Tyrosine and Thyroid Hormone Formation—"Organification" of Thyroglobulin. The binding of iodine with the thyroglobulin molecule is called *organification* of the thyroglobulin. Oxidized iodine even in the molecular form will bind directly but slowly with the amino acid tyrosine. In thyroid cells, however, the oxidized iodine is associated with thyroid peroxidase enzyme (see **Figure 77-2**) that causes the process to occur within seconds or minutes. Therefore, almost as rapidly as thyroglobulin is released from the Golgi apparatus or as it is secreted through the apical cell membrane into the follicle, iodine binds with about one sixth of the tyrosine amino acids within the thyroglobulin molecule.

Figure 77-3 shows the successive stages of iodination of tyrosine and final formation of thyroxine and triiodothyronine. Tyrosine is first iodized to *monoiodotyrosine* and then to *diiodotyrosine.* Then, during the next few minutes, hours, and even days, more and more of the iodotyrosine residues become *coupled* with one another.

The major hormonal product of the coupling reaction is the molecule *thyroxine (T_4),* which is formed when two molecules of diiodotyrosine are joined together; the thyroxine then remains part of the thyroglobulin molecule. Or one molecule of monoiodotyrosine couples with one molecule of diiodotyrosine to form *triiodothyronine (T_3),* which represents about one-fifteenth of the final hormones. Small amounts of *reverse T_3 (RT_3)* are formed by coupling of diiodotyrosine with monoiodotyrosine, but RT_3 does not appear to be of functional significance in humans.

Storage of Thyroglobulin. The thyroid gland is unusual among the endocrine glands in its ability to store large amounts of hormone. After synthesis of the thyroid hormones has run its course, each thyroglobulin molecule contains up to 30 thyroxine molecules and a few triiodothyronine molecules. In this form, the thyroid hormones are stored in the follicles in an amount sufficient to supply the body with its normal requirements of thyroid hormones for 2 to 3 months. Therefore, when synthesis of thyroid hormone ceases, the physiological effects of deficiency are not observed for several months.

RELEASE OF THYROXINE AND TRIIODOTHYRONINE FROM THE THYROID GLAND

Most of the thyroglobulin is not released into the circulating blood; instead, thyroxine and triiodothyronine are cleaved from the thyroglobulin molecule, and then these free hormones are released. This process occurs as follows: The apical surface of thyroid cells sends out pseudopod extensions that close around small portions of the colloid to form *pinocytic vesicles* that enter the apex of the thyroid cell. Then *lysosomes* in the cell cytoplasm immediately fuse with these vesicles to form digestive vesicles containing digestive enzymes from the lysosomes mixed with the colloid. Multiple *proteases* among the enzymes digest the thyroglobulin molecules and release thyroxine and triiodothyronine in free form, which then diffuse through the base of the thyroid cell into the surrounding capillaries. Thus, the thyroid hormones are released into the blood.

Some of the thyroglobulin in the colloid enters the thyroid cell by *endocytosis* after binding to *megalin*, a protein located on the lumen membrane of the cells. The megalin-thyroglobulin complex is then carried across the cell by *transcytosis* to the basolateral membrane, where a

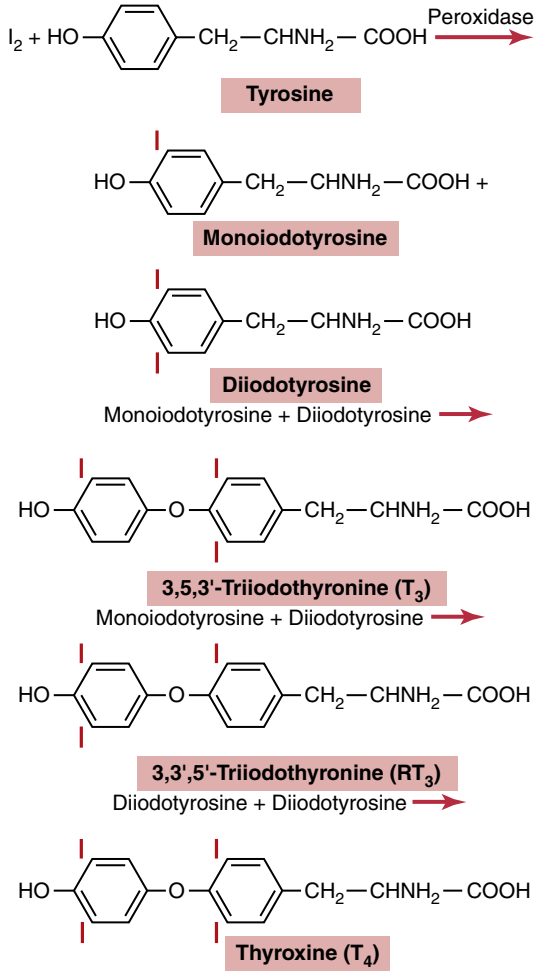

Figure 77-3 Chemistry of thyroxine and triiodothyronine formation.

portion of the megalin remains bound to thyroglobulin and is released into the capillary blood.

About three-quarters of the iodinated tyrosine in the thyroglobulin never become thyroid hormones but remain monoiodotyrosine and diiodotyrosine. During the digestion of the thyroglobulin molecule to cause release of thyroxine and triiodothyronine, these iodinated tyrosines also are freed from the thyroglobulin molecules. However, they are not secreted into the blood. Instead, their iodine is cleaved from them by a *deiodinase enzyme* that makes virtually all this iodine available again for recycling within the gland for forming additional thyroid hormones. Congenital absence of this deiodinase enzyme may cause iodine deficiency because of failure of this recycling process.

Daily Rate of Secretion of Thyroxine and Triiodothyronine. About 93% of the thyroid hormone released from the thyroid gland is normally thyroxine and only 7% is triiodothyronine. However, during the ensuing few days, about one-half of the thyroxine is slowly deiodinated to form additional triiodothyronine. Therefore, the hormone finally delivered to and used by the tissues is mainly triiodothyronine—a total of about 35 μg of triiodothyronine per day.

TRANSPORT OF THYROXINE AND TRIIODOTHYRONINE TO TISSUES

Thyroxine and Triiodothyronine Are Bound to Plasma Proteins. Upon entering the blood, more than 99% of the thyroxine and triiodothyronine combines immediately with several of the plasma proteins, all of which are synthesized by the liver. They combine mainly with *thyroxine-binding globulin* and much less so with *thyroxine-binding prealbumin* and *albumin*.

Thyroxine and Triiodothyronine Are Released Slowly to Tissue Cells. Because of high affinity of the plasma-binding proteins for the thyroid hormones, these substances—in particular, thyroxine—are released to the tissue cells slowly. Half the thyroxine in the blood is released to the tissue cells about every 6 days, whereas half the triiodothyronine—because of its lower affinity—is released to the cells in about 1 day.

Upon entering the tissue cells, both thyroxine and triiodothyronine again bind with intracellular proteins, with the thyroxine binding more strongly than the triiodothyronine. Therefore, they are again stored, but this time in the target cells, and they are used slowly over a period of days or weeks.

Thyroid Hormones Have Slow Onset and Long Duration of Action. After injection of a large quantity of thyroxine into a human being, essentially no effect on the metabolic rate can be discerned for 2 to 3 days, thereby demonstrating that there is a *long latent period* before thyroxine activity begins. Once activity does begin, it increases progressively and reaches a maximum in 10 to 12 days, as shown in **Figure 77-4**. Thereafter, it decreases with a half-life of about 15 days. Some of the activity persists for as long as 6 weeks to 2 months.

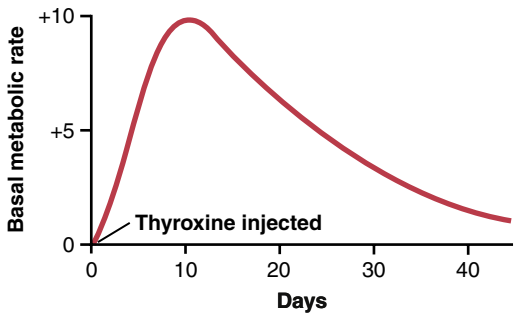

Figure 77-4 Approximate prolonged effect on the basal metabolic rate caused by administering a single large dose of thyroxine.

The actions of triiodothyronine occur about four times as rapidly as those of thyroxine, with a latent period as short as 6 to 12 hours and maximal cellular activity occurring within 2 to 3 days.

Most of the latency and the prolonged period of action of these hormones are probably caused by their binding with proteins both in the plasma and in the tissue cells, followed by their slow release. However, we shall see in subsequent discussions that part of the latent period also results from the manner in which these hormones perform their functions in the cells.

PHYSIOLOGICAL FUNCTIONS OF THE THYROID HORMONES

THYROID HORMONES INCREASE TRANSCRIPTION OF MANY GENES

The general effect of thyroid hormone is to activate nuclear transcription of many genes (**Figure 77-5**). Therefore, in virtually all cells of the body, great numbers of protein enzymes, structural proteins, transport proteins, and other substances are synthesized. The net result is a generalized increase in functional activity throughout the body.

Most of the Thyroxine Secreted by the Thyroid Is Converted to Triiodothyronine. Before acting on the genes to increase genetic transcription, one iodide is removed from almost all the thyroxine, thus forming triiodothyronine. Intracellular thyroid hormone receptors have a high affinity for triiodothyronine. Consequently, more than 90% of the thyroid hormone that binds with the receptors is triiodothyronine.

Thyroid Hormones Activate Nuclear Receptors. Thyroid hormone receptors are either attached to the DNA genetic strands or located in proximity to them. The thyroid hormone receptor usually forms a

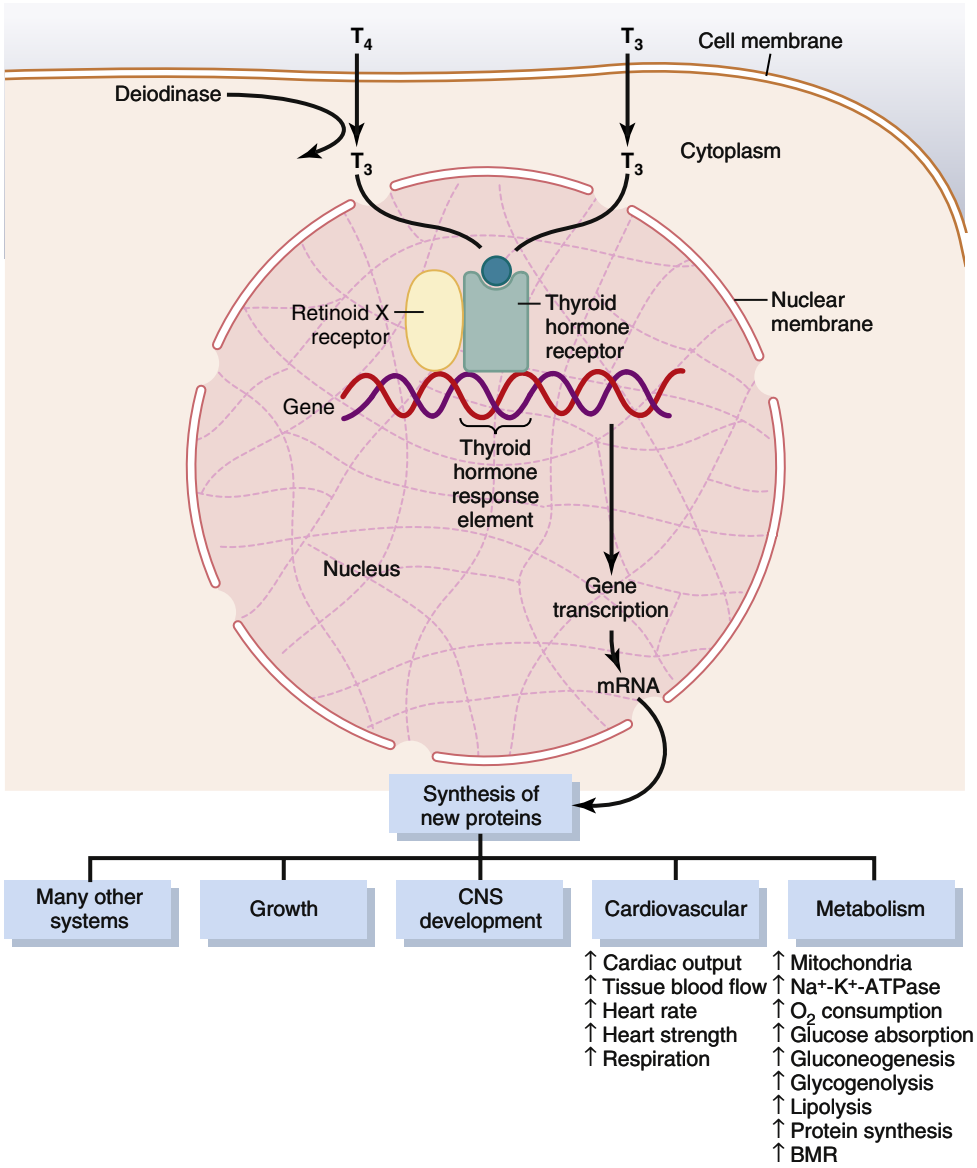

Figure 77-5 Thyroid hormone activation of target cells. Thyroxine (T_4) and triiodothyronine (T_3) enter the cell membrane by a carrier-mediated adenosine triphosphate–dependent transport process. Much of the T_4 is deiodinated to form T_3, which interacts with the thyroid hormone receptor, bound as a heterodimer with a retinoid X receptor, of the thyroid hormone response element of the gene. This action causes either increases or decreases in transcription of genes that lead to the formation of proteins, thus producing the thyroid hormone response of the cell. The actions of thyroid hormone on cells of several different systems are shown. BMR, Basal metabolic rate; CNS, central nervous system; mRNA, messenger ribonucleic acid; Na^+-K^+-ATPase, sodium–potassium–adenosine triphosphatase.

heterodimer with *retinoid X receptor* (RXR) at specific *thyroid hormone response elements* on the DNA. After binding with thyroid hormone, the receptors become activated and initiate the transcription process. Large numbers of different types of messenger RNA are then formed, followed within another few minutes or hours by RNA translation on the cytoplasmic ribosomes to form hundreds of new intracellular proteins. However, not all the proteins are increased by similar percentages—some are increased only slightly, and others at least as much as sixfold. Most of the actions of thyroid hormone result from the subsequent enzymatic and other functions of these new proteins.

Thyroid hormones also appear to have *nongenomic* cellular effects that are independent of their effects on gene transcription. For example, some effects of thyroid hormones occur within minutes, too rapidly to be explained by changes in protein synthesis, and are not affected by inhibitors of gene transcription and translation. Such actions have been described in several tissues, including the heart and pituitary, as well as adipose tissue. The site of nongenomic thyroid hormone action appears to be the plasma membrane, cytoplasm, and perhaps some cell organelles such as mitochondria. Nongenomic actions of thyroid hormone include regulation of ion channels and oxidative phosphorylation and appear to involve activation of intracellular secondary messengers such as cyclic

adenosine monophosphate (cAMP) or protein kinase signaling cascades.

THYROID HORMONES INCREASE CELLULAR METABOLIC ACTIVITY

Thyroid hormones increase the metabolic activities of almost all the tissues of the body. The basal metabolic rate can increase to 60% to 100% above normal when large quantities of thyroid hormones are secreted. The rate of utilization of foods for energy is greatly accelerated. Although the rate of protein synthesis is increased, at the same time the rate of protein catabolism is also increased. The growth rate of young people is greatly accelerated. The mental processes are excited, and the activities of most of the other endocrine glands are increased.

Thyroid Hormones Increase the Number and Activity of Mitochondria. When thyroxine or triiodothyronine is given to an animal, the mitochondria in most cells of the animal's body increase in size and number. Furthermore, the total membrane surface area of the mitochondria increases almost directly in proportion to the increased metabolic rate of the whole animal. Therefore, one of the principal functions of thyroxine might be simply to increase the number and activity of mitochondria, which in turn increases the rate of formation of adenosine triphosphate to energize cellular function. However, increases in the number and activity of mitochondria could be the *result* of increased activity of the cells, as well as the cause of the increase.

Thyroid Hormones Increase Active Transport of Ions Through Cell Membranes. One of the enzymes that increases its activity in response to thyroid hormone is *Na^+-K^+ ATPase*. This increased activity in turn increases the rate of transport of sodium and potassium ions through the cell membranes of some tissues. Because this process uses energy and increases the amount of heat produced in the body, it has been suggested that this might be one of the mechanisms by which thyroid hormone increases the body's metabolic rate. In fact, thyroid hormone also causes the cell membranes of most cells to become leaky to sodium ions, which further activates the sodium pump and further increases heat production.

EFFECT OF THYROID HORMONE ON GROWTH

Thyroid hormone has both general and specific effects on growth. For example, it has long been known that thyroid hormone is essential for the metamorphic change of the tadpole into the frog.

In humans, the effect of thyroid hormone on growth is manifest mainly in growing children. In children with hypothyroidism, the rate of growth is greatly retarded. In children with hyperthyroidism, excessive skeletal growth often occurs, causing the child to become considerably taller at an earlier age. However, the bones also mature more rapidly and the epiphyses close at an early age, so the duration of growth and the eventual height of the adult actually may be shortened.

An important effect of thyroid hormone is to promote growth and development of the brain during fetal life and for the first few years of postnatal life. If the fetus does not secrete sufficient quantities of thyroid hormone, growth and maturation of the brain both before birth and afterward are greatly retarded and the brain remains smaller than normal. Without specific thyroid therapy within days or weeks after birth, the child without a thyroid gland will remain mentally deficient throughout life. This condition is discussed later in the chapter.

EFFECTS OF THYROID HORMONE ON SPECIFIC BODY FUNCTIONS

Stimulation of Carbohydrate Metabolism. Thyroid hormone stimulates almost all aspects of carbohydrate metabolism, including rapid glucose uptake by cells, enhanced glycolysis, enhanced gluconeogenesis, increased rate of absorption from the gastrointestinal tract, and even increased insulin secretion with its resultant secondary effects on carbohydrate metabolism. All these effects probably result from the overall increase in cellular metabolic enzymes caused by thyroid hormone.

Stimulation of Fat Metabolism. Essentially all aspects of fat metabolism are also enhanced by thyroid hormone. In particular, lipids are mobilized rapidly from the fat tissue, which decreases fat stores of the body to a greater extent than almost any other tissue element. Mobilization of lipids from fat tissue also increases free fatty acid concentration in the plasma and greatly accelerates oxidation of free fatty acids by the cells.

Effect on Plasma and Liver Fats. *Increased* thyroid hormone *decreases* the concentrations of cholesterol, phospholipids, and triglycerides in the plasma, even though it *increases* the free fatty acids. Conversely, *decreased* thyroid secretion greatly *increases* the plasma concentrations of cholesterol, phospholipids, and triglycerides and almost always causes excessive deposition of fat in the liver as well. The large increase in circulating plasma cholesterol in prolonged hypothyroidism is often associated with severe atherosclerosis, as discussed in Chapter 69.

One of the mechanisms by which thyroid hormone decreases plasma cholesterol concentration is to increase significantly cholesterol secretion in the bile and consequent loss in the feces. A possible mechanism for the increased cholesterol secretion is that thyroid hormone induces increased numbers of low-density lipoprotein receptors on the liver cells, leading to rapid removal of low-density lipoproteins from the plasma by the liver and subsequent secretion of cholesterol in these lipoproteins by the liver cells.

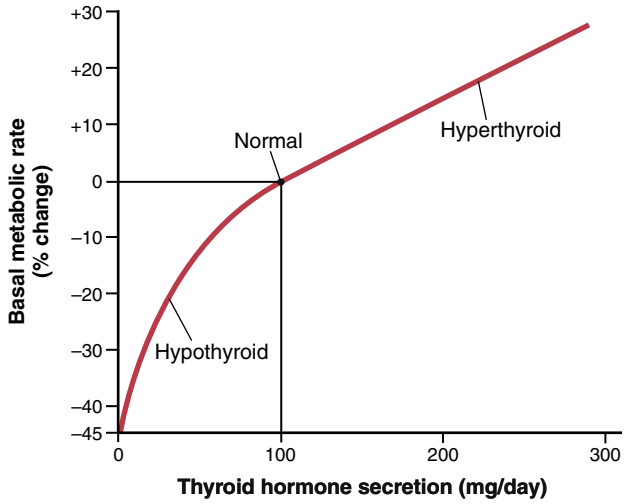

Figure 77-6 Approximate relation of the daily rate of thyroid hormone (T_3, triiodothyronine, and T_4, thyroxine) secretion to percent change in basal metabolic rate, compared with normal.

Increased Requirement for Vitamins. Because thyroid hormone increases the quantities of many bodily enzymes and because vitamins are essential parts of some of the enzymes or coenzymes, thyroid hormone increases the need for vitamins. Therefore, a relative vitamin deficiency can occur when excess thyroid hormone is secreted, unless at the same time increased quantities of vitamins are made available.

Increased Basal Metabolic Rate. Because thyroid hormone increases metabolism in almost all cells of the body, excessive quantities of the hormone can occasionally increase the basal metabolic rate by 60% to 100% above normal. Conversely, when no thyroid hormone is produced, the basal metabolic rate falls to almost one-half of normal. Figure 77-6 shows the approximate relation between the daily supply of thyroid hormones and the basal metabolic rate. Extreme amounts of the hormones are required to cause high basal metabolic rates.

Decreased Body Weight. A greatly increased amount of thyroid hormone almost always decreases body weight, and a greatly decreased amount of thyroid hormone almost always increases body weight. However, these effects do not always occur because thyroid hormone also increases the appetite, which may counterbalance the change in the metabolic rate.

Increased Blood Flow and Cardiac Output. Increased metabolism in the tissues causes more rapid utilization of oxygen than normal and increased release of metabolic end products from the tissues. These effects cause vasodilation in most body tissues, thus increasing blood flow. The rate of blood flow in the skin especially increases because of the increased need for heat elimination from the body. As a consequence of the increased blood flow, cardiac output also increases, sometimes rising to 60% or more above normal when excessive thyroid hormone is present and falling to only 50% of normal in severe hypothyroidism.

Increased Heart Rate. The heart rate increases considerably more under the influence of thyroid hormone than would be expected from the increase in cardiac output. Therefore, thyroid hormone seems to have a direct effect on the excitability of the heart, which in turn increases the heart rate. This effect is especially important because the heart rate is one of the sensitive physical signs that the clinician uses in determining whether a patient has excessive or diminished thyroid hormone production.

Increased Heart Strength. A slight excess of thyroid hormone can increase the strength of the heart. This effect is analogous to the increase in heart strength that occurs in mild fevers and during exercise. However, when thyroid hormone is increased markedly, heart muscle strength becomes depressed because of long-term excessive protein catabolism. Indeed, some severely thyrotoxic patients die of cardiac decompensation secondary to myocardial failure and increased cardiac workload imposed by the increase in cardiac output.

Normal Arterial Pressure. The *mean* arterial pressure usually remains about normal after administration of thyroid hormone. Because of increased blood flow through the tissues between heartbeats, the pulse pressure is often increased, with the systolic pressure elevated 10 to 15 mm Hg in hyperthyroidism and the diastolic pressure reduced a corresponding amount.

Increased Respiration. The increased rate of metabolism increases oxygen utilization and carbon dioxide formation; these effects activate all the mechanisms that increase the rate and depth of respiration.

Increased Gastrointestinal Motility. In addition to increased appetite and food intake, which has been discussed, thyroid hormone increases secretion of digestive juices and motility of the gastrointestinal tract. Hyperthyroidism therefore often results in diarrhea, whereas lack of thyroid hormone can cause constipation.

Excitatory Effects on the Central Nervous System. In general, thyroid hormone increases the rapidity of cerebration, although thought processes may be dissociated; conversely, lack of thyroid hormone decreases rapidity of cerebration. A person with hyperthyroidism is likely to be extremely nervous and have many psychoneurotic tendencies, such as anxiety complexes, extreme worry, and paranoia.

Effect on the Function of the Muscles. A slight increase in thyroid hormone usually makes the muscles react with vigor but, with excessive thyroid hormone, the

muscles become weakened because of excess protein catabolism. Conversely, lack of thyroid hormone causes the muscles to become sluggish, and they relax slowly after a contraction.

Muscle Tremor. One of the most characteristic signs of hyperthyroidism is a fine muscle tremor. This symptom is not the coarse tremor that occurs in Parkinson's disease or when a person shivers because it occurs at the rapid frequency of 10 to 15 times per second. The tremor can be observed easily by placing a sheet of paper on the extended fingers and noting the degree of vibration of the paper. This tremor is believed to be caused by increased reactivity of the neuronal synapses in the areas of the spinal cord that control muscle tone. The tremor is an important means for assessing the degree of thyroid hormone effect on the central nervous system.

Effect on Sleep. Because of the exhausting effect of thyroid hormone on the musculature and on the central nervous system, persons with hyperthyroidism often have a feeling of constant tiredness, but because of the excitable effects of thyroid hormone on the synapses, it is difficult to sleep. Conversely, extreme somnolence is characteristic of hypothyroidism, with sleep sometimes lasting 12 to 14 hours a day.

Effect on Other Endocrine Glands. Increased thyroid hormone increases the secretion rates of several other endocrine glands, but it also increases the need of the tissues for the hormones. For example, increased thyroxine secretion increases the rate of glucose metabolism almost everywhere in the body and therefore causes a corresponding need for increased insulin secretion by the pancreas. Also, thyroid hormone increases many metabolic activities related to bone formation and, as a consequence, increases the need for parathyroid hormone. Thyroid hormone also increases the rate at which adrenal glucocorticoids are inactivated by the liver. This increased rate of inactivation leads to feedback increase in adrenocorticotropic hormone production by the anterior pituitary and, therefore, an increased rate of glucocorticoid secretion by the adrenal glands.

Effect of Thyroid Hormone on Sexual Function. For normal sexual function, thyroid secretion needs to be approximately normal. In men, lack of thyroid hormone is likely to cause loss of libido; a great excess of the hormone, however, sometimes causes impotence.

In women, lack of thyroid hormone often causes *menorrhagia* and *polymenorrhea*—that is, excessive and frequent menstrual bleeding, respectively. Yet, strangely enough, in other women a lack of thyroid hormone may cause irregular periods and occasionally even *amenorrhea* (absence of menstrual bleeding).

Hypothyroidism in women, as in men, is likely to result in a greatly decreased libido. To make the picture still more confusing, in women with hyperthyroidism, *oligomenorrhea* (greatly reduced bleeding) is common, and occasionally amenorrhea occurs.

The action of thyroid hormone on the gonads cannot be pinpointed to a specific function but probably results from a combination of direct metabolic effects on the gonads, as well as excitatory and inhibitory feedback effects operating through the anterior pituitary hormones that control sexual functions.

REGULATION OF THYROID HORMONE SECRETION

To maintain normal levels of metabolic activity in the body, precisely the right amount of thyroid hormone must be secreted at all times; to achieve this ideal level of secretion, specific feedback mechanisms operate through the hypothalamus and anterior pituitary gland to control the rate of thyroid secretion. These mechanisms are described in the following sections.

TSH (FROM THE ANTERIOR PITUITARY GLAND) INCREASES THYROID SECRETION

TSH, also known as *thyrotropin,* is an anterior pituitary hormone; it is a glycoprotein with a molecular weight of about 28,000. This hormone, also discussed in Chapter 75, increases secretion of thyroxine and triiodothyronine by the thyroid gland. It has the following specific effects on the thyroid gland:

1. *Increased proteolysis of thyroglobulin* that has already been stored in the follicles, releasing the thyroid hormones into the circulating blood and diminishing the follicular substance
2. *Increased activity of the iodide pump,* which increases the rate of "iodide trapping" in the glandular cells, sometimes increasing the ratio of intracellular to extracellular iodide concentration in the glandular substance to as much as eight times normal
3. *Increased iodination of tyrosine* to form the thyroid hormones
4. *Increased size and increased secretory activity of the thyroid cells*
5. *Increased number of thyroid cells* plus a change from cuboidal to columnar cells and much infolding of the thyroid epithelium into the follicles

In summary, TSH increases all the known secretory activities of the thyroid glandular cells.

The most important early effect after administration of TSH is to initiate proteolysis of thyroglobulin, which causes release of thyroxine and triiodothyronine into the blood within 30 minutes. The other effects require hours or even days and weeks to develop fully.

Cyclic Adenosine Monophosphate Mediates the Stimulatory Effect of TSH. Most of the varied effects of TSH on the thyroid cell result from activation of the "second messenger" cAMP system of the cell.

The first event in this activation is binding of TSH with specific TSH receptors on the basal membrane surfaces of the thyroid cell. This binding then activates *adenylyl cyclase* in the membrane, which increases formation of cAMP inside the cell. Finally, cAMP acts as a *second messenger* to activate protein kinase, which causes multiple phosphorylations throughout the cell. The result is both an immediate increase in secretion of thyroid hormones and prolonged growth of the thyroid glandular tissue.

This method for control of thyroid cell activity is similar to the function of cAMP as a "second messenger" in many other target tissues of the body, as discussed in Chapter 75.

ANTERIOR PITUITARY SECRETION OF TSH IS REGULATED BY THYROTROPIN-RELEASING HORMONE FROM THE HYPOTHALAMUS

Anterior pituitary secretion of TSH is controlled by a hypothalamic hormone, *thyrotropin-releasing hormone* (TRH), which is synthesized by neurons in the paraventricular nucleus (PVN) of the hypothalamus and secreted from their nerve endings in the median eminence of the hypothalamus. From the median eminence, TRH is then transported to the anterior pituitary by way of the hypothalamic-hypophysial portal blood, as explained in Chapter 75.

TRH is a tripeptide amide—*pyroglutamyl-histidyl-proline-amide*. TRH stimulates the anterior pituitary gland cells to increase their output of TSH. When the blood portal system from the hypothalamus to the anterior pituitary gland becomes blocked, the rate of secretion of TSH by the anterior pituitary decreases greatly but is not reduced to zero.

The molecular mechanism by which TRH causes TSH-secreting cells of the anterior pituitary to produce TSH is first to bind with TRH receptors in the pituitary cell membrane. This binding in turn *activates the phospholipase second messenger system* inside the pituitary cells to produce large amounts of phospholipase C, followed by a cascade of other second messengers, including calcium ions and diacyl glycerol, which eventually leads to TSH release.

Effects of Cold and Other Neurogenic Stimuli on TRH and TSH Secretion. One of the best-known stimuli for increasing TRH secretion by the hypothalamus, and therefore TSH secretion by the anterior pituitary gland, is exposure of an animal to cold. This effect almost certainly results from excitation of the hypothalamic centers for body temperature control. Exposure of rats for several weeks to severe cold increases the output of thyroid hormones sometimes to more than 100% of normal and can increase the basal metabolic rate as much as 50%. Indeed, persons moving to arctic regions have been known to develop basal metabolic rates that are 15% to 20% above normal.

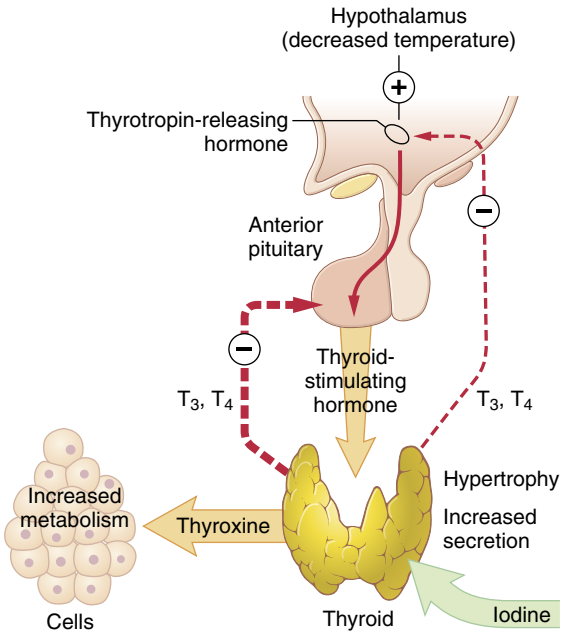

Figure 77-7 Regulation of thyroid secretion. T_3, triiodothyronine; T_4, thyroxine.

TRH neurons in the PVN receive input from leptin-responsive neurons in the arcuate nucleus of the hypothalamus that regulate energy balance—the *neuropeptide Y* (NPY)*/agouti-related protein* (AGRP) and *pro-opiomelanocortin* (POMC) neurons which were discussed in Chapter 72. Prolonged fasting reduces plasma leptin levels which, in turn, decreases POMC activity and increases NPY/AGRP neuronal activity. Decreased levels of leptin may also directly inhibit TRH neurons. Together these effects reduce expression of TRH, TSH, and thyroid hormone secretion, contributing to reduced metabolic rate and conservation of energy when food supplies are scarce.

Various emotional reactions can also affect the output of TRH and TSH and therefore indirectly affect the secretion of thyroid hormones. Excitement and anxiety—conditions that greatly stimulate the sympathetic nervous system—cause an acute decrease in secretion of TSH, perhaps because these states increase the metabolic rate and body heat and therefore exert an inverse effect on the heat control center.

FEEDBACK EFFECT OF THYROID HORMONE TO DECREASE ANTERIOR PITUITARY SECRETION OF TSH

Increased thyroid hormone in the body fluids decreases TSH secretion by the anterior pituitary. When the rate of thyroid hormone secretion rises to about 1.75 times normal, the rate of TSH secretion falls essentially to zero. Almost all this feedback depressant effect occurs even when the anterior pituitary has been separated from the hypothalamus. Therefore, as shown in **Figure 77-7**, it is probable that increased thyroid hormone inhibits anterior pituitary secretion of TSH mainly by a direct

effect on the anterior pituitary gland. However, there is also evidence for negative feedback effects of thyroid hormone to inhibit thyrotropin releasing hormone by the hypothalamus. Regardless of the mechanism, this feedback maintains an almost constant concentration of free thyroid hormones in the circulating body fluids.

Antithyroid Substances Suppress Thyroid Secretion

The best known antithyroid drugs are *thiocyanate, propylthiouracil,* and high concentrations of *inorganic iodides.* The mechanism by which each of these drugs blocks thyroid secretion is different from the others and can be explained as follows.

Thiocyanate Ions Decrease Iodide Trapping. The same active pump that transports iodide ions into the thyroid cells can also pump thiocyanate ions, perchlorate ions, and nitrate ions. Therefore, administration of thiocyanate (or one of the other ions as well) in a high enough concentration can cause competitive inhibition of iodide transport into the cell—that is, inhibition of the iodide-trapping mechanism.

The decreased availability of iodide in the glandular cells does not stop the formation of thyroglobulin; it merely prevents the thyroglobulin that is formed from becoming iodinated and therefore from forming thyroid hormones. This deficiency of thyroid hormones in turn leads to increased secretion of TSH by the anterior pituitary gland, which causes overgrowth of the thyroid gland even though the gland still does not form adequate quantities of thyroid hormones. Therefore, the use of thiocyanates and some other ions to block thyroid secretion can lead to the development of a greatly enlarged thyroid gland, which is called a *goiter.*

Propylthiouracil Decreases Thyroid Hormone Formation. Propylthiouracil (along with other similar compounds, such as methimazole and carbimazole) prevents formation of thyroid hormone from iodides and tyrosine. The mechanism of this action is partly to block the peroxidase enzyme that is required for iodination of tyrosine and partly to block the coupling of two iodinated tyrosines to form thyroxine or triiodothyronine.

Propylthiouracil, like thiocyanate, does not prevent formation of thyroglobulin. The absence of thyroxine and triiodothyronine in the thyroglobulin can lead to tremendous feedback enhancement of TSH secretion by the anterior pituitary gland, thus promoting growth of the glandular tissue and forming a goiter.

Iodides in High Concentrations Decrease Thyroid Activity and Thyroid Gland Size. When iodides are present in the blood in a *high concentration* (100 times the normal plasma level), most activities of the thyroid gland are decreased, but often they remain decreased for only a few weeks. The effect is to reduce the rate of iodide trapping so that the rate of iodination of tyrosine to form thyroid hormones is also decreased. Even more important, the normal endocytosis of colloid from the follicles by the thyroid glandular cells is paralyzed by the high iodide concentrations. Because this is the first step in release of thyroid hormones from the storage colloid, there is almost immediate shutdown of thyroid hormone secretion into the blood.

Because iodides in high concentrations decrease all phases of thyroid activity, they slightly decrease the size of the thyroid gland and especially decrease its blood supply, in contradistinction to the opposite effects caused by most of the other antithyroid agents. For this reason, iodides are frequently administered to patients for 2 to 3 weeks before surgical removal of the thyroid gland to decrease the necessary amount of surgery, and especially to decrease the amount of bleeding.

Diseases of the Thyroid

Hyperthyroidism

Most effects of hyperthyroidism are obvious from the preceding discussion of the various physiological effects of thyroid hormone. However, some specific effects should be mentioned, especially in connection with the development, diagnosis, and treatment of hyperthyroidism.

Causes of Hyperthyroidism (Toxic Goiter, Thyrotoxicosis, Graves' Disease). In most patients with hyperthyroidism, the thyroid gland is increased to two to three times its normal size, with tremendous hyperplasia and infolding of the follicular cell lining into the follicles, so the number of cells is increased greatly. Also, each cell increases its rate of secretion severalfold; radioactive iodine uptake studies indicate that some of these hyperplastic glands secrete thyroid hormone at rates 5 to 15 times normal.

Graves' disease, the most common form of hyperthyroidism, is an autoimmune disease in which antibodies called *thyroid-stimulating immunoglobulins* (TSIs) form against the TSH receptor in the thyroid gland. These antibodies bind with the same membrane receptors that bind TSH and induce continual activation of the cAMP system of the cells, with resultant development of hyperthyroidism. The TSI antibodies have a prolonged stimulating effect on the thyroid gland, lasting for as long as 12 hours, in contrast to a little over 1 hour for TSH. The high level of thyroid hormone secretion caused by TSI in turn suppresses anterior pituitary TSH formation. Therefore, TSH concentrations are less than normal (often essentially zero) rather than enhanced in almost all patients with Graves' disease.

The antibodies that cause hyperthyroidism almost certainly occur as the result of autoimmunity that has developed against thyroid tissue. Presumably, at some time in the person's history, an excess of thyroid cell antigens was released from the thyroid cells, resulting in formation of antibodies against the thyroid gland.

Thyroid Adenoma. Hyperthyroidism occasionally results from a localized adenoma (a tumor) that develops in the thyroid tissue and secretes large quantities of thyroid hormone. This presentation is different from the more usual type of hyperthyroidism in that it is usually not associated with evidence of any autoimmune disease. As long as the adenoma continues to secrete large quantities of thyroid hormone, secretory function in the remainder of the thyroid gland is almost totally inhibited because thyroid hormone from the adenoma depresses production of TSH by the pituitary gland.

Symptoms of Hyperthyroidism

The symptoms of hyperthyroidism are obvious from the preceding discussion of the physiology of the thyroid hormones: (1) a high state of excitability, (2) intolerance to heat, (3) increased sweating, (4) mild to extreme weight loss (sometimes as much as 100 pounds), (5)

Figure 77-8 A patient with exophthalmic hyperthyroidism. Note protrusion of the eyes and retraction of the superior eyelids. Her basal metabolic rate was +40. *(Courtesy Dr. Leonard Posey.)*

varying degrees of diarrhea, (6) muscle weakness, (7) nervousness or other psychic disorders, (8) extreme fatigue but inability to sleep, and (9) tremor of the hands.

Exophthalmos. Most people with hyperthyroidism exhibit some degree of protrusion of the eyeballs, as shown in Figure 77-8. This condition is called *exophthalmos.* A major degree of exophthalmos occurs in about one-third of patients with hyperthyroidism, with the condition sometimes becoming so severe that the eyeball protrusion stretches the optic nerve enough to damage vision. Much more often, the eyes are damaged because the eyelids do not close completely when the person blinks or is asleep. As a result, the epithelial surfaces of the eyes become dry and irritated and often infected, resulting in ulceration of the cornea.

The cause of the protruding eyes is edematous swelling of the retro-orbital tissues and degenerative changes in the extraocular muscles. In most patients, immunoglobulins that react with the eye muscles can be found in the blood. Furthermore, the concentration of these immunoglobulins is usually highest in patients who have high concentrations of TSIs. Therefore, exophthalmos, like hyperthyroidism, is likely an autoimmune process. The exophthalmos is usually greatly ameliorated with treatment of the hyperthyroidism.

Diagnostic Tests for Hyperthyroidism. For the usual case of hyperthyroidism, the most accurate diagnostic test is direct measurement of the concentration of "free" thyroxine (and sometimes triiodothyronine) in the plasma, using appropriate immunoassay procedures.

The following tests also are sometimes used:

1. The basal metabolic rate is usually increased to +30 to +60 in severe hyperthyroidism.
2. The concentration of TSH in the plasma is measured by immunoassay. In the usual type of thyrotoxicosis, anterior pituitary secretion of TSH is so completely suppressed by the large amounts of circulating thyroxine and triiodothyronine that there is almost no plasma TSH.
3. The concentration of TSI is measured by immunoassay. This concentration is usually high in thyrotoxicosis but low in thyroid adenoma.

Treatment in Hyperthyroidism. The most direct treatment for hyperthyroidism is surgical removal of most of the thyroid gland. In general, it is desirable to prepare the patient for surgical removal of the gland before the operation by administering propylthiouracil, usually for several weeks, until the basal metabolic rate of the patient has returned to normal. Then, administration of high concentrations of iodides for 1 to 2 weeks immediately before operation causes the gland to recede in size and its blood supply to diminish. With use of these preoperative procedures, the operative mortality is less than 1 in 1000, whereas before the development of modern procedures, operative mortality was 1 in 25.

Treatment of the Hyperplastic Thyroid Gland With Radioactive Iodine. Eighty to 90% of an injected dose of iodide is absorbed by the hyperplastic, toxic thyroid gland within 1 day after injection. If this injected iodine is radioactive, it can destroy most of the secretory cells of the thyroid gland. Usually 5 millicuries of radioactive iodine is given to the patient, whose condition is reassessed several weeks later. If the patient is still in a hyperthyroid state, additional doses are administered until normal thyroid status is reached.

Hypothyroidism

The effects of hypothyroidism, in general, are opposite to those of hyperthyroidism, but a few physiological mechanisms are peculiar to hypothyroidism. Hypothyroidism, like hyperthyroidism, is often initiated by autoimmunity against the thyroid gland (*Hashimoto's disease*), but in this case the autoimmunity destroys the gland rather than stimulates it. The thyroid glands of most of these patients first demonstrate autoimmune "thyroiditis," which means thyroid inflammation. Thyroiditis causes progressive deterioration and finally fibrosis of the gland, with resultant diminished or absent secretion of thyroid hormone. Several other types of hypothyroidism also occur that are often associated with development of enlarged thyroid glands, called *thyroid goiter,* as described in the following sections.

Endemic Colloid Goiter Caused by Dietary Iodide Deficiency. The term "goiter" means a greatly enlarged thyroid gland. As pointed out in the discussion of iodine metabolism, about 50 milligrams of iodine are required *each year* for the formation of adequate quantities of thyroid hormone. In certain areas of the world, notably in the Swiss Alps, the Andes, and the Great Lakes region of the United States, insufficient iodine is present in the soil for the foodstuffs to contain even this minute quantity. Therefore, in the days before iodized table salt, many people who lived in these areas developed extremely large thyroid glands, called *endemic goiters.*

The following mechanism results in the development of large endemic goiters: Lack of iodine prevents production of both thyroxine and triiodothyronine. As a result, no hormone is available to inhibit production of TSH by the anterior pituitary, which causes the pituitary to secrete exces-

sively large quantities of TSH. The TSH then stimulates the thyroid cells to secrete large amounts of thyroglobulin colloid into the follicles, and the gland grows larger and larger. However, because of lack of iodine, thyroxine and triiodothyronine production does not occur in the thyroglobulin molecule and therefore does not cause the normal suppression of TSH production by the anterior pituitary. The follicles greatly enlarge, and the thyroid gland may increase to 10 to 20 times its normal size.

Idiopathic Nontoxic Colloid Goiter. Enlarged thyroid glands similar to those of endemic colloid goiter can also occur in people who do not have iodine deficiency. These goitrous glands may secrete normal quantities of thyroid hormones, but more frequently, the secretion of hormone is depressed, as in endemic colloid goiter.

The exact cause of the enlarged thyroid gland in patients with idiopathic colloid goiter is not known, but most of these patients show signs of mild thyroiditis; therefore, it has been suggested that the thyroiditis causes slight hypothyroidism, which then leads to increased TSH secretion and progressive growth of the noninflamed portions of the gland. This theory could explain why these glands are usually nodular, with some portions of the gland growing while other portions are being destroyed by thyroiditis.

In some persons with colloid goiter, the thyroid gland has an abnormality of the enzyme system required for formation of thyroid hormones. The following abnormalities are often encountered:

1. A *deficient iodide-trapping mechanism,* in which iodine is not pumped adequately into the thyroid cells
2. A *deficient peroxidase system,* in which the iodides are not oxidized to the iodine state
3. *Deficient coupling of iodinated tyrosines in the thyroglobulin molecule* so that the final thyroid hormones cannot be formed
4. *Deficiency of the deiodinase enzyme,* which prevents recovery of iodine from the iodinated tyrosines that are not coupled to form the thyroid hormones (this is about two-thirds of the iodine), thus leading to iodine deficiency

Finally, some foods contain *goitrogenic substances* that have a propylthiouracil-type of antithyroid activity, thus also leading to TSH-stimulated enlargement of the thyroid gland. Such goitrogenic substances are found especially in some varieties of turnips and cabbages.

Physiological Characteristics of Hypothyroidism. Whether hypothyroidism is due to thyroiditis, endemic colloid goiter, idiopathic colloid goiter, destruction of the thyroid gland by irradiation, or surgical removal of the thyroid gland, the physiological effects are the same. They include fatigue and extreme somnolence, with persons sleeping up to 12 to 14 hours a day, extreme muscular sluggishness, a slowed heart rate, decreased cardiac output, decreased blood volume, sometimes increased body weight, constipation, mental sluggishness, failure of many trophic functions in the body as evidenced by depressed growth of hair and scaliness of the skin, development of a froglike, husky voice, and, in severe cases, development of an edematous appearance throughout the body called *myxedema*.

Myxedema. Myxedema develops in persons who have almost total lack of thyroid hormone function. Figure 77-9 shows such a patient, demonstrating bagginess under the eyes and swelling of the face. In this condition, for reasons that are not fully explained, greatly increased quantities of hyaluronic acid and chondroitin sulfate bound with protein form excessive tissue gel in the interstitial spaces, which causes the total quantity of interstitial fluid to increase. Because of the gel nature of the excess fluid, it is mainly immobile and the edema is the nonpitting type.

Figure 77-9 A patient with myxedema. *(Courtesy Dr. Herbert Langford.)*

Atherosclerosis in Hypothyroidism. As pointed out earlier, lack of thyroid hormone increases the quantity of blood cholesterol because of altered fat and cholesterol metabolism and diminished liver excretion of cholesterol in the bile. The increase in blood cholesterol is often associated with increased atherosclerosis. Therefore, many hypothyroid patients, particularly those with myxedema, develop atherosclerosis, which in turn results in peripheral vascular disease, deafness, and coronary artery disease with subsequent early death.

Diagnostic Tests for Hypothyroidism. The tests already described for diagnosis of hyperthyroidism give opposite results in hypothyroidism. The free thyroxine in the blood is low. The basal metabolic rate in myxedema is reduced by 30% to 50%. In addition, the secretion of TSH by the anterior pituitary when a test dose of TRH is administered is usually greatly increased (except in the rare cases of hypothyroidism caused by depressed response of the pituitary gland to TRH).

Treatment of Hypothyroidism. Figure 77-4 shows the effect of thyroxine on basal metabolic rate, demonstrating that the hormone normally has a duration of action of more

than 1 month. Consequently, a steady level of thyroid hormone activity is easily maintained in the body via daily oral ingestion of one or more tablets containing thyroxine. Furthermore, proper treatment of hypothyroidism results in such complete normality that formerly myxedematous patients have lived into their 90s after undergoing treatment for more than 50 years.

Cretinism

Cretinism is caused by extreme hypothyroidism during fetal life, infancy, or childhood. This condition is characterized especially by failure of body growth and by mental retardation. It results from congenital lack of a thyroid gland *(congenital cretinism),* from failure of the thyroid gland to produce thyroid hormone because of a genetic defect of the gland, or from a lack of iodine in the diet *(endemic cretinism).*

A neonate without a thyroid gland may have a normal appearance and function because she or he was supplied with some (but usually not enough) thyroid hormone by the mother while in utero. A few weeks after birth, however, the neonate's movements become sluggish and both physical and mental growth begin to be greatly retarded. Treatment of the neonate with cretinism at any time with adequate iodine or thyroxine usually causes normal return of physical growth, but unless the cretinism is treated within a few weeks after birth, mental growth remains permanently retarded. This state results from retardation of the growth, branching, and myelination of the neuronal cells of the central nervous system at this critical time in the normal development of the mental powers.

Skeletal growth in a child with cretinism is characteristically more inhibited than is soft tissue growth. As a result of this disproportionate rate of growth, the soft tissues are likely to enlarge excessively, giving the child with cretinism an obese, stocky, and short appearance. Occasionally the tongue becomes so large in relation to the skeletal growth that it obstructs swallowing and breathing, inducing a characteristic guttural breathing that sometimes chokes the child.

CHAPTER 78

Adrenocortical Hormones

The two *adrenal glands,* each of which weighs about 4 grams, lie at the superior poles of the two kidneys. As shown in **Figure 78-1**, each gland is composed of two major parts, the *adrenal medulla* and the *adrenal cortex.* The adrenal medulla, the central 20% of the gland, is functionally related to the sympathetic nervous system; it secretes the hormones *epinephrine* and *norepinephrine* in response to sympathetic stimulation. In turn, these hormones cause almost the same effects as direct stimulation of the sympathetic nerves in all parts of the body. These hormones and their effects are discussed in detail in Chapter 61 in relation to the sympathetic nervous system.

The adrenal cortex secretes an entirely different group of hormones, called *corticosteroids.* These hormones are all synthesized from the steroid cholesterol, and they all have similar chemical formulas. However, slight differences in their molecular structures give them several different but very important functions.

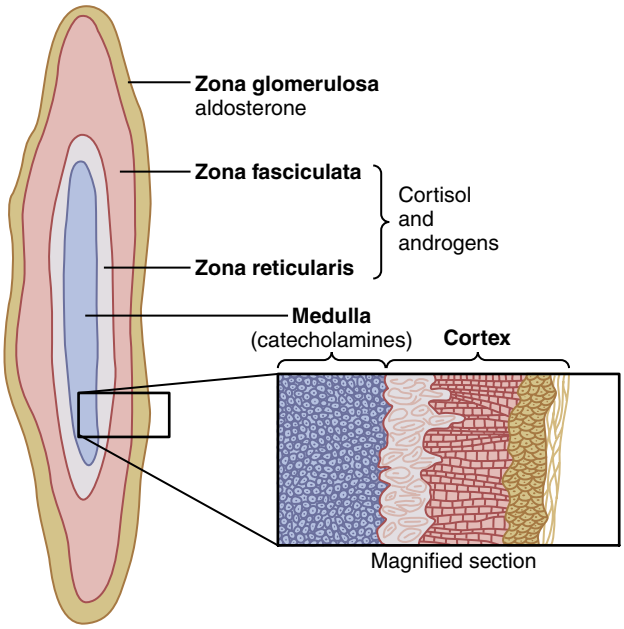

Figure 78-1. Secretion of adrenocortical hormones by the different zones of the adrenal cortex and secretion of catecholamines by the adrenal medulla.

CORTICOSTEROIDS: MINERALOCORTICOIDS, GLUCOCORTICOIDS, AND ANDROGENS

Two major types of adrenocortical hormones, the *mineralocorticoids* and the *glucocorticoids,* are secreted by the adrenal cortex. In addition to these hormones, small amounts of sex hormones are secreted, especially *androgenic hormones,* which exhibit about the same effects in the body as the male sex hormone testosterone. They are normally of only slight importance, although in certain abnormalities of the adrenal cortices, extreme quantities can be secreted (which is discussed later in the chapter) and can result in masculinizing effects.

The *mineralocorticoids* gained this name because they especially affect the electrolytes (the "minerals") of the extracellular fluids, especially sodium and potassium. The *glucocorticoids* gained their name because they exhibit important effects that increase blood glucose concentration. They have additional effects on protein and fat metabolism that are equally as important to body function as their effects on carbohydrate metabolism.

More than 30 steroids have been isolated from the adrenal cortex, but two are of exceptional importance to the normal endocrine function of the human body: *aldosterone,* which is the principal mineralocorticoid, and *cortisol,* which is the principal glucocorticoid.

SYNTHESIS AND SECRETION OF ADRENOCORTICAL HORMONES

THE ADRENAL CORTEX HAS THREE DISTINCT LAYERS

Figure 78-1 shows that the adrenal cortex is composed of three relatively distinct layers:

1. The *zona glomerulosa,* a thin layer of cells that lies just underneath the capsule, constitutes about 15% of the adrenal cortex. These cells are the only ones in the adrenal gland capable of secreting significant amounts of *aldosterone* because they contain the enzyme *aldosterone synthase,* which is necessary for synthesis of aldosterone. The secretion of these cells

is controlled mainly by the extracellular fluid concentrations of *angiotensin II* and *potassium,* both of which stimulate aldosterone secretion.

2. The *zona fasciculata,* the middle and widest zone, constitutes about 75% of the adrenal cortex and secretes the glucocorticoids *cortisol* and *corticosterone,* as well as small amounts of *adrenal androgens* and *estrogens.* The secretion of these cells is controlled in large part by the hypothalamic-pituitary axis via *adrenocorticotropic hormone* (ACTH).
3. The *zona reticularis,* the inner zone of the cortex, secretes the adrenal androgens *dehydroepiandrosterone* and *androstenedione,* as well as small amounts of estrogens and some glucocorticoids. ACTH also regulates secretion of these cells, although other factors such as *cortical androgen-stimulating hormone,* released from the pituitary, may also be involved. The mechanisms for controlling adrenal androgen production, however, are not nearly as well understood as those for glucocorticoids and mineralocorticoids.

Aldosterone and cortisol secretion are regulated by independent mechanisms. Factors such as angiotensin II that specifically increase the output of aldosterone and cause hypertrophy of the zona glomerulosa have no effect on the other two zones. Similarly, factors such as ACTH that increase secretion of cortisol and adrenal androgens and cause hypertrophy of the zona fasciculata and zona reticularis have little effect on the zona glomerulosa.

Adrenocortical Hormones Are Steroids Derived From Cholesterol. All human steroid hormones, including those produced by the adrenal cortex, are synthesized from cholesterol. Although the cells of the adrenal cortex can synthesize de novo small amounts of cholesterol from acetate, approximately 80% of the cholesterol used for steroid synthesis is provided by low-density lipoproteins (LDLs) in the circulating plasma. The LDLs, which have high concentrations of cholesterol, diffuse from the plasma into the interstitial fluid and attach to specific receptors contained in structures called *coated pits* on the adrenocortical cell membranes. The coated pits are then internalized by *endocytosis,* forming vesicles that eventually fuse with cell lysosomes and release cholesterol that can be used to synthesize adrenal steroid hormones.

Transport of cholesterol into the adrenal cells is regulated by feedback mechanisms that can markedly alter the amount available for steroid synthesis. For example, ACTH, which stimulates adrenal steroid synthesis, increases the number of adrenocortical cell receptors for LDL, as well as the activity of enzymes that liberate cholesterol from LDL.

Once the cholesterol enters the cell, it is delivered to the mitochondria, where it is cleaved by the enzyme *cholesterol desmolase* to form *pregnenolone;* this is the rate-limiting step in the eventual formation of adrenal steroids (**Figure 78-2**). In all three zones of the adrenal cortex, this initial step in steroid synthesis is stimulated by the different factors that control secretion of the major hormone products aldosterone and cortisol. For example, both ACTH, which stimulates cortisol secretion, and angiotensin II, which stimulates aldosterone secretion, increase conversion of cholesterol to pregnenolone.

Synthetic Pathways for Adrenal Steroids. **Figure 78-2** gives the principal steps in the formation of the important steroid products of the adrenal cortex: aldosterone, cortisol, and the androgens. Essentially all these steps occur in two of the organelles of the cell, the *mitochondria* and the *endoplasmic reticulum,* with some steps occurring in one of these organelles and some in the other. Each step is catalyzed by a specific enzyme system. A change in even a single enzyme in the schema can cause vastly different types and relative proportions of hormones to be formed. For example, very large quantities of masculinizing sex hormones or other steroid compounds not normally present in the blood can occur with altered activity of only one of the enzymes in this pathway.

The chemical formulas of aldosterone and cortisol, which are the major mineralocorticoid and glucocorticoid hormones, respectively, are shown in **Figure 78-2**. Cortisol has a keto oxygen on carbon number 3 and is hydroxylated at carbon numbers 11 and 21. The mineralocorticoid aldosterone has an oxygen atom bound at the number 18 carbon.

In addition to aldosterone and cortisol, other steroids having glucocorticoid or mineralocorticoid activities, or both, are normally secreted in small amounts by the adrenal cortex. Furthermore, several additional potent steroid hormones not normally formed in the adrenal glands have been synthesized and are used in various forms of therapy. Some of the more important of the corticosteroid hormones, including the synthetic ones, are the following, as summarized in **Table 78-1**.

Mineralocorticoids

- Aldosterone (very potent; accounts for ≈90% of all mineralocorticoid activity)
- Deoxycorticosterone (1/30 as potent as aldosterone, but very small quantities are secreted)
- Corticosterone (slight mineralocorticoid activity)
- 9α-Fluorocortisol (synthetic; slightly more potent than aldosterone)
- Cortisol (slight mineralocorticoid activity, but a large quantity is secreted)
- Cortisone (slight mineralocorticoid activity)

Glucocorticoids

- Cortisol (very potent; accounts for ≈95% of all glucocorticoid activity)
- Corticosterone (provides ≈4% of total glucocorticoid activity, but is much less potent than cortisol)
- Cortisone (almost as potent as cortisol)
- Prednisone (synthetic; four times as potent as cortisol)
- Methylprednisone (synthetic; five times as potent as cortisol)
- Dexamethasone (synthetic; 30 times as potent as cortisol)

It is clear from this list that some of these hormones and synthetic steroids have both glucocorticoid and mineralocorticoid activities. It is especially significant that cortisol normally has some mineralocorticoid activity, because some syndromes of excess cortisol secretion can cause significant mineralocorticoid effects, along with its much more potent glucocorticoid effects.

The intense glucocorticoid activity of the synthetic hormone dexamethasone, which has almost zero mineralocorticoid activity, makes it an especially important drug for stimulating specific glucocorticoid activity.

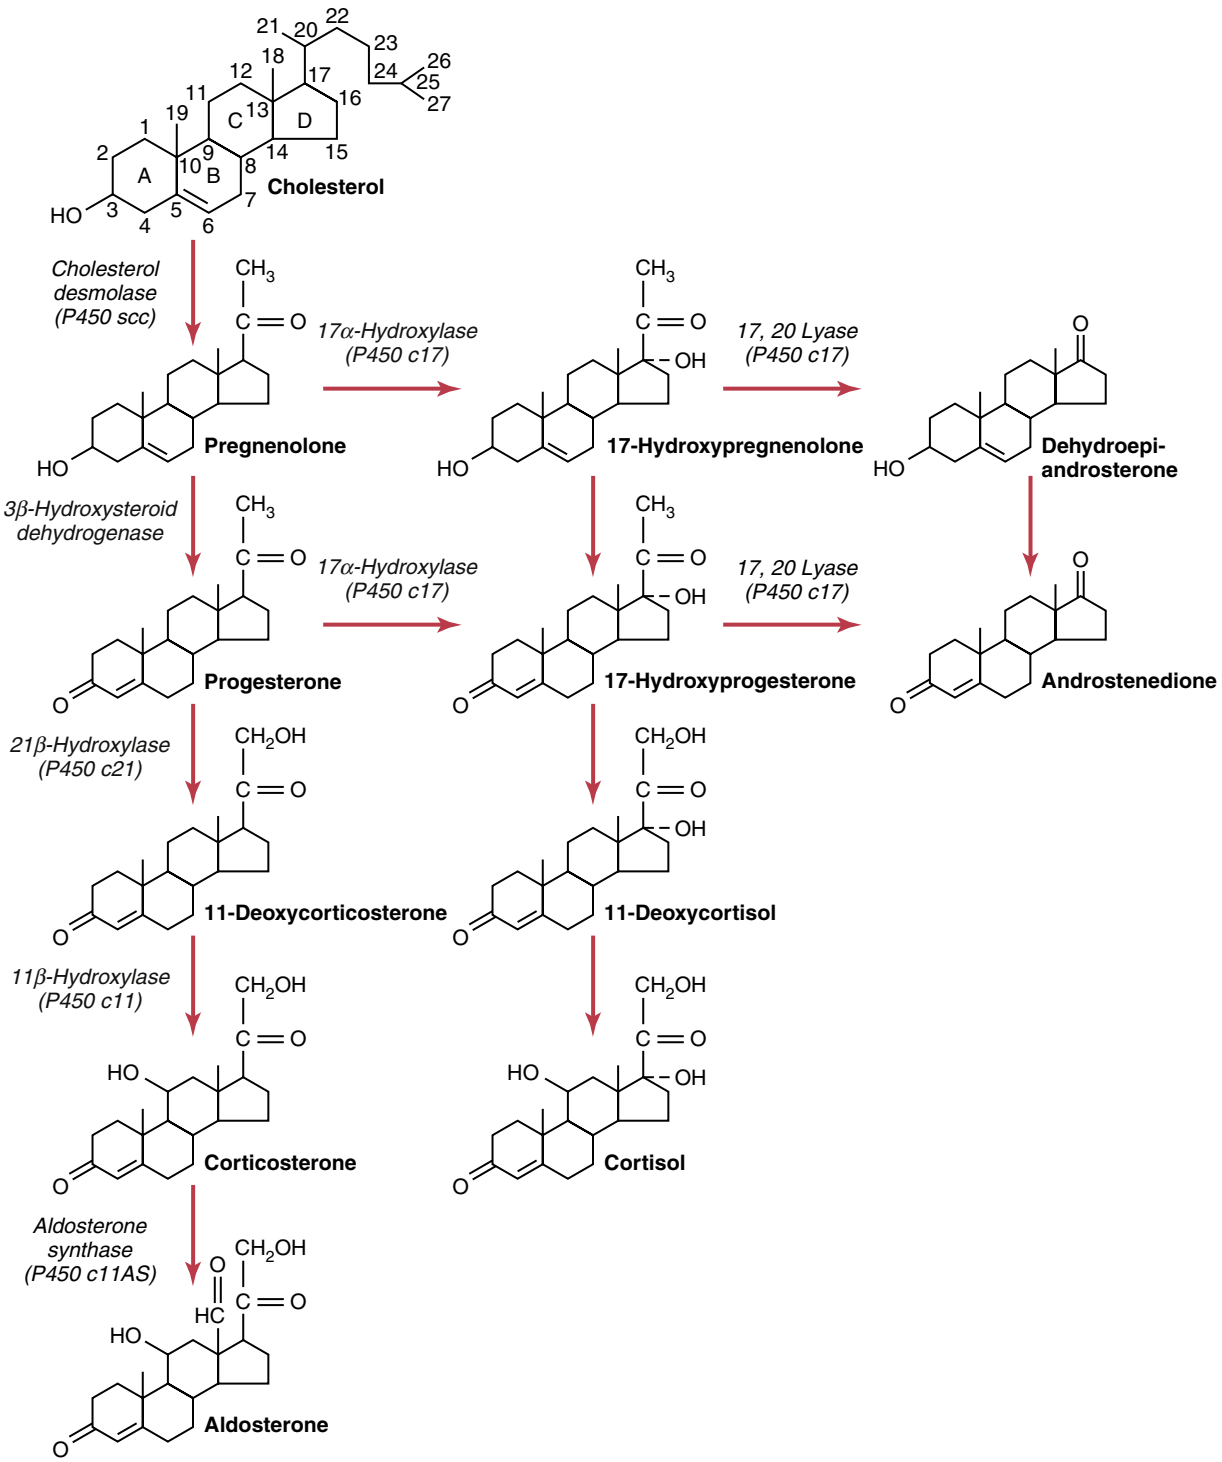

Figure 78-2. Pathways for synthesis of steroid hormones by the adrenal cortex. The enzymes are shown in italics.

Adrenocortical Hormones Are Bound to Plasma Proteins. Approximately 90% to 95% of the cortisol in plasma binds to plasma proteins, especially a globulin called *cortisol-binding globulin* or *transcortin* and, to a lesser extent, to albumin. This high degree of binding to plasma proteins slows the elimination of cortisol from the plasma; therefore, cortisol has a relatively long half-life of 60 to 90 minutes. Only about 60% of circulating aldosterone combines with the plasma proteins, and about 40% is in the free form; as a result, aldosterone has a relatively short half-life of about 20 minutes. These hormones are transported throughout the extracellular fluid compartment in both the combined and free forms.

Binding of adrenal steroids to the plasma proteins may serve as a reservoir to lessen rapid fluctuations in free hormone concentrations, as would occur, for example, with cortisol during brief periods of stress and episodic secretion of ACTH. This reservoir function may also help ensure

Table 78-1 Adrenal Steroid Hormones in Adults; Synthetic Steroids and Their Relative Glucocorticoid and Mineralocorticoid Activities

Steroids	Average Plasma Concentration (free and bound, μg/100 ml)	Average Amount Secreted (mg/24 hr)	Glucocorticoid Activity	Mineralocorticoid Activity
Adrenal steroids				
Cortisol	12	15	1.0	1.0
Corticosterone	0.4	3	0.3	15.0
Aldosterone	0.006	0.15	0.3	3000
Deoxycorticosterone	0.006	0.2	0.2	100
Dehydroepiandrosterone	175	20	—	—
Synthetic steroids				
Cortisone	—	—	0.7	0.5
Prednisolone	—	—	4	0.8
Methylprednisone	—	—	5	—
Dexamethasone	—	—	30	—
9α-Fluorocortisol	—	—	10	125

Glucocorticoid and mineralocorticoid activities of the steroids are relative to cortisol, with cortisol being 1.0.

a relatively uniform distribution of the adrenal hormones to the tissues.

Adrenocortical Hormones Are Metabolized in the Liver. The adrenal steroids are degraded mainly in the liver and are conjugated especially to *glucuronic acid* and, to a lesser extent, to sulfates. These substances are inactive and do not have mineralocorticoid or glucocorticoid activity. About 25% of these conjugates are excreted in the bile and then in the feces. The remaining conjugates formed by the liver enter the circulation but are not bound to plasma proteins, are highly soluble in the plasma, and are therefore filtered readily by the kidneys and excreted in the urine. Diseases of the liver markedly depress the rate of inactivation of adrenocortical hormones, and kidney diseases reduce the excretion of the inactive conjugates.

The normal concentration of aldosterone in blood is about 6 nanograms (6 billionths of a gram) per 100 milliliters, and the average secretory rate is approximately 150 μg/day (0.15 mg/day). The blood concentration of aldosterone, however, depends greatly on several factors, including dietary intake of sodium and potassium.

The concentration of cortisol in the blood averages 12 μg/100 ml, and the secretory rate averages 15 to 20 mg/day. However, blood concentration and secretion rate of cortisol fluctuate throughout the day, rising in the early morning and declining in the evening, as discussed later.

FUNCTIONS OF MINERALOCORTICOIDS—ALDOSTERONE

Mineralocorticoid Deficiency Causes Severe Renal Sodium Chloride Wasting and Hyperkalemia. Total loss of adrenocortical secretion may cause death within 3 to 14 days unless the person receives extensive salt therapy or injection of mineralocorticoids.

Without mineralocorticoids, potassium ion concentration of the extracellular fluid rises markedly, sodium and chloride are rapidly lost from the body, and the total extracellular fluid volume and blood volume become greatly reduced. Diminished cardiac output soon develops, which progresses to a shock-like state, followed by death. This entire sequence can be prevented by administration of aldosterone or some other mineralocorticoid. Therefore, the mineralocorticoids are said to be the acute "lifesaving" portion of the adrenocortical hormones. The glucocorticoids are equally necessary, however, because they allow the person to resist the destructive effects of life's intermittent physical and mental "stresses," as discussed later in the chapter.

Aldosterone Is the Major Mineralocorticoid Secreted by the Adrenals. In humans, aldosterone exerts nearly 90% of the mineralocorticoid activity of the adrenocortical secretions, but cortisol, the major glucocorticoid secreted by the adrenal cortex, also provides a significant amount of mineralocorticoid activity. The mineralocorticoid activity of aldosterone is about 3000 times greater than that of cortisol, but the plasma concentration of cortisol is nearly 2000 times that of aldosterone.

Cortisol can also bind to mineralocorticoid receptors with high affinity. However, the renal epithelial cells express the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which has actions that prevent cortisol from activating mineralocorticoid receptors. One action of 11β-HSD2 is to convert cortisol to cortisone, which does not avidly bind mineralocorticoid receptors. There is also evidence that 11β-HSD2 may have effects on the intracellular redox (reduction and oxidation) state that prevent cortisol from activating the mineralocorticoid receptors. In patients with genetic deficiency of 11β-HSD2 activity, cortisol may have substantial mineralocorticoid effects. This condition is called *apparent mineralocorticoid excess syndrome* (AME) because the patient has essentially the same pathophysiological

changes as a patient with excess aldosterone secretion, except that plasma aldosterone levels are very low in the patient with AME. Ingestion of large amounts of licorice, which contains glycyrrhetinic acid, may also cause AME because of its ability to block 11β-HSD2 enzyme activity.

RENAL AND CIRCULATORY EFFECTS OF ALDOSTERONE

Aldosterone Increases Renal Tubular Reabsorption of Sodium and Secretion of Potassium. As discussed in Chapter 28, aldosterone increases reabsorption of sodium and simultaneously increases secretion of potassium by the renal tubular epithelial cells, especially in the *principal cells of the collecting tubules* and, to a lesser extent, in the distal tubules and collecting ducts. Therefore, aldosterone causes sodium to be conserved in the extracellular fluid while increasing potassium excretion in the urine.

A high concentration of aldosterone in the plasma can transiently decrease the sodium loss into the urine to as little as a few milliequivalents per day. At the same time, potassium loss into the urine transiently increases severalfold. Therefore, the net effect of excess aldosterone in the plasma is to increase the total quantity of sodium in the extracellular fluid while decreasing the potassium.

Conversely, total lack of aldosterone secretion can cause transient loss of 10 to 20 grams of sodium in the urine a day, an amount equal to one tenth to one fifth of all the sodium in the body. At the same time, potassium is conserved tenaciously in the extracellular fluid.

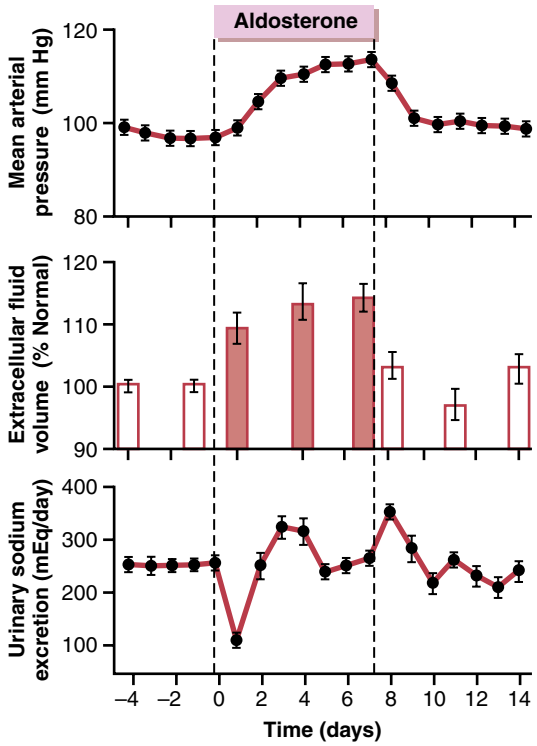

Figure 78-3. Effect of aldosterone infusion on arterial pressure, extracellular fluid volume, and sodium excretion in dogs. Although aldosterone was infused at a rate that raised plasma concentrations to about 20 times normal, note the "escape" from sodium retention on the second day of infusion as arterial pressure increased and urinary sodium excretion returned to normal. *(Data from Hall JE, Granger JP, Smith MJ Jr, et al: Role of hemodynamics and arterial pressure in aldosterone "escape." Hypertension 6[suppl I]:I183-I192, 1984.)*

Excess Aldosterone Increases Extracellular Fluid Volume and Arterial Pressure But Has Only a Small Effect on Plasma Sodium Concentration; Aldosterone Deficiency Causes Hyponatremia. Although aldosterone has a potent effect to decrease the rate of sodium excretion by the kidneys, the concentration of sodium in the extracellular fluid often rises only a few milliequivalents. The reason for this is that when sodium is reabsorbed by the tubules, simultaneous osmotic absorption of almost equivalent amounts of water occurs. Also, small increases in extracellular fluid sodium concentration stimulate thirst and increased water intake, if water is available, and increase secretion of antidiuretic hormone, which enhances water reabsorption by the distal and collecting tubules of the kidneys. Therefore, the extracellular fluid volume increases almost as much as the retained sodium, but without much change in sodium concentration.

Even though aldosterone is one of the body's most powerful sodium-retaining hormones, only transient sodium retention occurs when excess amounts are secreted. An aldosterone-mediated increase in extracellular fluid volume lasting more than 1 to 2 days also leads to an increase in arterial pressure, as explained in Chapter 19. The rise in arterial pressure then increases kidney excretion of both sodium and water, called *pressure natriuresis* and *pressure diuresis,* respectively. Thus, after the extracellular fluid volume increases 5% to 15% above normal, arterial pressure also increases 15 to 25 mm Hg, and this elevated blood pressure returns the renal output of sodium and water to normal despite excess aldosterone (**Figure 78-3**).

This return to normal sodium and water excretion by the kidneys as a result of pressure natriuresis and diuresis is called *aldosterone escape.* Thereafter, the rate of gain of sodium and water by the body is zero, and balance is maintained between sodium and water intake and output by the kidneys, despite continued excess aldosterone. In the meantime, however, hypertension has developed, which lasts as long as the person remains exposed to high levels of aldosterone.

In contrast, severe aldosterone deficiency may cause substantial reductions in plasma sodium concentration (hyponatremia) due to reduced renal sodium reabsorption and increased sodium excretion. The renal sodium wasting causes reductions in extracellular fluid volume, arterial pressure, and cardiac output, which stimulate secretion of antidiuretic hormone (ADH). Increased levels of ADH attenuate renal water excretion and contribute to hyponatremia, along with increases in thirst and water intake that are also stimulated by hypovolemia and hypotension.

When aldosterone secretion becomes zero, large amounts of sodium are lost in the urine, not only

diminishing the amount of sodium chloride in the extracellular fluid but also decreasing the extracellular fluid volume. The result is severe extracellular fluid dehydration and low blood volume, leading to *circulatory shock*. Without therapy, this usually causes death within a few days after the adrenal glands suddenly stop secreting aldosterone.

Excess Aldosterone Causes Hypokalemia and Muscle Weakness; Aldosterone Deficiency Causes Hyperkalemia and Cardiac Toxicity. Excess aldosterone not only causes loss of potassium ions from the extracellular fluid into the urine but also stimulates transport of potassium from the extracellular fluid into most cells of the body. Therefore, excessive secretion of aldosterone, as occurs with some types of adrenal tumors, may cause a serious decrease in the plasma potassium concentration *(hypokalemia),* sometimes from the normal value of 4.5 mEq/L to as low as 2 mEq/L. When plasma potassium ion concentration falls below about one-half normal, severe muscle weakness often develops. This muscle weakness is caused by alteration of the electrical excitability of the nerve and muscle fiber membranes (see Chapter 5), which prevents transmission of normal action potentials.

Conversely, when aldosterone is deficient, the extracellular fluid potassium ion concentration can rise far above normal. When it rises to 60% to 100% above normal, serious cardiac toxicity, including weakness of heart contraction and development of arrhythmia, becomes evident, and progressively higher concentrations of potassium lead inevitably to heart failure.

Excess Aldosterone Increases Tubular Hydrogen Ion Secretion and Causes Alkalosis. Aldosterone not only causes potassium to be secreted into the tubules in exchange for sodium reabsorption in the principal cells of the renal collecting tubules but also causes secretion of hydrogen ions in exchange for potassium in the *intercalated cells* of the cortical collecting tubules, as discussed in Chapters 28 and 31. This decreases the hydrogen ion concentration in the extracellular fluid, causing metabolic alkalosis.

ALDOSTERONE STIMULATES SODIUM AND POTASSIUM TRANSPORT IN SWEAT GLANDS, SALIVARY GLANDS, AND INTESTINAL EPITHELIAL CELLS

Aldosterone has almost the same effects on sweat glands and salivary glands as it has on the renal tubules. Both these glands form a primary secretion that contains large quantities of sodium chloride, but much of the sodium chloride, upon passing through the excretory ducts, is reabsorbed, whereas potassium and bicarbonate ions are secreted. Aldosterone greatly increases the reabsorption of sodium chloride and the secretion of potassium by the ducts. The effect on the sweat glands is important to conserve body salt in hot environments (see Chapter 74), and the effect on the salivary glands is necessary to conserve salt when excessive quantities of saliva are lost.

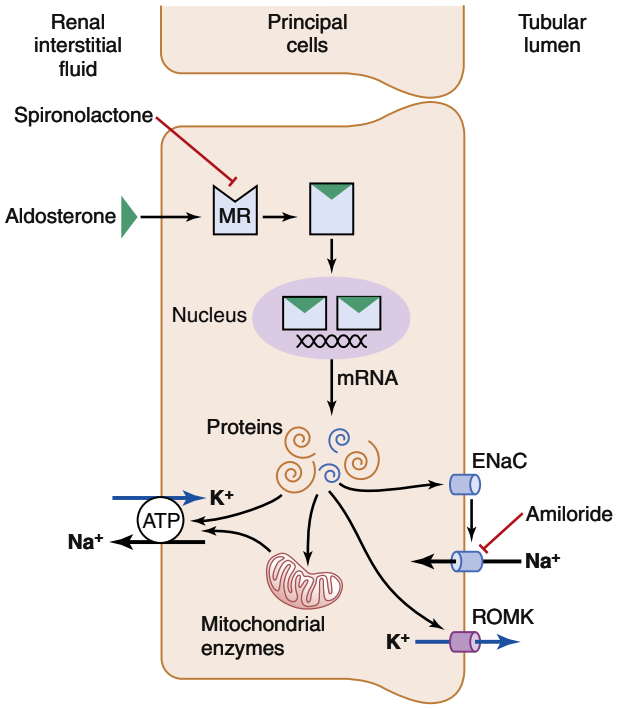

Figure 78-4. Aldosterone-responsive epithelial cell signaling pathways. Activation of the mineralocorticoid receptor (MR) by aldosterone can be antagonized with spironolactone. Amiloride is a drug that can be used to block epithelial sodium channel (ENaC) proteins. ATP, ROMK, Renal outer medullary potassium channel.

Aldosterone also greatly enhances sodium absorption by the intestines, especially in the colon, which prevents loss of sodium in the stools. Conversely, in the absence of aldosterone, sodium absorption can be poor, leading to failure to absorb chloride and other anions and water as well. The unabsorbed sodium chloride and water then lead to diarrhea, with further loss of salt from the body.

CELLULAR MECHANISM OF ALDOSTERONE ACTION

Although for many years we have known the overall effects of mineralocorticoids on the body, the molecular mechanisms of the actions of aldosterone on the tubular cells to increase transport of sodium are still not fully understood. However, the cellular sequence of events that leads to increased sodium reabsorption seems to unfold as follows.

First, because of its lipid solubility in the cellular membranes, aldosterone diffuses readily to the interior of the tubular epithelial cells.

Second, in the cytoplasm of the tubular cells, aldosterone combines with a highly specific cytoplasmic *mineralocorticoid receptor* (MR) protein (**Figure 78-4**), which has a stereomolecular configuration that allows only aldosterone or similar compounds to combine with it. Although renal tubular epithelial cell MR receptors also have a high affinity for cortisol, the enzyme 11β-HSD2

normally converts most of the cortisol to cortisone, which does not readily bind to MR receptors, as discussed previously.

Third, the aldosterone-receptor complex or a product of this complex diffuses into the nucleus, where it may undergo further alterations, finally inducing one or more specific portions of the DNA to form one or more types of messenger RNA (mRNA) related to the process of sodium and potassium transport.

Fourth, the mRNA diffuses back into the cytoplasm where, operating in conjunction with the ribosomes, it causes protein formation. The proteins formed are a mixture of (1) one or more enzymes and (2) membrane transport proteins that, all acting together, are required for sodium, potassium, and hydrogen transport through the cell membrane (see **Figure 78-4**). One of the enzymes especially increased is *sodium-potassium adenosine triphosphatase* (Na^+-K^+ ATPase), which serves as the principal part of the pump for sodium and potassium exchange at the *basolateral membranes* of the renal tubular cells. Additional proteins, perhaps equally important, are *epithelial sodium channels* and *potassium channels* inserted into the *luminal membrane* of the same tubular cells; these channels allow rapid diffusion of sodium ions from the tubular lumen into the cell and diffusion of potassium from the cell interior to the tubular lumen. (See Chapters 28 and 30 for further discussion of the effects of aldosterone on sodium, potassium, and hydrogen transport by renal tubular epithelial cells.)

Thus, aldosterone does not have a major immediate effect on sodium transport; rather, this effect must await the sequence of events that leads to the formation of the specific intracellular substances required for sodium transport. About 30 minutes is required before new RNA appears in the cells, and about 45 minutes is required before the rates of sodium and potassium transport begin to increase; these effects reach a maximum only after several hours.

POSSIBLE NONGENOMIC ACTIONS OF ALDOSTERONE AND OTHER STEROID HORMONES

Some studies suggest that many steroids, including aldosterone, elicit not only slowly developing *genomic* effects that have a latency of 45 to 60 minutes and require gene transcription and synthesis of new proteins but also more rapid *nongenomic* effects that take place in a few seconds or minutes.

These nongenomic actions are believed to be mediated by binding of steroids to cell membrane receptors that are coupled to second messenger systems, similar to those used for peptide hormone signal transduction. For example, aldosterone has been shown to increase formation of cyclic adenosine monophosphate (cAMP) in vascular smooth muscle cells and in epithelial cells of the renal collecting tubules in less than 2 minutes, a period that is far too short for gene transcription and synthesis of new proteins. In other cell types, aldosterone has been shown to rapidly stimulate the phosphatidylinositol second messenger system. However, the precise structure of receptors responsible for the rapid effects of aldosterone has not been determined, nor is the physiological significance of these nongenomic actions of steroids well understood.

REGULATION OF ALDOSTERONE SECRETION

Regulation of aldosterone secretion is so deeply intertwined with regulation of extracellular fluid electrolyte concentrations, extracellular fluid volume, blood volume, arterial pressure, and many special aspects of renal function that it is difficult to discuss control of aldosterone secretion independently of all these other factors. This subject is presented in more detail in Chapters 28 and 30, to which the reader is referred. However, it is important to list here some of the more important points of aldosterone secretion control.

Regulation of aldosterone secretion by the zona glomerulosa cells is almost entirely independent of regulation of cortisol and androgens by the zona fasciculata and zona reticularis.

The following factors are known to play roles in regulation of aldosterone:

1. Increased potassium ion concentration in the extracellular fluid greatly *increases* aldosterone secretion.
2. Increased angiotensin II concentration in the extracellular fluid also greatly *increases* aldosterone secretion.
3. Increased sodium ion concentration in the extracellular fluid *slightly decreases* aldosterone secretion.
4. Increased atrial natriuretic peptide (ANP), a hormone secreted by the heart when specific cells of the cardiac atria are stretched (see Chapter 28), *decreases* aldosterone secretion.
5. ACTH from the anterior pituitary gland is necessary for aldosterone secretion but has little effect in controlling the rate of secretion in most physiological conditions.

Of these factors, *potassium ion concentration* and the *angiotensin II* are by far the most potent in regulating aldosterone secretion. A small percentage increase in potassium concentration can cause a severalfold increase in aldosterone secretion. Likewise, increased angiotensin II,, usually in response to diminished blood flow to the kidneys or to sodium loss, can increase aldosterone secretion severalfold. In turn, the aldosterone acts on the kidneys (1) to help them excrete the excess potassium ions and (2) to increase the blood volume and arterial pressure, thus returning the renin-angiotensin system toward its normal level of activity. These feedback control mechanisms are essential for maintaining life, and the reader is referred again to Chapters 28 and 30 for a more complete description of their functions.

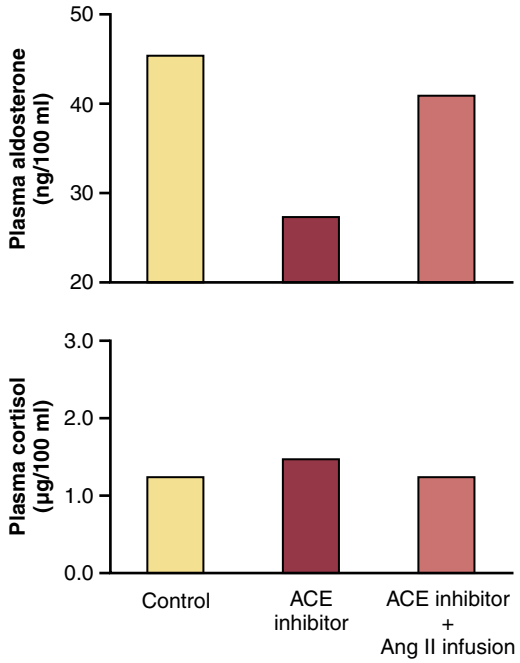

Figure 78-5. Effects of treating sodium-depleted dogs with an angiotensin-converting enzyme (ACE) inhibitor for 7 days to block formation of angiotensin II (Ang II) and of infusing exogenous Ang II to restore plasma Ang II levels after ACE inhibition. Note that blocking Ang II formation reduced plasma aldosterone concentration with little effect on cortisol, demonstrating the important role of Ang II in stimulating aldosterone secretion during sodium depletion. *(Data from Hall JE, Guyton AC, Smith MJ Jr, et al: Chronic blockade of angiotensin II formation during sodium deprivation. Am J Physiol 237:F424, 1979.)*

Figure 78-5 shows the effects on plasma aldosterone concentration caused by blocking formation of angiotensin II with an angiotensin-converting enzyme inhibitor after several weeks of a low-sodium diet that increases plasma aldosterone concentration. Note that blockade of angiotensin II formation markedly decreased plasma aldosterone concentration without significantly changing cortisol concentration, which indicates the important role of angiotensin II in stimulating aldosterone secretion when sodium intake and extracellular fluid volume are reduced.

By contrast, the effects of ANP, sodium ion concentration per se, and ACTH in controlling aldosterone secretion are usually minor. Nevertheless, a 10% to 20% decrease in extracellular fluid sodium ion concentration, which occurs on rare occasions, can perhaps increase aldosterone secretion by about 50%. An increase in ANP concentration, secondary to plasma volume expansion and stretch of the cardiac atria, may induce natriuresis, in part by inhibiting aldosterone secretion. In the case of ACTH, if even a small amount is secreted by the anterior pituitary gland, it is usually enough to permit the adrenal glands to secrete whatever amount of aldosterone is required, but total absence of ACTH can significantly reduce aldosterone secretion. Therefore, ACTH appears to play a "permissive" role in regulation of aldosterone secretion.

FUNCTIONS OF GLUCOCORTICOIDS

Even though mineralocorticoids can save the life of an acutely adrenalectomized animal, the animal still is far from normal. Instead, the animal's metabolic systems for utilization of proteins, carbohydrates, and fats remain considerably deranged. Furthermore, the animal cannot resist different types of physical or even mental stress, and minor illnesses such as respiratory tract infections can lead to death. Therefore, the glucocorticoids have functions just as important to the long-continued life of the animal as those of the mineralocorticoids. These functions are explained in the following sections.

At least 95% of the glucocorticoid activity of the adrenocortical secretions results from the secretion of *cortisol,* known also as *hydrocortisone.* In addition, a small but significant amount of glucocorticoid activity is provided by *corticosterone.*

EFFECTS OF CORTISOL ON CARBOHYDRATE METABOLISM

Stimulation of Gluconeogenesis. The best-known metabolic effect of cortisol and other glucocorticoids on metabolism is the ability to stimulate gluconeogenesis (i.e., the formation of carbohydrate from proteins and some other substances) by the liver, often increasing the rate of gluconeogenesis as much as 6- to 10-fold. This increased rate of gluconeogenesis results mainly from direct effects of cortisol on the liver, as well as by antagonizing the effects of insulin.

1. *Cortisol increases the enzymes required to convert amino acids into glucose in liver cells.* Glucocorticoids activate DNA transcription in the liver cell nuclei in the same way that aldosterone functions in renal tubular cells, with formation of mRNAs that in turn lead to the array of enzymes required for gluconeogenesis.
2. *Cortisol causes mobilization of amino acids from extrahepatic tissues, mainly from muscle.* As a result, more amino acids become available in the plasma to enter into the gluconeogenesis process of the liver and thereby to promote formation of glucose.
3. *Cortisol antagonizes insulin's effects to inhibit gluconeogenesis in the liver.* As discussed in Chapter 79, insulin stimulates glycogen synthesis in the liver and inhibits enzymes involved in glucose production by the liver. The net effect of cortisol is to increase glucose production by the liver.

The marked increase in glycogen storage in liver cells that accompanies increased gluconeogenesis potentiates the effects of other glycolytic hormones, such as epinephrine and glucagon, to mobilize glucose in times of need, such as between meals.

Decreased Glucose Utilization by Cells. Cortisol also causes a moderate decrease in glucose utilization by most cells in the body. Although the precise cause of this decrease is unclear, one important effect of cortisol is to decrease translocation of the glucose transporter *GLUT 4* to the cell membrane, especially in skeletal muscle cells, leading to *insulin resistance*. Glucocorticoids may also depress the expression and phosphorylation of other signaling cascades that influence glucose utilization directly or indirectly by affecting protein and lipid metabolism. For example, glucocorticoids reduce the expression of insulin receptor substrate–1 and phosphatidylinositol 3 kinase, both of which are involved in mediating the actions of insulin, as well as oxidation of nicotinamide-adenine dinucleotide (NADH) to form NAD^+. Because NADH must be oxidized to allow glycolysis, this effect could also contribute to diminished utilization of glucose by the cells.

Elevated Blood Glucose Concentration and "Adrenal Diabetes." Both the increased gluconeogenesis and moderate reduction in glucose utilization by the cells cause the blood glucose concentrations to rise. The rise in blood glucose in turn stimulates insulin secretion. The increased plasma levels of insulin, however, are not as effective in maintaining plasma glucose as they are under normal conditions. For reasons that were discussed previously, high levels of glucocorticoid reduce the sensitivity of many tissues, especially skeletal muscle and adipose tissue, to the stimulatory effects of insulin on glucose uptake and utilization. Besides potential direct effects of cortisol on expression of glucose transporters and enzymes involved in glucose regulation, the high levels of fatty acids, caused by the effect of glucocorticoids to mobilize lipids from fat depots, may impair the actions of insulin on the tissues. In this way, excess secretion of glucocorticoids produce disturbances of carbohydrate metabolism similar to those found in patients with excess levels of growth hormone.

The increase in blood glucose concentration is occasionally great enough (≥50% normal) that the condition is called *adrenal diabetes.* Administration of insulin lowers the blood glucose concentration only a moderate amount in adrenal diabetes—not nearly as much as it does in pancreatic diabetes—because the tissues are resistant to the effects of insulin.

EFFECTS OF CORTISOL ON PROTEIN METABOLISM

Reduction in Cellular Protein. One of the principal effects of cortisol on the metabolic systems of the body is reduction of protein stores in essentially all cells of the body, except those of the liver. This reduction is caused by both decreased protein synthesis and increased catabolism of protein already in the cells. Both these effects may result partly from decreased amino acid transport into extrahepatic tissues, as discussed later, but this is probably not the major cause because cortisol also depresses formation of RNA and subsequent protein synthesis in many extrahepatic tissues, especially in muscle and lymphoid tissue.

In the presence of great excesses of cortisol, the muscles can become so weak that the person cannot rise from the squatting position. In addition, the immunity functions of the lymphoid tissue can be decreased to a small fraction of normal.

Cortisol Increases Liver and Plasma Proteins. Coincidentally with the effect of glucocorticoids to reduce proteins elsewhere in the body, the liver proteins are increased. Furthermore, the plasma proteins (which are produced by the liver and then released into the blood) are also increased. These increases are exceptions to the protein depletion that occurs elsewhere in the body. It is believed that this difference results from a possible effect of cortisol to enhance amino acid transport into liver cells—but not into most other cells—and to enhance the liver enzymes required for protein synthesis.

Increased Blood Amino Acids, Diminished Transport of Amino Acids Into Extrahepatic Cells, and Enhanced Transport Into Hepatic Cells. Studies in isolated tissues have demonstrated that cortisol depresses amino acid transport into muscle cells and perhaps into other extrahepatic cells.

The decreased transport of amino acids into extrahepatic cells decreases their intracellular amino acid concentrations and consequently decreases the synthesis of protein. Yet, cell catabolism of proteins continues to release amino acids that diffuse out of the cells to increase the plasma amino acid concentration. Therefore, *cortisol mobilizes amino acids from nonhepatic tissues* and in doing so diminishes tissue stores of protein.

The increased plasma concentration of amino acids and enhanced amino acid transport into the hepatic cells by cortisol could also account for enhanced utilization of amino acids by the liver to cause such effects as (1) increased rate of deamination of amino acids by the liver, (2) increased protein synthesis in the liver, (3) increased formation of plasma proteins by the liver, and (4) increased conversion of amino acids to glucose—that is, enhanced gluconeogenesis. Thus, it is possible that many of the effects of cortisol on the metabolic systems of the body result mainly from this ability of cortisol to mobilize amino acids from the peripheral tissues while at the same time increasing the liver enzymes required for the hepatic effects.

EFFECTS OF CORTISOL ON FAT METABOLISM

Mobilization of Fatty Acids. In much the same manner that cortisol promotes amino acid mobilization from muscle, it also promotes mobilization of fatty acids from

adipose tissue. This mobilization increases the concentration of free fatty acids in the plasma, which also increases their utilization for energy. Cortisol also seems to have a direct effect to enhance the oxidation of fatty acids in the cells.

The mechanism by which cortisol promotes fatty acid mobilization is not completely understood. However, part of the effect probably results from diminished transport of glucose into the fat cells. Recall that α-glycerophosphate, which is derived from glucose, is required for both deposition and maintenance of triglycerides in these cells. In its absence, the fat cells begin to release fatty acids.

The increased mobilization of fats by cortisol, combined with increased oxidation of fatty acids in the cells, helps shift the metabolic systems of the cells from utilization of glucose for energy to utilization of fatty acids in times of starvation or other stresses. This cortisol mechanism, however, requires several hours to become fully developed—not nearly so rapid or so powerful an effect as a similar shift elicited by a decrease in insulin, as we discuss in Chapter 79. Nevertheless, the increased use of fatty acids for metabolic energy is an important factor for long-term conservation of body glucose and glycogen.

Excess Cortisol Causes Obesity. Although cortisol can cause a moderate degree of fatty acid mobilization from adipose tissue, a peculiar type of obesity develops in many people with excess cortisol secretion, with excess deposition of fat in the chest and head regions of the body, giving a buffalo-like torso and a rounded "moon face." Although the cause is unclear, it has been suggested that this obesity results from excess stimulation of food intake, with fat being generated in some tissues of the body more rapidly than it is mobilized and oxidized.

CORTISOL IS IMPORTANT IN RESISTING STRESS AND INFLAMMATION

Almost any type of stress, whether physical or neurogenic, causes an immediate and marked increase in ACTH secretion by the anterior pituitary gland, followed within minutes by greatly increased adrenocortical secretion of cortisol. This effect is demonstrated dramatically by the experiment shown in **Figure 78-6**, in which corticosteroid formation and secretion increased sixfold in a rat within 4 to 20 minutes after fracture of two leg bones.

The following list details some of the different types of stress that increase cortisol release:

1. Trauma
2. Infection
3. Intense heat or cold
4. Injection of norepinephrine and other sympathomimetic drugs
5. Surgery
6. Injection of necrotizing substances beneath the skin
7. Restraining an animal so it cannot move
8. Debilitating diseases

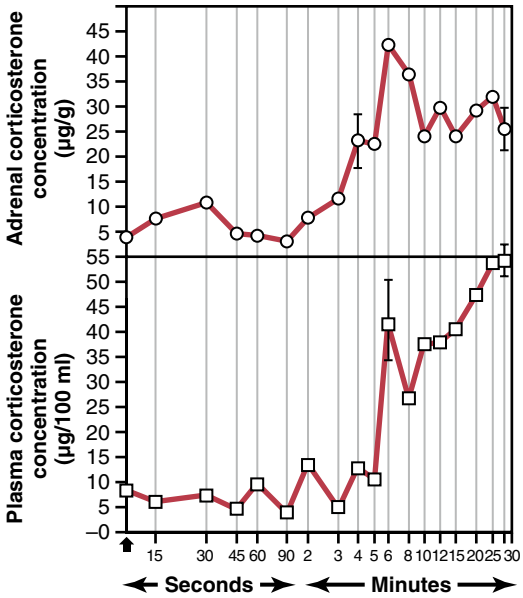

Figure 78-6. Rapid reaction of the adrenal cortex of a rat to stress caused by fracture of the tibia and fibula at time zero. (In the rat, corticosterone is secreted in place of cortisol.)

Even though cortisol secretion often increases greatly in stressful situations, we are not sure why this is of significant benefit to the animal. One possibility is that the glucocorticoids cause rapid mobilization of amino acids and fats from their cellular stores, making them immediately available both for energy and for synthesis of other compounds, including glucose, needed by different tissues of the body. Indeed, it has been shown in a few instances that damaged tissues that are momentarily depleted of proteins can use the newly available amino acids to form new proteins that are essential to the lives of the cells. Also, the amino acids are perhaps used to synthesize other essential intracellular substances, such as purines, pyrimidines, and creatine phosphate, which are necessary for maintenance of cellular life and reproduction of new cells.

All this is mainly supposition and is supported only by the fact that cortisol usually does not mobilize the basic functional proteins of the cells, such as the muscle contractile proteins and the proteins of neurons, until almost all other proteins have been released. This preferential effect of cortisol in mobilizing labile proteins could make amino acids available to needy cells to synthesize substances essential to life.

Anti-inflammatory Effects of High Levels of Cortisol

When tissues are damaged by trauma, by infection with bacteria, or in other ways, they almost always become "inflamed." In some conditions, such as in rheumatoid arthritis, the inflammation is more damaging than the trauma or disease itself. Administration of large amounts of cortisol can usually block this inflammation or even reverse many of its effects once it has begun. Before attempting to explain the way in which cortisol functions

to block inflammation, let us review the basic steps in the inflammation process, which are discussed in more detail in Chapter 34.

Five main stages of inflammation occur: (1) release from the damaged tissue cells of chemicals such as histamine, bradykinin, proteolytic enzymes, prostaglandins, and leukotrienes that activate the inflammation process; (2) an increase in blood flow in the inflamed area caused by some of the released products from the tissues, an effect called *erythema;* (3) leakage of large quantities of almost pure plasma out of the capillaries into the damaged areas because of increased capillary permeability, followed by clotting of the tissue fluid, thus causing a *nonpitting type of edema;* (4) infiltration of the area by leukocytes; and (5) after days or weeks, ingrowth of fibrous tissue that often helps in the healing process.

When large amounts of cortisol are secreted or injected into a person, the glucocorticoid has two basic *anti-inflammatory effects:* (1) it can block the early stages of the inflammation process before noticeable inflammation even begins, or (2) if inflammation has already begun, it causes rapid resolution of the inflammation and increased rapidity of healing. These effects are explained further in the following sections.

Cortisol Prevents the Development of Inflammation by Stabilizing Lysosomes and by Other Effects. Cortisol has the following effects in preventing inflammation:

1. *Cortisol stabilizes lysosomal membranes.* This stabilization is one of its most important anti-inflammatory effects because it is much more difficult than normal for the membranes of the intracellular lysosomes to rupture. Therefore, the proteolytic enzymes that are stored in lysosomes and are released by damaged cells to cause inflammation are released in greatly decreased quantities.
2. *Cortisol decreases permeability of the capillaries,* probably as a secondary effect of the reduced release of proteolytic enzymes. This decrease in permeability prevents loss of plasma into the tissues.
3. *Cortisol decreases migration of white blood cells into the inflamed area and phagocytosis of the damaged cells.* These effects probably result from the fact that cortisol diminishes formation of prostaglandins and leukotrienes that otherwise would increase vasodilation, capillary permeability, and mobility of white blood cells.
4. *Cortisol suppresses the immune system, causing lymphocyte reproduction to decrease markedly.* The T lymphocytes are especially suppressed. In turn, reduced amounts of T cells and antibodies in the inflamed area lessen tissue reactions that would otherwise promote inflammation.
5. *Cortisol attenuates fever mainly because it reduces release of interleukin-1 from white blood cells,* which is one of the principal excitants to the hypothalamic temperature control system. The decreased temperature in turn reduces the degree of vasodilation.

Thus, cortisol has an almost global effect in reducing all aspects of the inflammatory process. It is unclear how much of this reduction results from the simple effect of cortisol in stabilizing lysosomal and cell membranes versus its effect in reducing the formation of prostaglandins and leukotrienes from arachidonic acid in damaged cell membranes and other effects of cortisol.

Cortisol Causes Resolution of Inflammation. Even after inflammation has become well established, administration of cortisol can often reduce inflammation within hours to a few days. The immediate effect is to block most of the factors that promote inflammation. In addition, however, the rate of healing is enhanced. This probably results from the same, mainly undefined, factors that allow the body to resist many other types of physical stress when large quantities of cortisol are secreted. Perhaps this results from (1) mobilization of amino acids and use of these acids to repair the damaged tissues; (2) increased glucogenesis that makes extra glucose available in critical metabolic systems; (3) increased amounts of fatty acids available for cellular energy; or (4) some effect of cortisol for inactivating or removing inflammatory products.

Regardless of the precise mechanisms by which the anti-inflammatory effect occurs, this effect of cortisol plays a major role in combating certain types of diseases, such as rheumatoid arthritis, rheumatic fever, and acute glomerulonephritis. All these diseases are characterized by severe local inflammation, and the harmful effects on the body are caused mainly by the inflammation associated with the disease.

When cortisol or other glucocorticoids are administered to patients with these diseases, almost invariably the inflammation begins to subside within 24 hours. Even though the cortisol does not correct the basic disease condition, preventing the damaging effects of the inflammatory response can often be a lifesaving measure.

Other Effects of Cortisol

Cortisol Blocks the Inflammatory Response to Allergic Reactions. The basic allergic reaction between antigen and antibody is not affected by cortisol, and even some of the secondary effects of the allergic reaction still occur. However, because the inflammatory response is responsible for many of the serious and sometimes lethal effects of allergic reactions, administration of cortisol, followed by its effect in reducing inflammation and release of inflammatory products, can be lifesaving. For instance, cortisol effectively prevents shock or death as a result of anaphylaxis, a condition that otherwise kills many people, as explained in Chapter 35.

Effect on Blood Cells and on Immunity in Infectious Diseases. Cortisol decreases the number of eosinophils and lymphocytes in the blood; this effect begins within a few minutes after injection of cortisol and becomes marked within a few hours. Indeed, a finding of lymphocytopenia or eosinopenia is an important diagnostic criterion for overproduction of cortisol by the adrenal gland.

Likewise, administration of large doses of cortisol causes significant atrophy of lymphoid tissue throughout the body, which in turn decreases output of T cells and antibodies from the lymphoid tissue. As a result, the level of immunity for almost all foreign invaders of the body is decreased. This decrease occasionally can lead to fulminating infection and death from diseases that would otherwise not be lethal, such as fulminating tuberculosis in a person whose disease had previously been arrested. However, this ability of cortisol and other glucocorticoids to suppress immunity makes them useful drugs in preventing immunological rejection of transplanted hearts, kidneys, and other tissues.

Cortisol increases production of red blood cells by mechanisms that are unclear. When excess cortisol is secreted by the adrenal glands, polycythemia often results, and conversely, when the adrenal glands secrete no cortisol, anemia often results.

Cellular Mechanism of Cortisol Action

Cortisol, like other steroid hormones, exerts its effects by first interacting with intracellular receptors in target cells. Because cortisol is lipid soluble, it can easily diffuse through the cell membrane. Once inside the cell, cortisol binds with its protein receptor in the cytoplasm, and the hormone-receptor complex then interacts with specific regulatory DNA sequences, called *glucocorticoid response elements,* to induce or repress gene transcription. Other proteins in the cell, called *transcription factors,* are also necessary for the hormone-receptor complex to interact appropriately with the glucocorticoid response elements.

Glucocorticoids increase or decrease transcription of many genes to alter synthesis of mRNA for the proteins that mediate their multiple physiological effects. Thus, most of the metabolic effects of cortisol are not immediate but require 45 to 60 minutes for proteins to be synthesized, and up to several hours or days to fully develop. Some evidence suggests that glucocorticoids, especially at high concentrations, may also have some rapid *nongenomic effects* on cell membrane ion transport that may contribute to their therapeutic benefits.

Modulation of Glucocorticoid Effects by 11β-Hydroxysteroid Dehydrogenase

An important mechanism for modulating the physiological effects of cortisol is local tissue expression of isoforms of the enzyme 11β-hydroxysteroid dehydrogenase (11β-HSD). As discussed previously, one isoform, 11β-HSD2, metabolizes cortisol to inactive cortisone at the pre-receptor level in the renal tubules and therefore protects the mineralocorticoid receptor from activation by cortisol. This enzyme is also present in other tissues such as the colon, sweat glands, salivary glands, and the placenta (**Figure 78-7**). When 11β-HSD2 is deficient, as in *apparent mineralocorticoid excess syndrome* due to genetic mutations or excessive licorice ingestion, or when circulating cortisol concentrations are extremely high, as in Cushing's syndrome, this mechanism for cortisol metabolism may be overwhelmed. As a result, the high levels of cortisol strongly activate the mineralocorticoid receptor and cause sodium retention, hypertension, and hypokalemia.

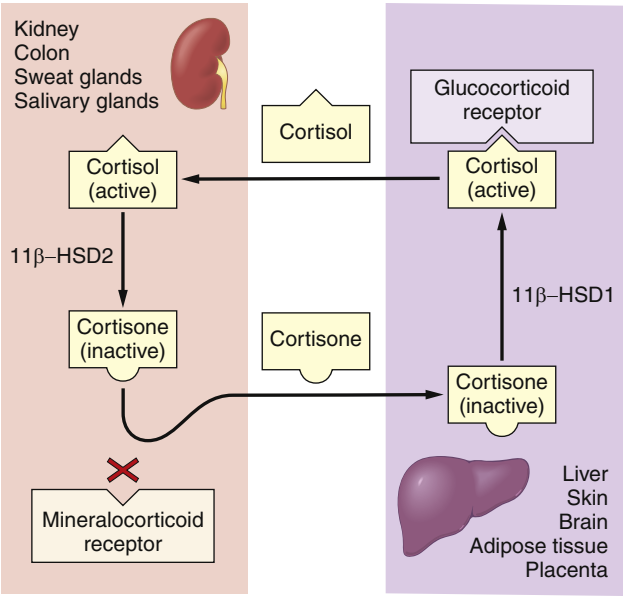

Figure 78-7. Interconversion of active cortisol and inactive cortisone by the two 11β-hydroxysteroid dehydrogenase isoforms (11β-HSD1 and 11β-HSD2) in various tissues.

Conversely, tissues such as the liver, brain, adipose tissue, skeletal muscle, lung, and skin express another isoform, 11β-HSD1, which converts inactive cortisone to active cortisol (see **Figure 78-7**). Thus, 11β-HSD1 expression amplifies the physiological effects of glucocorticoids in tissues whereas 11β-HSD2 has the opposite effect. For this reason the isoforms of 11β-HSD2 may serve as intracellular "gate-keepers" of tissue glucocorticoid action.

Some studies suggest that increased adipose tissue expression of 11β-HSD1 and excessive glucocorticoid activity may contribute to the metabolic abnormalities, including insulin resistance and diabetes mellitus, associated with obesity. Elevated brain 11β-HSD1 has also been associated with cognitive decline in aging. However, the physiological factors that regulate these isoforms of 11β-HSD and their role in common diseases such as obesity and dementia are still poorly understood.

REGULATION OF CORTISOL SECRETION BY ADRENOCORTICOTROPIC HORMONE FROM THE PITUITARY GLAND

ACTH Stimulates Cortisol Secretion. Unlike aldosterone secretion by the zona glomerulosa, which is controlled mainly by potassium and angiotensin II acting directly on the adrenocortical cells, secretion of cortisol is controlled almost entirely by ACTH that is secreted by the anterior pituitary gland. This hormone, also called *corticotropin* or *adrenocorticotropin,* also enhances the production of adrenal androgens.

Chemistry of ACTH. ACTH has been isolated in pure form from the anterior pituitary. It is a large polypeptide, having a chain length of 39 amino acids. A smaller polypeptide, a digested product of ACTH having a chain

length of 24 amino acids, has all the effects of the total molecule.

ACTH Secretion Is Controlled by Corticotropin-Releasing Factor From the Hypothalamus. In the same way that other pituitary hormones are controlled by releasing factors from the hypothalamus, an important releasing factor also controls ACTH secretion. This factor is called *corticotropin-releasing factor* (CRF). It is secreted into the primary capillary plexus of the hypophysial portal system in the median eminence of the hypothalamus and then carried to the anterior pituitary gland, where it induces ACTH secretion. CRF is a peptide composed of 41 amino acids. The cell bodies of the neurons that secrete CRF are located mainly in the paraventricular nucleus of the hypothalamus. This nucleus in turn receives many nervous connections from the limbic system and lower brain stem.

The anterior pituitary gland can secrete only minute quantities of ACTH in the absence of CRF. Instead, most conditions that cause high ACTH secretory rates initiate this secretion by signals that begin in the basal regions of the brain, including the hypothalamus, and are then transmitted by CRF to the anterior pituitary gland.

ACTH Activates Adrenocortical Cells to Produce Steroids by Increasing cAMP. The principal effect of ACTH on the adrenocortical cells is to activate *adenylyl cyclase* in the cell membrane. This activation then induces formation of cAMP in the cell cytoplasm, reaching its maximal effect in about 3 minutes. The cAMP in turn activates the intracellular enzymes that cause formation of the adrenocortical hormones, which is another example of cAMP as a *second messenger* signal system.

The most important of all the ACTH-stimulated steps for controlling adrenocortical secretion is activation of the enzyme *protein kinase A,* which *causes initial conversion of cholesterol to pregnenolone.* This initial conversion is the "rate-limiting" step for all the adrenocortical hormones, which explains why ACTH is normally necessary for any adrenocortical hormones to be formed. Long-term stimulation of the adrenal cortex by ACTH not only increases secretory activity but also causes hypertrophy and proliferation of the adrenocortical cells, especially in the zona fasciculata and zona reticularis, where cortisol and the androgens are secreted.

Physiological Stress Increases ACTH and Adrenocortical Secretion. As pointed out earlier in the chapter, almost any type of physical or mental stress can lead within minutes to greatly enhanced secretion of ACTH and consequently cortisol as well, often increasing cortisol secretion as much as 20-fold. This effect was demonstrated by the rapid and strong adrenocortical secretory responses after trauma shown in Figure 78-6.

Pain stimuli caused by physical stress or tissue damage are transmitted first upward through the brain stem

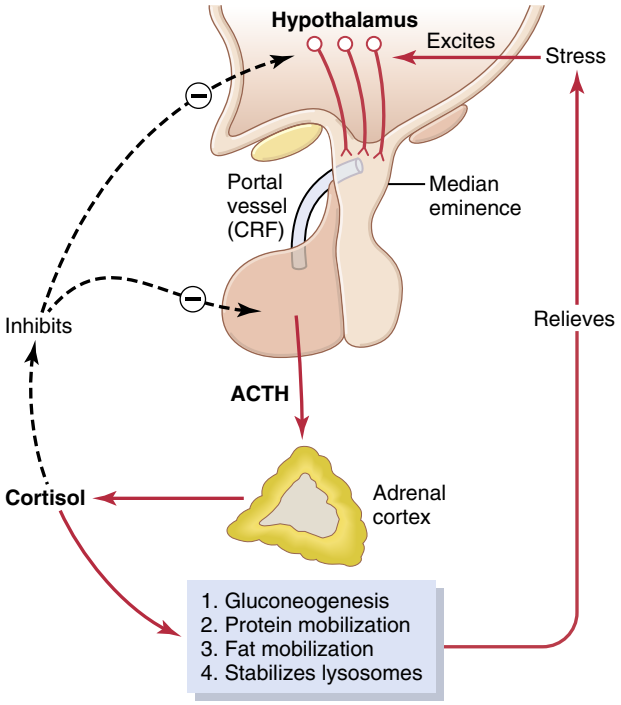

Figure 78-8. Mechanism for regulation of glucocorticoid secretion. ACTH, Adrenocorticotropic hormone; CRF, corticotropin-releasing factor.

to neurons of the paraventricular nucleus, and eventually to the median eminence of the hypothalamus, as shown in Figure 78-8. Here CRF is secreted into the hypophysial portal system. Within minutes the entire control sequence leads to large quantities of cortisol in the blood.

Mental stress can cause an equally rapid increase in ACTH secretion. This increase is believed to result from increased activity in the limbic system, especially in the region of the amygdala and hippocampus, both of which then transmit signals to the posterior medial hypothalamus.

Inhibitory Effect of Cortisol on the Hypothalamus and Anterior Pituitary to Decrease ACTH Secretion. Cortisol has direct negative feedback effects on (1) the hypothalamus to decrease formation of CRF and (2) the anterior pituitary gland to decrease formation of ACTH. Both of these feedbacks help regulate the plasma concentration of cortisol. That is, whenever the cortisol concentration becomes too great, the feedbacks automatically reduce the ACTH toward a normal control level.

Summary of the Cortisol Control System

Figure 78-8 shows the overall system for control of cortisol secretion. The key to this control is the excitation of the hypothalamus by different types of stress. Stress stimuli activate the entire system to cause rapid release of cortisol, and cortisol in turn initiates a series of metabolic effects directed toward relieving the damaging nature of the stressful state.

Direct feedback of cortisol to both the hypothalamus and the anterior pituitary gland also occurs to decrease the concentration of cortisol in the plasma at times when the body is not experiencing stress. However, the stress stimuli are the most potent ones; they can always break through this direct inhibitory feedback of cortisol, causing either periodic exacerbations of cortisol secretion at multiple times during the day (**Figure 78-9**) or prolonged cortisol secretion in times of chronic stress.

Circadian Rhythm of Glucocorticoid Secretion. The secretory rates of CRF, ACTH, and cortisol are high in the early morning but low in the late evening, as shown in **Figure 78-9**; plasma cortisol level ranges between a high of about 20 μg/dl an hour before arising in the morning and a low of about 5 μg/dl around midnight. This effect results from a 24-hour cyclical alteration in the signals from the hypothalamus that cause cortisol secretion. When a person changes his or her daily sleeping habits, the cycle changes correspondingly. Therefore, measurements of blood cortisol levels are meaningful only when expressed in terms of the time in the cycle at which the measurements are made.

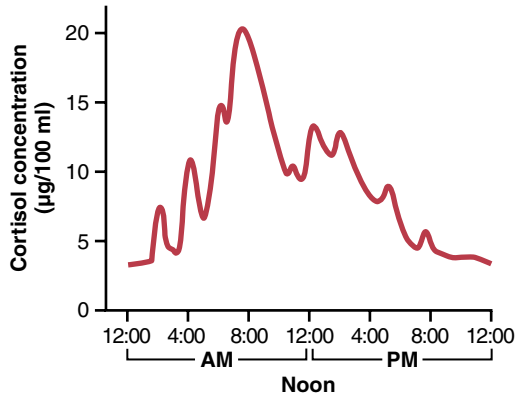

Figure 78-9. Typical pattern of cortisol concentration during the day. Note the oscillations in secretion, as well as a daily secretory surge an hour or so after waking in the morning.

Synthesis and Secretion of ACTH in Association With Melanocyte-Stimulating Hormone, Lipotropin, and Endorphin

When ACTH is secreted by the anterior pituitary gland, several other hormones that have similar chemical structures are secreted simultaneously. The gene that is transcribed to form the RNA molecule that causes ACTH synthesis initially causes formation of a considerably larger protein, a preprohormone called *pro-opiomelanocortin* (POMC), which is the precursor of ACTH and several other peptides, including *melanocyte-stimulating hormone* (MSH), *β-lipotropin, β-endorphin,* and a few others (**Figure 78-10**). Under normal conditions, most of these hormones are not secreted in enough quantity by the pituitary to have a major effect on the human body, but when the rate of secretion of ACTH is high, as may occur in persons with Addison's disease, formation of some of the other POMC-derived hormones may also be increased.

The POMC gene is actively transcribed in several tissues, including the corticotroph cells of the anterior pituitary, POMC neurons in the arcuate nucleus of the hypothalamus, cells of the dermis, and lymphoid tissue. In all of these cell types, POMC is processed to form a series of smaller peptides. The precise type of POMC-derived products from a particular tissue depends on the type of processing enzymes present in the tissue. Thus, pituitary corticotroph cells express *prohormone convertase 1* (PC1), resulting in the production of N-terminal peptide, joining peptide, ACTH, and β-lipotropin. In the hypothalamus, the expression of PC2 leads to production of α-MSH, β-MSH, γ-MSH, and β-endorphin, but not ACTH. As discussed in Chapter 72, α-MSH formed by neurons of the hypothalamus plays a major role in appetite regulation.

In *melanocytes* located in abundance between the dermis and epidermis of the skin, MSH stimulates formation of the black pigment *melanin* and disperses it to the epidermis. Injection of MSH into a person over 8 to 10 days can greatly increase darkening of the skin. The effect is

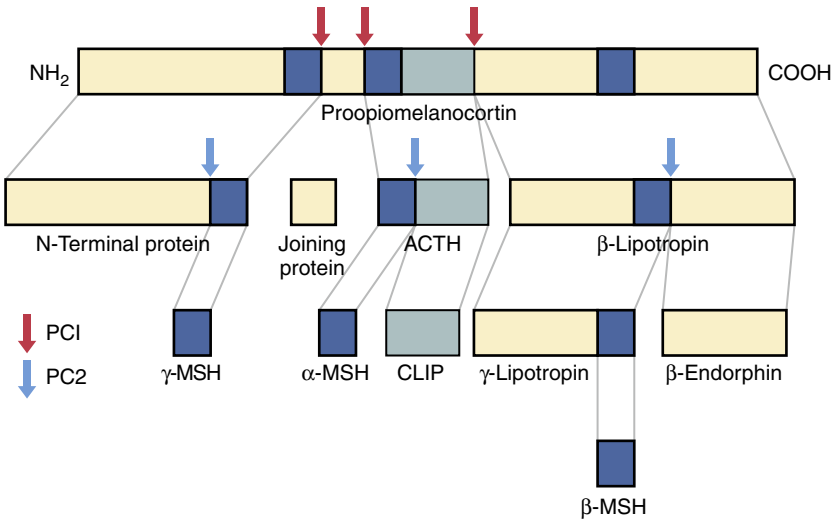

Figure 78-10. Pro-opiomelanocortin processing by prohormone convertase 1 (PC1; *red arrows*) and PC2 (*blue arrows*). Tissue-specific expression of these two enzymes results in different peptides produced in various tissues. ACTH, Adrenocorticotropic hormone; CLIP, corticotropin-like intermediate peptide; MSH, melanocyte-stimulating hormone.

much greater in people who have genetically dark skins than in light-skinned people.

In some animals, an intermediate "lobe" of the pituitary gland, called the *pars intermedia,* is highly developed, lying between the anterior and posterior pituitary lobes. This lobe secretes an especially large amount of MSH. Furthermore, this secretion is independently controlled by the hypothalamus in response to the amount of light to which the animal is exposed or in response to other environmental factors. For instance, some arctic animals develop darkened fur in the summer and yet have entirely white fur in the winter.

ACTH, because it contains an MSH sequence, has about 1/30 as much melanocyte-stimulating effect as MSH. Furthermore, because the quantities of pure MSH secreted in humans are extremely small, whereas those of ACTH are large, it is likely that ACTH is normally more important than MSH in determining the amount of melanin in the skin.

Adrenal Androgens

Several moderately active male sex hormones called *adrenal androgens* (the most important of which is *dehydroepiandrosterone*) are continually secreted by the adrenal cortex, especially during fetal life, as discussed in Chapter 84. Also, progesterone and estrogens, which are female sex hormones, are secreted in minute quantities.

Normally, the adrenal androgens have only weak effects in humans. It is possible that part of the early development of the male sex organs results from childhood secretion of adrenal androgens. The adrenal androgens also exert mild effects in the female, not only before puberty but also throughout life. Much of the growth of the pubic and axillary hair in the female results from the action of these hormones.

In extra-adrenal tissues, some of the adrenal androgens are converted to testosterone, the primary male sex hormone, which probably accounts for much of their androgenic activity. The physiological effects of androgens are discussed in Chapter 81 in relation to male sexual function.

Abnormalities of Adrenocortical Secretion

Hypoadrenalism (Adrenal Insufficiency)—Addison's Disease

Addison's disease results from an inability of the adrenal cortices to produce sufficient adrenocortical hormones, and this in turn is most frequently caused by *primary atrophy* or *injury* of the adrenal cortices. In about 80% of cases, the atrophy is caused by autoimmunity against the cortices. Adrenal gland hypofunction may also be caused by tuberculous destruction of the adrenal glands or invasion of the adrenal cortices by cancer.

In some cases, adrenal insufficiency is secondary to impaired function of the pituitary gland, which fails to produce sufficient ACTH. When ACTH output is too low, cortisol and aldosterone production decrease, and eventually the adrenal glands may atrophy because of a lack of ACTH stimulation. Secondary adrenal insufficiency is much more common than Addison's disease, which is sometimes called *primary adrenal insufficiency*. Disturbances in severe adrenal insufficiency are described in the following sections.

Mineralocorticoid Deficiency. Lack of aldosterone secretion greatly decreases renal tubular sodium reabsorption and consequently allows sodium ions, chloride ions, and water to be lost into urine in great profusion. The net result is a greatly decreased extracellular fluid volume and hyponatremia. Furthermore, hyperkalemia and mild acidosis develop because of failure of potassium and hydrogen ions to be secreted in exchange for sodium reabsorption.

As the extracellular fluid becomes depleted, plasma volume falls, red blood cell concentration rises markedly, cardiac output and blood pressure decrease, and the patient may in shock, with death usually occurring in the untreated patient 4 days to 2 weeks after complete cessation of mineralocorticoid secretion.

Glucocorticoid Deficiency. Loss of cortisol secretion makes it impossible for a person with Addison's disease to maintain normal blood glucose concentration between meals because he or she cannot synthesize significant quantities of glucose by gluconeogenesis. Furthermore, lack of cortisol reduces the mobilization of proteins and fats from the tissues, thereby depressing many other metabolic functions of the body. This sluggishness of energy mobilization when cortisol is not available is one of the major detrimental effects of glucocorticoid deficiency. Even when excess quantities of glucose and other nutrients are available, the person's muscles are weak, indicating that glucocorticoids are necessary to maintain other metabolic functions of the tissues in addition to energy metabolism.

Lack of adequate glucocorticoid secretion also makes a person with Addison's disease highly susceptible to the deteriorating effects of different types of stress, and even a mild respiratory infection can cause death.

Melanin Pigmentation. Another characteristic of most people with Addison's disease is melanin pigmentation of the mucous membranes and skin. This melanin is not always deposited evenly but occasionally is deposited in blotches, and it is deposited especially in the thin skin areas, such as the mucous membranes of the lips and the thin skin of the nipples.

When cortisol secretion is depressed, the normal negative feedback to the hypothalamus and anterior pituitary gland is also depressed, therefore allowing tremendous rates of ACTH secretion, as well as simultaneous secretion of increased amounts of MSH. The large amounts of ACTH probably cause most of the pigmenting effect because they can stimulate formation of melanin by the melanocytes in the same way that MSH does.

Treatment of People With Addison's Disease. An untreated person with total adrenal destruction dies within a few days to a few weeks because of weakness and, usually, circulatory shock. Yet, such a person can live for years if small quantities of mineralocorticoids and glucocorticoids are administered daily.

Adrenal Crisis. As noted earlier in the chapter, large quantities of glucocorticoids are occasionally secreted in response to different types of physical or mental stress. In a person with Addison's disease, the output of glucocorticoids does not increase during stress. Yet, during different types of trauma, disease, or other stresses, such as surgical operations, a person is likely to have an acute need for increased amounts of glucocorticoids and often must be given 10 or more times the normal quantities of glucocorticoids to prevent death.

Figure 78-11. A person with Cushing's syndrome before *(left)* and after *(right)* a subtotal adrenalectomy. *(Courtesy Dr. Leonard Posey.)*

This critical need for extra glucocorticoids and the associated severe debility in times of acute stress is called an *adrenal* (or *Addisonian) crisis.*

Hyperadrenalism—Cushing's Syndrome

Hypersecretion by the adrenal cortex causes a complex cascade of hormone effects called *Cushing's syndrome.* Many of the abnormalities of Cushing's syndrome can be ascribed to abnormal amounts of cortisol, but excess secretion of androgens may also cause important effects. Hypercortisolism can occur from multiple causes, including (1) adenomas of the anterior pituitary that secrete large amounts of ACTH, which then causes adrenal hyperplasia and excess cortisol secretion; (2) abnormal function of the hypothalamus that causes high levels of corticotropin-releasing hormone, which stimulates excess ACTH release; (3) "ectopic secretion" of ACTH by a tumor elsewhere in the body, such as an abdominal carcinoma; and (4) adenomas of the adrenal cortex. When Cushing's syndrome is secondary to excess secretion of ACTH by the anterior pituitary, this condition is referred to as *Cushing's disease.*

Excess ACTH secretion is the most common cause of Cushing's syndrome and is characterized by high plasma levels of ACTH and cortisol. Primary overproduction of cortisol by the adrenal glands accounts for about 20% to 25% of clinical cases of Cushing's syndrome and is usually associated with reduced ACTH levels due to cortisol feedback inhibition of ACTH secretion by the anterior pituitary gland.

Administration of large doses of dexamethasone, a synthetic glucocorticoid, can be used to distinguish between *ACTH-dependent* and *ACTH-independent* Cushing's syndrome. In patients who have overproduction of ACTH due to an ACTH-secreting pituitary adenoma or to hypothalamic-pituitary dysfunction, low doses of dexamethasone usually do not suppress ACTH secretion normally. By increasing the dose of dexamethasone to very high levels, ACTH eventually can be suppressed in most patients with Cushing's disease. In contrast, patients with primary adrenal overproduction of cortisol (ACTH-independent Cushing's syndrome) usually have low or undetectable levels of ACTH.

The dexamethasone test, although widely used, can sometimes result in an incorrect diagnosis because some ACTH-secreting pituitary tumors do respond to dexamethasone with suppressed ACTH secretion. Also, nonpituitary malignant tumors that produce ACTH ectopically, such as some lung carcinomas, are not responsive to glucocorticoid-negative feedback. Therefore, the dexamethasone test is usually considered to be a first step in the differential diagnosis of Cushing's syndrome.

Cushing's syndrome can also occur when large amounts of glucocorticoids are administered over prolonged periods for therapeutic purposes. For example, patients with chronic inflammation associated with diseases such as rheumatoid arthritis are often treated with glucocorticoids and may experience some of the clinical symptoms of Cushing syndrome.

A special characteristic of Cushing's syndrome is mobilization of fat from the lower part of the body, with concomitant extra deposition of fat in the thoracic and upper abdominal regions, giving rise to a buffalo-like torso. The excess secretion of steroids also leads to an edematous appearance of the face, and the androgenic potency of some of the hormones sometimes causes acne and hirsutism (excess growth of facial hair). The appearance of the face is frequently described as a "moon face," as demonstrated in the untreated patient with Cushing's syndrome to the left in **Figure 78-11**. About 80% of patients have hypertension, presumably because of the mineralocorticoid effects of cortisol.

Effects of Cushing's Syndrome on Carbohydrate and Protein Metabolism. The abundance of cortisol secreted in Cushing's syndrome can increase blood glucose concentration, sometimes to values as high as 200 mg/dl after meals—as much as twice normal. This increase results mainly from enhanced gluconeogenesis and decreased glucose utilization by the tissues.

The effects of glucocorticoids on protein catabolism are often profound in Cushing's syndrome, causing greatly decreased tissue proteins almost everywhere in the body with the exception of the liver; the plasma proteins also remain unaffected. The loss of protein from the muscles in particular causes severe weakness. The loss of protein synthesis in the lymphoid tissues leads to a suppressed immune system, and thus these patients are highly susceptible to infections. Even the protein collagen fibers in the subcutaneous tissue are diminished so that the subcutaneous tissues tear easily, resulting in development of large *purplish striae* where they have torn apart. In addition, severely diminished protein deposition in the bones often causes severe *osteoporosis* with consequent weakness of the bones.

Treatment of People With Cushing's Syndrome. Treatment of people with Cushing's syndrome consists of removing an adrenal tumor if this is the cause or decreasing the secretion of ACTH, if possible. Hypertrophied pituitary glands or even small tumors in the pituitary that oversecrete ACTH can sometimes be surgically removed or destroyed by radiation. Drugs that block steroidogenesis, such as *metyrapone, ketoconazole,* and *aminoglutethimide,* or that inhibit ACTH secretion, such as *serotonin antagonists* and GABA-*transaminase inhibitors,* can also be used when surgery is not feasible. If ACTH secretion cannot easily be decreased, the only satisfactory treatment is usually bilateral partial (or even total) adrenalectomy, followed by administration of adrenal steroids to make up for any insufficiency that develops.

Primary Aldosteronism (Conn's Syndrome)

Occasionally a small tumor of the zona glomerulosa cells occurs and secretes large amounts of aldosterone; the resulting condition is called *primary aldosteronism* or *Conn's syndrome.* Also, in a few instances, hyperplastic adrenal cortices secrete aldosterone rather than cortisol. The effects of the excess aldosterone are discussed in detail earlier in the chapter. The most important effects are hypokalemia, mild metabolic alkalosis, a slight increase in extracellular fluid volume and blood volume, a modest increase in plasma sodium concentration (usually <4–6-mEq/L increase) and, almost always, hypertension. Especially interesting in persons with primary aldosteronism are occasional periods of muscle paralysis caused by the hypokalemia. The paralysis is caused by a depressant effect of low extracellular potassium concentration on action potential transmission by the nerve fibers, as explained in Chapter 5.

One of the diagnostic criteria of primary aldosteronism is a decreased plasma renin concentration. This decrease results from feedback suppression of renin secretion caused by the excess aldosterone or by the excess extracellular fluid volume and arterial pressure resulting from the aldosteronism. Treatment of primary aldosteronism may include surgical removal of the tumor or of most of the adrenal tissue when hyperplasia is the cause. Another option for treatment is pharmacological antagonism of the mineralocorticoid receptor with spironolactone or eplerenone.

Adrenogenital Syndrome

Occasionally an adrenocortical tumor secretes excessive quantities of androgens that cause intense masculinizing effects throughout the body. If this phenomenon occurs in a female, virile characteristics develop, including growth of a beard, a much deeper voice, occasionally baldness if she also has the genetic trait for baldness, masculine distribution of hair on the body and the pubis, growth of the clitoris to resemble a penis, and deposition of proteins in the skin and especially in the muscles to give typical masculine characteristics.

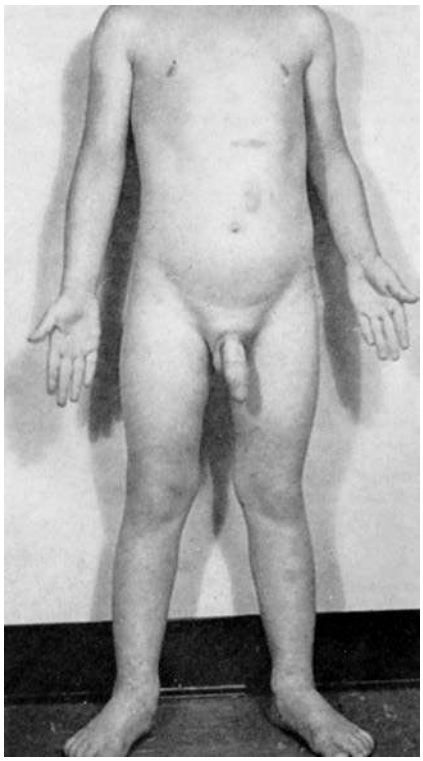

Figure 78-12. Adrenogenital syndrome in a 4-year-old boy. *(Courtesy Dr. Leonard Posey.)*

In the prepubertal male, a virilizing adrenal tumor causes the same characteristics as in the female plus rapid development of the male sexual organs, as shown in **Figure 78-12**, which depicts a 4-year-old boy with adrenogenital syndrome. In the adult male, the virilizing characteristics of adrenogenital syndrome are usually obscured by the normal virilizing characteristics of the testosterone secreted by the testes. It is often difficult to make a diagnosis of adrenogenital syndrome in the adult male. In adrenogenital syndrome, the excretion of 17-ketosteroids (which are derived from androgens) in the urine may be 10 to 15 times normal. This finding can be used in diagnosing the disease.

CHAPTER 79

UNIT XIV

Insulin, Glucagon, and Diabetes Mellitus

The pancreas, in addition to its digestive functions, secretes two major hormones, *insulin* and *glucagon*, that are crucial for normal regulation of glucose, lipid, and protein metabolism. Although the pancreas secretes other hormones, such as *amylin, somatostatin,* and *pancreatic polypeptide,* their functions are not as well established. The main purpose of this chapter is to discuss the physiological roles of insulin and glucagon and the pathophysiology of diseases, especially *diabetes mellitus*, caused by abnormal secretion or activity of these hormones.

Physiological Anatomy of the Pancreas

The pancreas is composed of two major types of tissues, as shown in **Figure 79-1**: (1) the *acini,* which secrete digestive juices into the duodenum, and (2) the *islets of Langerhans,* which secrete insulin and glucagon directly into the blood. The digestive secretions of the pancreas are discussed in Chapter 65.

The human pancreas has 1 to 2 million islets of Langerhans. Each islet is only about 0.3 millimeter in diameter and is organized around small capillaries, into which its cells secrete their hormones. The islets contain three major types of cells—*alpha, beta,* and *delta* cells—that are distinguished from one another by their morphological and staining characteristics.

The beta cells, constituting about 60% of all the cells of the islets, lie mainly in the middle of each islet and secrete *insulin* and *amylin,* a hormone that is often secreted in parallel with insulin, although its function is not well understood. The alpha cells, about 25% of the total, secrete *glucagon,* and the delta cells, about 10% of the total, secrete *somatostatin.* In addition, at least one other type of cell, the *PP cell*, is present in small numbers in the islets and secretes a hormone called *pancreatic polypeptide.*

The close interrelations among these cell types in the islets of Langerhans allow cell-to-cell communication and direct control of secretion of some of the hormones by the other hormones. For example, insulin inhibits glucagon secretion, amylin inhibits insulin secretion, and somatostatin inhibits the secretion of both insulin and glucagon.

INSULIN AND ITS METABOLIC EFFECTS

Insulin was first isolated from the pancreas in 1922 by Banting and Best, and almost overnight rescued patients with severe cases of diabetes mellitus from a rapid decline in health and early death. Historically, insulin has been associated with "blood sugar," and true enough, insulin has profound effects on carbohydrate metabolism. However, abnormalities of fat metabolism that cause conditions such as acidosis and arteriosclerosis are also important causes of morbidity and death in patients with diabetes mellitus. Patients with prolonged, untreated diabetes have diminished ability to synthesize proteins which leads to wasting of the tissues and many cellular functional disorders. Therefore, it is clear that insulin affects fat and protein metabolism almost as much as it affects carbohydrate metabolism.

INSULIN IS A HORMONE ASSOCIATED WITH ENERGY ABUNDANCE

As we discuss insulin in the next few pages, it will become apparent that insulin secretion is associated with energy abundance. That is, when a person's diet includes a great abundance of foods that provide energy, especially excess amounts of carbohydrates, insulin secretion increases. In turn, the insulin plays an important role in storing the excess energy. In the case of excess carbohydrates, it causes them to be stored as glycogen, mainly in the liver and muscles. Furthermore, all the excess carbohydrates that cannot be stored as glycogen are converted under the stimulus of insulin into fats and stored in adipose tissue. In the case of proteins, insulin has a direct effect

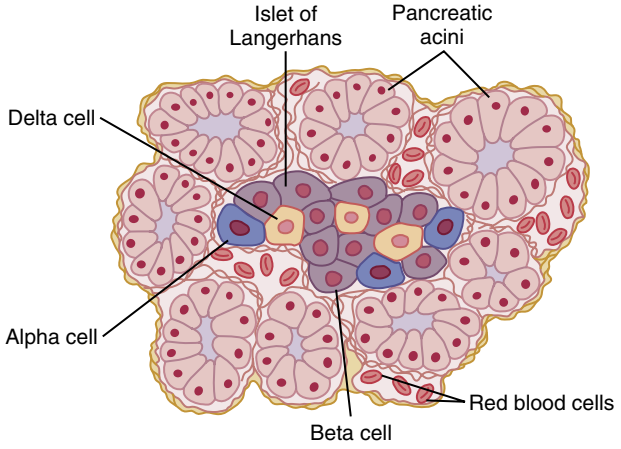

Figure 79-1. Physiological anatomy of an islet of Langerhans in the pancreas.

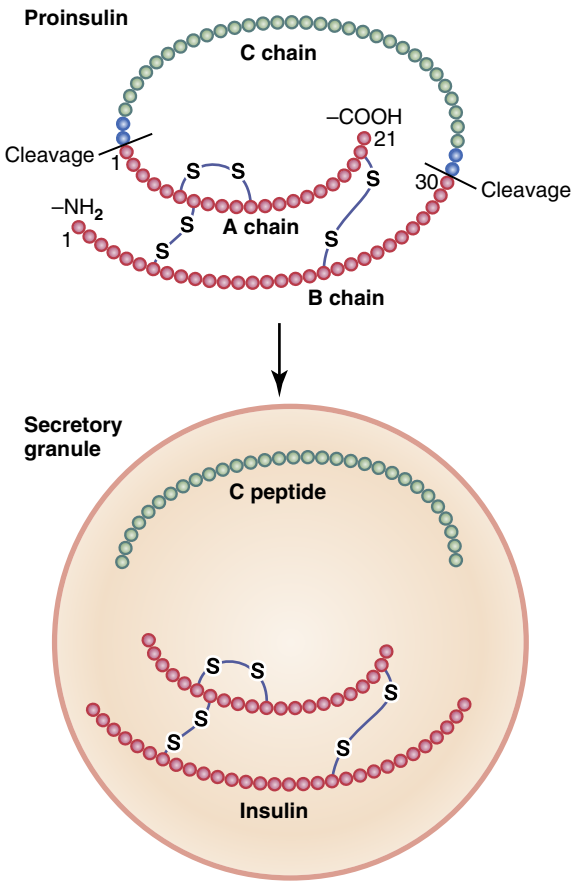

Figure 79-2. A schematic of the human proinsulin molecule, which is cleaved in the Golgi apparatus of the pancreatic beta cells to form connecting peptide (C peptide), and insulin, which is composed of the A and B chains connected by disulfide bonds. The C peptide and insulin are packaged in granules and secreted in equimolar amounts, along with a small amount of proinsulin.

in promoting amino acid uptake by cells and conversion of these amino acids into protein. In addition, it inhibits breakdown of proteins that are already in the cells.

INSULIN CHEMISTRY AND SYNTHESIS

Human insulin, which has a molecular weight of 5808, is composed of two amino acid chains, shown in **Figure 79-2**, that are connected to each other by disulfide linkages. When the two amino acid chains are split apart, insulin's functional activity is lost.

Insulin is synthesized in beta cells by the usual cell machinery for protein synthesis, as explained in Chapter 3, beginning with translation of the insulin RNA by ribosomes attached to the endoplasmic reticulum to form *preproinsulin*. This initial preproinsulin has a molecular weight of about 11,500, but it is then cleaved in the endoplasmic reticulum to form a *proinsulin* with a molecular weight of about 9000 and consisting of three chains of peptides, A, B, and C. Most of the proinsulin is further cleaved in the Golgi apparatus to form insulin, which is composed of the A and B chains connected by disulfide linkages, and the C chain peptide, called *connecting peptide* (C peptide). The insulin and C peptide are packaged in secretory granules and secreted in equimolar amounts. About 5% to 10% of the final secreted product is still in the form of proinsulin.

The proinsulin and C peptide have virtually no insulin activity. However, C peptide binds to a membrane structure, most likely a G protein–coupled membrane receptor, and elicits activation of at least two enzyme systems, sodium-potassium adenosine triphosphatase and endothelial nitric oxide synthase. Although both of these enzymes have multiple physiological functions, the importance of C peptide in regulating these enzymes is still uncertain.

C peptide levels can be measured by radioimmunoassay in insulin-treated diabetic patients to determine how much of their own natural insulin they are still producing. Patients with type 1 diabetes who are unable to produce insulin will usually also have greatly decreased levels of C peptide.

When insulin is secreted into the blood, it circulates almost entirely in an unbound form. Because it has a plasma half-life that averages only about 6 minutes, it is mainly cleared from the circulation within 10 to 15 minutes. Except for the portion of the insulin that combines with receptors in the target cells, the insulin is degraded by the enzyme *insulinase* mainly in the liver, to a lesser extent in the kidneys and muscles, and slightly in most other tissues. This rapid removal from the plasma is important because, at times, it is as important to rapidly turn off the control functions of insulin as it is to turn them on.

ACTIVATION OF TARGET CELL RECEPTORS BY INSULIN AND THE RESULTING CELLULAR EFFECTS

To initiate its effects on target cells, insulin must first bind with and activate a membrane receptor protein that has a molecular weight of about 300,000 (**Figure 79-3**).

The insulin receptor is a combination of four subunits held together by disulfide linkages: *two alpha subunits* that lie entirely outside the cell membrane and *two beta subunits* that penetrate through the membrane, protruding into the cell cytoplasm. Insulin binds with the alpha subunits on the outside of the cell, but because of the linkages with the beta subunits, portions of the beta subunits protruding into the cell become autophosphorylated. Thus, the insulin receptor is an example of an *enzyme-linked receptor,* discussed in Chapter 75. Autophosphorylation of the beta subunits of the receptor activates a local *tyrosine kinase,* which in turn causes phosphorylation of multiple other intracellular enzymes, including a group called *insulin-receptor substrates (IRS).* Different types of IRS (e.g., IRS-1, IRS-2, and IRS-3) are expressed in different tissues. The net effect is to activate some of these enzymes while inactivating others. In this way, insulin directs the intracellular metabolic machinery to produce the desired

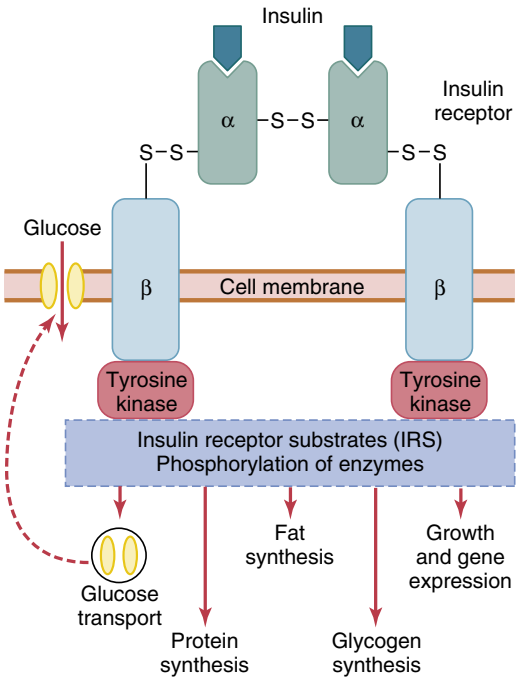

Figure 79-3. A schematic of the insulin receptor. Insulin binds to the α subunit of its receptor, which causes autophosphorylation of the β-subunit receptor, which in turn induces tyrosine kinase activity. The receptor tyrosine kinase activity begins a cascade of cell phosphorylation that increases or decreases the activity of enzymes, including insulin receptor substrates, that mediate the effects on glucose, fat, and protein metabolism. For example, glucose transporters are moved to the cell membrane to assist glucose entry into the cell.

effects on carbohydrate, fat, and protein metabolism. The following are the main end effects of insulin stimulation:

1. Within seconds after insulin binds with its membrane receptors, the membranes of about 80% of the body's cells markedly increase their uptake of glucose. This action is especially true of muscle cells and adipose cells, but *it is not true of most neurons in the brain.* The increased glucose transported into the cells is immediately phosphorylated and becomes a substrate for all the usual carbohydrate metabolic functions. The increased glucose transport is believed to result from translocation of multiple intracellular vesicles to the cell membranes; these vesicles carry multiple molecules of glucose transport proteins, which bind with the cell membrane and facilitate glucose uptake into the cells. When insulin is no longer available, these vesicles separate from the cell membrane within about 3 to 5 minutes and move back to the cell interior to be used again and again, as needed.
2. The cell membrane becomes more permeable to many of the amino acids, potassium ions, and phosphate ions, causing increased transport of these substances into the cell.
3. Slower effects occur during the next 10 to 15 minutes to change the activity levels of many more intracellular metabolic enzymes. These effects result mainly from the changed states of phosphorylation of the enzymes.
4. Much slower effects continue to occur for hours and even several days. These result from changed rates of translation of messenger RNAs at the ribosomes to form new proteins and still slower effects from changed rates of transcription of DNA in the cell nucleus. In this way, insulin remolds much of the cellular enzymatic machinery to achieve some of its metabolic effects.

EFFECT OF INSULIN ON CARBOHYDRATE METABOLISM

Immediately after a high-carbohydrate meal is consumed, glucose that is absorbed into the blood causes rapid secretion of insulin, which is discussed in detail later in the chapter. The insulin in turn causes rapid uptake, storage, and use of glucose by almost all tissues of the body but especially by the muscles, adipose tissue, and liver.

Insulin Promotes Muscle Glucose Uptake and Metabolism

During much of the day, muscle tissue depends not on glucose but on fatty acids for its energy. The principal reason for this dependence on fatty acids is that the normal *resting muscle membrane* is only slightly permeable to glucose, except when the muscle fiber is stimulated by insulin; between meals, the amount of insulin that is secreted is too small to promote significant amounts of glucose entry into the muscle cells.

However, under two conditions the muscles do use large amounts of glucose. One of these is during moderate or heavy exercise. This usage of glucose does not require large amounts of insulin because muscle contraction increases translocation of *glucose transporter 4 (GLUT 4)* from intracellular storage depots to the cell membrane, which, in turn, facilitates diffusion of glucose into the cell.

The second condition for usage of large amounts of glucose by muscles is during the few hours after a meal. At this time the blood glucose concentration is high and the pancreas is secreting large quantities of insulin. The extra insulin causes rapid transport of glucose into the muscle cells, which causes the muscle cell to use glucose preferentially over fatty acids during this period, as will be discussed later.

Storage of Glycogen in Muscle. If the muscles are not exercised after a meal and yet glucose is transported into the muscle cells in abundance, instead of being used for energy, most of the glucose is stored in the form of muscle glycogen, up to a limit of 2% to 3% concentration. The glycogen can be used by the muscle later for energy. Glycogen is especially useful for short periods of extreme energy usage by the muscles and even to provide spurts of anaerobic energy for a few minutes at a time via glycolytic

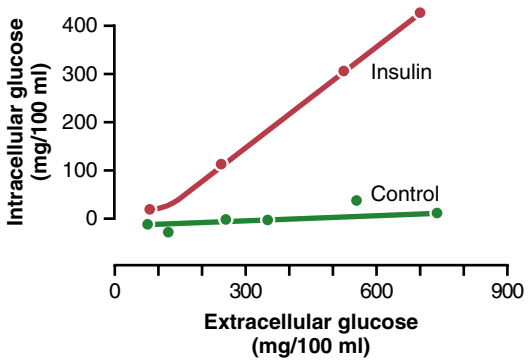

Figure 79-4. The effect of insulin in enhancing the concentration of glucose inside muscle cells. Note that in the absence of insulin (control), the intracellular glucose concentration remains near zero, despite high extracellular glucose concentrations. *(Data from Eisenstein AB: The Biochemical Aspects of Hormone Action. Boston: Little, Brown, 1964.)*

breakdown of the glycogen to lactic acid, which can occur even in the absence of oxygen.

Quantitative Effect of Insulin to Facilitate Glucose Transport Through the Muscle Cell Membrane

The quantitative effect of insulin to facilitate glucose transport through the muscle cell membrane is demonstrated by the experimental results shown in **Figure 79-4**. The lower curve labeled "control" shows the concentration of free glucose measured inside the cell, demonstrating that the glucose concentration remained almost zero despite increased extracellular glucose concentration up to as high as 750 mg/100 ml. In contrast, the curve labeled "insulin" demonstrates that the intracellular glucose concentration rose to as high as 400 mg/100 ml when insulin was added. Thus, it is clear that insulin can increase the rate of transport of glucose into the resting muscle cell by at least 15-fold.

Insulin Promotes Liver Uptake, Storage, and Use of Glucose

One of the most important effects of insulin is to cause most of the glucose absorbed after a meal to be rapidly stored in the liver in the form of glycogen. Then, between meals, when food is not available and the blood glucose concentration begins to fall, insulin secretion decreases rapidly and the liver glycogen is split back into glucose, which is released back into the blood to keep the glucose concentration from falling too low.

The mechanism by which insulin causes glucose uptake and storage in the liver includes several almost simultaneous steps:

1. Insulin *inactivates liver phosphorylase,* the principal enzyme that causes liver glycogen to split into glucose. This inactivation prevents breakdown of the glycogen that has been stored in liver cells.
2. Insulin *enhances uptake of glucose* from the blood by the liver cells by *increasing the activity of the enzyme glucokinase,* which is one of the enzymes that causes the initial phosphorylation of glucose after it diffuses into the liver cells. Once phosphorylated, the glucose is *temporarily* trapped inside the liver cells because phosphorylated glucose cannot diffuse back through the cell membrane.
3. Insulin increases the activities of enzymes that promote glycogen synthesis, including especially *glycogen synthase.* This is responsible for polymerization of the monosaccharide units to form glycogen molecules.

The net effect of all these actions is to increase the amount of glycogen in the liver. The glycogen can increase to a total of about 5% to 6% of the liver mass, which is equivalent to almost 100 grams of stored glycogen in the entire liver.

Glucose Is Released From the Liver Between Meals. When the blood glucose level begins to fall to a low level between meals, several events transpire that cause the liver to release glucose back into the circulating blood:

1. The decreasing blood glucose causes the pancreas to decrease its insulin secretion.
2. The lack of insulin then reverses all the effects listed earlier for glycogen storage, essentially stopping further synthesis of glycogen in the liver and preventing further uptake of glucose by the liver from the blood.
3. The lack of insulin (along with increased glucagon, which is discussed later) activates the enzyme *phosphorylase,* which causes the splitting of glycogen into *glucose phosphate.*
4. The enzyme *glucose phosphatase,* which had been inhibited by insulin, now becomes activated by the lack of insulin and causes the phosphate radical to split away from the glucose, allowing the free glucose to diffuse back into the blood.

Thus, the liver removes glucose from the blood when it is present in excess after a meal and returns it to the blood when the blood glucose concentration falls between meals. Ordinarily, about 60% of the glucose in the meal is stored in this way in the liver and then returned later.

Insulin Promotes Conversion of Excess Glucose Into Fatty Acids and Inhibits Gluconeogenesis in the Liver. When the quantity of glucose entering the liver cells is more than can be stored as glycogen or can be used for local hepatocyte metabolism, *insulin promotes the conversion of all this excess glucose into fatty acids.* These fatty acids are subsequently packaged as triglycerides in very low density lipoproteins, which are transported in the blood to adipose tissue, and deposited as fat.

Insulin also *inhibits gluconeogenesis* mainly by decreasing the quantities and activities of the liver enzymes required for gluconeogenesis. However, part of the effect is caused by an action of insulin that decreases release of amino acids from muscle and other extrahepatic tissues

and in turn the availability of these necessary precursors required for gluconeogenesis. This phenomenon is discussed further in relation to the effect of insulin on protein metabolism.

Lack of Effect of Insulin on Glucose Uptake and Usage by the Brain

The brain is quite different from most other tissues of the body in that insulin has little effect on uptake or use of glucose. Instead, *most of the brain cells are permeable to glucose and can use glucose without the intermediation of insulin*.

The brain cells are also quite different from most other cells of the body in that they normally use only glucose for energy and can use other energy substrates, such as fats, only with difficulty. Therefore, it is essential that the blood glucose level always be maintained above a critical level, which is one of the most important functions of the blood glucose control system. When the blood glucose level falls too low, into the range of 20 to 50 mg/100 ml, symptoms of *hypoglycemic shock* develop, characterized by progressive nervous irritability that leads to fainting, seizures, and even coma.

Effect of Insulin on Carbohydrate Metabolism in Other Cells

Insulin increases glucose transport into and glucose usage by most other cells of the body (with the exception of most brain cells, as noted) in the same way that it affects glucose transport and usage in muscle cells. The transport of glucose into adipose cells mainly provides substrate for the glycerol portion of the fat molecule. Therefore, in this indirect way, insulin promotes deposition of fat in these cells.

EFFECT OF INSULIN ON FAT METABOLISM

Although not quite as visible as the acute effects of insulin on carbohydrate metabolism, the effects of insulin on fat metabolism are, in the long run, equally important. Especially dramatic is the long-term effect of *insulin deficiency* in causing extreme atherosclerosis, often leading to heart attacks, cerebral strokes, and other vascular accidents. First, however, let us discuss the acute effects of insulin on fat metabolism.

Insulin Promotes Fat Synthesis and Storage

Insulin has several effects that lead to fat storage in adipose tissue. First, insulin increases glucose utilization by most of the body's tissues, which automatically decreases fat utilization, thus functioning as a fat sparer. However, insulin also promotes fatty acid synthesis, especially when more carbohydrates are ingested than can be used for immediate energy, thus providing the substrate for fat synthesis. Almost all this synthesis occurs in the liver cells, and the fatty acids are then transported from the liver by way of the blood lipoproteins to the adipose cells to be stored. The following factors lead to increased fatty acid synthesis in the liver:

1. *Insulin increases glucose transport into the liver cells.* After the liver glycogen concentration reaches 5% to 6%, further glycogen synthesis is inhibited. All the additional glucose entering the liver cells then becomes available to form fat. The glucose is first split to pyruvate in the glycolytic pathway, and the pyruvate subsequently is converted to acetyl coenzyme A (acetyl-CoA), the substrate from which fatty acids are synthesized.
2. *An excess of citrate and isocitrate ions is formed by the citric acid cycle when excess amounts of glucose are used for energy.* These ions then have a direct effect to activate *acetyl-CoA carboxylase,* the enzyme required to carboxylate acetyl-CoA to form *malonyl-CoA*, the first stage of fatty acid synthesis.
3. *Most of the fatty acids are then synthesized within the liver and used to form triglycerides*, the usual form of storage fat. They are released from the liver cells to the blood in the lipoproteins. Insulin activates *lipoprotein lipase* in the capillary walls of the adipose tissue, which splits the triglycerides again into fatty acids, a requirement for them to be absorbed into adipose cells, where they are again converted to triglycerides and stored.

Role of Insulin in Storage of Fat in the Adipose Cells. Insulin has two other essential effects that are required for fat storage in adipose cells:

1. *Insulin inhibits the action of hormone-sensitive lipase.* Lipase is the enzyme that causes hydrolysis of triglycerides already stored in fat cells. Therefore, release of fatty acids from adipose tissue into the circulating blood is inhibited.
2. *Insulin promotes glucose transport through cell membranes into fat cells* in the same way that it promotes glucose transport into muscle cells. Some of this glucose is then used to synthesize minute amounts of fatty acids, but more important, it also forms large quantities of α-glycerol phosphate. This substance supplies the *glycerol* that combines with fatty acids to form triglycerides, the storage form of fat in adipose cells. Therefore, when insulin is not available, even storage of the large amounts of fatty acids transported from the liver in lipoproteins is almost blocked.

Insulin Deficiency Increases Use of Fat for Energy

All aspects of fat breakdown and its use for providing energy are greatly enhanced in the absence of insulin. This enhancement occurs even normally between meals when secretion of insulin is minimal, but it becomes extreme in persons with diabetes mellitus when secretion of insulin is almost zero.

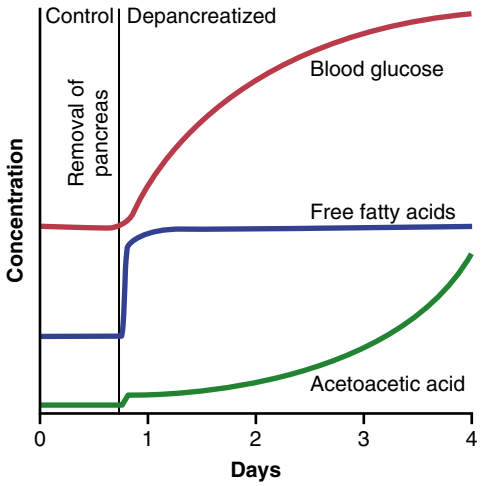

Figure 79-5. The effect of removing the pancreas on the approximate concentrations of blood glucose, plasma free fatty acids, and acetoacetic acid.

Insulin Deficiency Causes Lipolysis of Storage Fat and Release of Free Fatty Acids. In the absence of insulin, all the effects of insulin noted earlier that cause storage of fat are reversed. The most important effect is that the enzyme *hormone-sensitive lipase* in the fat cells becomes strongly activated. This activation causes hydrolysis of stored triglycerides, releasing large quantities of fatty acids and glycerol into the circulating blood. Consequently, plasma concentration of free fatty acids begins to rise within minutes. These free fatty acids then become the main energy substrate used by essentially all tissues of the body except the brain.

Figure 79-5 shows the effect of a lack of insulin on the plasma concentrations of free fatty acids, glucose, and acetoacetic acid. Note that almost immediately after removal of the pancreas, the free fatty acid concentration in the plasma begins to rise, more rapidly even than the concentration of glucose.

Insulin Deficiency Increases Plasma Cholesterol and Phospholipid Concentrations. The excess of fatty acids in the plasma associated with insulin deficiency also promotes liver conversion of some of the fatty acids into phospholipids and cholesterol, two of the major products of fat metabolism. These two substances, along with excess triglycerides formed at the same time in the liver, are then discharged into the blood in the lipoproteins. Occasionally the plasma lipoproteins increase as much as threefold in the absence of insulin, giving a total concentration of plasma lipids of several percent rather than the normal 0.6%. This high lipid concentration—especially the high concentration of cholesterol—promotes development of atherosclerosis in people with severe diabetes.

Excess Usage of Fats During Insulin Deficiency Causes Ketosis and Acidosis. Insulin deficiency also causes excessive amounts of *acetoacetic acid* to be formed in liver cells. In the absence of insulin but in the presence of excess fatty acids in the liver cells, the carnitine transport mechanism for transporting fatty acids into the mitochondria becomes increasingly activated. In the mitochondria, beta oxidation of the fatty acids then proceeds rapidly, releasing extreme amounts of acetyl-CoA. A large part of this excess acetyl-CoA is then condensed to form acetoacetic acid, which is then released into the circulating blood. Most of this acetoacetic acid passes to the peripheral cells, where it is again converted into acetyl-CoA and used for energy in the usual manner.

At the same time, the absence of insulin also depresses utilization of acetoacetic acid in peripheral tissues. Thus, so much acetoacetic acid is released from the liver that it cannot all be metabolized by the tissues. As shown in Figure 79-5, the concentration of acetoacetic acid rises during the days after cessation of insulin secretion, sometimes reaching concentrations of 10 mEq/L or more, which is a severe state of body fluid acidosis.

As explained in Chapter 69, some of the acetoacetic acid is also converted into β-hydroxybutyric acid and *acetone*. These two substances, along with the acetoacetic acid, are called *ketone bodies,* and their presence in large quantities in the body fluids is called *ketosis*. We will see later that in severe diabetes, the acetoacetic acid and the β-hydroxybutyric acid can cause severe *acidosis* and *coma,* which may lead to death.

EFFECT OF INSULIN ON PROTEIN METABOLISM AND GROWTH

Insulin Promotes Protein Synthesis and Storage

Proteins, carbohydrates, and fats are stored in the tissues during the few hours after a meal when excess quantities of nutrients are available in the circulating blood; insulin is required for this storage to occur. The manner in which insulin causes protein storage is not as well understood as the mechanisms for both glucose and fat storage. Here are some of the facts:

1. *Insulin stimulates transport of many of the amino acids into the cells.* Among the amino acids most strongly transported are *valine, leucine, isoleucine, tyrosine,* and *phenylalanine.* Thus, insulin shares with growth hormone the capability of increasing uptake of amino acids into cells. However, the amino acids affected are not necessarily the same ones.
2. *Insulin increases translation of messenger RNA,* thus forming new proteins. Insulin "turns on" the ribosomal machinery and, in the absence of insulin, the ribosomes stop working, almost as if insulin operates by an "on-off" mechanism.
3. Over a longer period, *insulin also increases the rate of transcription of selected DNA genetic sequences* in the cell nuclei, thus forming increased quantities of RNA and still more protein synthesis—especially promoting a vast array of enzymes for storage of carbohydrates, fats, and proteins.

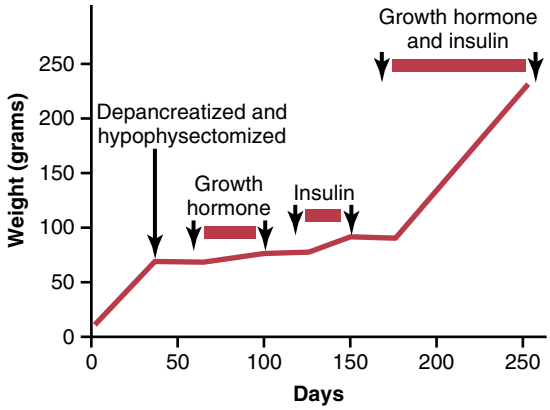

Figure 79-6. The effect of growth hormone, insulin, and growth hormone plus insulin on growth in a depancreatized and hypophysectomized rat.

4. *Insulin inhibits catabolism of proteins,* thus decreasing the rate of amino acid release from the cells, especially from muscle cells. Presumably this results from the ability of insulin to diminish the normal degradation of proteins by cellular lysosomes.
5. *In the liver, insulin depresses the rate of gluconeogenesis* by decreasing activity of the enzymes that promote gluconeogenesis. Because the substrates used most for synthesis of glucose by gluconeogenesis are plasma amino acids, this suppression of gluconeogenesis conserves amino acids in the protein stores of the body.

In summary, insulin promotes formation of protein and prevents degradation of proteins.

Insulin Deficiency Causes Protein Depletion and Increased Plasma Amino Acids

Virtually all protein storage comes to a halt when insulin is not available. Catabolism of proteins increases, protein synthesis stops, and large quantities of amino acids are dumped into the plasma. Amino acid concentration in the plasma rises considerably, and most of the excess amino acids are used either directly for energy or as substrates for gluconeogenesis. This degradation of amino acids also leads to enhanced urea excretion in the urine. The resulting protein wasting is one of the most serious of all the effects of severe diabetes mellitus. It can lead to extreme weakness and many deranged functions of the organs.

Insulin and Growth Hormone Interact Synergistically to Promote Growth

Because insulin is required for synthesis of proteins, it is as essential as growth hormone for the growth of an animal. As demonstrated in **Figure 79-6**, a depancreatized, hypophysectomized rat without replacement therapy hardly grows at all. Furthermore, administration of either growth hormone or insulin one at a time causes almost no growth. However, a combination of these hormones causes dramatic growth. Thus, it appears that the two hormones function synergistically to promote growth, with each performing a specific function separate from that of the other. Perhaps a small part of the necessity for both hormones results from the fact that each hormone promotes cellular uptake of a different selection of amino acids, all of which are required for growth.

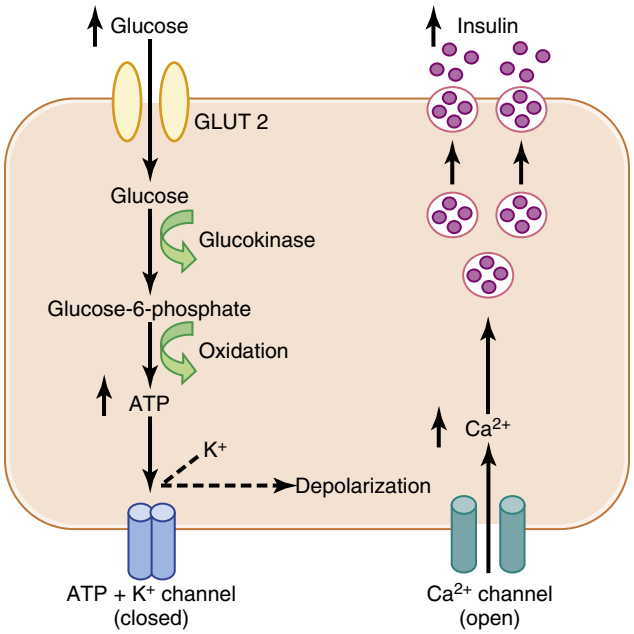

Figure 79-7. The basic mechanisms of glucose stimulation of insulin secretion by beta cells of the pancreas. GLUT, Glucose transporter.

MECHANISMS OF INSULIN SECRETION

Figure 79-7 shows the basic cellular mechanisms for insulin secretion by the pancreatic beta cells in response to increased blood glucose concentration, which is the primary controller of insulin secretion. The beta cells have a large number of *glucose transporters* that permit a rate of glucose influx that is proportional to the blood concentration in the physiological range. Once inside the cells, glucose is phosphorylated to glucose-6-phosphate by *glucokinase*. This phosphorylation appears to be the rate-limiting step for glucose metabolism in the beta cell and is considered the major mechanism for glucose sensing and adjustment of the amount of secreted insulin to the blood glucose levels.

The glucose-6-phosphate is subsequently oxidized to form adenosine triphosphate (ATP), which inhibits the *ATP-sensitive potassium channels* of the cell. Closure of the potassium channels depolarizes the cell membrane, thereby opening *voltage-gated calcium channels,* which are sensitive to changes in membrane voltage. This effect produces an influx of calcium that stimulates fusion of the docked insulin-containing vesicles with the cell membrane and secretion of insulin into the extracellular fluid by *exocytosis.*

TABLE 79-1 Factors and Conditions That Increase or Decrease Insulin Secretion

Increase Insulin Secretion	Decrease Insulin Secretion
Increased blood glucose	Decreased blood glucose
Increased blood free fatty acids	Fasting
Increased blood amino acids	Somatostatin
Gastrointestinal hormones (gastrin, cholecystokinin, secretin, glucose-dependent insulinotropic peptide, glucagon-like peptide-1)	α-Adrenergic activity
	Leptin
Glucagon, growth hormone, cortisol	
Parasympathetic stimulation; acetylcholine	
β-Adrenergic stimulation	
Insulin resistance; obesity	
Sulfonylurea drugs (glyburide, tolbutamide)	

Other nutrients, such as certain amino acids, can also be metabolized by the beta cells to increase intracellular ATP levels and stimulate insulin secretion. Some hormones, such as glucagon, glucagon-like peptide-1 (GLP-1), glucose-dependent insulinotropic peptide (gastric inhibitory peptide), and acetylcholine, increase intracellular calcium levels through other signaling pathways and enhance the effect of glucose, although they do not have major effects on insulin secretion in the absence of glucose. Other hormones, including somatostatin and norepinephrine (by activating α-adrenergic receptors), inhibit exocytosis of insulin.

Sulfonylurea drugs stimulate insulin secretion by binding to the ATP-sensitive potassium channels and blocking their activity. This mechanism results in a depolarizing effect that triggers insulin secretion, making these drugs useful in stimulating insulin secretion in patients with type 2 diabetes, as we will discuss later. Table 79-1 summarizes some of the factors that can increase or decrease secretion of insulin.

CONTROL OF INSULIN SECRETION

At one time it was believed that insulin secretion was controlled almost entirely by the concentration of glucose in the blood. However, as more has been learned about the metabolic functions of insulin for protein and fat metabolism, it has become apparent that blood amino acids and other factors also play important roles in controlling insulin secretion (see Table 79-1).

Increased Blood Glucose Stimulates Insulin Secretion. At the normal *fasting* level of blood glucose of 80 to 90 mg/100 ml, the rate of insulin secretion is minimal—on the order of 25 ng/min/kg of body weight, a level that has only slight physiological activity. If the blood glucose concentration is suddenly increased to a level two to three times normal and is kept at this high level thereafter, insulin secretion increases markedly in two stages, as shown by the changes in plasma insulin concentration in Figure 79-8.

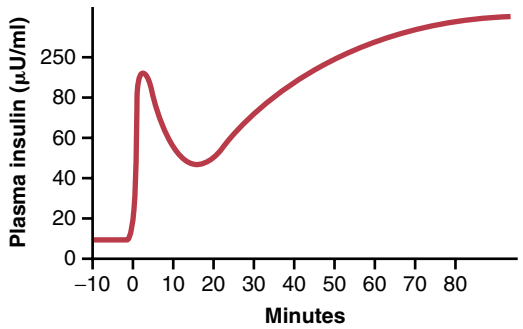

Figure 79-8. An increase in plasma insulin concentration after a sudden increase in blood glucose to two to three times the normal range. Note an initial rapid surge in insulin concentration and then a delayed but higher and continuing increase in concentration beginning 15 to 20 minutes later.

1. The concentration of insulin in plasma increases almost 10-fold within 3 to 5 minutes after acute elevation of the blood glucose. This increase results from immediate dumping of preformed insulin from the beta cells of the islets of Langerhans. However, the initial high rate of secretion is not maintained; instead, the insulin concentration decreases about halfway back toward normal in another 5 to 10 minutes.
2. Beginning at about 15 minutes, insulin secretion rises a second time and reaches a new plateau in 2 to 3 hours, this time usually at a rate of secretion even greater than that in the initial phase. This secretion results from additional release of preformed insulin and from activation of the enzyme system that synthesizes and releases new insulin from the cells.

Feedback Relation Between Blood Glucose Concentration and the Insulin Secretion Rate. As blood glucose concentration rises above 100 mg/100 ml of blood, secretion of insulin rises rapidly, reaching a peak some 10 to 25 times the basal level at blood glucose concentrations between 400 and 600 mg/100 ml, as shown in Figure 79-9. Thus, the increase in insulin secretion during a glucose stimulus is dramatic both in its rapidity and in the high level of secretion that is achieved. Furthermore, the turnoff of insulin secretion is almost equally as rapid, occurring within 3 to 5 minutes after a reduction in blood glucose concentration back to the fasting level.

This response of insulin secretion to an elevated blood glucose concentration provides an extremely important feedback mechanism for regulating blood glucose concentration. That is, any rise in blood glucose increases insulin secretion, and the insulin in turn increases the rate of transport of glucose into liver, muscle, and other cells, thereby reducing blood glucose concentration back toward the normal value.

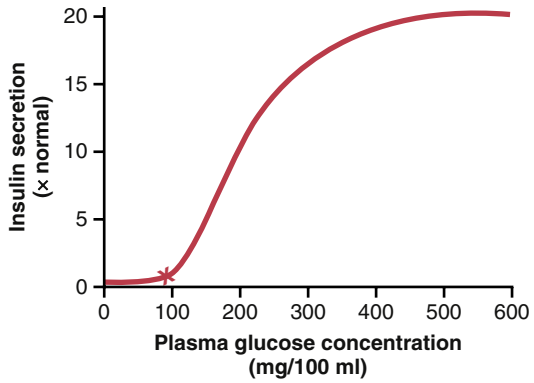

Figure 79-9. Approximate insulin secretion at different plasma glucose levels.

Other Factors That Stimulate Insulin Secretion

Amino Acids. Some of the amino acids have an effect similar to excess blood glucose in stimulating insulin secretion. The most potent of these amino acids are *arginine* and *lysine.* This effect differs from glucose stimulation of insulin secretion in the following way: Amino acids administered in the absence of a rise in blood glucose cause only a small increase in insulin secretion. However, when administered at the same time that the blood glucose concentration is elevated, the glucose-induced secretion of insulin may be as much as doubled in the presence of the excess amino acids. Thus, *amino acids strongly potentiate the glucose stimulus for insulin secretion.*

The stimulation of insulin secretion by amino acids is important because the insulin in turn promotes transport of amino acids into the tissue cells, as well as the intracellular formation of protein. That is, insulin is important for proper utilization of excess amino acids in the same way that it is important for utilization of carbohydrates.

Gastrointestinal Hormones. A mixture of several important gastrointestinal hormones—*gastrin*, *secretin*, *cholecystokinin*, *glucagonlike peptide–1 (GLP-1),* and *glucose-dependent insulinotropic peptide (GIP)*—can cause moderate increases in insulin secretion. Two of these hormones, GLP-1 and GIP, appear to be the most potent and are often called *incretins* because they enhance the rate of insulin release from the pancreatic beta cells in response to an increase in plasma glucose. They also inhibit glucagon secretion from the alpha cells of the islets of Langerhans.

These hormones are released in the gastrointestinal tract after a person eats a meal. They then cause an "anticipatory" increase in blood insulin in preparation for the glucose and amino acids to be absorbed from the meal. These gastrointestinal hormones generally act the same way as amino acids to increase the sensitivity of insulin response to increased blood glucose, almost doubling the rate of insulin secretion as the blood glucose level rises. As discussed later in the chapter, several drugs have been developed to mimic or enhance the actions of incretins for treatment of diabetes mellitus.

Other Hormones and the Autonomic Nervous System. Other hormones that either directly increase insulin secretion or potentiate the glucose stimulus for insulin secretion include *glucagon, growth hormone, cortisol,* and, to a lesser extent, *progesterone* and *estrogen.* The importance of the stimulatory effects of these hormones is that prolonged secretion of any one of them in large quantities can occasionally lead to exhaustion of the beta cells of the islets of Langerhans and thereby increase the risk for development of diabetes mellitus. Indeed, diabetes often occurs in people who receive high pharmacological maintenance doses of some of these hormones. Diabetes is particularly common in giants or in acromegalic people who have tumors that secrete growth hormone, as well as in people whose adrenal glands secrete excess glucocorticoids.

The pancreas islets are richly innervated with sympathetic and parasympathetic nerves. Stimulation of the parasympathetic nerves to the pancreas can increase insulin secretion during hyperglycemic conditions, whereas sympathetic nerve stimulation may increase glucagon secretion and decrease insulin secretion during hypoglycemia. Glucose concentrations are believed to be detected by specialized neurons of the hypothalamus and brain stem, as well as by glucose-sensing cells in peripheral locations such as the liver.

THE ROLE OF INSULIN (AND OTHER HORMONES) IN "SWITCHING" BETWEEN CARBOHYDRATE AND LIPID METABOLISM

From the preceding discussions, it should be clear that insulin promotes utilization of carbohydrates for energy and depresses utilization of fats. Conversely, lack of insulin causes fat utilization mainly to the exclusion of glucose utilization, except by brain tissue. Furthermore, the signal that controls this switching mechanism is principally the blood glucose concentration. When glucose concentration is low, insulin secretion is suppressed, and fat is used almost exclusively for energy everywhere except in the brain. When the glucose concentration is high, insulin secretion is stimulated, and carbohydrate is used instead of fat. The excess blood glucose is stored in the form of liver glycogen, liver fat, and muscle glycogen. Therefore, one of the most important functional roles of insulin in the body is to control which of these two foods will be used by the cells for energy from moment to moment.

At least four other known hormones also play important roles in this switching mechanism— *growth hormone* from the anterior pituitary gland, *cortisol* from the adrenal cortex, *epinephrine* from the adrenal medulla, and *glucagon* from the alpha cells of the islets of Langerhans in the pancreas. Glucagon is discussed in the next section of this chapter. Both growth hormone and cortisol are secreted in response to hypoglycemia, and both inhibit cellular utilization of glucose while promoting fat utilization. However, the effects of both of these hormones develop slowly, usually requiring many hours for maximal expression.

Epinephrine is especially important in increasing plasma glucose concentration during periods of stress when the sympathetic nervous system is excited. However, epinephrine acts differently from the other hormones in that it increases plasma fatty acid concentration at the same time. The reasons for these effects are as

follows: (1) epinephrine has the potent effect of causing glycogenolysis in the liver, thus releasing large quantities of glucose into the blood within minutes, and (2) it also has a direct lipolytic effect on the adipose cells because it activates adipose tissue hormone-sensitive lipase, thus greatly enhancing blood concentration of fatty acids as well. Quantitatively, the enhancement of fatty acids is far greater than the enhancement of blood glucose. Therefore, epinephrine especially increases utilization of fat in such stressful states as exercise, circulatory shock, and anxiety.

GLUCAGON AND ITS FUNCTIONS

Glucagon, a hormone secreted by the *alpha cells* of the islets of Langerhans when blood glucose concentration falls, has several functions that are diametrically opposed to those of insulin. The most important of these functions is to increase the blood glucose concentration, an effect that is opposite to that of insulin.

Like insulin, glucagon is a large polypeptide. It has a molecular weight of 3485 and is composed of a chain of 29 amino acids. Upon injection of purified glucagon into an animal, a profound *hyperglycemic* effect occurs. Only 1 μg/kg of glucagon can elevate the blood glucose concentration approximately 20 mg/100 ml of blood (a 25% increase) in about 20 minutes. For this reason, glucagon is also called the *hyperglycemic hormone*.

EFFECTS ON GLUCOSE METABOLISM

The major effects of glucagon on glucose metabolism are (1) breakdown of liver glycogen *(glycogenolysis)* and (2) increased *gluconeogenesis* in the liver. Both of these effects greatly enhance the availability of glucose to the other organs of the body.

Glucagon Causes Glycogenolysis and Increased Blood Glucose Concentration

The most dramatic effect of glucagon is its ability to cause glycogenolysis in the liver, which in turn increases the blood glucose concentration within minutes. It performs this function through the following complex cascade of events:

1. Glucagon activates *adenylyl cyclase* in the hepatic cell membrane,
2. Which causes the formation of *cyclic adenosine monophosphate*,
3. Which activates *protein kinase regulator protein*,
4. Which activates *protein kinase*,
5. Which activates *phosphorylase b kinase*,
6. Which converts *phosphorylase b* into *phosphorylase a*,
7. Which promotes the degradation of glycogen into glucose-1-phosphate,
8. Which is then dephosphorylated, and the glucose is released from the liver cells.

This sequence of events is exceedingly important for several reasons. First, it is one of the most thoroughly studied of all the *second messenger* functions of cyclic adenosine monophosphate (cAMP). Second, it demonstrates a cascade system in which *each succeeding product is produced in greater quantity than the preceding product*. Therefore, it represents a potent *amplifying* mechanism. This type of amplifying mechanism is widely used throughout the body for controlling many, if not most, cellular metabolic systems, often causing as much as a millionfold amplification in response. This mechanism explains how *only a few micrograms of glucagon can cause the blood glucose level to double or increase even more within a few minutes.*

Infusion of glucagon for about 4 hours can cause such intensive liver glycogenolysis that all the liver stores of glycogen become depleted.

Glucagon Increases Gluconeogenesis

Even after all the glycogen in the liver has been exhausted under the influence of glucagon, continued infusion of this hormone still causes continued hyperglycemia. This hyperglycemia results from the effect of glucagon to increase the rate of amino acid uptake by the liver cells and then the conversion of many of the amino acids to glucose by gluconeogenesis. This effect is achieved by activating multiple enzymes that are required for amino acid transport and gluconeogenesis, especially activation of the enzyme system for converting pyruvate to phosphoenolpyruvate, a rate-limiting step in gluconeogenesis.

Other Effects of Glucagon

Most other effects of glucagon occur only when its concentration rises well above the maximum normally found in the blood. Perhaps the most important effect is that *glucagon activates adipose cell lipase,* making increased quantities of fatty acids available to the energy systems of the body. Glucagon also inhibits storage of triglycerides in the liver, which prevents the liver from removing fatty acids from the blood; this also helps make additional amounts of fatty acids available for the other tissues of the body.

Glucagon in high concentrations also (1) enhances the strength of the heart; (2) increases blood flow in some tissues, especially the kidneys; (3) enhances bile secretion; and (4) inhibits gastric acid secretion. These effects of glucagon are probably of much less importance in the normal function of the body compared with its effects on glucose.

REGULATION OF GLUCAGON SECRETION

Increased Blood Glucose Inhibits Glucagon Secretion. Blood glucose concentration is by far the most potent factor that controls glucagon secretion. Note specifically, however, that *the effect of blood glucose concentration on glucagon secretion is in exactly the opposite direction from the effect of glucose on insulin secretion*.

This is demonstrated in **Figure 79-10**, which shows that a *decrease* in the blood glucose concentration from

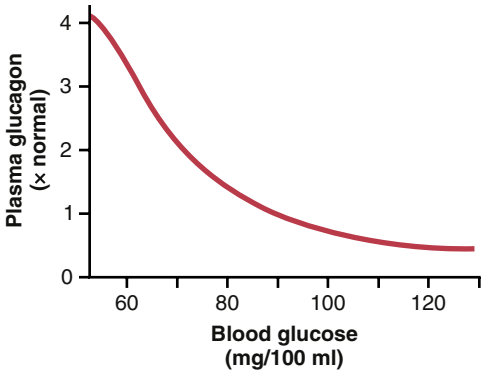

Figure 79-10. The approximate plasma glucagon concentration at different blood glucose levels.

its normal fasting level of about 90 mg/100 ml of blood down to hypoglycemic levels can increase the plasma concentration of glucagon severalfold. Conversely, increasing blood glucose to hyperglycemic levels decreases plasma glucagon concentration. Thus, in hypoglycemia, glucagon is secreted in large amounts; it then greatly increases the output of glucose from the liver and thereby serves the important function of correcting the hypoglycemia.

Increased Blood Amino Acids Stimulate Secretion of Glucagon. High concentrations of amino acids, such as those that occur in the blood after a meal containing protein (especially the amino acids *alanine* and *arginine*), *stimulate* secretion of glucagon. This is the same effect that amino acids have in stimulating insulin secretion. Thus, in this instance, the glucagon and insulin responses are not opposites. The importance of amino acid stimulation of glucagon secretion is that the glucagon then promotes rapid conversion of the amino acids to glucose, thus making even more glucose available to the tissues.

Exercise Stimulates Secretion of Glucagon. During exhaustive exercise, blood glucagon concentration often increases fourfold to fivefold. The cause of this increase is not well understood because the blood glucose concentration does not necessarily fall. A beneficial effect of the glucagon is that it prevents a decrease in blood glucose.

One of the factors that might increase glucagon secretion during exercise is increased circulating amino acids. Other factors, such as β-adrenergic stimulation of the islets of Langerhans, may also play a role.

Somatostatin Inhibits Glucagon and Insulin Secretion

The *delta cells* of the islets of Langerhans secrete the hormone *somatostatin,* a 14–amino acid polypeptide that has an extremely short half-life of only 3 minutes in the circulating blood. Almost all factors related to ingestion of food stimulate somatostatin secretion. These factors include (1) increased blood glucose, (2) increased amino acids, (3) increased fatty acids, and (4) increased concentrations of several of the gastrointestinal hormones released from the upper gastrointestinal tract in response to food intake.

In turn, somatostatin has multiple inhibitory effects, as follows:

1. Somatostatin acts locally within the islets of Langerhans themselves to depress secretion of both insulin and glucagon.
2. Somatostatin decreases motility of the stomach, duodenum, and gallbladder.
3. Somatostatin decreases both secretion and absorption in the gastrointestinal tract.

In putting all this information together, it has been suggested that the principal role of somatostatin is to extend the period over which the food nutrients are assimilated into the blood. At the same time, the effect of somatostatin in depressing insulin and glucagon secretion decreases utilization of the absorbed nutrients by the tissues, thus preventing rapid exhaustion of the food and therefore making it available over a longer period.

Somatostatin is also the same chemical substance as *growth hormone inhibitory hormone,* which is secreted in the hypothalamus and suppresses secretion of growth hormone by the anterior pituitary gland.

SUMMARY OF BLOOD GLUCOSE REGULATION

The blood glucose concentration is narrowly controlled normally, usually between 80 and 90 mg/100 ml of blood in the fasting person each morning before breakfast. This concentration increases to 120 to 140 mg/100 ml during the first hour or so after a meal, but the feedback systems for controlling blood glucose rapidly return glucose concentration back to the control level, usually within 2 hours after the last absorption of carbohydrates. Conversely, in a state of starvation, the gluconeogenesis function of the liver provides the glucose required to maintain the fasting blood glucose level.

The mechanisms for achieving this high degree of control have been presented in this chapter and may be summarized as follows:

1. *The liver functions as an important blood glucose buffer system.* That is, when blood glucose rises to a high concentration after a meal and insulin secretion also increases, as much as two-thirds of the glucose absorbed from the gut is rapidly stored as glycogen in the liver. Then, during the succeeding hours, when blood glucose concentration and insulin secretion fall, the liver releases the glucose back into the blood. In this way, the liver decreases fluctuations in blood glucose concentration to about one-third of what they would be otherwise. In fact, in patients with severe liver disease, it becomes almost impossible to maintain a narrow range of blood glucose concentration.
2. *Both insulin and glucagon function as important feedback control systems for maintaining a normal blood glucose concentration.* When the glucose concentration rises too high, increased insulin secretion causes blood glucose concentration to decrease

toward normal. Conversely, a decrease in blood glucose stimulates glucagon secretion; the glucagon then functions in the opposite direction to increase glucose toward normal. Under most normal conditions, the insulin feedback mechanism is more important than the glucagon mechanism, but in instances of starvation or excessive utilization of glucose during exercise and other stressful situations, the glucagon mechanism also becomes valuable.

3. In severe hypoglycemia, a direct effect of low blood glucose on the hypothalamus also stimulates the sympathetic nervous system. The epinephrine secreted by the adrenal glands further increases release of glucose from the liver, which also helps protect against severe hypoglycemia.
4. Finally, over a period of hours and days, both growth hormone and cortisol are secreted in response to prolonged hypoglycemia. They both decrease the rate of glucose utilization by most cells of the body, converting instead to greater fat utilization. This process, too, helps return blood glucose concentration toward normal.

Importance of Blood Glucose Regulation. One might ask, "Why is it so important to maintain a constant blood glucose concentration, particularly because most tissues can shift to utilization of fats and proteins for energy in the absence of glucose?" The answer is that glucose is the only nutrient that normally can be used by the *brain, retina,* and *germinal epithelium of the gonads* in sufficient quantities to supply them optimally with their required energy. Therefore, it is important to maintain blood glucose concentration at a level sufficient to provide this necessary nutrition.

Most of the glucose formed by gluconeogenesis during the interdigestive period is used for metabolism in the brain. Indeed, it is important that the pancreas not secrete insulin during this time; otherwise, the scant supplies of glucose that are available would all go into the muscles and other peripheral tissues, leaving the brain without a nutritive source.

It is also important that blood glucose concentration not rise too high for several reasons:

1. Glucose can exert a large amount of osmotic pressure in the extracellular fluid, and a rise in glucose concentration to excessive values can cause considerable cellular dehydration.
2. An excessively high level of blood glucose concentration causes loss of glucose in the urine.
3. Loss of glucose in the urine also causes osmotic diuresis by the kidneys, which can deplete the body of its fluids and electrolytes.
4. Long-term increases in blood glucose may cause damage to many tissues, especially to blood vessels. Vascular injury associated with uncontrolled diabetes mellitus leads to increased risk for heart attack, stroke, end-stage renal disease, and blindness.

Diabetes Mellitus

Diabetes mellitus is a syndrome of impaired carbohydrate, fat, and protein metabolism caused by either lack of insulin secretion or decreased sensitivity of the tissues to insulin. There are two general types of diabetes mellitus:

1. *Type 1 diabetes*, also called *insulin-dependent diabetes mellitus*, is caused by lack of insulin secretion.
2. *Type 2 diabetes*, also called *non–insulin-dependent diabetes mellitus*, is initially caused by decreased sensitivity of target tissues to the metabolic effect of insulin. This reduced sensitivity to insulin is often called *insulin resistance.*

In both types of diabetes mellitus, metabolism of all the main foodstuffs is altered. The basic effect of insulin deficiency or insulin resistance on glucose metabolism is to prevent efficient uptake and utilization of glucose by most cells of the body, except those of the brain. As a result, blood glucose concentration increases, cell utilization of glucose falls increasingly lower, and utilization of fats and proteins increases.

Type 1 Diabetes—Deficiency of Insulin Production by Beta Cells of the Pancreas

Injury to the beta cells of the pancreas or diseases that impair insulin production can lead to type 1 diabetes. *Viral infections* or *autoimmune disorders* may be involved in the destruction of beta cells in many patients with type 1 diabetes, although heredity also plays a major role in determining the susceptibility of the beta cells to destruction by these insults. In some cases, persons may have a hereditary tendency for beta cell degeneration even without viral infections or autoimmune disorders.

The usual onset of type 1 diabetes occurs at about 14 years of age in the United States, and for this reason it is often called *juvenile diabetes mellitus.* However, type 1 diabetes can occur at any age, including adulthood, following disorders that lead to the destruction of pancreatic beta cells. Type 1 diabetes may develop abruptly, over a period of a few days or weeks, with three principal sequelae: (1) increased blood glucose levels, (2) increased utilization of fats for energy and for formation of cholesterol by the liver, and (3) depletion of the body's proteins. Approximately 5% to 10% of people with diabetes mellitus have the type 1 form of the disease.

Blood Glucose Concentration Rises to High Levels in Diabetes Mellitus. Lack of insulin decreases the efficiency of peripheral glucose utilization and augments glucose production, raising plasma glucose to 300 to 1200 mg/100 ml. The increased plasma glucose then has multiple adverse effects throughout the body.

Increased Blood Glucose Causes Loss of Glucose in the Urine. High levels of blood glucose cause more glucose to filter into the renal tubules than can be reabsorbed, and the excess glucose spills into the urine as explained in Chapter 28. This spillage normally occurs when the blood glucose concentration rises above about 200 mg/100 ml, a level that is called the blood "threshold" for the appearance of glucose in the urine. When the blood glucose level rises to 300 to 500 mg/100 ml—common values in people with severe untreated diabetes—100 or more grams of glucose can be lost into the urine each day.

Increased Blood Glucose Causes Dehydration. Extremely high levels of blood glucose (sometimes as high as 8 to 10 times normal in severe untreated diabetes) can cause severe cell dehydration throughout the body. This dehydration occurs partly because glucose does not diffuse easily through the pores of the cell membrane, and the increased osmotic pressure in the extracellular fluids causes osmotic transfer of water out of the cells.

In addition to the direct cellular dehydrating effect of excessive glucose, loss of glucose in the urine causes *osmotic diuresis*—that is, the osmotic effect of glucose in the renal tubules greatly decreases tubular reabsorption of fluid. The overall effect is massive loss of fluid in the urine, causing dehydration of the extracellular fluid, which in turn causes compensatory dehydration of the intracellular fluid. Thus, *polyuria* (excessive urine excretion), *intracellular and extracellular dehydration,* and *increased thirst* are classic symptoms of diabetes.

Chronic High Glucose Concentration Causes Tissue Injury. When blood glucose is poorly controlled over long periods in diabetes mellitus, blood vessels in multiple tissues throughout the body begin to function abnormally and undergo structural changes that result in inadequate blood supply to the tissues. This situation in turn leads to increased risk for heart attack, stroke, end-stage kidney disease, retinopathy and blindness, and ischemia and gangrene of the limbs.

Chronic high glucose concentration also causes damage to many other tissues. For example, *peripheral neuropathy,* which is abnormal function of peripheral nerves, and *autonomic nervous system dysfunction* are frequent complications of chronic, uncontrolled diabetes mellitus. These abnormalities can result in impaired cardiovascular reflexes, impaired bladder control, decreased sensation in the extremities, and other symptoms of peripheral nerve damage.

The precise mechanisms that cause tissue injury in diabetes are not well understood but probably involve multiple effects of high glucose concentrations and other metabolic abnormalities on proteins of endothelial and vascular smooth muscle cells, as well as other tissues. In addition, *hypertension,* secondary to renal injury, and *atherosclerosis,* secondary to abnormal lipid metabolism, often develop in patients with diabetes and amplify the tissue damage caused by elevated glucose levels.

Diabetes Mellitus Causes Increased Utilization of Fats and Metabolic Acidosis. The shift from carbohydrate to fat metabolism in diabetes increases the release of keto acids, such as acetoacetic acid and β-hydroxybutyric acid, into the plasma more rapidly than they can be taken up and oxidized by the tissue cells. As a result, *metabolic acidosis* develops from the excess keto acids, which, in association with dehydration, can cause severe acidosis. This scenario leads rapidly to *diabetic coma* and death unless the patient is treated immediately with large amounts of insulin.

All the usual physiological compensations that occur in metabolic acidosis take place in diabetic acidosis, as discussed in Chapter 31. They include *rapid and deep breathing,* which causes increased expiration of carbon dioxide; this mechanism buffers the acidosis but also depletes extracellular fluid bicarbonate stores. The kidneys compensate by decreasing bicarbonate excretion and generating new bicarbonate that is added back to the extracellular fluid.

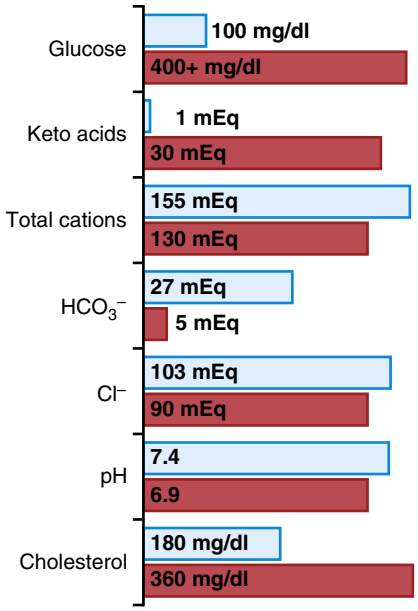

Figure 79-11. Changes in blood constituents in diabetic coma, showing normal values *(blue bars)* and diabetic coma values *(red bars).*

Although extreme acidosis occurs only in the most severe cases of uncontrolled diabetes, when the pH of the blood falls below about 7.0, *acidotic coma* and death can occur within hours. The overall changes in blood electrolytes as a result of severe diabetic acidosis are shown in Figure 79-11.

Excess fat utilization in the liver over a long time causes large amounts of cholesterol in the circulating blood and increased deposition of cholesterol in the arterial walls. This situation leads to severe *arteriosclerosis* and other vascular lesions, as discussed earlier.

Diabetes Causes Depletion of the Body's Proteins. Failure to use glucose for energy leads to increased utilization and decreased storage of proteins and fat. Therefore, a person with severe untreated diabetes mellitus experiences rapid weight loss and *asthenia* (lack of energy), despite eating large amounts of food *(polyphagia).* Without treatment, these metabolic abnormalities can cause severe wasting of the body tissues and death within a few weeks.

Treatment of Type 1 Diabetes. Effective treatment of type 1 diabetes mellitus requires administration of enough insulin so that the patient will have carbohydrate, fat, and protein metabolism that is as normal as possible. Insulin is available in several forms. "Regular" insulin has a duration of action that lasts from 3 to 8 hours, whereas other forms of insulin (precipitated with zinc or with various protein derivatives) are absorbed slowly from the injection site and therefore have effects that last as long as 10 to 48 hours. Ordinarily, a patient with severe type 1 diabetes is given a single dose of one of the longer-acting insulins each day to increase overall carbohydrate metabolism throughout the day. Additional quantities of regular insulin are then given during the day at the times when the blood glucose level tends to rise too high, such as at mealtimes. Thus, each patient is provided with an individualized pattern of treatment.

In the past, the insulin used for treatment was derived from animal pancreata. However, human insulin produced

by the recombinant DNA process has become more widely used because immunity and sensitization against animal insulin develops in some patients, thus limiting its effectiveness.

Type 2 Diabetes—Resistance to the Metabolic Effects of Insulin

Type 2 diabetes is far more common than type 1 diabetes, accounting for about 90% to 95% of all cases of diabetes mellitus. In most cases, the onset of type 2 diabetes occurs after age 30 years, often between the ages of 50 and 60 years, and the disease develops gradually. Therefore, this syndrome is often referred to as *adult-onset diabetes.* In recent years, however, there has been a steady increase in the number of younger individuals, some younger than 20 years old, with type 2 diabetes. This trend appears to be related mainly to the increasing prevalence of *obesity, the most important risk factor for type 2 diabetes* in children and adults.

Obesity, Insulin Resistance, and "Metabolic Syndrome" Usually Precede Development of Type 2 Diabetes. Type 2 diabetes, in contrast to type 1 diabetes, is associated with *increased* plasma insulin concentration. The *hyperinsulinemia* occurs as a compensatory response by the pancreatic beta cells for *insulin resistance*, a diminished sensitivity of target tissues to the metabolic effects of insulin. The decrease in insulin sensitivity impairs carbohydrate utilization and storage, raising blood glucose and stimulating a compensatory increase in insulin secretion.

The development of insulin resistance and impaired glucose metabolism is usually a gradual process, beginning with excess weight gain and obesity. Some studies suggest that obese subjects have fewer insulin receptors, especially in the skeletal muscle, liver, and adipose tissue, than do lean subjects. However, most of the insulin resistance appears to be caused by abnormalities of the signaling pathways that link receptor activation with multiple cellular effects. Impaired insulin signaling may be closely related to toxic effects of lipid accumulation in tissues such as skeletal muscle and liver as a result of excess weight gain.

Insulin resistance is part of a cascade of disorders that is often called the *"metabolic syndrome."* Some of the features of the metabolic syndrome include (1) obesity, especially accumulation of abdominal fat; (2) insulin resistance; (3) fasting hyperglycemia; (4) lipid abnormalities, such as increased blood triglycerides and decreased blood high-density lipoprotein-cholesterol; and (5) hypertension. All of the features of the metabolic syndrome are closely related to accumulation of excess adipose tissue in the abdominal cavity around the visceral organs.

The role of insulin resistance in contributing to some of the components of the metabolic syndrome is uncertain, although it is clear that insulin resistance is the primary cause of increased blood glucose concentration. A major adverse consequence of the metabolic syndrome is cardiovascular disease, including atherosclerosis and injury to various organs throughout the body. Several of the metabolic abnormalities associated with the syndrome increase the risk for cardiovascular disease, and insulin resistance predisposes to the development of type 2 diabetes mellitus, which is also a major cause of cardiovascular disease.

TABLE 79-2 Some Causes of Insulin Resistance

- Obesity/overweight (especially excess visceral adiposity)
- Excess glucocorticoids (Cushing's syndrome or steroid therapy)
- Excess growth hormone (acromegaly)
- Pregnancy, gestational diabetes
- Polycystic ovary disease
- Lipodystrophy (acquired or genetic; associated with lipid accumulation in liver)
- Autoantibodies to the insulin receptor
- Mutations of insulin receptor
- Mutations of the peroxisome proliferators' activator receptor γ (PPARγ)
- Mutations that cause genetic obesity (e.g., melanocortin receptor mutations)
- Hemochromatosis (a hereditary disease that causes tissue iron accumulation)

Other Factors That Can Cause Insulin Resistance and Type 2 Diabetes. Although most patients with type 2 diabetes are overweight or have substantial accumulation of visceral fat, severe insulin resistance and type 2 diabetes can also occur as a result of other acquired or genetic conditions that impair insulin signaling in peripheral tissues (Table 79-2).

Polycystic ovary syndrome (PCOS), for example, is associated with marked increases in ovarian androgen production and insulin resistance. PCOS is one of the most common endocrine disorders in women, affecting approximately 6% of all women during their reproductive life. Although the pathogenesis of PCOS remains uncertain, insulin resistance and hyperinsulinemia are found in approximately 80% of affected women. The long-term consequences include increased risk for diabetes mellitus, increased blood lipids, and cardiovascular disease.

Excess formation of glucocorticoids (Cushing's syndrome) or *excess formation of growth hormone (acromegaly)* also decreases the sensitivity of various tissues to the metabolic effects of insulin and can lead to development of diabetes mellitus. Genetic causes of obesity and insulin resistance, if severe enough, also can lead to type 2 diabetes and many other features of the metabolic syndrome, including cardiovascular disease.

Development of Type 2 Diabetes During Prolonged Insulin Resistance. With prolonged and severe insulin resistance, even the increased levels of insulin are not sufficient to maintain normal glucose regulation. As a result, moderate hyperglycemia occurs after ingestion of carbohydrates in the early stages of the disease.

In the later stages of type 2 diabetes, the pancreatic beta cells become "exhausted" or damaged and are unable to produce enough insulin to prevent more severe hyperglycemia, especially after the person ingests a carbohydrate-rich meal.

Clinically significant diabetes mellitus may not develop in some obese people, even though they have marked insulin resistance and greater than normal increases in blood glucose after a meal; apparently, the pancreas in these people produces enough insulin to prevent severe abnormalities of glucose metabolism. In other obese people, however, the pancreas gradually becomes exhausted from secreting

large amounts of insulin or damaged by factors associated with lipid accumulation in the pancreas, and full-blown diabetes mellitus occurs. Some studies suggest that genetic factors play an important role in determining whether an individual's pancreas can sustain the high output of insulin over many years that is necessary to avoid the severe abnormalities of glucose metabolism in type 2 diabetes.

Treatment of Type 2 Diabetes by Lifestyle Modifications, Increasing Insulin Sensitivity, and Enhancing Insulin Secretion. In many cases, type 2 diabetes can be effectively treated, at least in the early stages, with lifestyle modifications aimed at increasing physical activity, caloric restriction, and weight reduction, and no exogenous administration of insulin is required. Drugs that increase insulin sensitivity, such as *thiazolidinediones*, drugs that suppress liver glucose production, such as *metformin,* or drugs that cause additional release of insulin by the pancreas, such as *sulfonylureas,* may also be used. However, in the later stages of type 2 diabetes, insulin administration is usually required to control plasma glucose levels.

Incretin drugs that mimic the actions of the GLP-1 have been developed for treatment of type 2 diabetes. These drugs enhance insulin secretion and are intended to be used in conjunction with other antidiabetic drugs. Another therapeutic approach is to inhibit the enzyme *dipeptidyl peptidase 4 (DPP-4),* which inactivates GLP-1 and GIP. By blocking the actions of DPP-4, the incretin effects of GLP-1 and GIP can be prolonged, leading to increased insulin secretion and improved control of blood glucose levels.

Treatment of Type 2 Diabetes by Inhibition of Sodium-Glucose Transporter 2 (SGLT2). As discussed in Chapter 28, approximately 90% of the glucose filtered by renal glomerular capillaries is reabsorbed from the proximal tubules by the sodium glucose co-transporter 2 (SGLT2). Several medications, called *gliflozins*, have been developed to treat type 2 diabetes by inhibiting SGLT2. These *SGLT2 inhibitors* greatly reduce renal glucose reabsorption, causing large amounts of glucose to be excreted in the urine and reducing the blood glucose concentration. SGLT2 inhibitors are often used in combination with other drugs that enhance insulin sensitivity or stimulate insulin secretion and have been shown in clinical trials to provide significant protection against cardiovascular and kidney disease in patients with diabetes.

In addition to increasing glucose excretion, SGLT2 inhibitors also cause marked diuresis due to the osmotic effect of the glucose remaining in the renal tubules. The diuresis can be beneficial for causing small reductions in blood pressure in patients with type 2 diabetes who often suffer from hypertension, but may also increase the risk for dehydration and hypotension in patients who are already taking other diuretics and antihypertensive mediations.

Treatment of Type 2 Diabetes With Surgery. In many people who suffer from severe obesity and type 2 diabetes, treatment regimens focused on diet, exercise, and pharmacotherapy do not produce adequate reductions in adiposity and blood glucose. In these cases, various *bariatric surgery* procedures can be used to reduce fat mass and achieve improved control of blood glucose. The two most widely used procedures, *gastric bypass surgery* and *vertical sleeve gastrectomy* (discussed in Chapter 72), are often called *"metabolic surgery"* because many patients who undergo these operations experience complete remission of diabetes and no longer require antidiabetic drugs. Improvements of blood glucose, lipids and blood pressure often occur within a few days or weeks after surgery, suggesting that the mechanisms for these cardiovascular and metabolic benefits may extend beyond weight loss and reductions in adiposity. However, the physiological factors that contribute to the favorable metabolic effects of these surgical procedures are still unclear.

TABLE 79-3 Clinical Characteristics of Patients With Type 1 and Type 2 Diabetes Mellitus

Feature	Type 1	Type 2
Age at onset	Usually <20 yr	Usually >30 yr
Body mass	Low (wasted) to normal	Visceral obesity
Plasma insulin	Low or absent	Normal to high initially
Plasma glucagon	High, can be suppressed	High, resistant to suppression
Plasma glucose	Increased	Increased
Insulin sensitivity	Normal	Reduced
Therapy	Insulin	Weight loss, bariatric surgery, thiazolidinediones, metformin, sulfonylureas, SGLT2 inhibitors, insulin

SGLT2, Sodium glucose co-transporter 2.

Physiology of Diagnosis of Diabetes Mellitus

Table 79-3 compares some of the clinical features of type 1 and type 2 diabetes mellitus. The usual methods for diagnosing diabetes are based on various chemical tests of the urine and the blood.

Urinary Glucose. Simple office tests or more complicated quantitative laboratory tests may be used to determine the quantity of glucose excreted in the urine. In general, a nondiabetic person excretes undetectable amounts of glucose, whereas a person with diabetes loses glucose in small to large amounts, in proportion to the severity of the disease and the intake of carbohydrates.

Fasting Blood Glucose and Insulin Concentrations. Fasting blood glucose concentration in the early morning is normally 80 to 90 mg/100 ml, and 115 mg/100 ml is considered to be the upper limit of normal. A fasting blood glucose level above this value often indicates diabetes mellitus or at least marked insulin resistance and *prediabetes*.

In persons with type 1 diabetes, plasma insulin levels are very low or undetectable during fasting and even after a meal. In persons with type 2 diabetes, plasma insulin concentration may be severalfold higher than normal and usually increases to a greater extent after ingestion of a standard glucose load during a glucose tolerance test (see the next section).

Glycated Hemoglobin. When blood glucose levels are elevated for prolonged periods of time, glucose attaches to

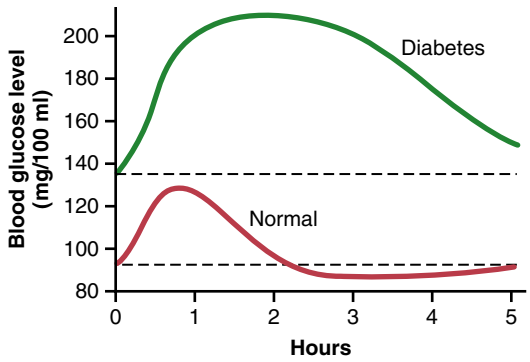

Figure 79-12. Glucose tolerance curve in a normal person and in a person with diabetes.

hemoglobin in red blood cells to form *glycated hemoglobin*, often called *hemoglobin A1c* (HbA1c). The longer hyperglycemia occurs, the more glucose binds to hemoglobin and once hemoglobin is glycated, it remains that way for the life of the cell. Therefore, buildup of HbA1c in a red blood cell reflects the average glucose concentration to which the cell has been exposed during its life-cycle. Because the average lifespan of red blood cells is about 120 days and individual cells have varying lifespans, the HbA1c test is used mainly to assess average blood glucose concentrations for the previous three months and can provide a diagnostic test for diabetes mellitus or an assessment test of glycemic control in people with diabetes.

Glucose Tolerance Test. As demonstrated by the bottom curve in Figure 79-12, called a "glucose tolerance curve," when a normal, fasting person ingests 1 gram of glucose per kilogram of body weight, the blood glucose level rises from about 90 mg/100 ml to 120 to 140 mg/100 ml and falls back to below normal in about 2 hours.

In a person with diabetes, the fasting blood glucose concentration is almost always above 115 mg/100 ml and often is above 140 mg/100 ml. In addition, results of the glucose tolerance test are almost always abnormal. After ingestion of glucose, these people exhibit a much greater than normal rise in blood glucose level, as demonstrated by the upper curve in Figure 79-12, and the glucose level falls back to the control value only after 4 to 6 hours; furthermore, it fails to fall *below* the control level. The slow fall of this curve and its failure to fall below the control level demonstrate that either (1) the normal increase in insulin secretion after glucose ingestion does not occur, or (2) the person has decreased sensitivity to insulin. A diagnosis of diabetes mellitus can usually be established on the basis of such a curve, and type 1 and type 2 diabetes can be distinguished from each other by measurements of plasma insulin, with plasma insulin being low or undetectable in type 1 diabetes and increased in type 2 diabetes.

Acetone Breath. As pointed out in Chapter 69, small quantities of acetoacetic acid in the blood, which increase greatly in severe diabetes, are converted to acetone. Acetone is volatile and is vaporized into the expired air. Consequently, one can frequently make a diagnosis of type 1 diabetes mellitus simply by smelling acetone on the breath of a patient. Also, keto acids can be detected by chemical means in the urine, and their quantitation aids in determining the severity of the diabetes. In the early stages of type 2 diabetes, however, keto acids are usually not produced in excess amounts. However, when insulin resistance becomes severe and there is greatly increased utilization of fats for energy, keto acids are then produced in persons with type 2 diabetes.

Relation of Treatment to Arteriosclerosis and Chronic Kidney Disease. Mainly because of the hypertension and high levels of circulating cholesterol and other lipids in diabetic patients, atherosclerosis, arteriosclerosis, severe coronary heart disease, chronic kidney disease, and multiple microcirculatory lesions develop far more easily than in nondiabetic people. Indeed, persons who have poorly controlled diabetes throughout childhood are likely to die of heart disease in early adulthood.

In the early days of diabetes treatment, the tendency was to severely reduce carbohydrates in the diet to minimize insulin requirements. This approach kept the blood glucose from reaching too high a level and attenuated the loss of glucose in the urine, but it did not prevent many of the abnormalities of fat metabolism. Consequently, the current tendency is to permit the patient to consume an almost normal carbohydrate diet while administering enough insulin to metabolize the carbohydrates. This approach decreases the rate of fat metabolism and depresses the high level of cholesterol in the blood.

Because complications of diabetes such as atherosclerosis, increased susceptibility to infection, diabetic retinopathy, cataracts, hypertension, and chronic renal disease are closely associated with the levels of lipids and glucose in the blood, most physicians also prescribe lipid-lowering drugs to help prevent these disturbances.

Insulinoma—Hyperinsulinism

Although excessive insulin production occurs much more rarely than does diabetes, it occasionally can be a consequence of an adenoma of an islet of Langerhans. About 10% to 15% of these adenomas are malignant, and occasionally metastases from the islets of Langerhans spread throughout the body, causing tremendous production of insulin by both the primary and metastatic cancers. Indeed, some of these patients have required more than 1000 grams of glucose every 24 hours to prevent hypoglycemia.

Insulin Shock and Hypoglycemia. As already emphasized, the central nervous system normally derives essentially all its energy from glucose metabolism, and insulin is not necessary for this use of glucose. However, if high levels of insulin cause blood glucose to fall to low levels, the metabolism of the central nervous system becomes depressed. Consequently, in patients with insulin-secreting tumors or in patients with diabetes who administer too much insulin to themselves, the syndrome called *insulin shock* may occur as follows.

As blood glucose level falls into the range of 50 to 70 mg/100 ml, the central nervous system usually becomes excitable because this degree of hypoglycemia sensitizes neuronal activity. Sometimes various forms of hallucinations result, but more often the patient simply experiences extreme nervousness, trembles all over, and breaks out in a sweat. As blood glucose level falls to 20 to 50 mg/100 ml, clonic seizures and loss of consciousness are likely to occur. As the glucose level falls still lower, the seizures cease and only a state of coma remains. Indeed, when using simple clinical observation, it is sometimes difficult to distinguish

between diabetic coma as a result of acidosis caused by a lack of insulin and coma due to hypoglycemia caused by excess insulin. The acetone breath and the rapid, deep breathing of persons in a diabetic coma are not present in persons in a hypoglycemic coma.

Proper treatment for a patient who has hypoglycemic shock or coma is immediate intravenous administration of large quantities of glucose. This treatment usually brings the patient out of shock within a minute or more. Also, administration of glucagon (or, less effectively, epinephrine) can cause glycogenolysis in the liver and thereby increase the blood glucose level extremely rapidly. If treatment is not administered immediately, permanent damage to the neuronal cells of the central nervous system often occurs.

CHAPTER 80

UNIT XIV

Parathyroid Hormone, Calcitonin, Calcium and Phosphate Metabolism, Vitamin D, Bone, and Teeth

The physiology of calcium and phosphate metabolism, formation of bone and teeth, and regulation of *vitamin D, parathyroid hormone* (PTH), and *calcitonin* are all closely intertwined. The extracellular calcium ion concentration, for example, is determined by the interplay of calcium absorption from the intestine, renal excretion of calcium, and bone uptake and release of calcium, each of which is regulated by the hormones just noted. Because phosphate homeostasis and calcium homeostasis are closely associated, they are discussed together in this chapter.

OVERVIEW OF CALCIUM AND PHOSPHATE REGULATION IN EXTRACELLULAR FLUID AND PLASMA

Extracellular fluid calcium concentration is normally regulated precisely; it seldom rises or falls more than a few percent from the normal value of about 9.4 mg/dl, which is equivalent to 2.4 millimoles of calcium per liter. This precise control is essential because calcium plays a key role in many physiological processes, including contraction of skeletal, cardiac, and smooth muscles, blood clotting, and transmission of nerve impulses, to name just a few. Excitable cells such as neurons are sensitive to changes in calcium ion concentrations, and increases above normal *(hypercalcemia)* cause progressive depression of the nervous system; conversely, decreases in calcium concentration *(hypocalcemia)* cause the nervous system to become more excited.

An important feature of extracellular calcium regulation is that only about 0.1% of the total body calcium is in the extracellular fluid, about 1% is in the cells and its organelles, and the rest is stored in bones. Therefore, the bones can serve as large reservoirs, storing excess calcium and releasing calcium when extracellular fluid concentration decreases.

Approximately 85% of the body's phosphate is stored in bones, 14% to 15% is in the cells, and less than 1% is in the extracellular fluid. Although extracellular fluid phosphate concentration is not nearly as well regulated as calcium concentration, phosphate serves several important functions and is controlled by many of the same factors that regulate calcium.

CALCIUM IN THE PLASMA AND INTERSTITIAL FLUID

Calcium in the plasma is present in three forms, as shown in **Figure 80-1**: (1) About 41% (1 mmol/L) of the calcium is combined with plasma proteins and in this form is nondiffusible through the capillary membrane; (2) about 9% of the calcium (0.2 mmol/L) is diffusible through the capillary membrane but is combined with anionic substances of the plasma and interstitial fluids (e.g., citrate and phosphate) in such a manner that it is not ionized; and (3) the remaining 50% of the calcium in plasma is diffusible through the capillary membrane and ionized.

Thus, the plasma and interstitial fluids have a normal calcium *ion* concentration of about 1.2 mmol/L (or 2.4 mEq/L, because it is a divalent ion), a level only one-half the total plasma calcium concentration. This ionic calcium is the form that is important for most functions of calcium in the body, including the effect of calcium on the heart, the nervous system, and bone formation.

INORGANIC PHOSPHATE IN THE EXTRACELLULAR FLUIDS

Inorganic phosphate in the plasma is mainly in two forms, $HPO_4^=$ and $H_2PO_4^-$. The concentration of $HPO_4^=$ is about

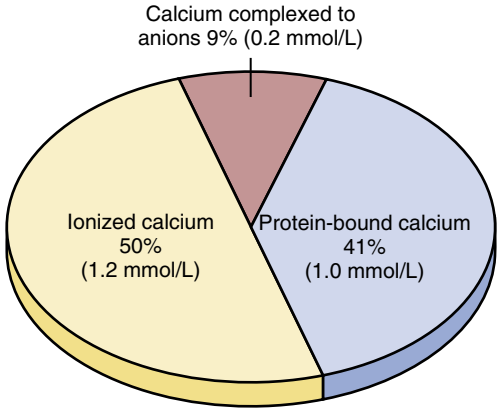

Figure 80-1. Distribution of ionized calcium (Ca^{2+}), diffusible but un-ionized calcium complexed to anions, and nondiffusible protein-bound calcium in blood plasma.

1.05 mmol/L, and the concentration of $H_2PO_4^-$ is about 0.26 mmol/L. When the total quantity of phosphate in the extracellular fluid rises, so does the quantity of each of these two types of phosphate ions. Furthermore, when the pH of the extracellular fluid becomes more acidic, there is a relative increase in $H_2PO_4^-$ and a decrease in $HPO_4^=$, whereas the opposite occurs when the extracellular fluid becomes alkaline. These relations were presented in the discussion of acid-base balance in Chapter 31.

Because it is difficult to determine chemically the exact quantities of $HPO_4^=$ and $H_2PO_4^-$ in the blood, ordinarily the total quantity of phosphate is expressed in terms of milligrams of *phosphorus* per deciliter (100 milliliters) of blood. The average total quantity of inorganic phosphorus represented by both phosphate ions is about 4 mg/dl, varying between normal limits of 3 to 4 mg/dl in adults and 4 to 5 mg/dl in children.

NONBONE PHYSIOLOGICAL EFFECTS OF ALTERED CALCIUM AND PHOSPHATE CONCENTRATIONS IN THE BODY FLUIDS

Changing the level of phosphate in the extracellular fluid from far below normal to two to three times normal does not cause major immediate effects on the body. In contrast, even slight increases or decreases of calcium ion in the extracellular fluid can cause extreme immediate physiological effects. In addition, chronic hypocalcemia or hypophosphatemia greatly decreases bone mineralization, as is explained later in the chapter.

Hypocalcemia Causes Nervous System Excitement and Tetany. When the extracellular fluid concentration of calcium ions falls below normal, the nervous system becomes progressively more excitable because of increased neuronal membrane permeability to sodium ions, allowing easy initiation of action potentials. At plasma calcium ion concentrations about 50% below normal, the peripheral nerve fibers become so excitable that they begin to discharge spontaneously, initiating trains of nerve impulses that pass to the peripheral skeletal muscles to elicit tetanic muscle contraction. Consequently, hypocalcemia causes tetany. It also occasionally causes seizures because of its action of increasing excitability in the brain.

Figure 80-2 shows tetany in the hand, which usually occurs before tetany develops in most other parts of the body. This is called *carpopedal spasm.*

Tetany ordinarily occurs when the blood concentration of calcium falls from its normal level of 9.4 mg/dl to about 6 mg/dl, which is only 35% below the normal calcium concentration, and it is usually lethal at about 4 mg/dl.

In laboratory animals, extreme hypocalcemia can cause other effects that are seldom evident in patients, such as marked dilation of the heart, changes in cellular enzyme activities, increased membrane permeability in some cells (in addition to nerve cells), and impaired blood clotting.

Figure 80-2. Hypocalcemic tetany in the hand, called *carpopedal spasm.*

Hypercalcemia Depresses Nervous System and Muscle Activity. When calcium concentration in the body fluids rises above normal, the nervous system becomes depressed and reflex activities of the central nervous system are sluggish. Also, increased calcium ion concentration decreases the QT interval of the heart and causes lack of appetite and constipation, probably because of depressed contractility of the muscle walls of the gastrointestinal tract.

These depressive effects begin to appear when the blood level of calcium rises above about 12 mg/dl, and they can become marked as the calcium level rises above 15 mg/dl. When the calcium concentration rises above about 17 mg/dl in the blood, calcium phosphate crystals are likely to precipitate throughout the body; this condition is discussed later in connection with parathyroid poisoning.

ABSORPTION AND EXCRETION OF CALCIUM AND PHOSPHATE

Intestinal Absorption and Fecal Excretion of Calcium and Phosphate. The usual rates of intake are approximately 1000 mg/day each for calcium and phosphorus, about the amounts in 1 liter of milk. Normally, divalent cations such as calcium ions are poorly absorbed from the intestines. However, as discussed later, *vitamin D* promotes calcium absorption by the intestines, and about 35% (350 mg/day) of the ingested calcium is usually absorbed; the remaining calcium in the intestine is excreted in the feces. An additional 250 mg/day of calcium enters the intestines via secreted gastrointestinal juices and sloughed mucosal cells. Thus, about 90% (900 mg/day) of the daily intake of calcium is excreted in the feces (Figure 80-3).

Intestinal absorption of phosphate occurs easily. Except for the portion of phosphate that is excreted in the feces in combination with nonabsorbed calcium, almost all the dietary phosphate is absorbed into the blood from the gut and later excreted in the urine.

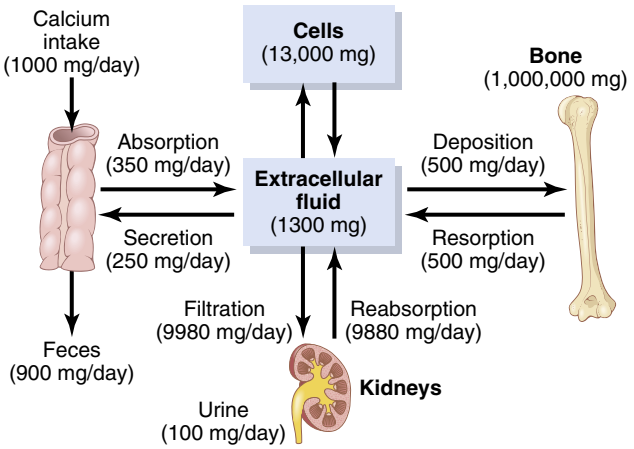

Figure 80-3. Overview of calcium exchange between different tissue compartments in a person ingesting 1000 mg of calcium per day. Note that most of the ingested calcium is normally eliminated in the feces, although the kidneys have the capacity to excrete large amounts by reducing tubular reabsorption of calcium.

Renal Excretion of Calcium and Phosphate. Approximately 10% (100 mg/day) of the ingested calcium is excreted in the urine. About 41% of the plasma calcium is bound to plasma proteins and is therefore not filtered by the glomerular capillaries. The remainder is combined with anions such as phosphate (9%) or ionized (50%) and filtered through the glomeruli into the renal tubules.

Normally, the renal tubules reabsorb 99% of the filtered calcium, and about 100 mg/day are excreted in the urine (see Chapter 30 for further discussion of renal calcium excretion). Approximately 90% of the calcium in the glomerular filtrate is reabsorbed in the proximal tubules, loops of Henle, and early distal tubules.

In the late distal tubules and early collecting ducts, reabsorption of the remaining 10% is more variable, depending on the calcium ion concentration in the blood.

When calcium concentration is low, this reabsorption is great, and almost no calcium is lost in the urine. Conversely, even a minute increase in blood calcium ion concentration above normal increases calcium excretion markedly. We shall see later in this chapter that the most important factor controlling this reabsorption of calcium in the distal portions of the nephron, and therefore controlling the rate of calcium excretion, is PTH.

Renal phosphate excretion is controlled by an *overflow mechanism,* as explained in Chapter 30. That is, when phosphate concentration in the plasma is below the critical value of about 1 mmol/L, all the phosphate in the glomerular filtrate is reabsorbed and no phosphate is lost in the urine. Above this critical concentration, however, the rate of phosphate loss is directly proportional to the additional increase. Thus, the kidneys regulate the phosphate concentration in the extracellular fluid by altering the rate of phosphate excretion in accordance with the plasma phosphate concentration and the rate of phosphate filtration by the kidneys.

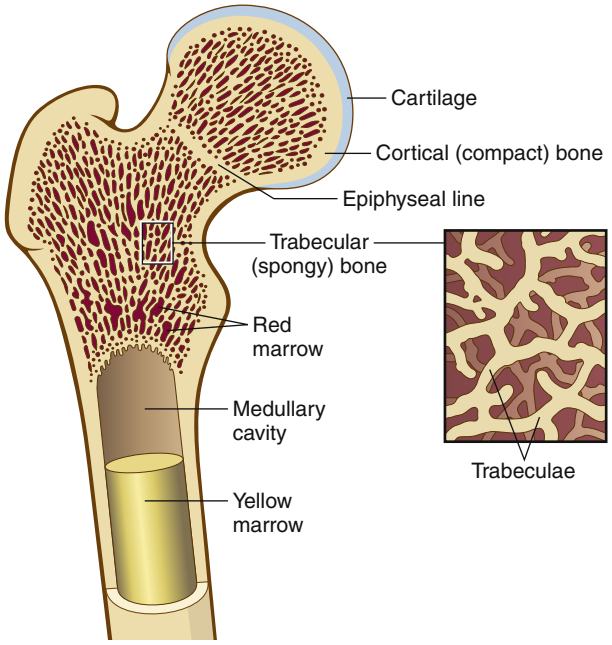

Figure 80-4. Cortical (compact) and trabecular (spongy) bone.

However, as discussed later in this chapter, PTH can greatly increase phosphate excretion by the kidneys, thereby playing an important role in the control of plasma phosphate and calcium concentrations.

BONE AND ITS RELATIONSHIP TO EXTRACELLULAR CALCIUM AND PHOSPHATE

There are two general type of bony tissue—*cortical (compact)* and *trabecular (spongy)* bone (**Figure 80-4**). Cortical bone forms the hard outer (cortex) layer, is much denser than trabecular bone, and accounts for about 80% of the total bone mass of the human skeleton. Cortical bone is especially thick in the shaft of long bones, such as those in the legs, which support the weight of the entire body.

Trabecular bone accounts for about 20% of bone mass and is found in the interior of skeletal bones. It is much more porous than cortical bone and is usually located at the ends of long bones, near joints and in the interior of vertebrae. Trabecular bone contains lattice-shaped units with bony spicules *(trabeculae)* that branch and unite with one another form an irregular meshwork. The spaces between the trabeculae are filled with red bone marrow where *hematopoiesis*, the production of blood cells, occurs. The rates of synthesis and resorption, and therefore bone turnover rate, are much higher for trabecular bone than for cortical bone.

Bone is composed of a tough *organic matrix* that is greatly strengthened by deposits of *calcium salts*. Average *cortical bone* contains by weight about 30% matrix and 70% salts. *Newly formed bone* may have a considerably higher percentage of matrix in relation to salts.

Organic Matrix of Bone. The organic matrix of bone is 90% to 95% *collagen fibers,* and the remainder is a homogeneous gelatinous medium called *ground substance*. The collagen fibers extend primarily along the lines of tensional force and give bone its powerful tensile strength.

The ground substance is composed of extracellular fluid plus *proteoglycans,* especially *chondroitin sulfate* and *hyaluronic acid*. These proteoglycans help control the deposition of calcium salts and are important in bone repair after injury, although some of their functions are still unclear.

Bone Salts. The crystalline salts deposited in the organic matrix of bone are composed principally of *calcium* and *phosphate.* The formula for the major crystalline salt, known as *hydroxyapatite,* is as follows:

$$Ca_{10}(PO_4)_6(OH)_2$$

Each crystal—about 400 angstroms (Å) long, 10 to 30 Å thick, and 100 Å—is shaped like a long, flat plate. The relative ratio of calcium to phosphorus can vary markedly under different nutritional conditions, with the calcium to phosphorus ratio on a weight basis varying between 1.3 and 2.0.

Magnesium, sodium, potassium, and *carbonate* ions are also present among the bone salts, although x-ray diffraction studies fail to show definite crystals formed by them. Therefore, they are believed to be conjugated to the hydroxyapatite crystals rather than organized into distinct crystals of their own. This ability of many types of ions to conjugate to bone crystals extends to many ions normally foreign to bone, such as *strontium, uranium, plutonium, the other transuranic elements, lead, gold,* and *other heavy metals.* Deposition of radioactive substances in the bone can cause prolonged irradiation of the bone tissues, and if a sufficient amount is deposited, an osteogenic sarcoma (bone cancer) may eventually develop.

Tensile and Compressional Strength of Bone. Each collagen fiber of *cortical (compact)* bone is composed of repeating periodic segments every 640 Å along its length; hydroxyapatite crystals lie adjacent to each segment of the fiber and are bound tightly to it. This intimate bonding prevents "shear" in the bone; that is, it prevents the crystals and collagen fibers from slipping out of place, which is essential in providing strength to the bone. In addition, the segments of adjacent collagen fibers overlap, also causing hydroxyapatite crystals to be overlapped like bricks keyed to one another in a brick wall.

The collagen fibers of bone, like those of tendons, have great tensile strength, whereas the calcium salts have great compressional strength. These combined properties plus the degree of bondage between the collagen fibers and the crystals provide a bony structure that has both extreme tensile strength and compressional strength.

PRECIPITATION AND ABSORPTION OF CALCIUM AND PHOSPHATE IN BONE—EQUILIBRIUM WITH THE EXTRACELLULAR FLUIDS

Hydroxyapatite Does Not Precipitate in Extracellular Fluid Despite Supersaturation of Calcium and Phosphate Ions. The concentrations of calcium and phosphate ions in extracellular fluid are considerably greater than those required to cause precipitation of hydroxyapatite. However, inhibitors are present in almost all tissues of the body, as well as in plasma, to prevent precipitation; one such inhibitor is *pyrophosphate.* Therefore, hydroxyapatite crystals fail to precipitate in normal tissues except in bone despite the state of supersaturation of the ions.

Mechanism of Bone Calcification. The initial stage in bone production is secretion of *collagen molecules* (called *collagen monomers*) and *ground substance* (mainly proteoglycans) by *osteoblasts*. The collagen monomers polymerize rapidly to form collagen fibers; the resultant tissue becomes *osteoid,* a cartilage-like material differing from cartilage in that calcium salts readily precipitate in it. As the osteoid is formed, some of the osteoblasts become entrapped in the osteoid and become quiescent. At this stage, they are called *osteocytes.*

Within a few days after the osteoid is formed, calcium salts begin to precipitate on the surfaces of the collagen fibers. The precipitates first appear at intervals along each collagen fiber, forming minute nidi that rapidly multiply and grow over a period of days and weeks into the finished product, *hydroxyapatite crystals.*

The initial calcium salts to be deposited are not hydroxyapatite crystals but amorphous compounds (noncrystalline), a mixture of salts such as $CaHPO_4 \times 2H_2O$, $Ca_3(PO_4)_2 \times 3H_2O$, and others. Then, by a process of substitution and addition of atoms, or reabsorption and reprecipitation, these salts are converted into the hydroxyapatite crystals over a period of weeks or months. A few percent may remain permanently in the amorphous form, which is important because these amorphous salts can be absorbed rapidly when there is a need for extra calcium in the extracellular fluid.

Although the mechanism that causes calcium salts to be deposited in the osteoid is not fully understood, regulation of this process appears to depend to a great extent on *pyrophosphate,* which inhibits hydroxyapatite crystallization and calcification of the bone. The levels of pyrophosphate, in turn, are regulated by at least three other molecules. One of the most important of these molecules is a substance called *tissue-nonspecific alkaline phosphatase (TNAP),* which breaks down pyrophosphate and keeps its levels in check so that bone calcification can occur as needed. TNAP is secreted by osteoblasts into the osteoid to neutralize pyrophosphate, and once pyrophosphate has been neutralized, the natural affinity of the collagen fibers for calcium salts causes hydroxyapatite

crystallization. The importance of TNAP in bone mineralization is illustrated by the finding that mice with genetic deficiency of TNAP, which causes pyrophosphate levels to rise too high, are born with soft bones that are not adequately calcified.

The osteoblast also secretes at least two other substances that regulate bone calcification: (1) *nucleotide pyrophosphatase phosphodiesterase 1 (NPP1),* which produces pyrophosphate outside the cells, and (2) *ankylosis protein (ANK),* which contributes to the extracellular pool of pyrophosphate by transporting it from the interior to the surface of the cell. Deficiencies of NPP1 or ANK cause decreased extracellular pyrophosphate and excessive calcification of bone, such as bone spurs, or even calcification of other tissues such as tendons and ligaments of the spine, which occurs in people with a form of arthritis called *ankylosing spondylitis*.

Precipitation of Calcium in Nonosseous Tissues Under Abnormal Conditions. Although calcium salts usually do not precipitate in normal tissues besides bone, under abnormal conditions, they can precipitate. For example, they precipitate in arterial walls in *arteriosclerosis* and cause the arteries to become bonelike tubes. Likewise, calcium salts frequently deposit in degenerating tissues or in old blood clots. Presumably, in these cases, the inhibitor factors that normally prevent deposition of calcium salts disappear from the tissues, thereby allowing precipitation.

CALCIUM EXCHANGE BETWEEN BONE AND EXTRACELLULAR FLUID

If soluble calcium salts are injected intravenously, calcium ion concentration may increase immediately to high levels. However, within 30 to 60 minutes, calcium ion concentration returns to normal. Likewise, if large quantities of calcium ions are removed from the circulating body fluids, the calcium ion concentration again returns to normal within 30 minutes to about 1 hour. These effects result largely from the fact that the bone contains a type of *exchangeable* calcium that is always in equilibrium with calcium ions in the extracellular fluids.

A small portion of this exchangeable calcium is also the calcium found in all tissue cells, especially in highly permeable types of cells such as those of the liver and the gastrointestinal tract. However, most of the exchangeable calcium is in the bone, normally comprising about 0.4% to 1% of the total bone calcium. This calcium is deposited in the bones in a form of readily mobilizable salt such as $CaHPO_4$ and other amorphous calcium salts.

This exchangeable calcium provides a rapid *buffering* mechanism to keep calcium ion concentration in the extracellular fluids from rising to excessive levels or falling to low levels under transient conditions of excess or decreased availability of calcium.

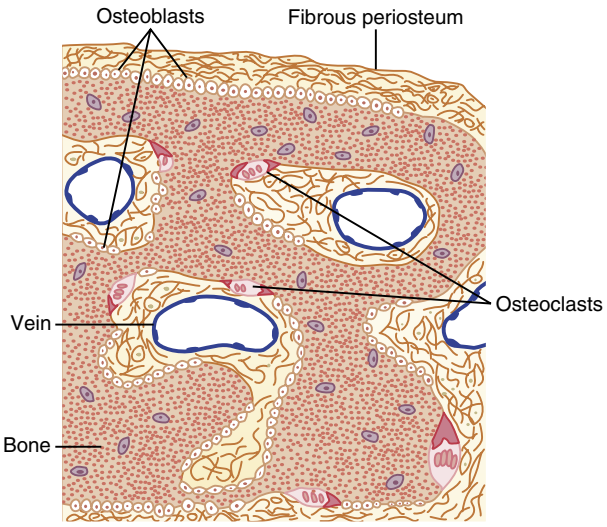

Figure 80-5. Osteoblastic and osteoclastic activity in the same bone.

DEPOSITION AND RESORPTION OF BONE—REMODELING OF BONE

Deposition of Bone by the Osteoblasts. Bone is continually being deposited by *osteoblasts,* and it is continually being resorbed where *osteoclasts* are active (**Figure 80-5**). Osteoblasts are found on the outer surfaces of the bones and in the bone trabecular cavities. A small amount of osteoblastic activity occurs continually in all living bones (on ≈4% of all surfaces at any given time in an adult), so at least some new bone is being formed constantly.

Resorption of Bone—Function of the Osteoclasts. Bone is also being continually resorbed in the presence of osteoclasts, which are large, phagocytic, multinucleated cells (containing as many as 50 nuclei) that are derivatives of monocytes or monocyte-like cells formed in the bone marrow. The osteoclasts are normally active on less than 1% of the bone surfaces of an adult and, as discussed later, PTH controls the bone resorptive activity of osteoclasts.

Histologically, bone absorption occurs immediately adjacent to the osteoclasts. The mechanism of this resorption is believed to be the following: The osteoclasts send out villus-like projections toward the bone, forming a ruffled border adjacent to the bone (**Figure 80-6**). The villi secrete two types of substances: (1) proteolytic enzymes, released from the lysosomes of the osteoclasts, and (2) several acids, including citric acid and lactic acid, released from the mitochondria and secretory vesicles. The enzymes digest or dissolve the organic matrix of the bone, and the acids cause dissolution of the bone salts. The osteoclastic cells also imbibe minute particles of bone matrix and crystals by phagocytosis, eventually also dissoluting these particles and releasing the products into the blood.

As discussed later, PTH stimulates osteoclast activity and bone resorption, but this process occurs through an indirect mechanism. The bone-resorbing osteoclast

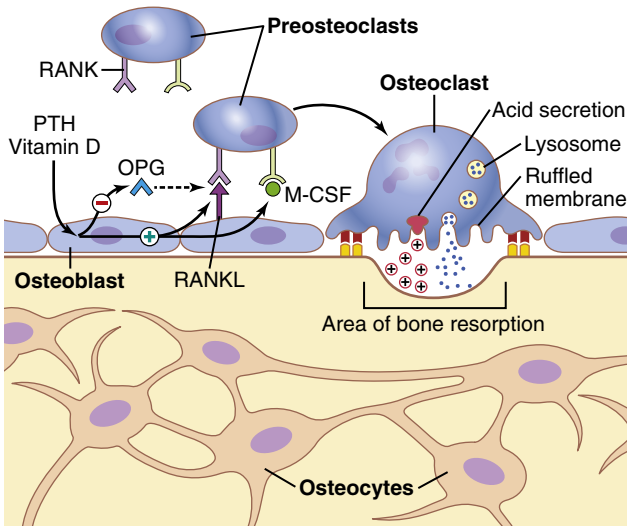

Figure 80-6. Bone resorption by osteoclasts. Parathyroid hormone (PTH) binds to receptors on osteoblasts, causing them to form receptor activator for nuclear factor κB ligand (RANKL) and to release macrophage-colony stimulating factor (M-CSF). RANKL binds to RANK and M-CSF binds to its receptors on preosteoclast cells, causing them to differentiate into mature osteoclasts. PTH also decreases production of osteoprotegerin (OPG), which inhibits differentiation of preosteoclasts into mature osteoclasts by binding to RANKL and preventing it from interacting with its receptor on preosteoclasts. The mature osteoclasts develop a ruffled border and release enzymes from lysosomes, as well as acids that promote bone resorption. Osteocytes are osteoblasts that have become encased in bone matrix during bone tissue production; the osteocytes form a system of interconnected cells that spreads throughout the bone.

cells do not have PTH receptors. Instead, the osteoblasts signal osteoclast precursors to form mature osteoclasts. Two osteoblast proteins responsible for this signaling are *receptor activator for nuclear factor κB ligand* (RANKL) and *macrophage colony-stimulating factor,* which are both necessary for formation of mature osteoclasts.

PTH binds to receptors on the adjacent osteoblasts, stimulating synthesis of RANKL, which is also called *osteoprotegerin ligand (OPGL).* RANKL binds to its receptors (RANK) on preosteoclast cells, causing them to differentiate into mature multinucleated osteoclasts. The mature osteoclasts then develop a ruffled border and release enzymes and acids that promote bone resorption.

Osteoblasts also produce *osteoprotegerin* (OPG), sometimes called *osteoclastogenesis inhibitory factor*, a cytokine that inhibits bone resorption. OPG acts as a "decoy," binding to RANKL and preventing it from interacting with its receptor, thereby inhibiting differentiation of preosteoclasts into mature osteoclasts that resorb bone. OPG opposes the bone resorptive activity of PTH, and mice with a genetic deficiency of OPG have severe decreases in bone mass compared with mice that have normal OPG formation.

Although the factors regulating OPG are not well understood, vitamin D and PTH appear to stimulate production of mature osteoclasts through the dual action of inhibiting OPG production and stimulating RANKL formation. Glucocorticoids also promote osteoclast activity and bone resorption by increasing RANKL production and decreasing formation of OPG. On the other hand, the hormone *estrogen* stimulates OPG production. The balance of OPG and RANKL produced by osteoblasts therefore plays a major role in determining osteoclast activity and bone resorption.

The therapeutic importance of the OPG-RANKL pathway is currently being exploited. Novel drugs that mimic the action of OPG by blocking the interaction of RANKL with its receptor appear to be useful for treating bone loss in postmenopausal women and in some patients with bone cancer.

Bone Deposition and Resorption Are Normally in Equilibrium. Except in growing bones, the rates of bone deposition and resorption are normally equal, so the total mass of bone remains constant. Osteoclasts usually exist in small but concentrated masses, and once a mass of osteoclasts begins to develop, it usually eats away at the bone for about 3 weeks, creating a tunnel that ranges in diameter from 0.2 to 1 millimeter and is several millimeters long. At the end of this time, the osteoclasts disappear, the tunnel is invaded by osteoblasts, and new bone begins to develop. Bone deposition continues for several months, with the new bone being laid down in successive layers of concentric circles *(lamellae)* on the inner surfaces of the cavity until the tunnel is filled. Deposition of new bone ceases when the bone begins to encroach on the blood vessels supplying the area. The canal through which these vessels run, called the *haversian canal,* is all that remains of the original cavity. Each new area of bone deposited in this way is called an *osteon,* as shown in **Figure 80-7**.

Value of Continual Bone Remodeling. The continual deposition and resorption of bone have several important functions. First, bone ordinarily adjusts its strength in proportion to the degree of bone stress. Consequently, bones thicken when subjected to heavy loads. Second, even the shape of the bone can be rearranged for proper support of mechanical forces by deposition and resorption of bone in accordance with stress patterns. Third, because old bone becomes relatively brittle and weak, new organic matrix is needed as the old organic matrix degenerates. In this manner, the normal toughness of bone is maintained. Indeed, the bones of children, in whom the rates of deposition and absorption are rapid, show little brittleness in comparison with the bones of the elderly, in whom the rates of deposition and resorption are slow.

Control of the Rate of Bone Deposition by Bone "Stress" Bone is deposited in proportion to the compressional load that the bone must carry. For example, the bones of athletes become considerably heavier than those of nonathletes. Also, if a person has one leg in a cast but continues to walk on the opposite leg, the bone of the leg in

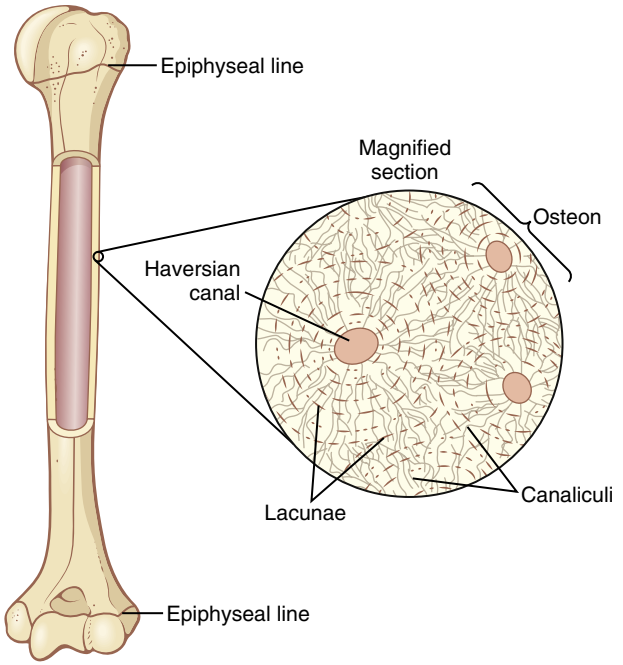

Figure 80-7. Structure of cortical bone.

the cast becomes thin and as much as 30% decalcified within a few weeks, whereas the opposite bone remains thick and normally calcified. Therefore, continual physical stress stimulates osteoblastic deposition and calcification of bone.

Bone stress also determines the shape of bones under certain circumstances. For example, if a long bone of the leg breaks in its center and then heals at an angle, the compression stress on the inside of the angle causes increased deposition of bone. Increased resorption occurs on the outer side of the angle where the bone is not compressed. After many years of increased deposition on the inner side of the angulated bone and resorption on the outer side, the bone can become almost straight, especially in children because of the rapid remodeling of bone at younger ages.

Repair of a Fracture Activates Osteoblasts. Fracture of a bone in some way maximally activates all the periosteal and intraosseous osteoblasts involved in the break. Also, immense numbers of new osteoblasts are formed almost immediately from *osteoprogenitor cells,* which are bone stem cells in the surface tissue lining bone, called the *"bone membrane."* Therefore, within a short time, a large bulge of osteoblastic tissue and new organic bone matrix, followed shortly by the deposition of calcium salts, develops between the two broken ends of the bone. This area is called a *callus.*

Many orthopedic surgeons use the phenomenon of bone stress to accelerate fracture healing. This acceleration is achieved through use of special mechanical fixation apparatuses for holding the ends of the broken bone together so that the patient can continue to use the bone immediately. This use causes stress on the opposed ends of the broken bones, which accelerates osteoblastic activity at the break and often shortens convalescence.

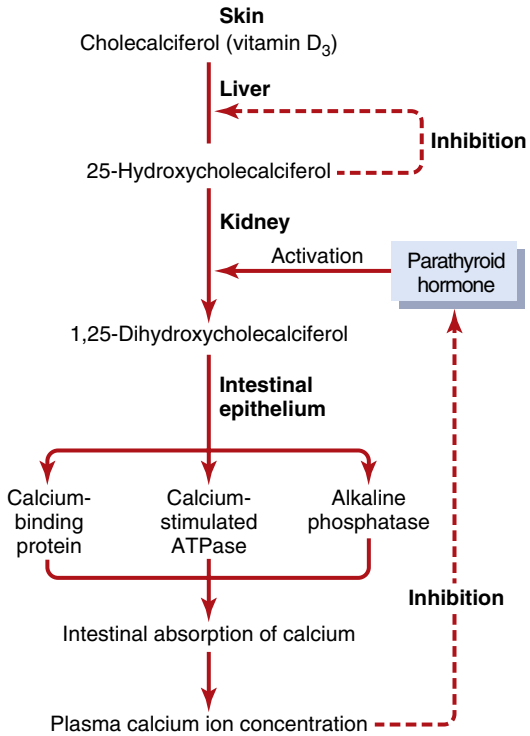

Figure 80-8. Activation of vitamin D_3 to form 1,25-dihydroxycholecalciferol and the role of vitamin D in controlling the plasma calcium concentration.

VITAMIN D

Vitamin D has a potent effect to increase calcium absorption from the intestinal tract; it also has important effects on bone deposition and bone resorption, as discussed later. However, vitamin D itself is not the active substance that actually causes these effects. Instead, vitamin D must first be converted through a succession of reactions in the liver and the kidneys to the final active product, *1,25-dihydroxycholecalciferol,* also called $1,25(OH)_2D_3$. Figure 80-8 shows the succession of steps that lead to formation of this substance from vitamin D.

Cholecalciferol (Vitamin D_3) Is Formed in the Skin. Several compounds derived from sterols belong to the vitamin D family, and they all perform similar functions. Vitamin D_3 (also called *cholecalciferol*) is the most important of these compounds and is formed in the skin as a result of irradiation of *7-dehydrocholesterol,* a substance normally in the skin, by ultraviolet rays from the sun. Consequently, appropriate exposure to the sun prevents vitamin D deficiency. The additional vitamin D compounds that we ingest in food are identical to the cholecalciferol formed in the skin, except for the substitution of one or more atoms that do not affect their function.

Cholecalciferol Is Converted to 25-Hydroxycholecalciferol in the Liver. The first step in the activation of cholecalciferol is to convert it to 25-hydroxycholecalciferol, which occurs in the liver. The process is limited because

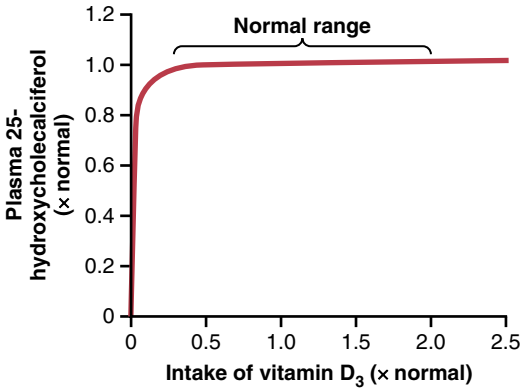

Figure 80-9. Effect of increasing vitamin D_3 intake on the plasma concentration of 25-hydroxycholecalciferol. This figure shows that increases in vitamin D intake, up to 2.5 times normal, have little effect on the final quantity of activated vitamin D that is formed. Deficiency of activated vitamin D occurs only at very low levels of vitamin D intake.

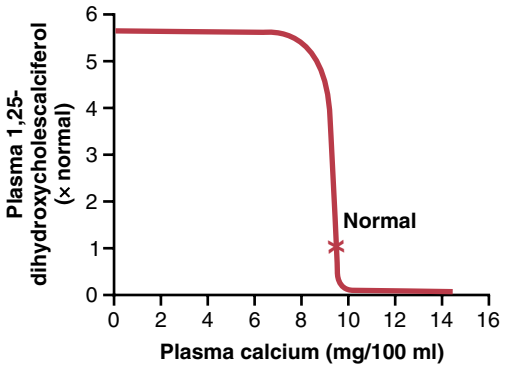

Figure 80-10. Effect of plasma calcium concentration on the plasma concentration of 1,25-dihydroxycholecalciferol. This figure shows that a slight decrease in calcium concentration below normal causes increased formation of activated vitamin D, which in turn leads to greatly increased absorption of calcium from the intestine.

the 25-hydroxycholecalciferol has a feedback inhibitory effect on the conversion reactions. This feedback effect is extremely important for two reasons.

First, the feedback mechanism precisely regulates the concentration of 25-hydroxycholecalciferol in the plasma, an effect that is shown in Figure 80-9. Note that intake of vitamin D_3 can increase many times, and yet the concentration of 25-hydroxycholecalciferol remains nearly normal. This high degree of feedback control prevents excessive action of vitamin D when intake of vitamin D_3 is altered over a wide range.

Second, this controlled conversion of vitamin D_3 to 25-hydroxycholecalciferol conserves the vitamin D stored in the liver for future use. Once vitamin D_3 is converted, the 25-hydroxycholecalciferol persists in the body for only a few weeks, whereas in the vitamin D form, it can be stored in the liver for many months.

Formation of 1,25-Dihydroxycholecalciferol in the Kidneys and Its Control by Parathyroid Hormone. Figure 80-8 also shows the conversion in the proximal tubules of the kidneys of 25-hydroxycholecalciferol to *1,25-dihydroxycholecalciferol*. This latter substance is by far the most active form of vitamin D because the previous products in the scheme of Figure 80-8 have less than 1/1000 of the vitamin D effect. Therefore, in the absence of the kidneys, vitamin D loses almost all its effectiveness.

Note also in Figure 80-8 that the conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol requires PTH. In the absence of PTH, almost none of the 1,25-dihydroxycholecalciferol is formed. Therefore, PTH exerts a potent influence in determining the functional effects of vitamin D in the body.

Calcium Ion Concentration Controls the Formation of 1,25-Dihydroxycholecalciferol. Figure 80-10 demonstrates that plasma concentration of 1,25-dihydroxycholecalciferol is inversely affected by the concentration of calcium in the plasma. There are two reasons for this effect. First, the calcium ion has a slight effect in preventing conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol. Second, and even more important, as we discuss later in the chapter, the rate of PTH secretion is greatly suppressed when plasma calcium ion concentration rises above 9 to 10 mg/100 ml. Therefore, at calcium concentrations below this level, PTH promotes conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol in the kidneys. At higher calcium concentrations, when PTH is suppressed, 25-hydroxycholecalciferol is converted to a different compound—24,25-dihydroxycholecalciferol—that has almost no vitamin D effect.

When plasma calcium concentration is already too high, formation of 1,25-dihydroxycholecalciferol is greatly depressed. Lack of 1,25-dihydroxycholecalciferol, in turn, decreases absorption of calcium from the intestines, bones, and renal tubules, thus causing the calcium ion concentration to fall back toward its normal level.

ACTIONS OF VITAMIN D

The active form of vitamin D, 1,25-dihydroxycholecalciferol, has several effects on the intestines, kidneys, and bones that increase absorption of calcium and phosphate into the extracellular fluid and contribute to feedback regulation of these substances.

Vitamin D receptors are present in most cells in the body and are located mainly in the nuclei of target cells. Similar to receptors for steroids and thyroid hormone, the vitamin D receptor has hormone-binding and DNA-binding domains. The vitamin D receptor forms a complex with another intracellular receptor, the *retinoid-X receptor,* and this complex binds to DNA and activates transcription in most cases. In some cases, however, vitamin D suppresses transcription. Although the vitamin D receptor binds several forms of cholecalciferol, its affinity for 1,25-dihydroxycholecalciferol is roughly 1000 times

that for 25-hydroxycholecalciferol, which explains their relative biological potencies.

"Hormonal" Effect of Vitamin D to Promote Intestinal Calcium Absorption. 1,25-Dihydroxycholecalciferol functions as a type of "hormone" to promote intestinal absorption of calcium mainly by increasing, over a period of about 2 days, formation of *calbindin,* a *calcium-binding protein,* in intestinal epithelial cells. This protein functions in the brush border of these cells to transport calcium into the cell cytoplasm. The calcium then moves through the basolateral membrane of the cell by facilitated diffusion. The rate of calcium absorption is directly proportional to the quantity of this calcium-binding protein. Furthermore, this protein remains in the cells for several weeks after the 1,25-dihydroxycholecalciferol has been removed from the body, thus causing a prolonged effect on calcium absorption.

Other effects of 1,25-dihydroxycholecalciferol that might play a role in promoting calcium absorption are the formation of (1) a calcium-stimulated adenosine triphosphatase in the brush border of the epithelial cells and (2) an alkaline phosphatase in the epithelial cells. The precise details of all these effects are unclear.

Vitamin D Promotes Phosphate Absorption by the Intestines. Although phosphate is usually absorbed easily, phosphate flux through the gastrointestinal epithelium is enhanced by vitamin D. This enhancement is thought to result from a direct effect of 1,25-dihydroxycholecalciferol, but it is possible that it occurs secondarily from this hormone's action on calcium absorption, with the calcium in turn acting as a transport mediator for the phosphate.

Vitamin D Decreases Renal Calcium and Phosphate Excretion. Vitamin D also increases calcium and phosphate reabsorption by the epithelial cells of renal tubules, thereby tending to decrease excretion of these substances in the urine. However, this effect is weak and probably not of major importance in regulating extracellular fluid concentration of these substances.

Effect of Vitamin D on Bone and Its Relation to Parathyroid Hormone Activity. Vitamin D plays important roles in bone resorption and bone deposition. Administration of *extreme quantities of vitamin D causes resorption of bone.* In the absence of vitamin D, the effect of PTH in causing bone resorption (discussed in the next section) is greatly reduced or even prevented. The mechanism of this action of vitamin D is not fully understood but is believed to result from the effect of 1,25-dihydroxycholecalciferol to increase calcium transport through cellular membranes.

Vitamin D in smaller quantities promotes bone calcification. One of the ways it promotes this calcification is to increase calcium and phosphate absorption from the intestines. However, even in the absence of such an increase, it enhances the mineralization of bone. Here again, the mechanism of the effect is unclear, but it probably also results from the ability of 1,25-dihydroxycholecalciferol to cause transport of calcium ions through cell membranes—but in this case, perhaps in the opposite direction through the osteoblastic or osteocytic cell membranes.

PARATHYROID HORMONE

PTH provides a powerful mechanism for controlling extracellular calcium and phosphate concentrations by regulating intestinal reabsorption, renal excretion, and exchange between the extracellular fluid and bone of these ions. Excess activity of the parathyroid gland causes rapid release of calcium salts from the bones, with resultant *hypercalcemia* in the extracellular fluid; conversely, hypofunction of the parathyroid glands causes *hypocalcemia,* often with resultant tetany.

Physiological Anatomy of the Parathyroid Glands. Normally humans have four parathyroid glands, which are located immediately behind the thyroid gland—one behind each of the upper and each of the lower poles of the thyroid. Each parathyroid gland is about 6 millimeters long, 3 millimeters wide, and 2 millimeters thick and has a macroscopic appearance of dark brown fat. The parathyroid glands are difficult to locate during thyroid operations because they often look like just another lobule of the thyroid gland. For this reason, before the importance of these glands was generally recognized, total or subtotal thyroidectomy frequently resulted in removal of the parathyroid glands as well.

Removal of half the parathyroid glands usually causes no major physiological abnormalities. Removal of three of the four normal glands causes transient hypoparathyroidism, but even a small quantity of remaining parathyroid tissue is usually capable of hypertrophying to satisfactorily perform the function of all the glands.

The parathyroid gland of the adult human being, shown in **Figure 80-11**, contains mainly *chief cells* and a small to moderate number of *oxyphil cells,* but oxyphil cells are absent in many animals and in young humans. The chief cells are believed to secrete most, if not all, of the PTH. The function of the oxyphil cells is not certain, but the cells are believed to be modified or depleted chief cells that no longer secrete hormone.

Chemistry of Parathyroid Hormone. PTH is first synthesized on the ribosomes in the form of a preprohormone, a polypeptide chain of 110 amino acids. The endoplasmic reticulum and Golgi apparatus first cleave this preprohormone to a prohormone with 90 amino acids and then to the hormone itself with 84 amino acids, and it is finally packaged in secretory granules in the cytoplasm of the cells. The final hormone has a molecular weight of about 9500. Smaller compounds with as few as 34 amino acids adjacent to the N terminus of the molecule have also been isolated from the parathyroid glands that exhibit full PTH activity. In fact, because the kidneys rapidly remove the whole 84–amino acid hormone within minutes but fail to remove many of the fragments for hours, a large share of the hormonal activity is caused by the fragments.

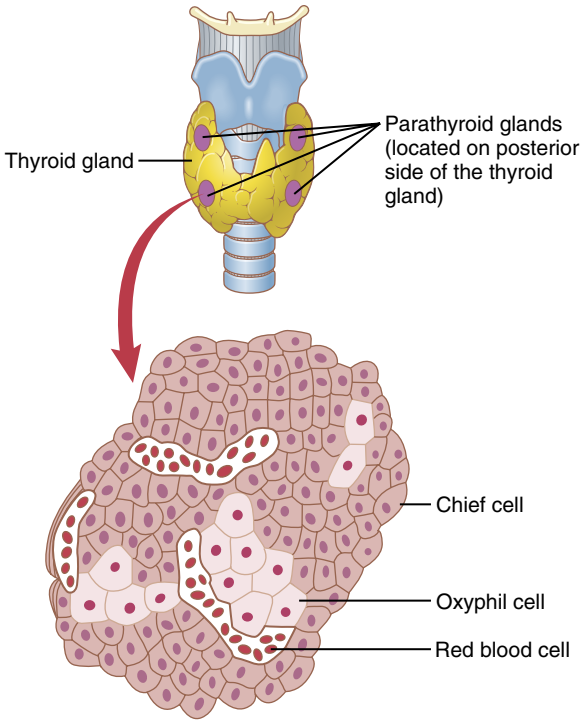

Figure 80-11. The four parathyroid glands lie immediately behind the thyroid gland. Almost all of the parathyroid hormone (PTH) is synthesized and secreted by the chief cells. The function of the oxyphil cells is uncertain, but they may be modified or depleted chief cells that no longer secrete PTH.

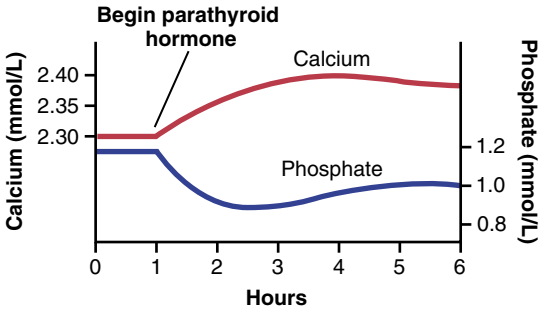

Figure 80-12. Approximate changes in calcium and phosphate concentrations during the first 5 hours of parathyroid hormone infusion at a moderate rate.

PARATHYROID HORMONE EFFECTS ON EXTRACELLULAR FLUID CALCIUM AND PHOSPHATE CONCENTRATIONS

Figure 80-12 shows the approximate effects on the blood calcium and phosphate concentrations caused by suddenly infusing PTH into an animal and continuing this infusion for several hours. Note that at the onset of infusion the calcium ion concentration begins to rise and reaches a plateau in about 4 hours. However, the phosphate concentration falls more rapidly than the calcium rises and reaches a depressed level within 1 or 2 hours. The rise in calcium concentration is caused mainly by two effects: (1) an effect of PTH to increase calcium and phosphate absorption from the bone, and (2) a rapid effect of PTH to decrease excretion of calcium by the kidneys. The decline in phosphate concentration is caused by a strong effect of PTH to increase renal phosphate excretion, an effect that is usually great enough to override increased phosphate absorption from the bone.

Parathyroid Hormone Mobilizes Calcium and Phosphate From Bone

PTH has two effects to mobilize calcium and phosphate from bone. One is a rapid phase that begins in minutes and increases progressively for several hours. This phase results from activation of the already existing bone cells (mainly the osteocytes) to promote calcium and phosphate release. The second phase is a much slower one, requiring several days or even weeks to become fully developed; it results from proliferation of the osteoclasts, followed by greatly increased osteoclastic resorption of bone, not merely release of the calcium phosphate salts from the bone.

Rapid Phase of Calcium and Phosphate Mobilization From Bone—Osteolysis. When large quantities of PTH are injected, calcium ion concentration in the blood begins to rise within minutes, long before any new bone cells can be developed. Histological and physiological studies have shown that PTH causes removal of bone salts from two areas in bone: (1) from the bone matrix in the vicinity of osteocytes lying within the bone and (2) in the vicinity of osteoblasts along the bone surface.

One does not usually think of either osteoblasts or osteocytes functioning to mobilize bone salt, because both these types of cells are osteoblastic in nature and are normally associated with bone deposition and its calcification. However, the osteoblasts and osteocytes form a system of interconnected cells that spreads all through the bone and over all the bone surfaces except the small surface areas adjacent to the osteoclasts (see Figure 80-6). In fact, long, filmy processes extend from osteocyte to osteocyte throughout the bone structure and also connect with the surface osteocytes and osteoblasts. This extensive system is called the *osteocytic membrane system,* and it is believed to provide a membrane that separates the bone from the extracellular fluid.

Between the osteocytic membrane and the bone is a small amount of *bone fluid.* Experiments suggest that the osteocytic membrane pumps calcium ions from the bone fluid into the extracellular fluid, creating a calcium ion concentration in the bone fluid only one-third that in the extracellular fluid. When the osteocytic pump becomes excessively activated, the bone fluid calcium concentration falls even lower, and calcium phosphate salts are then released from the bone. This effect is called *osteolysis,* and it occurs without resorption of the bone's fibrous and gel matrix. When the pump is inactivated, the bone fluid calcium concentration rises to a higher level and calcium phosphate salts are redeposited in the matrix.

Where does PTH fit into this picture? First, the cell membranes of both the osteoblasts and the osteocytes have PTH receptors. PTH activates the calcium pump strongly, thereby causing rapid removal of calcium phosphate salts from the amorphous bone crystals that lie near the cells. PTH is believed to stimulate this pump by increasing the calcium permeability of the bone fluid side of the osteocytic membrane, thus allowing calcium ions to diffuse into the membrane cells from the bone fluid. Then the calcium pump on the other side of the cell membrane transfers the calcium ions the rest of the way into the extracellular fluid.

Slow Phase of Bone Resorption and Calcium Phosphate Release—Activation of the Osteoclasts. A much better known effect of PTH and one for which the evidence is much clearer is its activation of the osteoclasts. Yet, the osteoclasts do not themselves have membrane receptors for PTH. Instead, the activated osteoblasts and osteocytes send secondary "signals" to the osteoclasts. As discussed previously, a major secondary signal is *RANKL,* which activates receptors on preosteoclast cells and transforms them into mature osteoclasts that set about their usual task of gobbling up the bone over a period of weeks or months.

Activation of the osteoclastic system occurs in two stages: (1) immediate activation of the osteoclasts that are already formed and (2) formation of new osteoclasts. Several days of excess PTH usually cause the osteoclastic system to become well developed, but it can continue to grow for months under the influence of strong PTH stimulation.

After a few months of excess PTH, osteoclastic resorption of bone can lead to weakened bones and secondary stimulation of the osteoblasts that attempt to correct the weakened state. Therefore, the late effect is actually to enhance both osteoblastic and osteoclastic activity. Still, even in the late stages, there is more bone resorption than bone deposition in the presence of continued excess PTH.

Bone contains such great amounts of calcium in comparison with the total amount in all the extracellular fluids (≈1000 times as much) that even when PTH causes a great rise in calcium concentration in the fluids, it is impossible to discern any immediate effect on the bones. Prolonged administration or excess secretion of PTH—over a period of many months or years—finally results in very evident resorption in all the bones and even development of large cavities filled with large, multinucleated osteoclasts.

Parathyroid Hormone Decreases Calcium Excretion and Increases Phosphate Excretion by the Kidneys

Administration of PTH causes rapid loss of phosphate in the urine as a result of the effect of the hormone to diminish proximal tubular reabsorption of phosphate ions.

PTH also increases renal tubular reabsorption of calcium at the same time that it diminishes phosphate reabsorption (see Chapter 30). Moreover, it increases reabsorption of magnesium ions and hydrogen ions while it decreases reabsorption of sodium, potassium, and amino acid ions in much the same way that it affects phosphate. The increased calcium reabsorption occurs mainly in the *thick ascending loop of Henle and distal tubules.*

Were it not for the effect of PTH on the kidneys to increase calcium reabsorption, continual loss of calcium into the urine would eventually deplete both the extracellular fluid and the bones of this mineral.

Parathyroid Hormone Increases Intestinal Absorption of Calcium and Phosphate

At this point, we should be reminded again that PTH greatly enhances both calcium and phosphate absorption from the intestines by increasing formation in the kidneys of 1,25-dihydroxycholecalciferol from vitamin D, as discussed earlier in the chapter.

Cyclic Adenosine Monophosphate Mediates the Effects of Parathyroid Hormone. A large share of the effect of PTH on its target organs is mediated by the cyclic adenosine monophosphate (cAMP) *second messenger* mechanism. Within a few minutes after PTH administration, the concentration of cAMP increases in the osteocytes, osteoclasts, and other target cells. This cAMP in turn is probably responsible for such functions as osteoclastic secretion of enzymes and acids to cause bone resorption and formation of 1,25-dihydroxycholecalciferol in the kidneys. Other direct effects of PTH may function independently of the second messenger mechanism.

CONTROL OF PARATHYROID SECRETION BY CALCIUM ION CONCENTRATION

Even the slightest decrease in calcium ion concentration in the extracellular fluid causes the parathyroid glands to increase PTH secretion within minutes; if the decreased calcium concentration persists, the glands will hypertrophy, sometimes fivefold or more. For example, the parathyroid glands become greatly enlarged in persons with *rickets,* in whom the calcium level is usually depressed only a small amount. These glands also become greatly enlarged during *pregnancy,* even though the decrease in calcium ion concentration in the mother's extracellular fluid is hardly measurable, and they are greatly enlarged during *lactation* because calcium is used for the formation of milk.

Conversely, conditions that increase the calcium ion concentration above normal cause decreased activity and reduced size of the parathyroid glands. Such conditions include (1) excess quantities of calcium in the diet, (2) increased vitamin D in the diet, and (3) bone resorption caused by factors other than PTH (e.g., disuse of the bones).

Changes in extracellular fluid calcium ion concentration are detected by a *calcium-sensing receptor* (CSR) in

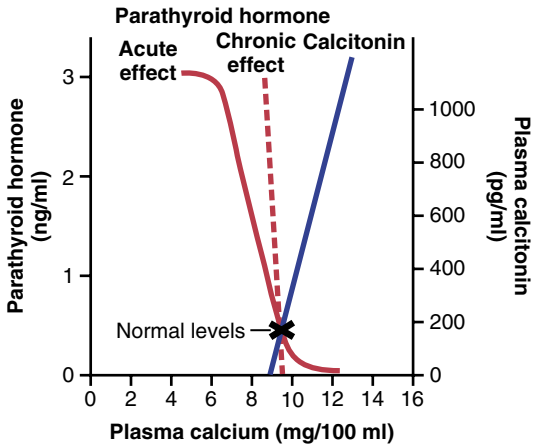

Figure 80-13. The approximate effect of plasma calcium concentration on the plasma concentrations of parathyroid hormone and calcitonin. Note especially that long-term changes in calcium concentration of only a few percentage points can cause as much as 100% change in parathyroid hormone concentration.

parathyroid cell membranes. The calcium-sensing receptor is a G protein–coupled receptor that, when stimulated by calcium ions, activates phospholipase C and increases intracellular inositol 1,4,5-triphosphate and diacylglycerol formation. This activity stimulates release of calcium from intracellular stores, which, in turn, *decreases* PTH secretion. Conversely, decreased extracellular fluid calcium ion concentration inhibits these pathways and stimulates PTH secretion. This process contrasts with that in many endocrine tissues in which hormone secretion is stimulated when these pathways are activated.

Figure 80-13 shows the approximate relation between plasma calcium concentration and plasma PTH concentration. The solid red curve shows the acute effect when the calcium concentration is changed over a period of a few hours and illustrates that even small decreases in calcium concentration from the normal value can double or triple the plasma PTH. The approximate chronic effect when calcium ion concentration changes over a period of many weeks, thus allowing time for the glands to hypertrophy greatly, is shown by the dashed red line, which demonstrates that a decrease of only a fraction of a milligram per deciliter in plasma calcium concentration can double PTH secretion. This is the basis of the body's extremely potent feedback system for long-term control of plasma calcium ion concentration.

SUMMARY OF EFFECTS OF PARATHYROID HORMONE

Figure 80-14 summarizes the main effects of increased PTH secretion in response to decreased extracellular fluid calcium ion concentration: (1) PTH stimulates bone resorption, causing release of calcium into the extracellular fluid; (2) PTH increases calcium reabsorption and decreases phosphate reabsorption by the renal tubules, leading to decreased excretion of calcium and

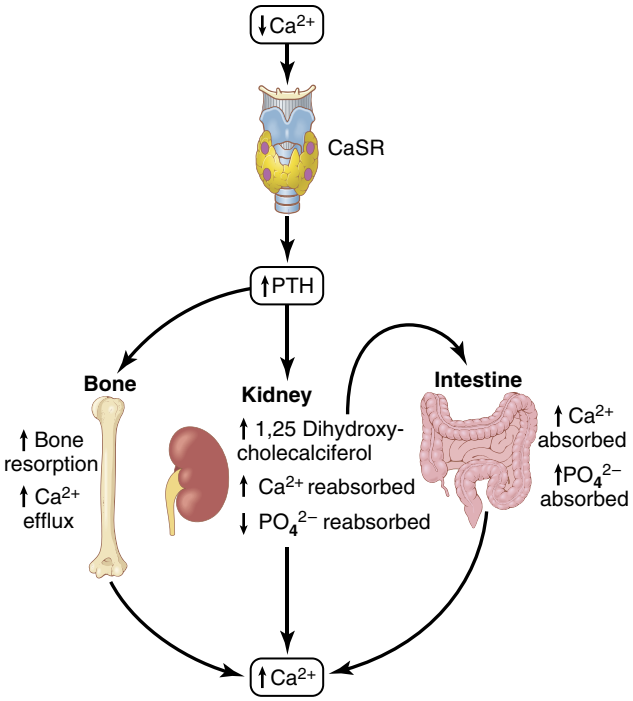

Figure 80-14. Summary of effects of parathyroid hormone (PTH) on bone, the kidneys, and the intestine in response to decreased extracellular fluid calcium ion concentration. CaSR, Calcium-sensing receptor.

increased excretion of phosphate; and (3) PTH is necessary for conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol, which, in turn, increases calcium absorption by the intestines. These actions together provide a powerful means of regulating extracellular fluid calcium concentration.

CALCITONIN

Calcitonin, a peptide hormone secreted by the thyroid gland, tends to *decrease* plasma calcium concentration and, in general, has effects opposite to those of PTH. However, the quantitative role of calcitonin in humans is far less than that of PTH in regulating calcium ion concentration.

Synthesis and secretion of calcitonin occur in the *parafollicular cells,* or *C cells,* lying in the interstitial fluid between the follicles of the thyroid gland. These cells constitute only about 0.1% of the human thyroid gland and are the remnants of the *ultimobranchial glands* of fish, amphibians, reptiles, and birds. Calcitonin is a 32–amino acid peptide with a molecular weight of about 3400.

Increased Plasma Calcium Concentration Stimulates Calcitonin Secretion. The primary stimulus for calcitonin secretion is increased extracellular fluid calcium ion concentration. In contrast, PTH secretion is stimulated by decreased calcium concentration.

In young animals, but much less so in older animals and in humans, an increase in plasma calcium concentration of

about 10% causes an immediate twofold or more increase in calcitonin secretion rate, which is shown by the blue line in **Figure 80-13**. This increase provides a second hormonal feedback mechanism for controlling plasma calcium ion concentration, but one that is relatively weak and works in a way opposite that of the PTH system.

Calcitonin Decreases Plasma Calcium Concentration. In some young animals, calcitonin decreases blood calcium ion concentration rapidly, beginning within minutes after injection of the calcitonin, in at least two ways.

1. The immediate effect is to decrease the absorptive activities of the osteoclasts and possibly the osteolytic effect of the osteocytic membrane throughout the bone, thus shifting the balance in favor of deposition of calcium in the exchangeable bone calcium salts. This effect is especially significant in young animals because of the rapid interchange of absorbed and deposited calcium.
2. The second and more prolonged effect of calcitonin is to decrease formation of new osteoclasts. Also, because osteoclastic resorption of bone leads secondarily to osteoblastic activity, decreased numbers of osteoclasts are followed by decreased numbers of osteoblasts. Therefore, over a long period, the net result is reduced osteoclastic and osteoblastic activity and, consequently, little prolonged effect on plasma calcium ion concentration. That is, the effect on plasma calcium is mainly a transient one, lasting for a few hours to a few days at most.

Calcitonin also has minor effects on calcium handling in the kidney tubules and the intestines. Again, the effects are opposite those of PTH, but they appear to be of such little importance that they are seldom considered.

Calcitonin Has a Weak Effect on Plasma Calcium Concentration in Adult Humans. The reason for the weak effect of calcitonin on plasma calcium is twofold. First, any initial reduction of the calcium ion concentration caused by calcitonin leads within hours to a powerful stimulation of PTH secretion, which almost overrides the calcitonin effect. When the thyroid gland is removed, and calcitonin is no longer secreted, the long-term blood calcium ion concentration is not measurably altered, which again demonstrates the overriding effect of the PTH system of control.

Second, in the adult human, the daily rates of absorption and deposition of calcium are small, and even after the rate of absorption is slowed by calcitonin, this still has only a small effect on plasma calcium ion concentration. The effect of calcitonin in children is much greater because bone remodeling occurs rapidly in children, with absorption and deposition of calcium as great as 5 grams or more per day—equal to 5 to 10 times the total calcium in all the extracellular fluid. Also, in certain bone diseases, such as *Paget's disease*, in which osteoclastic activity is greatly accelerated, calcitonin has a much more potent effect of reducing the calcium absorption.

SUMMARY OF CONTROL OF CALCIUM ION CONCENTRATION

At times, the amount of calcium absorbed into or lost from the body fluids is as much as 0.3 gram in 1 hour. For example, in cases of diarrhea, several grams of calcium can be secreted in the intestinal juices, passed into the intestinal tract, and lost into the feces each day.

Conversely, after ingestion of large quantities of calcium, particularly when there is also excess vitamin D activity, a person may absorb as much as 0.3 gram in 1 hour. This figure compares with a *total quantity of calcium in all the extracellular fluid of about 1 gram.* The addition or subtraction of 0.3 gram to or from such a small amount of calcium in the extracellular fluid would cause serious hypercalcemia or hypocalcemia. However, there is a first line of defense to prevent this from occurring even before the parathyroid and calcitonin hormonal feedback systems have a chance to act.

Buffer Function of the Exchangeable Calcium in Bones—The First Line of Defense. The exchangeable calcium salts in the bones, discussed earlier in this chapter, are amorphous calcium phosphate compounds, probably mainly $CaHPO_4$ or some similar compound loosely bound in the bone and in reversible equilibrium with the calcium and phosphate ions in the extracellular fluid.

The quantity of these salts that is available for exchange is about 0.5% to 1% of the total calcium salts of the bone, which is a total of 5 to 10 grams of calcium. Because of the ease of deposition of these exchangeable salts and their ease of resolubility, an increase in the concentrations of extracellular fluid calcium and phosphate ions above normal causes immediate deposition of exchangeable salt. Conversely, a decrease in these concentrations causes immediate absorption of exchangeable salt. This reaction is rapid because the amorphous bone crystals are extremely small and their total surface area exposed to the fluids of the bone is large—perhaps 1 acre or more.

In addition, about 5% of all the blood flows through the bones each minute—that is, about 1% of all the extracellular fluid each minute. Therefore, about one-half of any excess calcium that appears in the extracellular fluid is removed by this buffer function of the bones in about 70 minutes.

In addition to the buffer function of the bones, the *mitochondria* of many of the tissues of the body, especially of the liver and intestine, contain a significant amount of exchangeable calcium (≈10 grams in the whole body) that provides an additional buffer system to help maintain constancy of the extracellular fluid calcium ion concentration.

Hormonal Control of Calcium Ion Concentration—The Second Line of Defense. At the same time that the exchangeable calcium mechanism in the bones is "buffering" the calcium in the extracellular fluid, both the parathyroid

and the calcitonin hormonal systems are beginning to act. Within 3 to 5 minutes after an acute increase in the calcium ion concentration, the rate of PTH secretion decreases. As already explained, this sets into play multiple mechanisms for reducing the calcium ion concentration back toward normal.

At the same time that PTH decreases, calcitonin increases. In young animals and possibly in young children (but probably to a smaller extent in adults), the calcitonin causes rapid deposition of calcium in the bones, and perhaps in some cells of other tissues. Therefore, in very young animals, excess calcitonin can cause a high calcium ion concentration to return to normal perhaps considerably more rapidly than can be achieved by the exchangeable calcium-buffering mechanism alone.

In prolonged calcium excess or prolonged calcium deficiency, only the PTH mechanism seems to be really important in maintaining a normal plasma calcium ion concentration. When a person has a continuing deficiency of calcium in the diet, PTH can often stimulate enough calcium absorption from the bones to maintain a normal plasma calcium ion concentration for 1 year or more, but eventually, even the bones will run out of calcium. Thus, in effect, the bones are a large buffer-reservoir of calcium that can be manipulated by PTH. Yet, when the bone reservoir either runs out of calcium or, alternately, becomes saturated with calcium, the long-term control of extracellular calcium ion concentration resides almost entirely in the roles of PTH and vitamin D in controlling calcium absorption from the gut and calcium excretion in the urine.

Pathophysiology of Parathyroid Hormone, Vitamin D, and Bone Disease

Hypoparathyroidism

When the parathyroid glands do not secrete sufficient PTH, the osteocytic resorption of exchangeable calcium decreases, and the osteoclasts become almost totally inactive. As a result, calcium release from the bones is so depressed that the level of calcium in the body fluids decreases. Yet, because calcium and phosphates are not being released from the bone, the bone usually remains strong.

When the parathyroid glands are suddenly removed, the calcium level in the blood falls from the normal of 9.4 mg/dl to 6 to 7 mg/dl within 2 to 3 days and the blood phosphate concentration may double. When this low calcium level is reached, the usual signs of tetany develop. Among the muscles of the body especially sensitive to tetanic spasm are the laryngeal muscles. Spasm of these muscles obstructs respiration, which is the usual cause of death in persons with tetany unless appropriate treatment is provided.

Treatment of Hypoparathyroidism With PTH and Vitamin D. PTH is occasionally used to treat hypoparathyroidism. However, hypoparathyroidism is usually not treated with PTH because this hormone is expensive, its effect lasts for a few hours at most, and the tendency of the body to develop antibodies against it makes it progressively less and less effective.

In most patients with hypoparathyroidism, administration of extremely large quantities of vitamin D, along with intake of 1 to 2 grams of calcium, keeps the calcium ion concentration in a normal range. At times, it might be necessary to administer 1,25-dihydroxycholecalciferol instead of the nonactivated form of vitamin D because of its much more potent and much more rapid action. However, administration of 1,25-dihydroxycholecalciferol can also cause unwanted effects because it is sometimes difficult to prevent overactivity by this activated form of vitamin D.

Primary Hyperparathyroidism

In primary hyperparathyroidism, an abnormality of the parathyroid glands causes inappropriate, excess PTH secretion. The cause of primary hyperparathyroidism ordinarily is a tumor of one of the parathyroid glands; such tumors occur much more frequently in women than in men or children, mainly because pregnancy and lactation stimulate the parathyroid glands and therefore predispose to the development of such a tumor.

Hyperparathyroidism causes extreme osteoclastic activity in the bones, which elevates calcium ion concentration in the extracellular fluid while usually depressing the concentration of phosphate ions because of increased renal excretion of phosphate.

Bone Disease in Hyperparathyroidism. In persons with mild hyperparathyroidism new bone can be deposited rapidly enough to compensate for the increased osteoclastic resorption of bone. However, in severe hyperparathyroidism, the osteoclastic absorption soon far outstrips osteoblastic deposition, and the bone may be eaten away almost entirely. Indeed, a broken bone is often the reason a person with hyperparathyroidism seeks medical attention. Radiographs of the bone typically show extensive decalcification and, occasionally, large punched-out cystic areas of the bone that are filled with osteoclasts in the form of so-called giant cell osteoclast "tumors." Multiple fractures of the weakened bones can result from only slight trauma, especially where cysts develop. The cystic bone disease of hyperparathyroidism is called *osteitis fibrosa cystica.*

Osteoblastic activity in the bones also increases greatly in a vain attempt to form enough new bone to make up for the old bone absorbed by the osteoclastic activity. When the osteoblasts become active, they secrete large quantities of *alkaline phosphatase.* Therefore, one of the important diagnostic findings in hyperparathyroidism is a high level of plasma alkaline phosphatase.

Effects of Hypercalcemia in Hyperparathyroidism. Hyperparathyroidism can at times cause plasma calcium level to rise to 12 to 15 mg/dl and, rarely, even higher. The effects of such elevated calcium levels, as detailed earlier in the chapter, are depression of the central and peripheral nervous systems, muscle weakness, constipation, abdominal pain, peptic ulcer, lack of appetite, and depressed relaxation of the heart during diastole.

Parathyroid Poisoning and Metastatic Calcification. When, on rare occasions, extreme quantities of PTH are secreted, the level of calcium in the body fluids rises rapidly to high values. Even the extracellular fluid phosphate concentration often rises markedly instead of falling, as is usually the case, probably because the kidneys cannot excrete

all the phosphate being absorbed from the bone rapidly enough. Therefore, the calcium and phosphate in the body fluids become greatly supersaturated, and calcium phosphate ($CaHPO_4$) crystals begin to deposit in the alveoli of the lungs, the tubules of the kidneys, the thyroid gland, the acid-producing area of the stomach mucosa, and the walls of the arteries throughout the body. This extensive *metastatic* deposition of calcium phosphate can develop within a few days.

Ordinarily, the level of calcium in the blood must rise above 17 mg/dl before there is danger of parathyroid poisoning, but once such elevation develops along with concurrent elevation of phosphate, death can occur in only a few days.

Formation of Kidney Stones in Hyperparathyroidism. Most patients with mild hyperparathyroidism show few signs of bone disease and few general abnormalities as a result of elevated levels of calcium, but they do have an extreme tendency to form kidney stones. The reason for this tendency is that the excess calcium and phosphate absorbed from the intestines or mobilized from the bones in hyperparathyroidism must eventually be excreted by the kidneys, causing a proportionate increase in the concentrations of these substances in the urine. As a result, crystals of calcium phosphate tend to precipitate in the kidney, forming calcium phosphate stones. Also, calcium oxalate stones develop because even normal levels of oxalate cause calcium precipitation at high calcium levels.

Because the solubility of most renal stones is slight in alkaline media, the tendency for formation of renal calculi is considerably greater in alkaline urine than in acid urine. For this reason, acidotic diets and acidic drugs are frequently used to treat renal calculi.

Secondary Hyperparathyroidism

In secondary hyperparathyroidism, high levels of PTH occur as a compensation for *hypocalcemia* rather than as a primary abnormality of the parathyroid glands. In contrast, primary hyperparathyroidism is associated with hypercalcemia.

Secondary hyperparathyroidism can be caused by vitamin D deficiency or chronic renal disease in which the damaged kidneys are unable to produce sufficient amounts of the active form of vitamin D, 1,25-dihydroxycholecalciferol. As discussed in more detail in the next section, the vitamin D deficiency leads to *osteomalacia* (inadequate mineralization of the bones), and high levels of PTH cause absorption of the bones.

Rickets Caused by Vitamin D Deficiency

Rickets occurs mainly in children. It results from calcium or phosphate deficiency in the extracellular fluid, usually caused by lack of vitamin D. If the child is adequately exposed to sunlight, the 7-dehydrocholesterol in the skin becomes activated by the ultraviolet rays and forms vitamin D_3, which prevents rickets by promoting calcium and phosphate absorption from the intestines, as discussed earlier in this chapter.

Children who remain indoors through the winter in general do not receive adequate quantities of vitamin D without some supplementation in the diet. Rickets tends to occur especially in the spring months because vitamin D formed during the preceding summer is stored in the liver and is available for use during the early winter months. In addition, calcium and phosphate mobilization from the bones can prevent clinical signs of rickets for the first few months of vitamin D deficiency.

Plasma Concentrations of Calcium and Phosphate Decrease in Rickets. The plasma calcium concentration in rickets is only slightly depressed, but the level of phosphate is greatly depressed. This phenomenon occurs because the parathyroid glands prevent the calcium level from falling by promoting bone resorption whenever the calcium level begins to fall. However, no good regulatory system exists for preventing a falling level of phosphate, and the increased parathyroid activity actually increases excretion of phosphates in the urine.

Rickets Weakens the Bones. During prolonged cases of rickets, the marked compensatory increase in PTH secretion causes extreme osteoclastic bone resorption. This in turn causes the bone to become progressively weaker and imposes marked physical stress on the bone, resulting in rapid osteoblastic activity as well. The osteoblasts lay down large quantities of osteoid, which does not become calcified because of insufficient calcium and phosphate ions. Consequently, the newly formed, uncalcified, and weak osteoid gradually takes the place of the older bone that is being resorbed.

Tetany in Rickets. In the early stages of rickets, tetany almost never occurs because the parathyroid glands continually stimulate osteoclastic resorption of bone and, therefore, maintain an almost normal level of calcium in the extracellular fluid. However, when the bones finally become exhausted of calcium, calcium concentration may fall rapidly. As the blood level of calcium falls below 7 mg/dl, the usual signs of tetany develop and the child may die of tetanic respiratory spasm unless calcium is administered intravenously, which relieves the tetany immediately.

Treatment of Rickets. Treatment of rickets entails supplying adequate calcium and phosphate in the diet and, equally important, administering large amounts of vitamin D. If vitamin D is not administered, little calcium and phosphate are absorbed from the gut.

Osteomalacia—"Adult Rickets." Adults seldom have a serious *dietary* deficiency of vitamin D or calcium because large quantities of calcium are not needed for bone growth, as is the case in children. However, serious deficiencies of both vitamin D and calcium occasionally occur as a result of *steatorrhea* (failure to absorb fat), because vitamin D is fat-soluble and calcium tends to form insoluble soaps with fat; consequently, in steatorrhea, vitamin D and calcium tend to pass into the feces. Under these conditions, an adult occasionally has such poor calcium and phosphate absorption that rickets can occur. Rickets in adults almost never proceeds to the stage of tetany but often is a cause of severe bone disability.

Osteomalacia and Rickets Caused by Renal Disease. "Renal rickets" is a type of osteomalacia that results from prolonged kidney damage. The cause of this condition is mainly failure of the damaged kidneys to form 1,25-dihydroxycholecalciferol, the active form of vitamin D. In patients whose kidneys have been removed or destroyed and who are being treated by hemodialysis, the problem of renal rickets may be severe.

Another type of renal disease that leads to rickets and osteomalacia is *congenital hypophosphatemia,* resulting from congenitally reduced reabsorption of phosphates by the renal tubules. This type of rickets must be treated with phosphate compounds instead of calcium and vitamin D, and it is called *vitamin D–resistant rickets.*

Osteoporosis—Decreased Bone Matrix

Osteoporosis is the most common of all bone diseases in adults, especially in old age. It is different from osteomalacia and rickets because it results from diminished organic bone matrix rather than from poor bone calcification. In persons with osteoporosis the osteoblastic activity in the bone is usually less than normal, and consequently the rate of bone osteoid deposition is depressed. Occasionally, however, as in hyperparathyroidism, the cause of the diminished bone is excess osteoclastic activity.

The many common causes of osteoporosis are the following: (1) *lack of physical stress on the bones* because of inactivity; (2) *malnutrition* to the extent that sufficient protein matrix cannot be formed; (3) *lack of vitamin C,* which is necessary for secretion of intercellular substances by all cells, including formation of osteoid by the osteoblasts; (4) *postmenopausal lack of estrogen secretion* because estrogens decrease the number and activity of osteoclasts; (5) *old age,* in which growth hormone and other growth factors diminish greatly, plus the fact that many of the protein anabolic functions also deteriorate with age, so bone matrix cannot be deposited adequately; and (6) *Cushing syndrome*, because massive quantities of glucocorticoids secreted in this disease cause decreased deposition of protein throughout the body and increased catabolism of protein and have the specific effect of depressing osteoblastic activity. Thus, many diseases of deficiency of protein metabolism can cause osteoporosis.

PHYSIOLOGY OF THE TEETH

The teeth cut, grind, and mix the food that is eaten. To perform these functions, the jaws have powerful muscles capable of providing an occlusive force between the front teeth of 50 to 100 pounds and for the jaw teeth, 150 to 200 pounds. In addition, the upper and lower teeth are provided with projections and facets that interdigitate, so the upper set of teeth fits with the lower. This fitting is called *occlusion,* and it allows even small particles of food to be caught and ground between the tooth surfaces.

FUNCTION OF THE DIFFERENT PARTS OF THE TEETH

Figure 80-15 shows a sagittal section of a tooth, demonstrating its major functional parts—the *enamel, dentin, cementum,* and *pulp.* The tooth can also be divided into the *crown,* which is the portion that protrudes out from the gum into the mouth, and the *root,* which is the portion within the bony socket of the jaw. The collar between the crown and the root where the tooth is surrounded by the gum is called the *neck.*

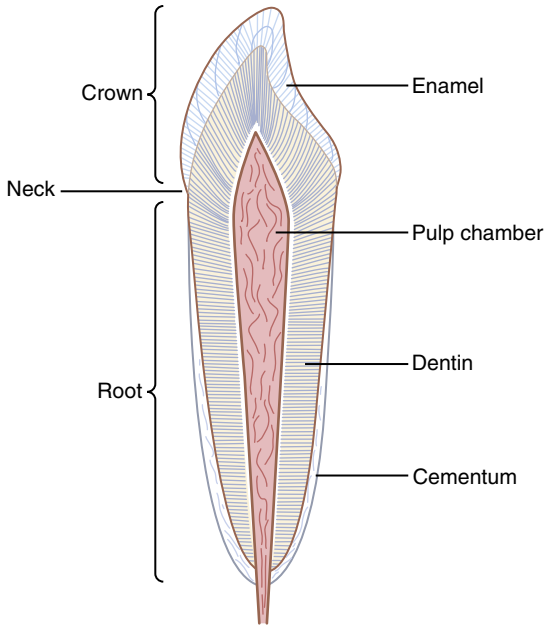

Figure 80-15. The functional parts of a tooth.

Enamel. The outer surface of the tooth is covered by a layer of enamel that is formed before eruption of the tooth by special epithelial cells called *ameloblasts.* Once the tooth has erupted, no more enamel is formed. Enamel is composed of large and dense crystals of hydroxyapatite with adsorbed carbonate, magnesium, sodium, potassium, and other ions embedded in a fine meshwork of strong and almost insoluble protein fibers that are similar in physical characteristics (but not chemically identical) to the keratin of hair.

The crystalline structure of the salts makes the enamel extremely hard, much harder than the dentin. Also, the special protein fiber meshwork, although constituting only about 1% of the enamel mass, makes enamel resistant to acids, enzymes, and other corrosive agents because this protein is one of the most insoluble and resistant proteins known.

Dentin. The main body of the tooth is composed of dentin, which has a strong bony structure. Dentin is made up principally of hydroxyapatite crystals similar to those in bone but much denser. These crystals are embedded in a strong meshwork of collagen fibers. Thus, the principal constituents of dentin are much the same as those of bone. The major difference is its histological organization because dentin does not contain any osteoblasts, osteocytes, osteoclasts, or spaces for blood vessels or nerves. Instead, it is deposited and nourished by a layer of cells called *odontoblasts,* which line its inner surface along the wall of the pulp cavity.

The calcium salts in dentin make it extremely resistant to compressional forces, and the collagen fibers make it

tough and resistant to tensional forces that might result when the teeth are struck by solid objects.

Cementum. Cementum is a bony substance secreted by cells of the *periodontal membrane,* which lines the tooth socket. Many collagen fibers pass directly from the bone of the jaw, through the periodontal membrane, and then into the cementum. These collagen fibers and the cementum hold the tooth in place. When the teeth are exposed to excessive strain, the layer of cementum becomes thicker and stronger. Also, it increases in thickness and strength with age, causing the teeth to become more firmly seated in the jaws by adulthood and later.

Pulp. The pulp cavity of each tooth is filled with *pulp,* which is composed of connective tissue with an abundant supply of nerve fibers, blood vessels, and lymphatics. The cells lining the surface of the pulp cavity are the odontoblasts, which, during the formative years of the tooth, lay down the dentin but at the same time encroach more and more on the pulp cavity, making it smaller. In later life, the dentin stops growing and the pulp cavity remains essentially constant in size. However, the odontoblasts are still viable and send projections into small *dentinal tubules* that penetrate all the way through the dentin; they are of importance for exchange of calcium, phosphate, and other minerals with the dentin.

Dentition. Humans and most other mammals develop two sets of teeth during a lifetime. The first teeth are called *deciduous teeth,* or *milk teeth,* and they number 20 in humans. They erupt between the seventh month and the second year of life, and they last until the sixth to the 13th year. After each deciduous tooth is lost, a permanent tooth replaces it, and an additional 8 to 12 molars appear posteriorly in the jaws, making the total number of permanent teeth 28 to 32, depending on whether the four *wisdom teeth* finally appear, which does not occur in everyone.

Formation of the Teeth. Figure 80-16 shows the formation and eruption of teeth. Figure 80-16*A* shows invagination of the oral epithelium into the *dental lamina,* which is followed by the development of a tooth-producing organ. The epithelial cells above form ameloblasts, which form the enamel on the outside of the tooth. The epithelial cells below invaginate upward into the middle of the tooth to form the pulp cavity and the odontoblasts that secrete dentin. Thus, enamel is formed on the outside of the tooth and dentin is formed on the inside, giving rise to an early tooth, as shown in Figure 80-16*B*.

Eruption of Teeth. During early childhood, the teeth begin to protrude outward from the bone through the oral epithelium into the mouth. The cause of "eruption" is unknown, although the most likely explanation is that growth of the tooth root and the bone underneath the tooth progressively shoves the tooth forward.

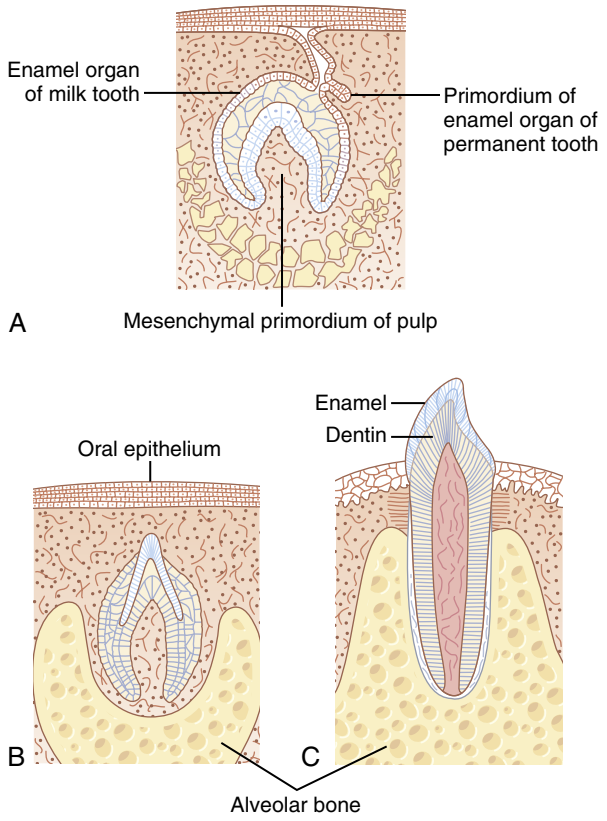

Figure 80-16. A, Primordial tooth organ. B, Developing tooth. C, Erupting tooth.

Development of the Permanent Teeth. During embryonic life, a tooth-forming organ also develops in the deeper dental lamina for each permanent tooth that will form after the deciduous teeth are gone. These tooth-producing organs slowly form the permanent teeth throughout the first 6 to 20 years of life. When each permanent tooth becomes fully formed, it, like the deciduous tooth, pushes outward through the bone. In so doing, it erodes the root of the deciduous tooth and eventually causes it to loosen and fall out. Soon thereafter, the permanent tooth erupts to take the place of the original one.

Metabolic Factors Influence Development of the Teeth. The rate of development and the speed of eruption of teeth can be accelerated by thyroid and growth hormones. Also, the deposition of salts in the early-forming teeth is affected considerably by various factors of metabolism, such as the availability of calcium and phosphate in the diet, the amount of vitamin D present, and the rate of PTH secretion. When all these factors are normal, the dentin and enamel will be correspondingly healthy, but when they are deficient, calcification of the teeth also may be defective and the teeth will be abnormal throughout life.

Mineral Exchange in Teeth. The salts of teeth, like those of bone, are composed of hydroxyapatite with adsorbed carbonates and various cations bound together in a hard

crystalline substance. Also, new salts are constantly being deposited while old salts are being absorbed from the teeth, as occurs in bone. Deposition and absorption occur mainly in the dentin and cementum and to a limited extent in the enamel. In the enamel, these processes occur mostly by diffusional exchange of minerals with the saliva instead of with the fluids of the pulp cavity.

The rate of absorption and deposition of minerals in the cementum is about equal to that in the surrounding bone of the jaw, whereas the rate of deposition and absorption of minerals in the dentin is only one third that of bone. The cementum has characteristics almost identical to those of usual bone, including the presence of osteoblasts and osteoclasts, whereas dentin does not have these characteristics, as explained earlier. This difference undoubtedly explains the different rates of mineral exchange.

In summary, continual mineral exchange occurs in the dentin and cementum of teeth, although the mechanism of this exchange in dentin is unclear. However, enamel exhibits extremely slow mineral exchange, so it maintains most of its original mineral complement throughout life.

Dental Abnormalities

The two most common dental abnormalities are *caries* and *malocclusion*. Caries refers to erosion of the teeth, whereas malocclusion is failure of the projections of the upper and lower teeth to interdigitate properly.

Caries and the Role of Bacteria and Ingested Carbohydrates. Caries result from the action of bacteria on the teeth, the most common of which is *Streptococcus mutans.* The first event in the development of caries is deposit of *plaque,* a film of precipitated products of saliva and food, on the teeth. Large numbers of bacteria inhabit this plaque and are readily available to cause caries. These bacteria depend to a great extent on carbohydrates for their food. When carbohydrates are available, their metabolic systems are strongly activated and they multiply. In addition, they form acids (particularly lactic acid) and proteolytic enzymes. The acids are the major culprit in causing caries because the calcium salts of teeth are slowly dissolved in a highly acidic medium. Once the salts have become absorbed, the remaining organic matrix is rapidly digested by the proteolytic enzymes.

The enamel of the tooth is the primary barrier to development of caries. Enamel is far more resistant to demineralization by acids than is dentin, primarily because the crystals of enamel are dense, but also because each enamel crystal is about 200 times as large in volume as each dentin crystal. Once the carious process has penetrated through the enamel to the dentin, it proceeds many times as rapidly because of the high degree of solubility of the dentin salts.

Because of the dependence of the caries bacteria on carbohydrates for their nutrition, it has frequently been taught that eating a diet high in carbohydrate content will lead to excessive development of caries. However, it is not the quantity of carbohydrate ingested but the frequency with which it is eaten that is important. If carbohydrates are eaten in many small parcels throughout the day, such as in the form of candy, the bacteria are supplied with their preferential metabolic substrate for many hours of the day and the development of caries is greatly increased.

Role of Fluorine in Preventing Caries. Teeth formed in children who drink water that contains small amounts of fluorine develop enamel that is more resistant to caries than the enamel in children who drink water that does not contain fluorine. Fluorine does not make the enamel harder than usual, but fluorine ions replace many of the hydroxyl ions in the hydroxyapatite crystals, which in turn makes the enamel several times less soluble. Fluorine may also be toxic to the bacteria. Finally, when small pits do develop in the enamel, fluorine is believed to promote deposition of calcium phosphate to "heal" the enamel surface. Regardless of the precise means by which fluorine protects the teeth, it is known that small amounts of fluorine deposited in enamel make teeth about three times as resistant to caries as teeth without fluorine.

Malocclusion. Malocclusion is usually caused by a hereditary abnormality that causes the teeth of one jaw to grow to abnormal positions. In malocclusion, the teeth do not interdigitate properly and therefore cannot perform their normal grinding or cutting action adequately. Malocclusion occasionally also results in abnormal displacement of the lower jaw in relation to the upper jaw, causing such undesirable effects as pain in the mandibular joint and deterioration of the teeth.

The orthodontist can usually correct malocclusion by applying prolonged gentle pressure against the teeth with appropriate braces. The gentle pressure causes absorption of alveolar jaw bone on the compressed side of the tooth and deposition of new bone on the tensional side of the tooth. In this way, the tooth gradually moves to a new position as directed by the applied pressure.

CHAPTER 81

UNIT XIV

Reproductive and Hormonal Functions of the Male (and Function of the Pineal Gland)

Male reproductive functions can be divided into three major subdivisions: (1) formation of sperm—spermatogenesis; (2) performance of the male sexual act; and (3) regulation of male reproductive functions by the various hormones. Associated with these reproductive functions are the effects of the male sex hormones on the accessory sexual organs, cellular metabolism, growth, and other functions of the body.

Physiological Anatomy of the Male Sexual Organs

Figure 81-1*A* shows various portions of the male reproductive system, and **Figure 81-1*B*** gives a more detailed structure of the testis and epididymis. The testis is composed of up to 900 coiled *seminiferous tubules,* each averaging more than one-half meter long, in which the sperm are formed. The sperm then empty into the *epididymis,* which is another coiled tube about 6 meters long. The epididymis leads into the *vas deferens,* which enlarges into the *ampulla of the vas deferens* immediately before the vas enters the body of the *prostate gland.*

Two *seminal vesicles,* one located on each side of the prostate, empty into the prostatic end of the ampulla, and the contents from both the ampulla and the seminal vesicles pass into an *ejaculatory duct* leading through the body of the prostate gland and then emptying into the *internal urethra. Prostatic ducts* also empty from the prostate gland into the ejaculatory duct and from there into the prostatic urethra.

Finally, the *urethra* is the last connecting link from the testis to the exterior. The urethra is supplied with mucus derived from a large number of minute *urethral glands* located along its entire extent and even more so from bilateral *bulbourethral glands* (*Cowper glands*) located near the origin of the urethra.

SPERMATOGENESIS

During formation of the embryo, the *primordial germ cells* migrate into the testes and become immature germ cells called *spermatogonia,* which lie in two or three layers of the inner surfaces of the *seminiferous tubules* (a cross section of a tubule is shown in **Figure 81-2*A***). At puberty the spermatogonia begin to undergo mitotic division and continually proliferate and differentiate through definite stages of development to form sperm, as shown in **Figure 81-2*B***.

STEPS OF SPERMATOGENESIS

Spermatogenesis occurs in the seminiferous tubules during active sexual life as the result of stimulation by anterior pituitary gonadotropic hormones. Spermatogenesis begins in the male at an average age of 13 years and continues throughout most of the remainder of life but decreases markedly in old age.

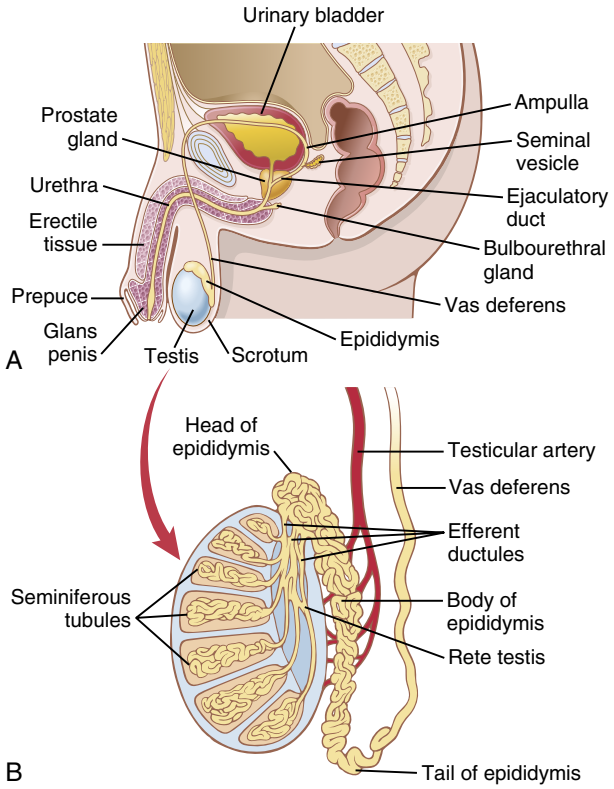

Figure 81-1 **A,** The male reproductive system. **B,** The internal structure of the testis and the relation of the testis to the epididymis. (**A,** *Modified from Bloom V, Fawcett DW: Textbook of Histology, 10th ed. Philadelphia: WB Saunders, 1975.* **B,** *Modified from Guyton AC: Anatomy and Physiology. Philadelphia: Saunders College Publishing, 1985.)*

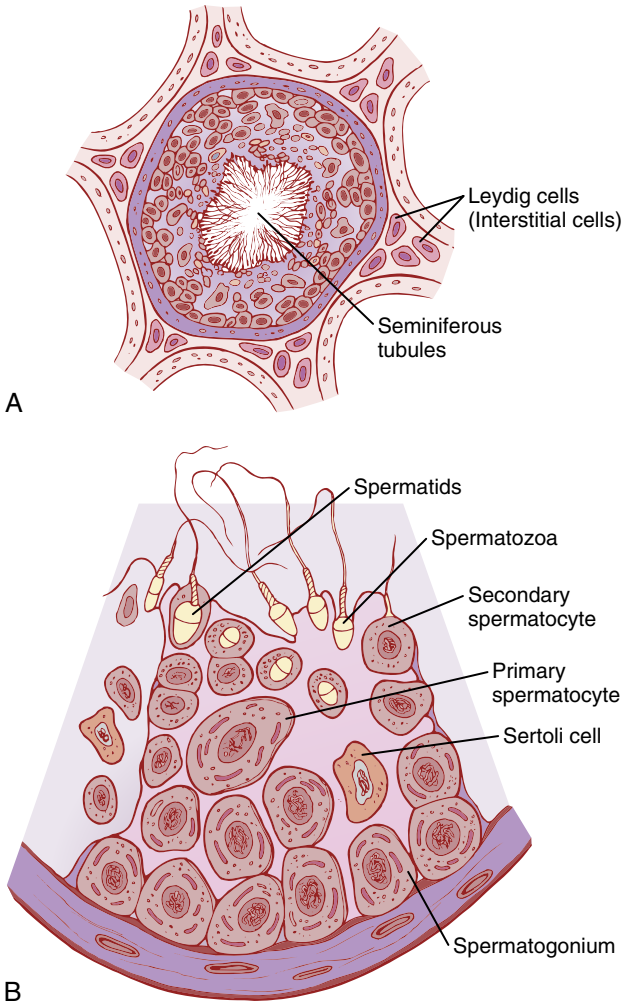

Figure 81-2 **A,** Cross section of a seminiferous tubule. **B,** Stages in the development of sperm from spermatogonia.

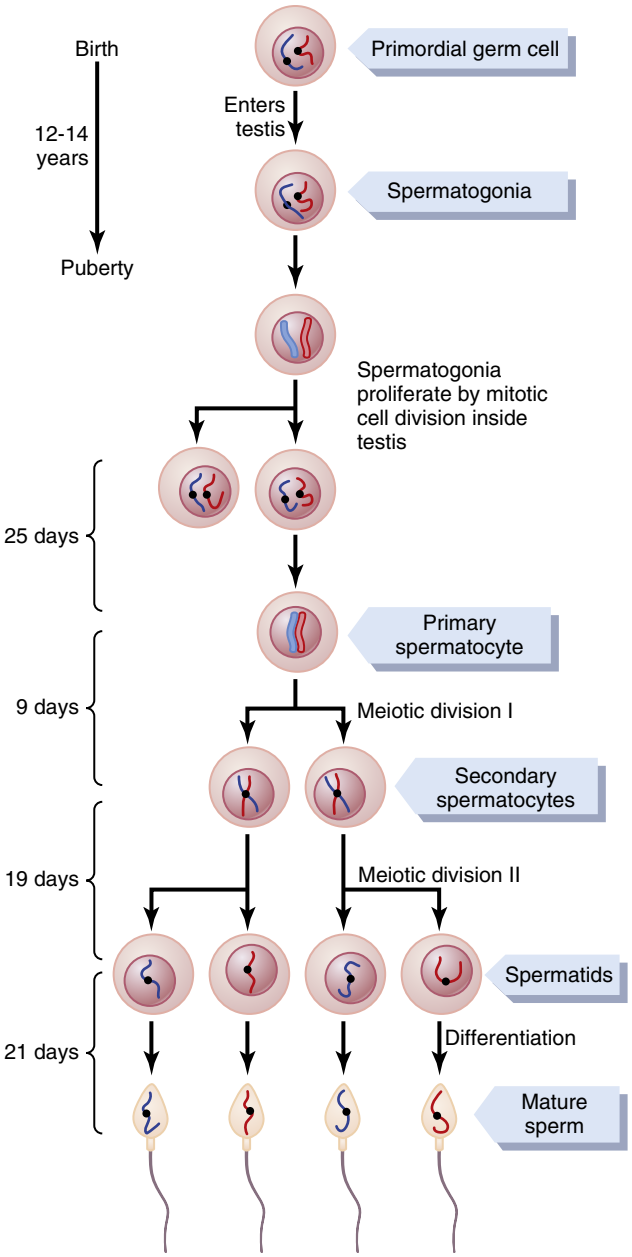

Figure 81-3 Cell divisions during spermatogenesis. During embryonic development, the primordial germ cells migrate to the testis, where they become spermatogonia. At puberty (usually 12 to 14 years after birth), the spermatogonia proliferate rapidly by mitosis. Some begin meiosis to become primary spermatocytes and continue through meiotic division I to become secondary spermatocytes. After completion of meiotic division II, the secondary spermatocytes produce spermatids, which differentiate to form spermatozoa.

In the first stage of spermatogenesis, the spermatogonia migrate among *Sertoli cells* toward the central lumen of the seminiferous tubule. The Sertoli cells are large, with overflowing cytoplasmic envelopes that surround the developing spermatogonia all the way to the central lumen of the tubule.

Meiosis. Spermatogonia that cross the barrier into the Sertoli cell layer become progressively modified and enlarged to form large *primary spermatocytes* (**Figure 81-3**). Each of these primary spermatocytes, in turn, undergoes meiotic division to form two *secondary spermatocytes.* After another few days, these secondary spermatocytes also divide to form *spermatids* that are eventually modified to become *spermatozoa* (sperm).

During the change from the spermatocyte stage to the spermatid stage, the 46 chromosomes (23 pairs of chromosomes) of the spermatocyte are divided, and thus 23 chromosomes go to one spermatid and the other 23 go to the second spermatid. The chromosomal genes are also divided so that only one-half of the genetic characteristics of the eventual fetus are provided by the father, with the other half being derived from the oocyte provided by the mother.

The entire period of spermatogenesis, from spermatogonia to spermatozoa, takes about 74 days.

Sex Chromosomes. In each spermatogonium, one of the 23 pairs of chromosomes carries the genetic information that determines the sex of each eventual offspring. This pair is composed of one X chromosome, which is

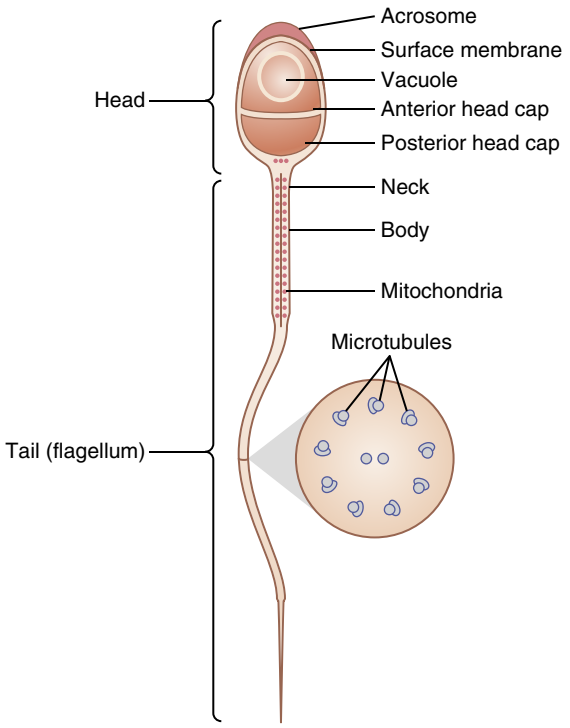

Figure 81-4 Structure of the human spermatozoon.

called the *female chromosome,* and one Y chromosome, the *male chromosome.* During meiotic division, the male Y chromosome goes to one spermatid that then becomes a *male sperm,* and the female X chromosome goes to another spermatid that becomes a *female sperm.* The sex of the eventual offspring is determined by which of these two types of sperm fertilizes the ovum. This process is discussed further in Chapter 83.

Formation of Sperm. When the spermatids are first formed, they still have the usual characteristics of epithelioid cells, but soon they begin to differentiate and elongate into spermatozoa. As shown in **Figure 81-4**, each spermatozoon is composed of a *head* and a *tail.* The head comprises the condensed nucleus of the cell, with only a thin cytoplasmic and cell membrane layer around its surface. On the outside of the anterior two-thirds of the head is a thick cap called the *acrosome* that is formed mainly from the Golgi apparatus. The acrosome contains several enzymes similar to those found in lysosomes of the typical cell, including *hyaluronidase* (which can digest proteoglycan filaments of tissues) and powerful *proteolytic enzymes* (which can digest proteins). These enzymes play important roles in allowing the sperm to enter the ovum and fertilize it.

The tail of the sperm, called the *flagellum,* has three major components: (1) a central skeleton constructed of 11 microtubules, collectively called the *axoneme*; the structure of the axoneme is similar to that of cilia found on the surfaces of other types of cells described in Chapter 2; (2) a thin cell membrane covering the axoneme; and (3) a collection of mitochondria surrounding the axoneme in the proximal portion of the tail, called the *body of the tail.*

Back-and-forth movement of the tail (flagellar movement) provides motility for the sperm. This movement results from a rhythmic longitudinal sliding motion between the anterior and posterior tubules that make up the axoneme. The energy for this process is supplied in the form of adenosine triphosphate, which is synthesized by the mitochondria in the body of the tail.

Normal sperm move in a fluid medium at a velocity of 1 to 4 mm/min, which allows them to move through the female genital tract in quest of the ovum.

Hormonal Factors That Stimulate Spermatogenesis

The role of hormones in reproduction is discussed later in detail; for now, note that several hormones play essential roles in spermatogenesis. Some of these roles are as follows:

1. *Testosterone,* secreted by the *Leydig cells* located in the interstitium of the testis (see **Figure 81-2**), is essential for growth and division of the testicular germinal cells, which is the first stage in forming sperm.
2. *Luteinizing hormone,* secreted by the anterior pituitary gland, stimulates the Leydig cells to secrete testosterone.
3. *Follicle-stimulating hormone,* also secreted by the anterior pituitary gland, stimulates the *Sertoli cells;* without this stimulation, conversion of the spermatids to sperm (the process of spermiogenesis) will not occur.
4. *Estrogens,* formed from testosterone by the Sertoli cells when they are stimulated by follicle-stimulating hormone, are probably also essential for spermiogenesis.
5. *Growth hormone* (as well as most of the other body hormones) is necessary for controlling background metabolic functions of the testes. Growth hormone specifically promotes early division of the spermatogonia; in its absence, as in pituitary dwarfs, spermatogenesis is severely deficient or absent, thus causing infertility.

Maturation of Sperm in the Epididymis

After formation in the seminiferous tubules, the sperm require several days to pass through the 6-meter-long tubule of the *epididymis.* Sperm removed from the seminiferous tubules and from the early portions of the epididymis are nonmotile and cannot fertilize an ovum. However, after the sperm have been in the epididymis for 18 to 24 hours, they develop the *capability of motility,* even though several inhibitory proteins in the epididymal fluid still prevent final motility until after ejaculation.

Storage of Sperm in the Testes. The two testes of the human adult form up to 120 million sperm each day. Most

of these sperm are stored in the epididymis, although a small quantity is stored in the vas deferens. They can remain stored, while maintaining their fertility, for at least a month. During this time, they are kept in a deeply suppressed, inactive state by multiple inhibitory substances in the secretions of the ducts. Conversely, with a high level of sexual activity and ejaculations, they may be stored no longer than a few days.

After ejaculation, the sperm become motile and capable of fertilizing the ovum, a process called *maturation.* The Sertoli cells and the epithelium of the epididymis secrete a special nutrient fluid that is ejaculated along with the sperm. This fluid contains hormones (including both testosterone and estrogens), enzymes, and special nutrients that are essential for sperm maturation.

Physiology of the Mature Sperm. The normal motile, fertile sperm are capable of flagellated movement through the fluid medium at velocities of 1 to 4 mm/min. The activity of sperm is greatly enhanced in a neutral and slightly alkaline medium, as exists in the ejaculated semen, but it is greatly depressed in a mildly acidic medium. A strong acidic medium can cause the rapid death of sperm.

The activity of sperm increases markedly with increasing temperature, but so does the rate of metabolism, causing the life of the sperm to be considerably shortened. Although sperm can live for many weeks in the suppressed state in the genital ducts of the testes, the life expectancy of ejaculated sperm in the female genital tract is only 1 to 2 days.

FUNCTION OF THE SEMINAL VESICLES

Each seminal vesicle is a tortuous, loculated tube lined with a secretory epithelium that secretes a mucoid material containing an abundance of *fructose, citric acid,* and other nutrient substances, as well as large quantities of *prostaglandins* and *fibrinogen.* During the process of emission and ejaculation, each seminal vesicle empties its contents into the ejaculatory duct shortly after the vas deferens empties the sperm. This action adds greatly to the bulk of the ejaculated semen, and the fructose and other substances in the seminal fluid are of considerable nutrient value for the ejaculated sperm until one of the sperm fertilizes the ovum.

Prostaglandins are believed to aid fertilization in two ways: (1) by reacting with the female cervical mucus to make it more receptive to sperm movement and (2) by possibly causing backward, reverse peristaltic contractions in the uterus and fallopian tubes to move the ejaculated sperm toward the ovaries (a few sperm reach the upper ends of the fallopian tubes within 5 minutes).

FUNCTION OF THE PROSTATE GLAND

The prostate gland secretes a thin, milky fluid that contains calcium, citrate ion, phosphate ion, a clotting enzyme, and a profibrinolysin. During emission, the capsule of the prostate gland contracts simultaneously with the contractions of the vas deferens so that the thin, milky fluid of the prostate gland adds further to the bulk of the semen. A slightly alkaline characteristic of the prostatic fluid may be quite important for successful fertilization of the ovum because the fluid of the vas deferens is relatively acidic owing to the presence of citric acid and metabolic end products of the sperm and, consequently, helps inhibit sperm fertility. Also, the vaginal secretions of the female are acidic (with a pH of 3.5–4.0). Sperm do not become optimally motile until the pH of the surrounding fluids rises to about 6.0 to 6.5. Consequently, it is probable that the slightly alkaline prostatic fluid helps neutralize the acidity of the other seminal fluids during ejaculation and thus enhances the motility and fertility of the sperm.

SEMEN

Semen, which is ejaculated during the male sexual act, is composed of the fluid and sperm from the vas deferens (≈10% of the total), fluid from the seminal vesicles (almost 60%), fluid from the prostate gland (≈30%), and small amounts from the mucous glands, especially the bulbourethral glands. Thus, the bulk of the semen is seminal vesicle fluid, which is the last to be ejaculated and serves to wash the sperm through the ejaculatory duct and urethra.

The average pH of the combined semen is about 7.5, with the alkaline prostatic fluid having more than neutralized the mild acidity of the other portions of the semen. The prostatic fluid gives the semen a milky appearance, and fluid from the seminal vesicles and mucous glands gives the semen a mucoid consistency. Also, a clotting enzyme from the prostatic fluid causes the fibrinogen of the seminal vesicle fluid to form a weak fibrin coagulum that holds the semen in the deeper regions of the vagina where the uterine cervix lies. The coagulum then dissolves during the next 15 to 30 minutes because of lysis by fibrinolysin formed from the prostatic profibrinolysin. In the early minutes after ejaculation, the sperm remain relatively immobile, possibly because of the viscosity of the coagulum. As the coagulum dissolves, the sperm simultaneously become highly motile.

Although sperm can live for many weeks in the male genital ducts, once they are ejaculated in the semen, their maximal life span is only 24 to 48 hours at body temperature. At lowered temperatures, however, semen can be stored for several weeks, and when frozen at temperatures below –100°C, sperm have been preserved for years.

"Capacitation" of Spermatozoa Is Required for Fertilization of the Ovum

Although spermatozoa are said to be "mature" when they leave the epididymis, their activity is held in

check by multiple inhibitory factors secreted by the genital duct epithelia. Therefore, when they are first expelled in the semen, they are unable to fertilize the ovum. However, on coming in contact with the fluids of the female genital tract, multiple changes occur that activate the sperm for the final processes of fertilization. These collective changes are called *capacitation of the spermatozoa,* which normally requires from 1 to 10 hours. The following changes are believed to occur:

1. The uterine and fallopian tube fluids wash away the various inhibitory factors that suppress sperm activity in the male genital ducts.
2. While the spermatozoa remain in the fluid of the male genital ducts, they are continually exposed to many floating vesicles from the seminiferous tubules containing large amounts of cholesterol. This cholesterol is continually added to the cellular membrane covering the sperm acrosome, toughening this membrane and preventing release of its enzymes. After ejaculation, the sperm deposited in the vagina swim away from the cholesterol vesicles upward into the uterine cavity, and they gradually lose much of their other excess cholesterol during the next few hours. In so doing, the membrane at the head of the sperm (the acrosome) becomes much weaker.
3. The membrane of the sperm also becomes much more permeable to calcium ions, so calcium now enters the sperm in abundance and changes the activity of the flagellum, giving it a powerful whiplash motion in contrast to its previously weak undulating motion. In addition, the calcium ions cause changes in the cellular membrane that cover the leading edge of the acrosome, making it possible for the acrosome to release its enzymes rapidly and easily as the sperm penetrates the granulosa cell mass surrounding the ovum, and even more so as it attempts to penetrate the zona pellucida of the ovum.

Thus, multiple changes occur during the process of capacitation. Without these changes, the sperm cannot make its way to the interior of the ovum to cause fertilization.

Acrosome Enzymes, the "Acrosome Reaction," and Penetration of the Ovum

Stored in the acrosome of the sperm are large quantities of *hyaluronidase* and *proteolytic enzymes.* Hyaluronidase depolymerizes the hyaluronic acid polymers in the intercellular cement that holds the ovarian granulosa cells together. The proteolytic enzymes digest proteins in the structural elements of tissue cells that still adhere to the ovum.

When the ovum is expelled from the ovarian follicle into the fallopian tube, it still carries with it multiple layers of granulosa cells. Before a sperm can fertilize the ovum, it must dissolute these granulosa cell layers, and then it must penetrate through the *zona pellucida*, the thick covering of the ovum. To achieve this penetration, the stored enzymes in the acrosome begin to be released. The hyaluronidase among these enzymes is especially important in opening pathways between the granulosa cells so that the sperm can reach the ovum.

When the sperm reaches the zona pellucida of the ovum, the anterior membrane of the sperm binds specifically with receptor proteins in the zona pellucida. Next, the entire acrosome rapidly dissolves, and all the acrosomal enzymes are released. Within minutes, these enzymes open a penetrating pathway for passage of the sperm head through the zona pellucida to the inside of the ovum. Within another 30 minutes, the cell membranes of the sperm head and of the oocyte fuse with each other to form a single cell. At the same time, the genetic material of the sperm and the oocyte combine to form a completely new cell genome, containing equal numbers of chromosomes and genes from mother and father. This is the process of *fertilization;* the embryo then begins to develop, as discussed in Chapter 83.

Why Does Only One Sperm Enter the Oocyte? With as many sperm as there are, why does only one enter the oocyte? The reason is not entirely known, but within a few minutes after the first sperm penetrates the zona pellucida of the ovum, calcium ions diffuse inward through the oocyte membrane and cause multiple cortical granules to be released by exocytosis from the oocyte into the perivitelline space. These granules contain substances that permeate all portions of the zona pellucida and prevent binding of additional sperm, and they even cause any sperm that have already begun to bind to fall off. Thus, almost never does more than one sperm enter the oocyte during fertilization.

Abnormal Spermatogenesis and Male Fertility

The seminiferous tubular epithelium can be destroyed by several diseases. For example, bilateral *orchitis* (inflammation) of the testes resulting from *mumps* causes sterility in some affected males. Also, some male infants are born with degenerate tubular epithelia as a result of strictures in the genital ducts or other abnormalities. Finally, another cause of sterility, usually temporary, is *excessive temperature of the testes.*

Effect of Temperature on Spermatogenesis. Increasing the temperature of the testes can prevent spermatogenesis by causing degeneration of most cells of the seminiferous tubules besides the spermatogonia. It has often been stated that the reason the testes are located in the dangling scrotum is to maintain the temperature of these glands below the internal temperature of the body, although usually only about 2°C below the internal temperature. On cold days, scrotal reflexes cause the musculature of the scrotum to contract, pulling the testes close to the body to maintain this 2°C differential. Thus, the scrotum acts as a cooling

mechanism for the testes (but a *controlled* cooling), without which spermatogenesis might be deficient during hot weather.

Cryptorchidism. Cryptorchidism means failure of a testis to descend from the abdomen into the scrotum at or near the time of birth of a fetus. During development of the male fetus, the testes are derived from the genital ridges in the abdomen. However, at about 3 weeks to 1 month before birth of the baby, the testes normally descend through the inguinal canals into the scrotum. Occasionally this descent does not occur or occurs incompletely, and as a result one or both testes remain in the abdomen, in the inguinal canal, or elsewhere along the route of descent.

A testis that remains in the abdominal cavity throughout life is incapable of forming sperm. The tubular epithelium becomes degenerate, leaving only the interstitial structures of the testis. It has been claimed that even the few degrees higher temperature in the abdomen than in the scrotum is sufficient to cause this degeneration of the tubular epithelium and, consequently, to cause sterility, although this effect is not certain. Nevertheless, for this reason, operations to relocate the cryptorchid testes from the abdominal cavity into the scrotum before the beginning of adult sexual life can be performed on boys who have undescended testes.

Testosterone secretion by the fetal testes is the normal stimulus that causes the testes to descend into the scrotum from the abdomen. Therefore, many, if not most, cases of cryptorchidism are caused by abnormally formed testes that are unable to secrete enough testosterone. The surgical operation for cryptorchidism in these patients is unlikely to be successful.

Effect of Sperm Count on Fertility. The usual quantity of semen ejaculated during each coitus averages about 3.5 milliliters, and each milliliter of semen contains an average of about 120 million sperm, although even in "normal" males this quantity can vary from 35 million to 200 million. This means an average total of about 400 million sperm are usually present in the several milliliters of each ejaculate. When the number of sperm in each milliliter falls below about 20 million, the person is likely to be infertile. Thus, even though only a single sperm is necessary to fertilize the ovum, for reasons that are not understood, the ejaculate usually must contain a tremendous number of sperm for only one sperm to fertilize the ovum.

Effect of Sperm Morphology and Motility on Fertility. Occasionally, a man has a normal number of sperm but is still infertile. When this situation occurs, sometimes as many as one-half of the sperm are found to be abnormal physically, having two heads, abnormally shaped heads, or abnormal tails, as shown in **Figure 81-5**. At other times, the sperm appear to be structurally normal, but for reasons not understood, they are either entirely nonmotile or relatively nonmotile. Whenever most of the sperm are morphologically abnormal or are nonmotile, the person is likely to be infertile, even though the remainder of the sperm appear to be normal.

Figure 81-5 Abnormal infertile sperm, compared with a normal sperm on the *right*.

MALE SEXUAL ACT

NEURONAL STIMULUS FOR PERFORMANCE OF THE MALE SEXUAL ACT

The most important source of sensory nerve signals for initiating the male sexual act is the *glans penis*. The glans contains an especially sensitive sensory end-organ system that transmits into the central nervous system that special modality of sensation called *sexual sensation*. The slippery massaging action of intercourse on the glans stimulates the sensory end organs, and the sexual signals in turn pass through the pudendal nerve, then through the sacral plexus into the sacral portion of the spinal cord, and finally up the cord to the brain.

Impulses may also enter the spinal cord from areas adjacent to the penis to aid in stimulating the sexual act. For example, stimulation of the anal epithelium, the scrotum, and perineal structures in general can send signals into the cord that add to the sexual sensation. Sexual sensations can even originate in internal structures, such as in areas of the urethra, bladder, prostate, seminal vesicles, testes, and vas deferens. Indeed, one of the causes of "sexual drive" is filling of the sexual organs with secretions. Mild infection and inflammation of these sexual organs may sometimes stimulate sexual desire, and some "aphrodisiac" drugs, such as cantharidin, irritate the bladder and urethral mucosa, inducing inflammation and vascular congestion.

Psychic Element of Male Sexual Stimulation. Appropriate psychic stimuli can greatly enhance the ability of a person to perform the sexual act. Simply thinking sexual thoughts or even dreaming that the act of intercourse is being performed can initiate the male act, culminating in ejaculation. Indeed, *nocturnal emissions* during dreams, often called "wet dreams," occur in many males during some stages of sexual life, especially during the teens.

Integration of the Male Sexual Act in the Spinal Cord. Although psychic factors usually play an important part in the male sexual act and can initiate or inhibit it, brain function is probably not necessary for its performance

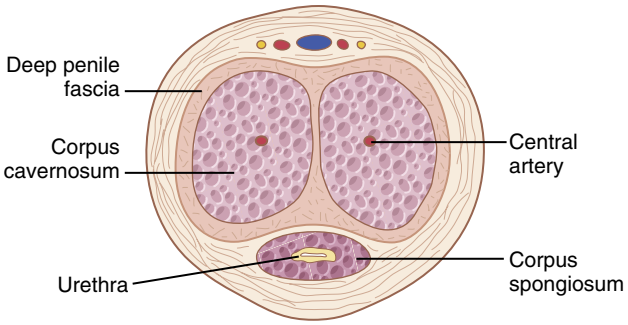

Figure 81-6 Erectile tissue of the penis.

because appropriate genital stimulation can cause ejaculation in some animals and occasionally in humans after their spinal cords have been cut above the lumbar region. The male sexual act results from inherent reflex mechanisms integrated in the sacral and lumbar spinal cord, and these mechanisms can be initiated by either psychic stimulation from the brain or actual sexual stimulation from the sex organs, but usually it is a combination of both.

STAGES OF THE MALE SEXUAL ACT

Penile Erection—Role of the Parasympathetic Nerves. Penile erection is the first effect of male sexual stimulation, and the degree of erection is proportional to the degree of stimulation, whether psychic or physical. Erection is caused by parasympathetic impulses that pass from the sacral portion of the spinal cord through the pelvic nerves to the penis. These parasympathetic nerve fibers, in contrast to most other parasympathetic fibers, are believed to release *nitric oxide* and/or *vasoactive intestinal peptide* in addition to acetylcholine. Nitric oxide activates the enzyme *guanylyl cyclase,* causing increased formation of *cyclic guanosine monophosphate* (GMP). The cyclic GMP especially relaxes the arteries of the penis and the trabecular meshwork of smooth muscle fibers in the *erectile tissue* of the *corpora cavernosa* and *corpus spongiosum* in the shaft of the penis, shown in **Figure 81-6**. As the vascular smooth muscles relax, blood flow into the penis increases, causing release of nitric oxide from the vascular endothelial cells and further vasodilation.

The erectile tissue of the penis consists of large cavernous sinusoids that are normally relatively empty of blood but become dilated tremendously when arterial blood flows rapidly into them under pressure while the venous outflow is partially occluded. Also, the erectile bodies, especially the two corpora cavernosa, are surrounded by strong fibrous coats; therefore, high pressure within the sinusoids causes ballooning of the erectile tissue to such an extent that the penis becomes hard and elongated, which is the phenomenon of *erection.*

Lubrication Is a Parasympathetic Function. During sexual stimulation, the parasympathetic impulses, in addition to promoting erection, cause the urethral glands and the bulbourethral glands to secrete mucus. This mucus flows through the urethra during intercourse to aid in lubrication during coitus. However, most of the lubrication of coitus is provided by the female sexual organs rather than by the male organs. Without satisfactory lubrication, the male sexual act is seldom successful because unlubricated intercourse causes grating, painful sensations that inhibit rather than excite sexual sensations.

Emission and Ejaculation Are Functions of the Sympathetic Nerves. Emission and ejaculation are the culmination of the male sexual act. When the sexual stimulus becomes extremely intense, the reflex centers of the spinal cord begin to emit *sympathetic impulses* that leave the cord at T12 to L2 and pass to the genital organs through the hypogastric and pelvic sympathetic nerve plexuses to initiate *emission,* the forerunner of ejaculation.

Emission begins with contraction of the vas deferens and the ampulla to cause expulsion of sperm into the internal urethra. Then, contractions of the muscular coat of the prostate gland followed by contraction of the seminal vesicles expel prostatic and seminal fluid also into the urethra, forcing the sperm forward. All these fluids mix in the internal urethra with mucus already secreted by the bulbourethral glands to form the semen. The process to this point is *emission.*

The filling of the internal urethra with semen elicits sensory signals that are transmitted through the pudendal nerves to the sacral regions of the cord, giving the feeling of sudden fullness in the internal genital organs. Also, these sensory signals further excite rhythmic contraction of the internal genital organs and cause contraction of the ischiocavernosus and bulbocavernosus muscles that compress the bases of the penile erectile tissue. These effects together cause rhythmic wavelike increases in pressure in the erectile tissue of the penis and the genital ducts and urethra, which "ejaculate" the semen from the urethra to the exterior. This final process is called *ejaculation.* At the same time, rhythmic contractions of the pelvic muscles and even of some of the muscles of the body trunk cause thrusting movements of the pelvis and penis, which also help propel the semen into the deepest recesses of the vagina and perhaps even slightly into the cervix of the uterus.

This entire period of emission and ejaculation is called the *male orgasm.* At its termination, the male sexual excitement disappears almost entirely within 1 to 2 minutes and erection ceases, a process called *resolution.*

TESTOSTERONE AND OTHER MALE SEX HORMONES

SECRETION, METABOLISM, AND CHEMISTRY OF THE MALE SEX HORMONES

Secretion of Testosterone by the Interstitial Cells of Leydig in the Testes. The testes secrete several male sex hormones, which are collectively called *androgens,* including *testosterone, dihydrotestosterone,* and *androstenedione.* Testosterone is so much more abundant than the others that one can consider it to be the primary testicular hormone, although much of the testosterone is eventually converted into the more active hormone dihydrotestosterone in target tissues.

Testosterone is formed by the *interstitial cells of Leydig,* which lie in the interstices between the seminiferous tubules and constitute about 20% of the mass of the adult testes, as shown in **Figure 81-7**. Leydig cells are almost nonexistent in the testes during childhood, when the testes secrete almost no testosterone, but they *are* numerous in the newborn male infant for the first few months of life and in the adult male after puberty; at both these times the testes secrete large quantities of testosterone. Furthermore, when tumors develop from the interstitial cells of Leydig, great quantities of testosterone are secreted. When the germinal epithelium of the testes is destroyed by x-ray treatment or excessive heat, the Leydig cells, which are less easily destroyed, often continue to produce testosterone.

Secretion of Androgens Elsewhere in the Body. The term "androgen" means any steroid hormone that has masculinizing effects, including testosterone; it also includes male sex hormones produced elsewhere in the body besides the testes. For example, the adrenal glands secrete at least five androgens, although the total masculinizing activity of all these androgens is normally so slight (<5% of the total in the adult male) that even in women they do not cause significant masculine characteristics, except for causing growth of pubic and axillary hair. However, when a tumor of the adrenal androgen-producing cells occurs, the quantity of androgenic hormones may then become great enough to cause all the usual male secondary sexual characteristics to occur, even in females. These effects are described in connection with the adrenogenital syndrome in Chapter 78.

Rarely, embryonic crest cells in the ovary can develop into a tumor that produces excessive quantities of androgens in women; one such tumor is the *arrhenoblastoma.* The normal ovary also produces minute quantities of androgens, but they are not significant.

Androgens Are Steroids. All androgens are steroid compounds, as shown by the formulas in **Figure 81-8** for *testosterone* and *dihydrotestosterone.* Both in the testes and in the adrenals, the androgens can be synthesized either from cholesterol or directly from acetyl coenzyme A.

Metabolism of Testosterone. After secretion by the testes, about 97% of the testosterone becomes either loosely bound with plasma albumin or more tightly bound with a beta globulin called *sex hormone–binding globulin* and circulates in the blood in these states for 30 minutes to several hours. By that time, the testosterone is either transferred to the tissues or degraded into inactive products that are subsequently excreted.

Much of the testosterone that becomes fixed to the tissues is converted within the tissue cells to *dihydrotestosterone,* especially in certain target organs such as the prostate gland in the adult and the external genitalia of the male fetus. Some but not all actions of testosterone depend on this conversion. The intracellular functions are discussed later in this chapter.

Degradation and Excretion of Testosterone. The testosterone that does not become fixed to the tissues is rapidly converted, mainly by the liver, into *androsterone* and *dehydroepiandrosterone* and simultaneously conjugated as either glucuronides or sulfates (glucuronides, particularly). These substances are excreted either into the gut by way of the liver bile or into the urine through the kidneys.

Production of Estrogen in the Male. In addition to testosterone, small amounts of estrogens are formed in the male (about one fifth the amount in the nonpregnant female), and a reasonable quantity of estrogens can be recov-

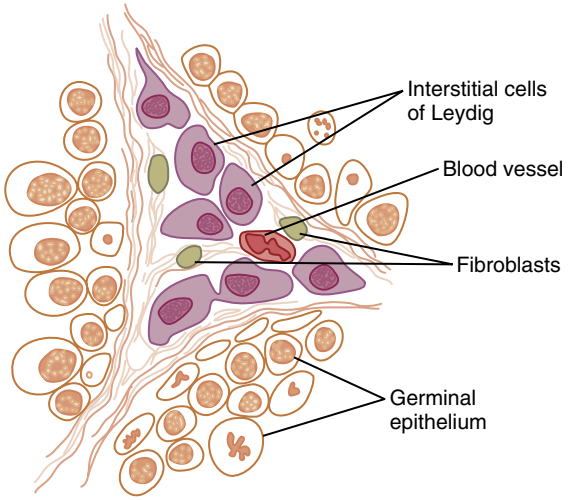

Figure 81-7 Interstitial cells of Leydig, the cells that secrete testosterone, located in the interstices between the seminiferous tubules.

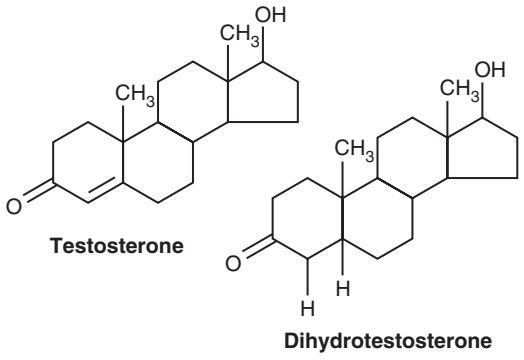

Figure 81-8 Testosterone and dihydrotestosterone.

ered from a man's urine. The exact source of estrogens in the male is unclear, but the following information is known:

1. The concentration of estrogens in the fluid of the seminiferous tubules is quite high and probably plays an important role in spermiogenesis. This estrogen is believed to be formed by the Sertoli cells by converting testosterone to estradiol.
2. Much larger amounts of estrogens are formed from testosterone and androstanediol in other tissues of the body, especially the liver, probably accounting for as much as 80% of the total male estrogen production.

FUNCTIONS OF TESTOSTERONE

In general, testosterone is responsible for the distinguishing characteristics of the masculine body. Even during fetal life, the testes are stimulated by chorionic gonadotropin from the placenta to produce moderate quantities of testosterone throughout the entire period of fetal development and for 10 or more weeks after birth; thereafter, essentially no testosterone is produced during childhood until about the ages of 10 to 13 years. Testosterone production then increases rapidly under the stimulus of anterior pituitary gonadotropic hormones at the onset of puberty and lasts throughout most of the remainder of life, as shown in **Figure 81-9**, dwindling somewhat beyond age 50 to 60 years. Some studies, however, suggest that plasma testosterone levels may remain in the normal range in most healthy males as they age; only about 10% to 20% of men over 60 years of age and 50% of men over 80 years of age have "low" testosterone levels below 3 ng/ml (usually expressed clinically as <300 ng/dl or <10.4 nmol/L). In recent years, it has become clear that there is a clear association between late onset reductions in testosterone and metabolic disorders such as obesity and type 2 diabetes mellitus.

Functions of Testosterone During Fetal Development

Testosterone begins to be elaborated by the male fetal testes at about the seventh week of embryonic life. Indeed, one of the major functional differences between the female and the male sex chromosome is that the male chromosome has the *sex-determining region Y (SRY) gene* that encodes a protein called the *testis determining factor* (also called the *SRY protein*). The SRY protein initiates a cascade of gene activations that cause the genital ridge cells to differentiate into cells that eventually become the testes and secrete testosterone, whereas the female chromosome causes this ridge to differentiate into cells that secrete estrogens.

Injection of large quantities of male sex hormone into pregnant animals causes development of male sexual organs, even though the fetus is female. Also, early removal of the testes in the male fetus causes development of female sexual organs.

Thus, testosterone secreted by the fetal testes is responsible for development of the male body characteristics, including the formation of a penis and a scrotum rather than formation of a clitoris and a vagina. It also causes formation of the prostate gland, seminal vesicles, and male genital ducts, while at the same time suppressing formation of female genital organs.

Effect of Testosterone to Cause Descent of the Testes. The testes usually descend into the scrotum during the last 2 to 3 months of gestation when the testes begin secreting reasonable quantities of testosterone. If a male child is born with undescended but otherwise normal testes, administration of testosterone usually causes the tes-

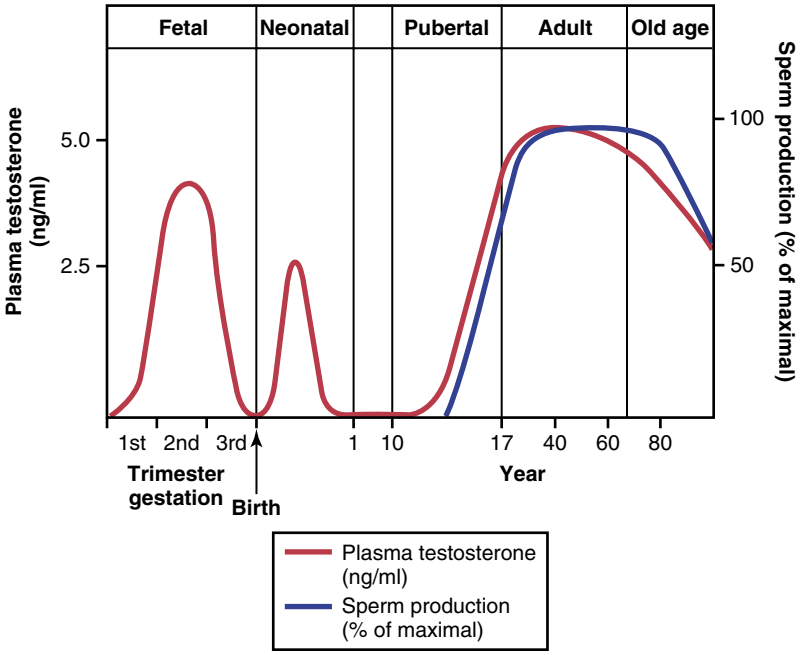

Figure 81-9 The different stages of male sexual function as reflected by average plasma testosterone concentrations *(red line)* and sperm production *(blue line)* at different ages. *(Modified from Griffin JF, Wilson JD: The testis. In: Bondy PK, Rosenberg LE [eds]: Metabolic Control and Disease, 8th ed. Philadelphia: WB Saunders, 1980.)*

tes to descend in the usual manner if the inguinal canals are large enough to allow the testes to pass.

Administration of gonadotropic hormones, which stimulate the Leydig cells of the newborn child's testes to produce testosterone, can also cause the testes to descend. Thus, the stimulus for descent of the testes is testosterone, indicating again that testosterone is an important hormone for male sexual development during fetal life.

Effect of Testosterone on Development of Adult Primary and Secondary Sexual Characteristics

After puberty, increasing amounts of testosterone secretion cause the penis, scrotum, and testes to enlarge about eightfold before the age of 20 years. In addition, testosterone causes the secondary sexual characteristics of the male to develop, beginning at puberty and ending at maturity. These secondary sexual characteristics, in addition to the sexual organs, distinguish the male from the female as follows.

Effect on the Distribution of Body Hair. Testosterone causes growth of hair (1) over the pubis, (2) upward along the linea alba of the abdomen sometimes to the umbilicus and above, (3) on the face, (4) usually on the chest, and (5) less often on other regions of the body, such as the back. It also causes the hair on most other portions of the body to become more prolific.

Male Pattern Baldness. Testosterone decreases the growth of hair on the top of the head; a man who does not have functional testes does not become bald. However, many virile men never become bald because baldness is a result of two factors: first, a *genetic background* for the development of baldness and, second, superimposed on this genetic background, *large quantities of androgenic hormones*. When a long-sustained androgenic tumor develops in a woman who has the appropriate genetic background, she becomes bald in the same manner as does a man.

Effect on the Voice. Testosterone secreted by the testes or injected into the body causes hypertrophy of the laryngeal mucosa and enlargement of the larynx. The effects at first cause a relatively discordant, "cracking" voice that gradually changes into the typical adult masculine voice.

Testosterone Increases Thickness of the Skin and Can Contribute to Development of Acne. Testosterone increases the thickness of the skin over the entire body and the ruggedness of the subcutaneous tissues. Testosterone also increases the rate of secretion by some or perhaps all of the body's sebaceous glands. Especially important is excessive secretion by the sebaceous glands of the face, which can result in *acne.* Therefore, acne is one of the most common features of male adolescence when the body is first becoming introduced to increased testosterone. After several years of testosterone secretion, the skin normally adapts to the testosterone in a way that allows it to overcome the acne.

Testosterone Increases Protein Formation and Muscle Development. One of the most important male characteristics is development of increasing musculature after puberty, averaging about a 50% increase in muscle mass over that in the female. This increase in muscle mass is also associated with increased protein in the nonmuscle parts of the body. Many of the changes in the skin are due to deposition of proteins in the skin, and changes in the voice also result partly from this protein anabolic function of testosterone.

Because of the great effect that testosterone and other androgens have on the body's musculature, synthetic androgens are widely used by athletes to improve their muscular performance. This practice is to be severely deprecated because of prolonged harmful effects of excess androgens, as discussed in Chapter 85 in relation to sports physiology. Testosterone or synthetic androgens are also occasionally used in old age as a "youth hormone" to improve muscle strength and vigor, but with questionable results. Some studies suggest that testosterone replacement therapy in elderly men may increase the risk of adverse cardiovascular events.

Testosterone Increases Bone Matrix and Causes Calcium Retention. After the great increase in circulating testosterone that occurs at puberty (or after prolonged injection of testosterone), the bones grow considerably thicker and deposit considerable additional calcium salts. Thus, testosterone increases the total quantity of bone matrix and causes calcium retention. The increase in bone matrix is believed to result from the general protein anabolic function of testosterone plus deposition of calcium salts in response to the increased protein.

Testosterone has a specific effect on the pelvis to (1) narrow the pelvic outlet, (2) lengthen it, (3) cause a funnel-like shape instead of the broad ovoid shape of the female pelvis, and (4) greatly increase the strength of the entire pelvis for load bearing. In the absence of testosterone, the male pelvis develops into a pelvis that is similar to that of the female.

Because of the ability of testosterone to increase the size and strength of bones, it is sometimes used in older men to treat osteoporosis.

When great quantities of testosterone (or any other androgen) are secreted abnormally in the still-growing child, the rate of bone growth increases markedly, causing a spurt in total body height. However, the testosterone also causes the epiphyses of the long bones to unite with the shafts of the bones at an early age. Therefore, despite the rapidity of growth, this early uniting of the epiphyses prevents the person from growing as tall as he would have grown had testosterone not been secreted at all. Even in normal men, the final adult height is slightly less than that which occurs in males castrated before puberty.

Testosterone Increases the Basal Metabolic Rate. Injection of large quantities of testosterone can increase the basal metabolic rate by as much as 15%. Also, even the usual quantity of testosterone secreted by the testes during adolescence and early adult life increases the rate of metabolism some 5% to 10% above the value that it would be were the testes not active. This increased metabolic rate is possibly an indirect result of the effect of testosterone on protein anabolism, with the increased quantity of proteins—the enzymes, especially—increasing activities of all cells.

Testosterone Increases Red Blood Cells. When normal quantities of testosterone are injected into a castrated adult, the number of red blood cells per cubic millimeter of blood increases 15% to 20%. Also, the average man has about 700,000 more red blood cells per cubic millimeter than the average woman. Despite the strong association of testosterone and increased hematocrit, testosterone does not appear to directly increase erythropoietin levels or have a direct effect on red blood cell production. The effect of testosterone to increase red blood cell production may be at least partly indirect because of the increased metabolic rate that occurs after testosterone administration.

Effect on Electrolyte and Water Balance. As pointed out in Chapter 78, many steroid hormones can increase the reabsorption of sodium in the distal tubules of the kidneys. Testosterone also has such an effect, but only to a minor degree in comparison with the adrenal mineralocorticoids. Nevertheless, after puberty, the blood and extracellular fluid volumes of the male in relation to body weight increase as much as 5% to 10%.

BASIC INTRACELLULAR MECHANISM OF ACTION OF TESTOSTERONE

Most of the effects of testosterone result basically from increased rate of protein formation in the target cells. In the prostate gland, for example, testosterone enters the prostatic cells within a few minutes after secretion. Then it is most often converted, under the influence of the intracellular enzyme 5α-reductase, to *dihydrotestosterone* which binds with a cytoplasmic "receptor protein." This combination migrates to the cell nucleus where it binds with a nuclear protein and induces DNA-RNA transcription. Within 30 minutes, RNA polymerase has become activated, and the concentration of RNA begins to increase in the prostatic cells, which is followed by a progressive increase in cellular protein. After several days, the quantity of DNA in the prostate gland has also increased, and a simultaneous increase in the number of prostatic cells has occurred.

Testosterone stimulates production of proteins virtually everywhere in the body, although more specifically affecting the proteins in "target" organs or tissues responsible for the development of primary and secondary male sexual characteristics.

Some studies suggest that testosterone, like other steroidal hormones, may also exert some rapid, *nongenomic effects* that do not require synthesis of new proteins. The physiological role of these nongenomic actions of testosterone, however, has yet to be determined.

CONTROL OF MALE SEXUAL FUNCTIONS BY HORMONES FROM THE HYPOTHALAMUS AND ANTERIOR PITUITARY GLAND

A major share of the control of sexual functions in both the male and the female begins with secretion of *gonadotropin-releasing hormone* (GnRH) by the hypothalamus (**Figure 81-10**). This hormone stimulates the anterior pituitary gland to secrete two other hormones called *gonadotropic hormones:* (1) *luteinizing hormone* (LH) and (2) *follicle-stimulating hormone* (FSH). In turn, LH is the primary stimulus for the secretion of testosterone by the testes, and FSH mainly stimulates spermatogenesis.

Gonadotropin-Releasing Hormone Increases Secretion of Luteinizing Hormone and Follicle-Stimulating Hormone

GnRH is a 10–amino acid peptide secreted by neurons whose cell bodies are located in the *arcuate nuclei of the hypothalamus*. The endings of these neurons terminate mainly in the median eminence of the hypothalamus, where they release GnRH into the hypothalamic-hypophysial portal vascular system. The GnRH is then transported to the anterior pituitary gland in the hypophysial portal blood and stimulates release of the two gonadotropins, LH and FSH.

GnRH is secreted intermittently a few minutes at a time once every 1 to 3 hours. The intensity of this hormone's stimulus is determined in two ways: (1) by the frequency of these cycles of secretion and (2) by the quantity of GnRH released with each cycle.

Secretion of LH by the anterior pituitary gland is also cyclical, with LH following fairly faithfully the pulsatile release of GnRH. In contrast, FSH secretion increases and decreases only slightly with each fluctuation of GnRH secretion; instead, it changes more slowly over a period of many hours in response to longer-term changes in GnRH. Because of the much closer relation between GnRH secretion and LH secretion, GnRH is also widely known as *LH-releasing hormone.*

Gonadotropic Hormones: Luteinizing Hormone and Follicle-Stimulating Hormone

Both of the gonadotropic hormones, LH and FSH, are secreted by the same cells, called *gonadotropes,* in the anterior pituitary gland. In the absence of GnRH secretion from the hypothalamus, the gonadotropes in the pituitary gland secrete almost no LH or FSH.

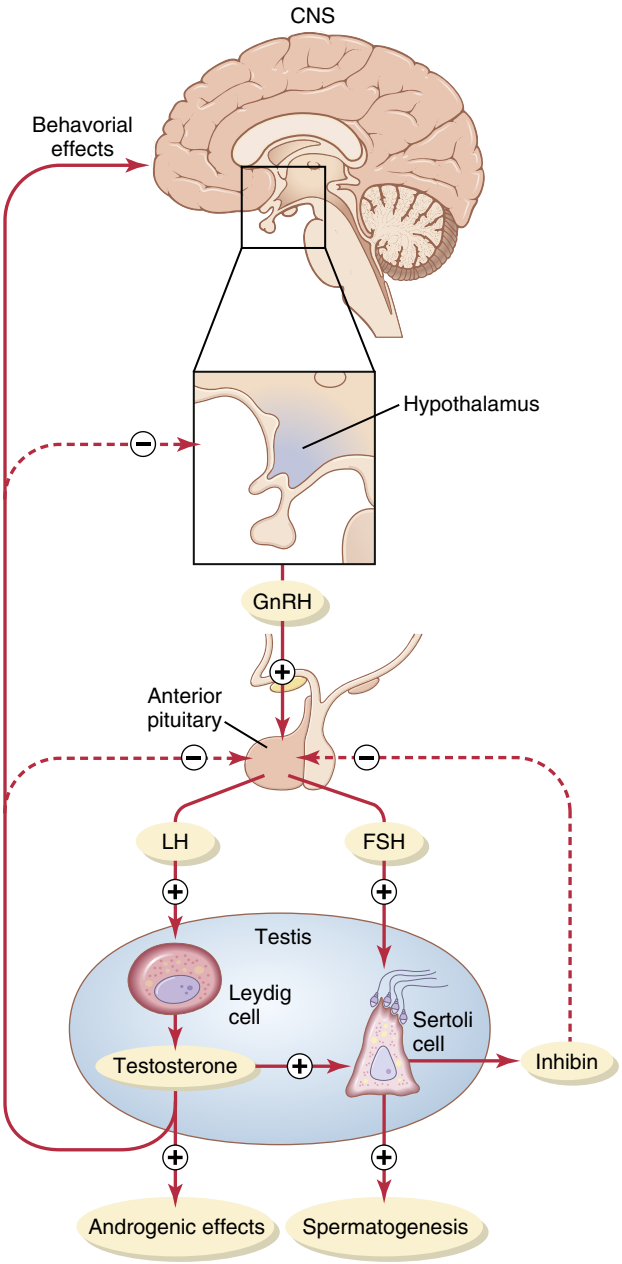

Figure 81-10 Feedback regulation of the hypothalamic-pituitary-testicular axis in males. Stimulatory effects are shown by *plus signs,* and negative feedback inhibitory effects are shown by *minus signs.* CNS, Central nervous system; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

LH and FSH are *glycoproteins*. They exert their effects on their target tissues in the testes mainly by *activating the cyclic adenosine monophosphate second messenger system,* which in turn activates specific enzyme systems in the respective target cells.

Regulation of Testosterone Production by Luteinizing Hormone. *Testosterone* is secreted by the *interstitial cells of Leydig* in the testes, but only when they are stimulated by LH from the anterior pituitary gland. Furthermore, the quantity of testosterone that is secreted increases approximately in direct proportion to the amount of LH that is available.

Mature Leydig cells are normally found in a child's testes for a few weeks after birth but then disappear until after the age of about 10 years. However, injection of purified LH into a child at any age or secretion of LH at puberty causes testicular interstitial cells that look like fibroblasts to evolve into functioning Leydig cells.

Inhibition of Anterior Pituitary Secretion of Luteinizing and Follicle-Stimulating Hormones by Testosterone—Negative Feedback Control of Testosterone Secretion. Testosterone secreted by the testes in response to LH has the reciprocal effect of inhibiting anterior pituitary secretion of LH (see **Figure 81-10**). Most of this inhibition probably results from a direct effect of testosterone on the hypothalamus to decrease secretion of GnRH. This effect in turn causes a corresponding decrease in secretion of LH and FSH by the anterior pituitary, and the decrease in LH reduces secretion of testosterone by the testes. Thus, whenever testosterone secretion becomes too great, this automatic negative feedback effect, operating through the hypothalamus and anterior pituitary gland, reduces testosterone secretion back toward the desired operating level. Conversely, too little testosterone allows the hypothalamus to secrete large amounts of GnRH, with a corresponding increase in anterior pituitary LH and FSH secretion and consequent increase in testicular testosterone secretion.

Regulation of Spermatogenesis by Follicle-Stimulating Hormone and Testosterone

FSH binds with specific FSH receptors attached to the Sertoli cells in the seminiferous tubules, which causes the Sertoli cells to grow and secrete various spermatogenic substances. Simultaneously, testosterone (and dihydrotestosterone) diffusing into the seminiferous tubules from the Leydig cells in the interstitial spaces also has a strong tropic effect on spermatogenesis. Thus, both FSH and testosterone are necessary to initiate spermatogenesis.

Role of Inhibin in Negative Feedback Control of Seminiferous Tubule Activity. When the seminiferous tubules fail to produce sperm, secretion of FSH by the anterior pituitary gland increases markedly. Conversely, when spermatogenesis proceeds too rapidly, pituitary secretion of FSH diminishes. The cause of this negative feedback effect on the anterior pituitary is believed to be secretion by the Sertoli cells of still another hormone called *inhibin* (see **Figure 81-10**). This hormone has a strong direct effect on the anterior pituitary gland to inhibit FSH secretion.

Inhibin is a glycoprotein, like LH and FSH, with a molecular weight between 10,000 and 30,000. It has been isolated from cultured Sertoli cells. Its potent inhibitory effect on

the anterior pituitary gland provides an important negative feedback mechanism for control of spermatogenesis, operating simultaneously with and in parallel to the negative feedback mechanism for control of testosterone secretion.

Human Chorionic Gonadotropin Secreted by the Placenta During Pregnancy Stimulates Testosterone Secretion by the Fetal Testes

During pregnancy, the hormone *human chorionic gonadotropin* (hCG) is secreted by the placenta and circulates in the mother and in the fetus. This hormone has almost the same effects on the sexual organs as LH.

During pregnancy, if the fetus is a male, hCG from the placenta causes the testes of the fetus to secrete testosterone. This testosterone is critical for promoting formation of the male sexual organs, as pointed out earlier. We discuss hCG and its functions during pregnancy in greater detail in Chapter 83.

Puberty and Regulation of Its Onset

Initiation of the onset of puberty has long been a mystery, but it has now been determined that *during childhood the hypothalamus does not secrete significant amounts of GnRH*. One of the reasons for this is that, during childhood, the slightest secretion of any sex steroid hormones exerts a strong inhibitory effect on hypothalamic secretion of GnRH. Yet, for reasons still not fully understood, at the time of puberty, the secretion of hypothalamic GnRH breaks through the childhood inhibition and adult sexual life begins.

Male Adult Sexual Life and Male Climacteric. After puberty, gonadotropic hormones are produced by the male pituitary gland for the remainder of life, and at least some spermatogenesis usually continues until death. Many men, however, begin to exhibit slowly decreasing sexual functions in their late 50s or 60s, especially if they smoke or are obese and have associated cardiovascular and metabolic disorders, such as hypertension, atherosclerosis, and type 2 diabetes mellitus. There is considerable variation in the decline of sexual function, with healthy men continuing to be virile until their 80s and 90s.

The slow, gradual decline in sexual function is also related, in part, to a decrease in testosterone secretion, as shown in **Figure 81-9**. The decrease in male sexual function is called the *male climacteric.*

Abnormalities of Male Sexual Function

The Prostate Gland and Its Abnormalities

The prostate gland remains relatively small throughout childhood and begins to grow at puberty under the stimulus of testosterone. This gland reaches an almost stationary size by the age of 20 years and remains at this size up to the age of about 50 years. At that time, in some men it begins to involute, along with decreased production of testosterone by the testes.

A benign prostatic fibroadenoma frequently develops in the prostate in many older men and can cause urinary obstruction. This hypertrophy is caused not by testosterone but instead by abnormal overgrowth of prostate tissue.

Cancer of the prostate gland is a different problem that accounts for about 2% to 3% of all male deaths. Once cancer of the prostate gland occurs, the cancerous cells are usually stimulated to more rapid growth by testosterone and are inhibited by removal of both testes so that testosterone cannot be formed. Prostatic cancer usually can be inhibited by administration of estrogens. Even some patients who have prostatic cancer that has already metastasized to almost all the bones of the body can be successfully treated for a few months to years by removal of the testes, estrogen therapy, or both; after initiation of this therapy, the metastases usually diminish in size, and the bones partially heal. This treatment does not stop the cancer but slows it and sometimes greatly diminishes the severe bone pain.

Hypogonadism in the Male

When the testes of a male fetus are nonfunctional during fetal life, none of the male sexual characteristics develop in the fetus. Instead, female organs are formed. The reason for this is that the basic genetic characteristic of the fetus, whether male or female, is to form female sexual organs if there are no sex hormones. However, in the presence of testosterone, formation of female sexual organs is suppressed and male organs are induced instead.

When a boy loses his testes before puberty, a state of eunuchism ensues in which he continues to have infantile sex organs and other infantile sexual characteristics throughout life. The height of an adult eunuch is slightly greater than that of a normal man because the bone epiphyses are slow to unite, although the bones are quite thin and the muscles are considerably weaker than those of a normal man. The voice is childlike, there is no loss of hair on the head, and the normal adult masculine hair distribution on the face and elsewhere does not occur.

When a man is castrated after puberty, some of his male secondary sexual characteristics revert to those of a child, and others remain of adult masculine character. The sexual organs regress slightly in size but not to a childlike state, and the voice regresses from the bass quality only slightly. However, there is loss of masculine hair production, loss of the thick masculine bones, and loss of the musculature of the virile male.

Also in a castrated adult male, sexual desires are decreased but not lost, provided sexual activities have been practiced previously. Erection can still occur as before, although with less ease, but it is rare that ejaculation can take place, primarily because the semen-forming organs degenerate and there has been a loss of the testosterone-driven psychic desire.

Some cases of hypogonadism are caused by a genetic inability of the hypothalamus to secrete normal amounts of GnRH. This condition is often associated with a simultaneous abnormality of the feeding center of the hypothalamus, causing the person to greatly overeat. Consequently, obesity occurs along with eunuchism. A patient with this condition is shown in **Figure 81-11**; the condition is called *adiposogenital syndrome, Fröhlich's syndrome,* or *hypothalamic eunuchism.*

Testicular Tumors and Hypergonadism in the Male

Interstitial Leydig cell tumors develop in rare cases in the testes. These tumors sometimes produce as much as 100 times the normal quantities of testosterone. When such tumors develop in young children, they cause rapid growth of the musculature and bones but also early uniting of the epiphyses, so that the eventual adult height is actually considerably less than that which would have been achieved otherwise. Such interstitial cell tumors also cause excessive development of the male sexual organs, all skeletal muscles, and other male sexual characteristics. In the adult male, small interstitial cell tumors are difficult to diagnose because masculine features are already present.

Much more common than interstitial Leydig cell tumors are *tumors of the germinal epithelium.* Because germinal cells are capable of differentiating into almost any type of cell, many of these tumors contain multiple tissues, such as placental tissue, hair, teeth, bone, skin, and so forth, all found together in the same tumorous mass called a *teratoma.* These tumors often secrete few hormones, but if a significant quantity of placental tissue develops in the tumor, it may secrete large quantities of hCG with functions similar to those of LH. Also, estrogenic hormones are sometimes secreted by these tumors and cause the condition called *gynecomastia* (overgrowth of the breasts).

Erectile Dysfunction in the Male

Erectile dysfunction, also called "impotence," is characterized by an inability of the man to develop or maintain an erection of sufficient rigidity for satisfactory sexual intercourse. Neurological problems, such as trauma to the parasympathetic nerves from prostate surgery, deficient levels of testosterone, and some *drugs* (e.g., *nicotine, alcohol,* and *antidepressants*) can also contribute to erectile dysfunction.

In men older than 40 years, erectile dysfunction is most often caused by underlying vascular disease. As discussed previously, adequate blood flow and nitric oxide formation are essential for penile erection. Vascular disease, which can occur as a result of uncontrolled *hypertension, diabetes,* and *atherosclerosis,* reduces the ability of the body's blood vessels, including those in the penis, to dilate. Part of this impaired vasodilation is due to decreased release of nitric oxide.

Erectile dysfunction caused by vascular disease can often be successfully treated with *phosphodiesterase-5* (PDE-5) *inhibitors* such as sildenafil (Viagra), vardenafil (Levitra), or tadalafil (Cialis). These drugs increase cyclic GMP levels in the erectile tissue by inhibiting the enzyme *phosphodiesterase-5,* which rapidly degrades cyclic GMP. Thus, by inhibiting the degradation of cyclic GMP, the PDE-5 inhibitors enhance and prolong the effect of cyclic GMP to cause erection.

Function of the Pineal Gland in Controlling Seasonal Fertility in Some Animals

For as long as the pineal gland has been known to exist, myriad functions have been ascribed to it, including (1) enhancing sex, (2) staving off infection, (3) promoting sleep, (4) enhancing mood, and (5) increasing longevity (as much as 10% to 25%). It is known from comparative anatomy that the pineal gland is a vestigial remnant of what was a third eye located high in the back of the head in some lower animals. Many physiologists have been content with the idea that this gland is a nonfunctional remnant, but others have claimed for many years that it plays important roles in the control of sexual activities and reproduction.

Now, after years of research, it appears that the pineal gland does indeed play a regulatory role in sexual and reproductive function. In animals that bear their young at certain seasons of the year and in which the pineal gland has been removed or the nervous circuits to the pineal gland have been sectioned, the normal periods of seasonal fertility are lost. To these animals, such seasonal fertility is important because it allows birth of the offspring at the time of year, usually springtime or early summer, when survival is most likely. The mechanism of this effect is not entirely clear, but it seems to be the following.

First, the pineal gland is controlled by the amount of light or "time pattern" of light seen by the eyes each day. For example, in the hamster, more than 13 hours of *darkness* each day activates the pineal gland, whereas less than that amount of darkness fails to activate it, with a critical balance between activation and nonactivation. The nervous pathway involves the passage of light signals from the eyes to the suprachiasmal nucleus of the hypothalamus and then to the pineal gland, activating pineal secretion.

Second, the pineal gland secretes *melatonin* and several other similar substances. Either melatonin or one of the other substances is believed to pass either by way of the blood or through the fluid of the third ventricle to the anterior pituitary gland to *decrease* gonadotropic hormone secretion.

Thus, in the presence of pineal gland secretion, gonadotropic hormone secretion is suppressed in some species of animals, and the gonads become inhibited and even partly involuted, which is what presumably occurs during the early winter months when there is increasing darkness. However, after about 4 months of dysfunction, gonadotropic hormone secretion breaks through the inhibitory effect of the pineal gland and the gonads become functional once more, ready for a full springtime of activity.

Does the pineal gland have a similar function for control of reproduction in humans? The answer to this question is unknown. However, tumors sometimes occur in the region of the pineal gland. Some of these tumors secrete excessive quantities of pineal hormones, whereas others are tumors of surrounding tissue and press on the pineal gland to destroy it. Both types of tumors are often associated with hypogonadal or hypergonadal function, so perhaps the pineal gland does play at least some role in controlling sexual drive and reproduction in humans.

CHAPTER 82

UNIT XIV

Female Physiology Before Pregnancy and Female Hormones

Female reproductive functions can be divided into two major phases: (1) preparation of the female body for conception and pregnancy and (2) the period of pregnancy itself. This chapter is concerned with preparation of the female body for pregnancy, and Chapter 83 presents the physiology of pregnancy and childbirth.

PHYSIOLOGIC ANATOMY OF THE FEMALE SEXUAL ORGANS

Figures 82-1 and **82-2** show the principal organs of the human female reproductive tract, including the *ovaries, fallopian tubes* (also called *uterine tubes*), *uterus,* and *vagina.* Reproduction begins with the development of ova in the ovaries. In the middle of each monthly sexual cycle, a single ovum is expelled from an ovarian follicle into the abdominal cavity near the open fimbriated ends of the two fallopian tubes. This ovum then passes through one of the fallopian tubes into the uterus; if it has been fertilized by a sperm, it implants in the uterus, where it develops into a fetus, a placenta, and fetal membranes—and eventually into a baby.

OOGENESIS AND FOLLICULAR DEVELOPMENT IN THE OVARIES

A developing egg *(oocyte)* differentiates into a mature egg *(ovum)* through a series of steps called *oogenesis* (**Figure 82-3**). During early embryonic development, *primordial germ cells* from the dorsal endoderm of the yolk sac migrate along the mesentery of the hindgut to the outer surface of the ovary, which is covered by a germinal epithelium, derived embryologically from the epithelium of the germinal ridges. During this migration, the germ cells divide repeatedly. Once these primordial germ cells reach the germinal epithelium, they migrate into the substance of the ovarian cortex and become *oogonia* or *primordial ova*.

Each primordial ovum then collects around it a layer of spindle cells from the ovarian *stroma* (the supporting tissue of the ovary) and causes them to take on epithelioid characteristics; these epithelioid-like cells are then called *granulosa cells*. The ovum surrounded by a single layer of granulosa cells is called a *primordial follicle*. At this stage, the ovum is still immature and is called a *primary oocyte*, requiring two more cell divisions before it can be fertilized by a sperm.

The oogonia in the embryonic ovary complete mitotic replication, and the first stage of meiosis starts by the fifth month of fetal development. The germ cell mitosis then ceases and no additional oocytes are formed. At birth the ovary contains about 1 to 2 million primary oocytes.

The first stage of meiosis starts during fetal development but is arrested in the late stage of prophase I until puberty, which usually occurs between ages 10 and 14 in females. The first meiotic division of the oocyte is completed after puberty. Each oocyte divides into two cells, a large ovum *(secondary oocyte)* and a small first *polar body*. Each of these cells contains 23 duplicated chromosomes. The first polar body may or may not undergo a second meiotic division and then disintegrates. The ovum undergoes a second meiotic division, and after the sister chromatids separate, there is a pause in meiosis. If the ovum is fertilized, the final step in meiosis occurs and the sister chromatids in the ovum go to separate cells.

When the ovary releases the ovum *(ovulation),* and if the ovum is fertilized, the final meiosis occurs. Half of the sister chromatids remain in the fertilized ovum, and the other half are released in a second polar body, which then disintegrates.

At puberty, only about 300,000 oocytes remain in the ovaries, and only a small percentage of these oocytes become mature. The many thousands of oocytes that do not mature degenerate. During all the reproductive years of adult life, between about 13 and 46 years of age on average, only 400 to 500 of the primordial follicles develop enough to expel their ova, one each month; the remainder degenerate (i.e., become *atretic*). At the end of reproductive capability (at *menopause*), only a few primordial follicles remain in the ovaries, and even these follicles degenerate soon thereafter.

FEMALE HORMONAL SYSTEM

The female hormonal system, like that of the male hormonal system, consists of three hierarchies of hormones, as follows:

1. A hypothalamic releasing hormone, called *gonadotropin-releasing hormone* (GnRH)

2. The anterior pituitary sex hormones, *follicle-stimulating hormone* (FSH) and *luteinizing hormone* (LH), both of which are secreted in response to release of GnRH from the hypothalamus
3. The ovarian hormones, *estrogen* and *progesterone,* which are secreted by the ovaries in response to the two female sex hormones from the anterior pituitary gland

These various hormones are secreted at drastically differing rates during different parts of the female monthly sexual cycle. **Figure 82-4** shows the approximate changing concentrations of the anterior pituitary gonadotropic hormones FSH and LH (bottom two curves) and of the ovarian hormones estradiol (estrogen) and progesterone (top two curves).

The amount of GnRH released from the hypothalamus increases and decreases much less drastically during the monthly sexual cycle. It is secreted in short pulses averaging once every 90 minutes, as occurs in males.

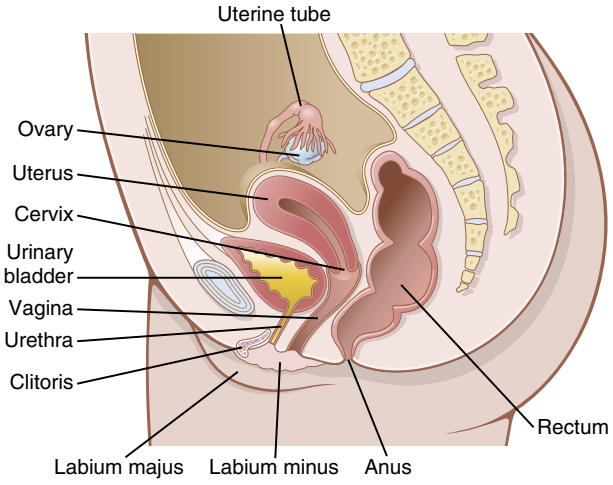

Figure 82-1. The female reproductive organs.

MONTHLY OVARIAN CYCLE AND FUNCTION OF GONADOTROPIC HORMONES

The normal reproductive years of the female are characterized by monthly rhythmic changes in the rates of secretion of the female hormones and corresponding physical changes in the ovaries and other sexual organs. This rhythmic pattern is called the *female monthly sexual cycle* (or, less accurately, the *menstrual cycle*). The duration of the cycle averages 28 days. It may be as short as 20 days or as long as 45 days in some women, although abnormal cycle length is frequently associated with decreased fertility.

The female sexual cycle has two significant results. First, only a *single* ovum is normally released from the ovaries each month, so normally only a single fetus will begin to grow at a time. Second, the uterine endometrium is prepared in advance for implantation of the fertilized ovum at the required time of the month.

GONADOTROPIC HORMONES AND THEIR EFFECTS ON THE OVARIES

The ovarian changes that occur during the sexual cycle depend completely on the gonadotropic hormones FSH and LH, which are secreted by the anterior pituitary gland. Both FSH and LH are small glycoproteins that have molecular weights of about 30,000. In the absence of these hormones, the ovaries remain inactive, which is the case throughout childhood, when almost no pituitary gonadotropic hormones are secreted. At age 9 to 12 years, the pituitary begins to secrete progressively more FSH and LH, which leads to the onset of normal monthly sexual cycles beginning between the ages of 11 and 15 years. This period of change is called *puberty,* and the time of the first menstrual cycle is called *menarche.* During each month of the female sexual cycle, there is a cyclical increase and decrease of FSH and LH, as shown in the bottom of **Figure 82-4**. These cyclical variations

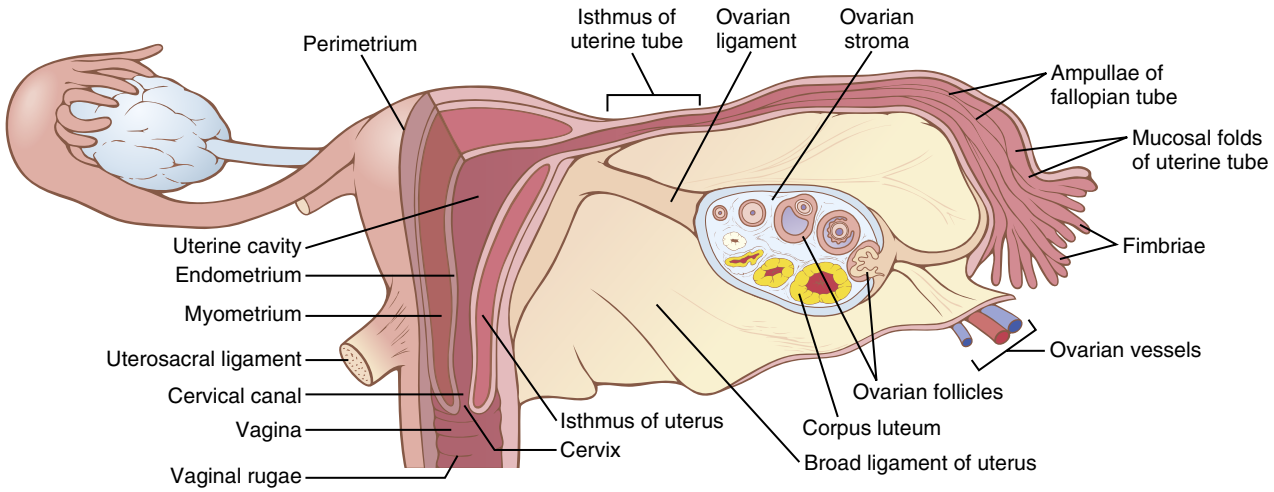

Figure 82-2. Internal structures of the uterus, ovary, and a uterine tube.

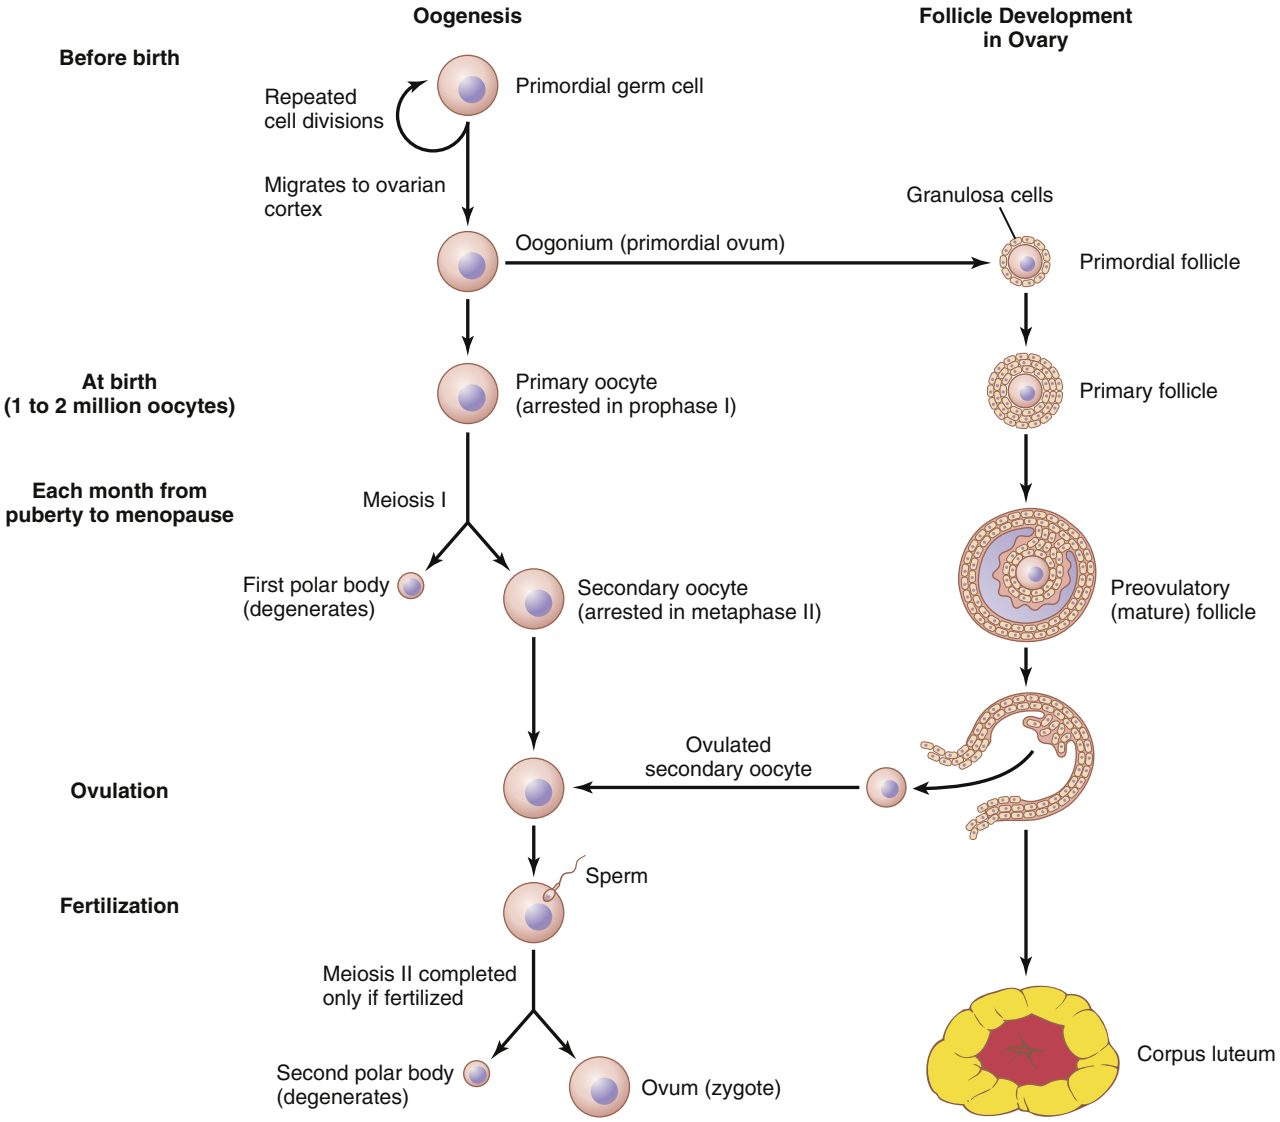

Figure 82-3. Oogenesis and follicle development.

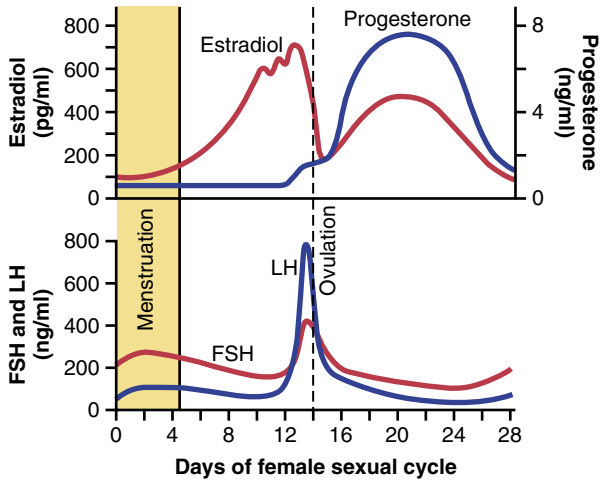

Figure 82-4. Approximate plasma concentrations of the gonadotropins and ovarian hormones during the normal female sexual cycle. FSH, Follicle-stimulating hormone; LH, luteinizing hormone.

cause cyclical ovarian changes, which are explained in the following sections.

Both FSH and LH stimulate their ovarian target cells by combining with highly specific FSH and LH receptors in the ovarian target cell membranes. In turn, the activated receptors increase the cells' secretion rates and usually the growth and proliferation of the cells as well. Almost all these stimulatory effects result from *activation of the cyclic adenosine monophosphate second messenger system* in the cell cytoplasm, which causes formation of *protein kinase* and multiple *phosphorylations of key enzymes* that stimulate sex hormone synthesis, as explained in Chapter 75.

OVARIAN FOLLICLE GROWTH—THE FOLLICULAR PHASE OF THE OVARIAN CYCLE

Figure 82-5 shows the progressive stages of follicular growth in the ovaries. When a female child is born,

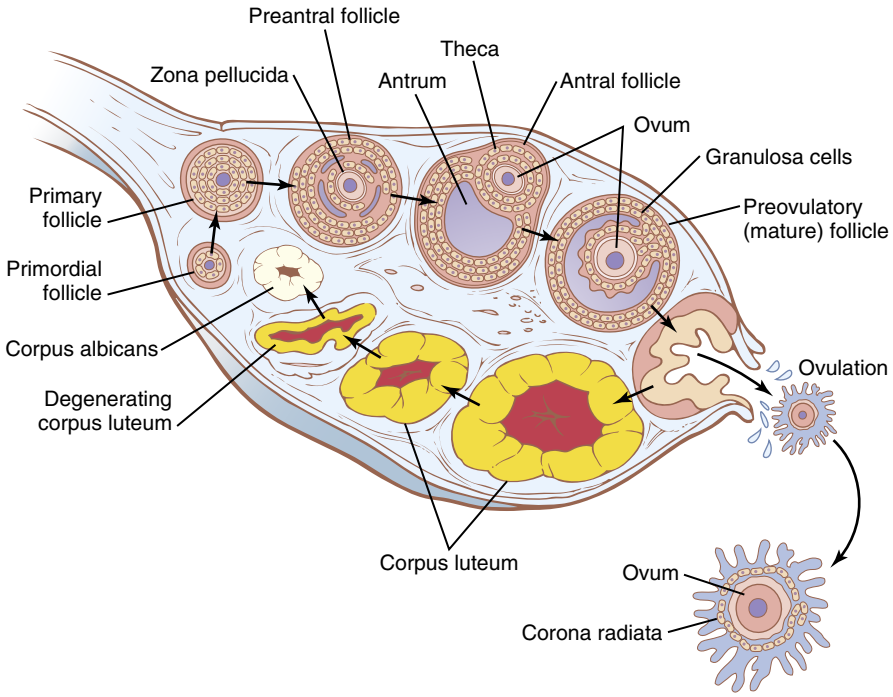

Figure 82-5. Stages of follicular growth in the ovary, also showing formation of the corpus luteum.

each ovum is surrounded by a single layer of granulosa cells; the ovum, with this granulosa cell sheath, is called a *primordial follicle,* as shown in the figure. Throughout childhood, the granulosa cells are believed to provide nourishment for the ovum and to secrete an *oocyte maturation inhibiting factor* that keeps the ovum suspended in its primordial state in the prophase stage of meiotic division. Then, after puberty, when FSH and LH from the anterior pituitary gland begin to be secreted in significant quantities, the ovaries (together with some of the follicles within them) begin to grow.

The first stage of follicular growth is moderate enlargement of the ovum, which increases in diameter 2-fold to 3-fold. That stage is followed by growth of additional layers of granulosa cells in some of the follicles. These follicles are known as *primary follicles.*

Development of Antral and Vesicular Follicles. During the first few days of each monthly female sexual cycle, the concentrations of FSH and LH secreted by the anterior pituitary gland increase slightly to moderately, with the increase in FSH slightly greater than that of LH and preceding it by a few days. These hormones, especially FSH, cause accelerated growth of 6 to 12 primary follicles each month. The initial effect is rapid proliferation of the granulosa cells, giving rise to many more layers of these cells. In addition, spindle cells derived from the ovary interstitium collect in several layers outside the granulosa cells, giving rise to a second mass of cells called the *theca.* The theca is divided into two layers. In the *theca interna,* the cells take on epithelioid characteristics similar to those of the granulosa cells and develop the ability to secrete additional steroid sex hormones (estrogen and progesterone). The outer layer, the *theca externa,* develops into a highly vascular connective tissue capsule that becomes the capsule of the developing follicle.

After the early proliferative phase of growth, which lasts for a few days, the mass of granulosa cells secretes a *follicular fluid* that contains a high concentration of estrogen, one of the important female sex hormones (discussed later). Accumulation of this fluid causes an *antrum* to appear within the mass of granulosa cells, as shown in **Figure 82-5**.

The early growth of the primary follicle up to the antral stage is stimulated mainly by FSH alone. Greatly accelerated growth then occurs, leading to still larger follicles called *vesicular follicles.* This accelerated growth is caused by the following mechanisms:

1. Estrogen is secreted into the follicle and causes the granulosa cells to form increasing numbers of FSH receptors, which causes a positive feedback effect because it makes the granulosa cells even more sensitive to FSH.
2. The pituitary FSH and the estrogens combine to promote LH receptors on the original granulosa cells, thus allowing LH stimulation to occur in addition to FSH stimulation and creating an even more rapid increase in follicular secretion.
3. The increasing estrogens from the follicle plus the increasing LH from the anterior pituitary gland act together to cause proliferation of the follicular thecal cells and increase their secretion.

Once the antral follicles begin to grow, their growth occurs almost explosively. The ovum also enlarges in diameter another 3-fold to 4-fold, giving a total ovum diameter increase up to 10-fold, or a mass increase of 1000-fold. As the follicle enlarges, the ovum remains

embedded in a mass of granulosa cells located at one pole of the follicle.

Only One Follicle Fully Matures Each Month, and the Remainder Undergo Atresia. After a week or more of growth—but before ovulation occurs—one of the follicles begins to outgrow all the others, and the remaining 5 to 11 developing follicles involute (a process called *atresia*).

The cause of the atresia is unclear, but it has been postulated to be the following: The large amounts of estrogen from the most rapidly growing follicle act on the hypothalamus to depress further enhancement of FSH secretion by the anterior pituitary gland, in this way blocking further growth of the less well-developed follicles. Therefore, the largest follicle continues to grow because of its intrinsic positive feedback effects, while all the other follicles stop growing and actually involute.

This process of atresia is important because it normally allows only one of the follicles to grow large enough each month to ovulate, which usually prevents more than one child from developing with each pregnancy. The single follicle reaches a diameter of 1 to 1.5 centimeters at the time of ovulation and is called the *mature follicle.*

Ovulation

Ovulation in a woman who has a normal 28-day female sexual cycle occurs 14 days after the onset of menstruation. Shortly before ovulation, the protruding outer wall of the follicle swells rapidly, and a small area in the center of the follicular capsule, called the *stigma,* protrudes like a nipple. In another 30 minutes or so, fluid begins to ooze from the follicle through the stigma, and about 2 minutes later, the stigma ruptures widely, allowing a more viscous fluid, which has occupied the central portion of the follicle, to evaginate outward. This viscous fluid carries with it the ovum surrounded by a mass of several thousand small granulosa cells, called the *corona radiata.*

A Surge of Luteinizing Hormone Is Necessary for Ovulation. LH is necessary for final follicular growth and ovulation. Without this hormone, even when large quantities of FSH are available, the follicle will not progress to the ovulation stage.

About 2 days before ovulation, the rate of secretion of LH by the anterior pituitary gland increases markedly, rising 6- to 10-fold and peaking about 16 hours before ovulation. FSH also increases about 2-fold to 3-fold at the same time, and the FSH and LH act synergistically to cause rapid swelling of the follicle during the last few days before ovulation. The LH also has a specific effect on the granulosa and theca cells, converting them mainly to progesterone-secreting cells. Therefore, the rate of estrogen secretion begins to fall about 1 day before ovulation, while increasing amounts of progesterone begin to be secreted.

It is in this environment of (1) rapid growth of the follicle, (2) diminishing estrogen secretion after a prolonged phase of excessive estrogen secretion, and (3) initiation of secretion of progesterone that ovulation occurs. Without the initial preovulatory surge of LH, ovulation will not take place.

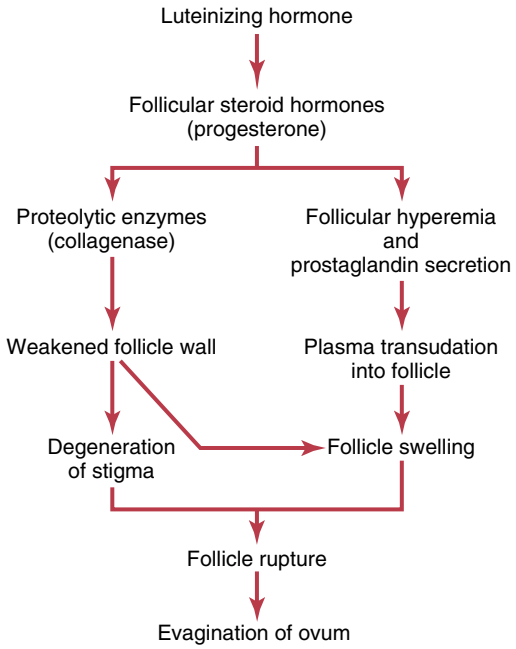

Figure 82-6. The postulated mechanism of ovulation.

Initiation of Ovulation. Figure 82-6 provides a schema for the initiation of ovulation, showing the role of the large quantity of LH secreted by the anterior pituitary gland. This LH causes rapid secretion of follicular steroid hormones that contain progesterone. Within a few hours, two events occur, both of which are necessary for ovulation:

1. The *theca externa* (i.e., the capsule of the follicle) begins to release proteolytic enzymes from lysosomes. These enzymes cause dissolution of the follicular capsular wall and consequent weakening of the wall, resulting in further swelling of the entire follicle and degeneration of the stigma.
2. Simultaneously there is rapid growth of new blood vessels into the follicle wall. At the same time, prostaglandins (local hormones that cause vasodilation) are secreted into the follicular tissues.

These two effects cause plasma transudation into the follicle, which contributes to follicle swelling. Finally, the combination of follicle swelling and simultaneous degeneration of the stigma causes follicle rupture, with discharge of the ovum.

CORPUS LUTEUM—THE LUTEAL PHASE OF THE OVARIAN CYCLE

During the first few hours after expulsion of the ovum from the follicle, the remaining granulosa and theca interna cells change rapidly into *lutein cells.* They enlarge

in diameter two or more times and become filled with lipid inclusions that give them a yellowish appearance. This process is called *luteinization,* and the total mass of cells together is called the *corpus luteum,* which is shown in **Figure 82-5**. A well-developed vascular supply also grows into the corpus luteum.

The *granulosa cells* in the corpus luteum develop extensive intracellular smooth endoplasmic reticula that form large amounts of the female sex hormones *progesterone* and *estrogen* (with more progesterone than estrogen during the luteal phase). The *theca cells* form mainly the androgens *androstenedione* and *testosterone* rather than female sex hormones. However, most of these hormones are also converted by the enzyme *aromatase* in the granulosa cells into estrogens.

The corpus luteum normally grows to about 1.5 centimeters in diameter, reaching this stage of development 7 to 8 days after ovulation. Then the corpus luteum begins to involute and eventually loses its secretory function and its yellowish, lipid characteristic about 12 days after ovulation, becoming the *corpus albicans;* during the ensuing few weeks, the corpus albicans is replaced by connective tissue and over months is absorbed.

Luteinizing Function of Luteinizing Hormone. The change of granulosa and theca interna cells into lutein cells depends mainly on LH secreted by the anterior pituitary gland. In fact, this function gives LH its name—"luteinizing," for "yellowing." Luteinization also depends on extrusion of the ovum from the follicle. A yet uncharacterized factor in the follicular fluid, called *luteinization-inhibiting factor,* seems to hold the luteinization process in check until after ovulation.

Secretion by the Corpus Luteum: An Additional Function of Luteinizing Hormone. The corpus luteum is a highly secretory organ, secreting large amounts of *progesterone* and *estrogen.* Once LH (mainly that secreted during the ovulatory surge) has acted on the granulosa and theca cells to cause luteinization, the newly formed lutein cells go through a sequence of (1) proliferation, (2) enlargement, and (3) secretion, followed by (4) degeneration. All this occurs in about 12 days. As discussed in Chapter 83, another hormone with almost exactly the same properties as LH, *chorionic gonadotropin,* which is secreted by the placenta, can act on the corpus luteum to prolong its life—usually maintaining it for at least the first 2 to 4 months of pregnancy.

Involution of the Corpus Luteum and Onset of the Next Ovarian Cycle. Estrogen in particular and progesterone to a lesser extent, secreted by the corpus luteum during the luteal phase of the ovarian cycle, have strong feedback effects on the anterior pituitary gland to maintain low secretory rates of FSH and LH.

In addition, the lutein cells secrete small amounts of the hormone *inhibin,* the same as the inhibin secreted by the Sertoli cells of the male testes. This hormone inhibits FSH secretion by the anterior pituitary gland. Low blood concentrations of FSH and LH result, and loss of these hormones finally causes the corpus luteum to degenerate completely, a process called *involution* of the corpus luteum.

Final involution normally occurs at the end of almost exactly 12 days of corpus luteum life, which is around the 26th day of the normal female sexual cycle, 2 days before menstruation begins. At this time, the sudden cessation of estrogen, progesterone, and inhibin secretion by the corpus luteum removes the feedback inhibition of the anterior pituitary gland, allowing it to begin secreting increasing amounts of FSH and LH again. FSH and LH initiate the growth of new follicles, beginning a new ovarian cycle. The paucity of progesterone and estrogen secretion at this time also leads to menstruation by the uterus, which will be explained later.

SUMMARY

About every 28 days, gonadotropic hormones from the anterior pituitary gland cause 8 to 12 new follicles to begin to grow in the ovaries. One of these follicles finally becomes "mature" and ovulates on the 14th day of the cycle. During growth of the follicles, estrogen is mainly secreted.

After ovulation, the secretory cells of the ovulating follicle develop into a corpus luteum that secretes large quantities of progesterone and estrogen. After another 2 weeks, the corpus luteum degenerates, whereupon the ovarian hormones estrogen and progesterone decrease greatly, and menstruation begins. A new ovarian cycle then follows.

FUNCTIONS OF OVARIAN HORMONES—ESTRADIOL AND PROGESTERONE

The two types of ovarian sex hormones are the *estrogens* and the *progestins.* By far the most important of the estrogens is *estradiol,* and by far the most important progestin is *progesterone.* The estrogens mainly promote proliferation and growth of specific cells in the body that are responsible for development of most secondary sexual characteristics of females. The progestins function mainly to prepare the uterus for pregnancy and the breasts for lactation.

CHEMISTRY OF THE SEX HORMONES

Estrogens. In the normal *nonpregnant* female, estrogens are secreted in significant quantities only by the ovaries, although minute amounts are also secreted by the adrenal cortices. During *pregnancy,* large quantities of estrogens are also secreted by the placenta, as discussed in Chapter 83.

Only three estrogens are present in significant quantities in the plasma of the human female—β-estradiol, estrone, and *estriol,* the formulas for which are shown in **Figure 82-7**. The principal estrogen secreted by the ovaries is β-estradiol. Small amounts of estrone are also secreted, but most of this is formed in peripheral tissues from androgens secreted by the adrenal cortices and by ovarian thecal cells. Estriol is a weak estrogen; it is an oxidative product derived from both estradiol and estrone, with the conversion occurring mainly in the liver.

The estrogenic potency of β-estradiol is 12 times that of estrone and 80 times that of estriol. Considering these relative potencies, one can see that the total estrogenic effect of β-estradiol is usually many times that of the other two together. For this reason, β-estradiol is considered the major estrogen, although the estrogenic effects of estrone are not negligible.

Progestins. By far the most important of the progestins is progesterone. However, small amounts of another progestin, 17α-hydroxyprogesterone, are secreted along with progesterone and have essentially the same effects. Yet, for practical purposes, progesterone is usually considered to be the only important progestin.

In nonpregnant females, progesterone is usually secreted in significant amounts only during the latter half of each ovarian cycle, when it is secreted by the corpus luteum.

As discussed in Chapter 83, large amounts of progesterone are also secreted by the placenta during pregnancy, especially after the fourth month of gestation.

Synthesis of the Estrogens and Progestins. Note from the chemical formulas of the estrogens and progesterone in **Figure 82-7** that they are all steroids. They are synthesized in the ovaries mainly from cholesterol derived from the blood but also to a slight extent from acetyl coenzyme A, multiple molecules of which can combine to form the appropriate steroid nucleus.

During synthesis, mainly progesterone and androgens (testosterone and androstenedione) are synthesized first; then, during the follicular phase of the ovarian cycle, before these two initial hormones can leave the ovaries, almost all the androgens and much of the progesterone are converted into estrogens by the enzyme *aromatase* in the granulosa cells. Because the theca cells lack aromatase, they cannot convert androgens to estrogens. However, androgens diffuse out of the theca cells into the adjacent granulosa cells, where they are converted to estrogens by aromatase, the activity of which is stimulated by FSH (**Figure 82-8**).

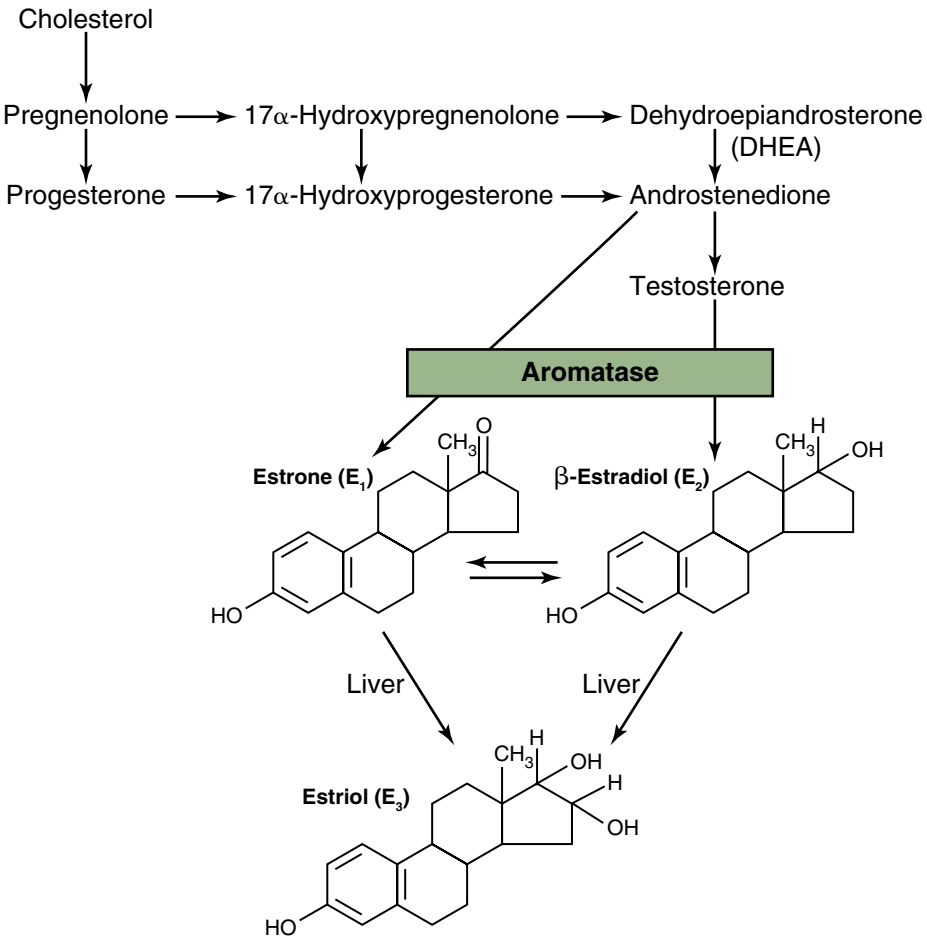

Figure 82-7. Synthesis of the principal female hormones. The chemical structures of the precursor hormones, including progesterone, are shown in Figure 78-2.

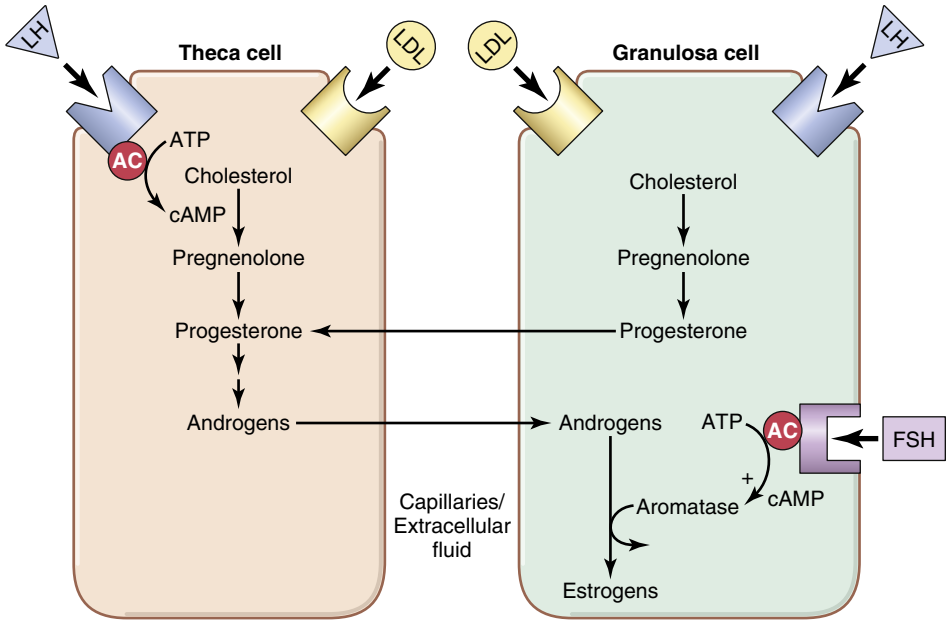

Figure 82-8. Interaction of follicular theca and granulosa cells for production of estrogens. The theca cells, under the control of luteinizing hormone (LH), produce androgens that diffuse into the granulosa cells. In mature follicles, follicle-stimulating hormone (FSH) acts on granulosa cells to stimulate aromatase activity, which converts the androgens to estrogens. AC, Adenylate cyclase; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; LDL, low-density lipoproteins.

During the luteal phase of the cycle, far too much progesterone is formed for all of it to be converted, which accounts for the large secretion of progesterone into the circulating blood at this time. Also, about one-fifteenth as much testosterone is secreted into the plasma of the female by the ovaries as is secreted into the plasma of the male by the testes.

Estrogens and Progesterone Are Transported in the Blood Bound to Plasma Proteins. Both estrogens and progesterone are transported in the blood bound mainly with plasma albumin and with specific estrogen- and progesterone-binding globulins. The binding between these hormones and the plasma proteins is loose enough that they are rapidly released to the tissues over a period of 30 minutes or so.

Functions of the Liver in Estrogen Degradation. The liver conjugates estrogens to form glucuronides and sulfates, and about one-fifth of these conjugated products is excreted in the bile; most of the remainder is excreted in the urine. Also, the liver converts the potent estrogens estradiol and estrone into the almost totally impotent estrogen estriol. Therefore, diminished liver function actually *increases* the activity of estrogens in the body, sometimes causing *hyperestrinism.*

Fate of Progesterone. Within a few minutes after secretion, almost all the progesterone is degraded to other steroids that have no progestational effect. As with the estrogens, the liver is especially important for this metabolic degradation.

The major end product of progesterone degradation is *pregnanediol.* About 10% of the original progesterone is excreted in the urine in this form. Therefore, one can estimate the rate of progesterone formation in the body from the rate of this excretion.

FUNCTIONS OF THE ESTROGENS—THEIR EFFECTS ON THE PRIMARY AND SECONDARY FEMALE SEX CHARACTERISTICS

A primary function of the estrogens is to cause cellular proliferation and growth of the tissues of the sex organs and other tissues related to reproduction.

Effect of Estrogens on the Uterus and External Female Sex Organs. During childhood, estrogens are secreted only in minute quantities, but at puberty, the quantity secreted in the female under the influence of the pituitary gonadotropic hormones increases 20-fold or more. At this time, the female sex organs change from those of a child to those of an adult. The ovaries, fallopian tubes, uterus, and vagina all increase several times in size. Also, the external genitalia enlarge, with deposition of fat in the mons pubis and labia majora and enlargement of the labia minora.

In addition, estrogens change the vaginal epithelium from a cuboidal into a stratified type, which is considerably more resistant to trauma and infection than is the prepubertal cuboidal cell epithelium. Vaginal infections in children can often be cured by the administration of estrogens simply because of the resulting increased resistance of the vaginal epithelium.

During the first few years after puberty, the size of the uterus increases 2-fold to 3-fold, but more important than the increase in uterus size are the changes that take place in the uterine endometrium under the influence of estrogens. Estrogens cause marked proliferation of the endometrial stroma and greatly increased development of the endometrial glands, which will later aid in providing nutrition to the implanted ovum. These effects are discussed later in the chapter in connection with the endometrial cycle.

Effect of Estrogens on the Fallopian Tubes. The estrogens' effects on the mucosal lining of the fallopian tubes are similar to their effects on the uterine endometrium. They cause the glandular tissues of this lining to proliferate, and especially important, they cause the number of ciliated epithelial cells that line the fallopian tubes to increase. Also, activity of the cilia is considerably enhanced. These cilia always beat toward the uterus, which helps propel the fertilized ovum in that direction.

Effect of Estrogens on the Breasts. The primordial breasts of females and males are exactly alike. In fact, under the influence of appropriate hormones, the masculine breast during the first 2 decades of life can develop sufficiently to produce milk in the same manner as the female breast.

Estrogens cause (1) development of the stromal tissues of the breasts, (2) growth of an extensive ductile system, and (3) deposition of fat in the breasts. The lobules and alveoli of the breast develop to a slight extent under the influence of estrogens alone, but it is progesterone and prolactin that ultimately complete the growth and function of these structures.

In summary, the estrogens initiate growth of the breasts and of the milk-producing apparatus. They are also responsible for the characteristic growth and external appearance of the mature female breast. However, they do not complete the job of converting the breasts into milk-producing organs.

Effect of Estrogens on the Skeleton. Estrogens inhibit osteoclastic activity in the bones and therefore stimulate bone growth. As discussed in Chapter 80, at least part of this effect is due to stimulation of *osteoprotegerin,* which is also called *osteoclastogenesis inhibitory factor,* a cytokine that inhibits bone resorption.

At puberty, when the female enters her reproductive years, her growth in height becomes rapid for several years. However, estrogens also cause uniting of the epiphyses with the shafts of the long bones. This effect of estrogen in the female is much stronger than the similar effect of testosterone in the male. As a result, growth of the female usually ceases several years earlier than growth of the male. A female eunuch who is devoid of estrogen production usually grows several inches taller than a normal mature female because her epiphyses do not unite at the normal time.

Osteoporosis of the Bones Caused by Estrogen Deficiency in Old Age. After menopause, almost no estrogens are secreted by the ovaries. This estrogen deficiency leads to (1) increased osteoclastic activity in the bones, (2) decreased bone matrix, and (3) decreased deposition of bone calcium and phosphate. In some women this effect is extremely severe, and the resulting condition is called *osteoporosis,* described in Chapter 80. Because osteoporosis can greatly weaken the bones and lead to bone fracture, especially fracture of the vertebrae, many postmenopausal women are treated prophylactically with estrogen replacement to prevent the osteoporotic effects.

Estrogens Slightly Increase Protein Deposition. Estrogens cause a slight increase in total body protein, which is evidenced by a slight positive nitrogen balance when estrogens are administered. This effect mainly results from the growth-promoting effect of estrogen on the sexual organs, the bones, and a few other tissues of the body. The enhanced protein deposition caused by testosterone is much more general and much more powerful than that caused by estrogens.

Estrogens Increase Body Metabolism and Fat Deposition. Estrogens increase the whole-body metabolic rate slightly, but only about one-third as much as the increase caused by testosterone. Estrogens also cause deposition of increased quantities of fat in the subcutaneous tissues. As a result, the percentage of body fat in females is considerably greater than that in the males whose bodies contain more protein. In addition to deposition of fat in the breasts and subcutaneous tissues, estrogens cause deposition of fat in the buttocks and thighs, which is characteristic of the feminine figure.

Estrogens Have Little Effect on Hair Distribution. Estrogens do not greatly affect hair distribution. However, hair does develop in the pubic region and in the axillae after puberty. Androgens formed in increased quantities by the female adrenal glands after puberty are mainly responsible for this development of hair.

Effect of Estrogens on the Skin. Estrogens cause the skin to develop a texture that is soft and usually smooth, but even so, the skin of a woman is thicker than that of a child or a castrated female. Estrogens also cause the skin to become more vascular, which is often associated with increased warmth of the skin and greater bleeding of cut surfaces than is observed in men.

Effect of Estrogens on Electrolyte Balance. The chemical similarity of estrogenic hormones to adrenocortical hormones has been discussed previously. Estrogens, like aldosterone and some other adrenocortical hormones, cause sodium and water retention by the kidney tubules. This effect of estrogens is normally slight and rarely of significance, but during pregnancy the tremendous formation of estrogens by the placenta may contribute to body fluid retention, as discussed in Chapter 83.

FUNCTIONS OF PROGESTERONE

Progesterone Promotes Secretory Changes in the Uterus. A major function of progesterone is *to promote secretory changes in the uterine endometrium* during the latter half of the monthly female sexual cycle, thus preparing the uterus for implantation of the fertilized ovum.

This function is discussed later in connection with the endometrial cycle of the uterus.

In addition to this effect on the endometrium, progesterone decreases the frequency and intensity of uterine contractions, thereby helping to prevent expulsion of the implanted ovum.

Progesterone Promotes Secretion by the Fallopian Tubes. Progesterone also promotes increased secretion by the mucosal lining of the fallopian tubes. These secretions are necessary for nutrition of the fertilized, dividing ovum as it traverses the fallopian tube before implantation.

Progesterone Promotes Development of the Breasts. Progesterone promotes development of the lobules and alveoli of the breasts, causing the alveolar cells to proliferate, enlarge, and become secretory. However, progesterone does not cause the alveoli to secrete milk; as discussed in Chapter 83, milk is secreted only after the prepared breast is further stimulated by *prolactin* from the anterior pituitary gland.

Progesterone also causes the breasts to swell. Part of this swelling is due to the secretory development in the lobules and alveoli, but part also results from increased fluid in the tissue.

MONTHLY ENDOMETRIAL CYCLE AND MENSTRUATION

Associated with the monthly cyclical production of estrogens and progesterone by the ovaries is an endometrial cycle in the lining of the uterus that operates through the following stages: (1) proliferation of the uterine endometrium; (2) development of secretory changes in the endometrium; and (3) desquamation of the endometrium, which is known as *menstruation.* The various phases of this endometrial cycle are shown in **Figure 82-9**. See Video 82-1.

Proliferative Phase (Estrogen Phase) of the Endometrial Cycle Occurs Before Ovulation. At the beginning of each monthly cycle, most of the endometrium has been desquamated by menstruation. After menstruation, only a thin layer of endometrial stroma remains, and the only epithelial cells that are left are those located in the remaining deeper portions of the glands and crypts of the endometrium. *Under the influence of estrogens,* secreted in increasing quantities by the ovary during the first part of the monthly ovarian cycle, the stromal cells and the epithelial cells proliferate rapidly. The endometrial surface is re-epithelialized within 4 to 7 days after the beginning of menstruation.

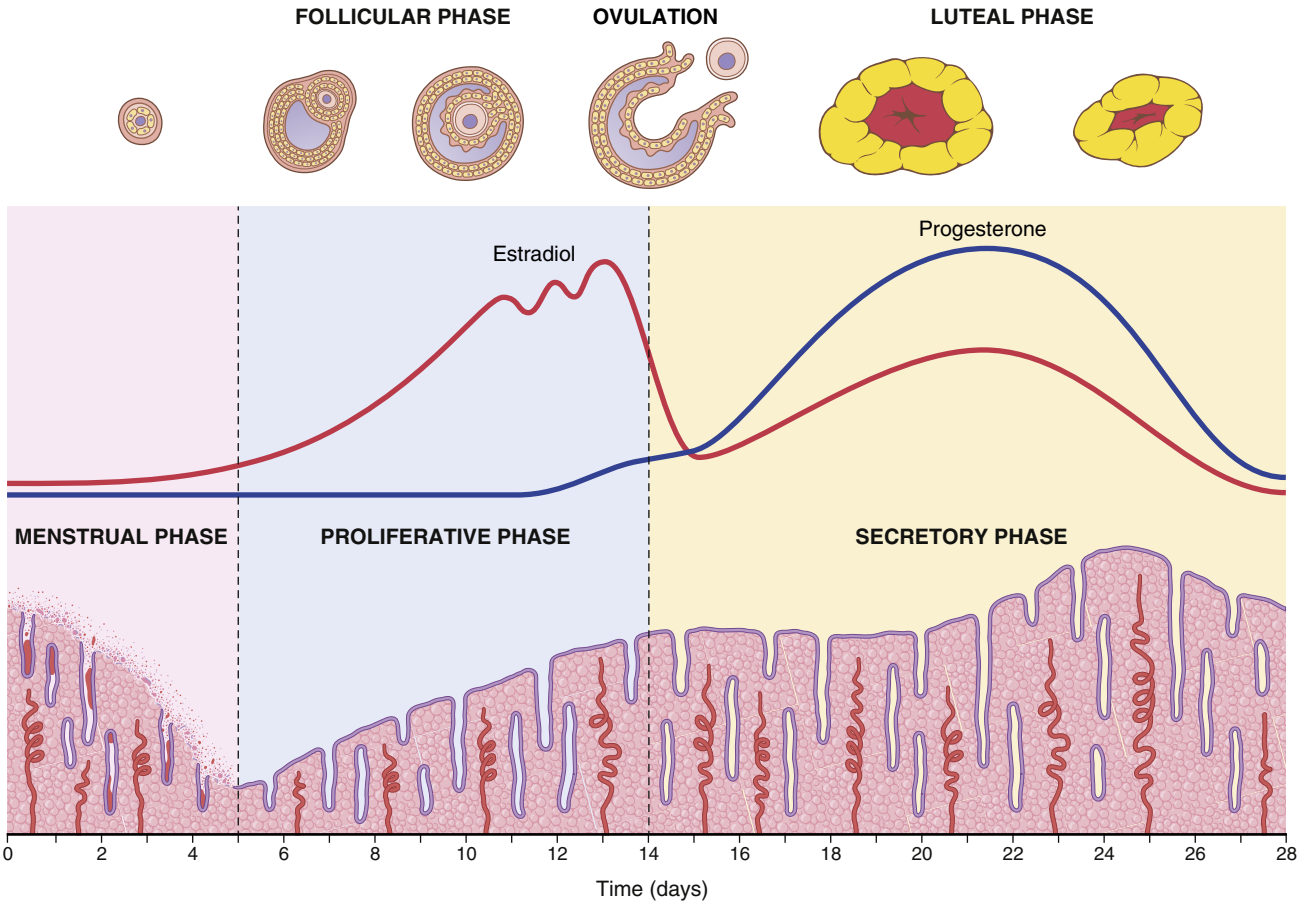

Figure 82-9. Phases of endometrial growth and menstruation during each monthly female sexual cycle.

Then, during the next week and a half, before ovulation occurs, the endometrium increases greatly in thickness, owing to increasing numbers of stromal cells and to progressive growth of the endometrial glands and new blood vessels into the endometrium. At the time of ovulation, the endometrium is 3 to 5 millimeters thick.

The endometrial glands, especially those of the cervical region, secrete thin, stringy mucus. The mucus strings actually align themselves along the length of the cervical canal, forming channels that help guide sperm in the proper direction from the vagina into the uterus.

Secretory Phase (Progestational Phase) of the Endometrial Cycle Occurs After Ovulation. During most of the latter half of the monthly cycle, after ovulation has occurred, progesterone and estrogen together are secreted in large quantities by the corpus luteum. The estrogens cause slight additional cellular proliferation in the endometrium during this phase of the cycle, whereas progesterone causes marked swelling and secretory development of the endometrium. The glands increase in tortuosity, and excess secretory substances accumulate in the glandular epithelial cells. In addition, the cytoplasm of the stromal cells increases, lipid and glycogen deposits increase greatly in the stromal cells, and the blood supply to the endometrium further increases in proportion to the developing secretory activity, with the blood vessels becoming highly tortuous. At the peak of the secretory phase, about 1 week after ovulation, the endometrium has a thickness of 5 to 6 millimeters.

The purpose of all these endometrial changes is to produce a highly secretory endometrium that contains large amounts of stored nutrients to provide appropriate conditions for implantation of a *fertilized* ovum during the latter half of the monthly cycle. From the time a fertilized ovum enters the uterine cavity from the fallopian tube (which occurs 3 to 4 days after ovulation) until the time the ovum implants (7 to 9 days after ovulation), the uterine secretions, called "uterine milk," provide nutrition for the early dividing ovum. Then, once the ovum implants in the endometrium, the trophoblastic cells on the surface of the implanting ovum (in the blastocyst stage) begin to digest the endometrium and absorb the endometrial stored substances, thus making great quantities of nutrients available to the early implanting embryo.

Menstruation. If the ovum is not fertilized, about 2 days before the end of the monthly cycle, the corpus luteum in the ovary involutes, and the ovarian hormones (estrogens and progesterone) decrease to low levels of secretion, as shown in **Figure 82-9**. Menstruation follows.

Menstruation is caused by the reduction of estrogens and progesterone, especially progesterone, at the end of the monthly ovarian cycle. The first effect is decreased stimulation of the endometrial cells by these two hormones, followed rapidly by involution of the endometrium to about 65% of its previous thickness. Then, during the 24 hours preceding the onset of menstruation, the tortuous blood vessels leading to the mucosal layers of the endometrium become vasospastic, presumably because of some effect of involution, such as release of a vasoconstrictor material—possibly one of the vasoconstrictor types of prostaglandins that are present in abundance at this time.

The vasospasm, the decrease in nutrients to the endometrium, and the loss of hormonal stimulation initiate necrosis in the endometrium, especially of the blood vessels. As a result, blood at first seeps into the vascular layer of the endometrium and the hemorrhagic areas grow rapidly over a period of 24 to 36 hours. Gradually, the necrotic outer layers of the endometrium separate from the uterus at the sites of the hemorrhages until, about 48 hours after the onset of menstruation, all the superficial layers of the endometrium have desquamated. The mass of desquamated tissue and blood in the uterine cavity, plus contractile effects of prostaglandins or other substances in the decaying desquamate, all acting together, initiate uterine contractions that expel the uterine contents.

During normal menstruation, approximately 40 milliliters of blood and an additional 35 milliliters of serous fluid are lost. The menstrual fluid is normally nonclotting because a *fibrinolysin* is released along with the necrotic endometrial material. If heavy bleeding occurs from the uterine surface, the quantity of fibrinolysin may be insufficient to prevent clotting, resulting in the passage of blood clots. Menstrual blood clots are not uncommon and usually occur during the first couple of days of menstruation, when bleeding is greatest; however, excessive bleeding and large clots during menstruation can be clinical evidence of uterine disease.

Within 4 to 7 days after menstruation starts, the loss of blood ceases because, by this time, the endometrium has become re-epithelialized.

Leukorrhea During Menstruation. During menstruation, large numbers of leukocytes are released, along with the necrotic material and blood. A substance liberated by the endometrial necrosis likely causes this outflow of leukocytes. As a result of the presence of these leukocytes and possibly other factors, the uterus is highly resistant to infection during menstruation, even though the endometrial surfaces are denuded. This resistance to infection is of extreme protective value.

REGULATION OF FEMALE MONTHLY RHYTHM—INTERPLAY BETWEEN OVARIAN AND HYPOTHALAMIC-PITUITARY HORMONES

Now that we have presented the major cyclical changes that occur during the monthly female sexual cycle, we can explain the basic rhythmic mechanism that causes the cyclical variations.

THE HYPOTHALAMUS SECRETES GNRH, WHICH STIMULATES THE ANTERIOR PITUITARY GLAND TO SECRETE LH AND FSH

As discussed in Chapter 75, secretion of most of the anterior pituitary hormones is controlled by "releasing hormones" formed in the hypothalamus and then transported to the anterior pituitary gland by way of the hypothalamic-hypophysial portal system. In the case of the gonadotropins, one releasing hormone, *GnRH,* is important. This hormone has been purified and has been found to be a decapeptide with the following formula:

Glu - His - Trp - Ser - Tyr - Gly - Leu - Arg - Pro - Gly - NH_2

Intermittent, Pulsatile Secretion of GnRH by the Hypothalamus Stimulates Pulsatile Release of LH From the Anterior Pituitary Gland. The hypothalamus does not secrete GnRH continuously but instead secretes it in pulses lasting 5 to 25 minutes that occur every 1 to 2 hours. The lower curve in **Figure 82-10** shows the electrical pulsatile signals in the hypothalamus that cause the hypothalamic pulsatile output of GnRH.

It is intriguing that when GnRH is infused continuously so that it is available all the time rather than in pulses, its ability to cause release of LH and FSH by the anterior pituitary gland is lost. Therefore, the pulsatile nature of GnRH release is essential to its function.

The pulsatile release of GnRH also causes intermittent output of LH secretion about every 90 minutes, which is shown by the upper curve in **Figure 82-10**.

Hypothalamic Centers for Release of Gonadotropin-Releasing Hormone. The neuronal activity that causes pulsatile release of GnRH in humans occurs primarily in the mediobasal hypothalamus, especially in the arcuate nuclei of this area. Neurons located in the preoptic area of the anterior hypothalamus also secrete GnRH in moderate amounts. Multiple neuronal centers in the higher brain's "limbic" system (the system for psychic control) transmit signals into the hypothalamus to modify the intensity of GnRH release and the frequency of the pulses, thus providing a partial explanation of why psychic factors often modify female sexual function.

NEGATIVE FEEDBACK EFFECTS OF ESTROGEN AND PROGESTERONE TO DECREASE LH AND FSH SECRETION

Estrogen in small amounts has a strong inhibitory effect on production of LH and FSH. Also, when progesterone is available, the inhibitory effect of estrogen is multiplied, even though progesterone by itself has little effect (**Figure 82-11**).

These feedback effects seem to operate mainly on the anterior pituitary gland directly, but they also operate to a lesser extent on the hypothalamus to decrease secretion of GnRH, especially by altering the frequency of the GnRH pulses.

Inhibin From the Corpus Luteum Inhibits FSH and LH Secretion. In addition to the feedback effects of estrogen and progesterone, other hormones are involved, especially *inhibin,* which is secreted along with the steroid sex hormones by the granulosa cells of the ovarian corpus luteum in the same way that Sertoli cells secrete inhibin in the male testes (see **Figure 82-11**). This hormone has the same effect in the female as in the male—it inhibits secretion of FSH and, to a lesser extent, LH by the anterior pituitary gland. Therefore, inhibin may be especially important in causing the decrease in secretion of FSH and LH at the end of the monthly female sexual cycle.

POSITIVE FEEDBACK EFFECT OF ESTROGEN BEFORE OVULATION—THE PREOVULATORY LUTEINIZING HORMONE SURGE

The anterior pituitary gland secretes greatly increased amounts of LH for 1 to 2 days beginning 24 to 48 hours

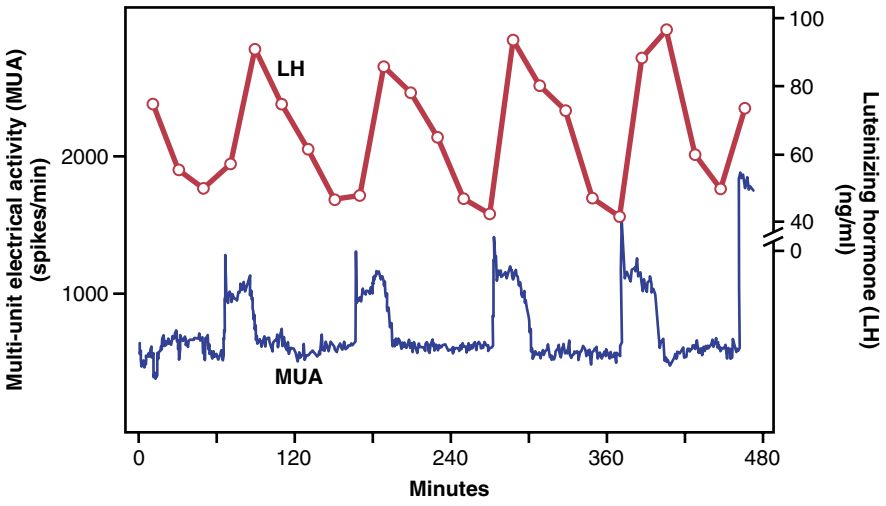

Figure 82-10. Shown is a pulsatile change in luteinizing hormone (LH) in the peripheral circulation of a pentobarbital-anesthetized ovariectomized rhesus monkey *(red line)* and a minute by minute recording of *multi-unit electrical activity* (MUA) in the mediobasal hypothalamus *(blue line). (Data from Wilson RC, Kesner JS, Kaufman JM, et al: Central electrophysiologic correlates of pulsatile luteinizing hormone secretion. Neuroendocrinology 39:256, 1984.)*

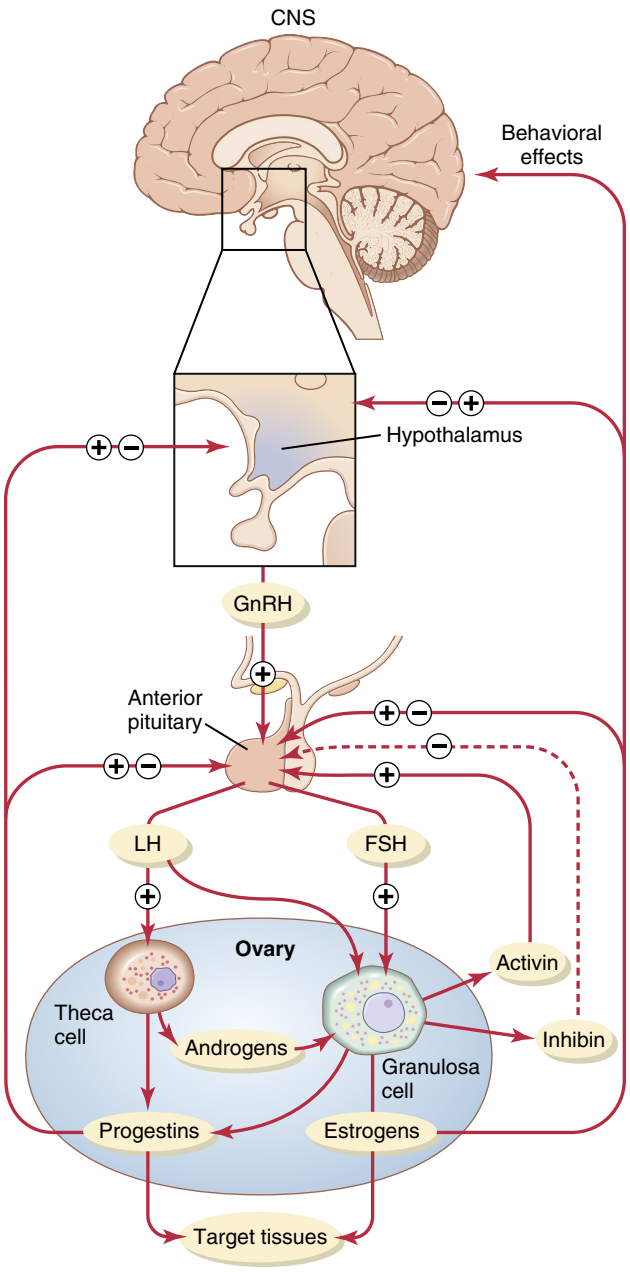

Figure 82-11. Feedback regulation of the hypothalamic-pituitary-ovarian axis in females. Stimulatory effects are shown by plus signs (+); negative feedback inhibitory effects are shown by minus signs (–). Estrogens and progestins exert negative and positive feedback effects on the anterior pituitary and hypothalamus, depending on the stage of the ovarian cycle. Inhibin has a negative feedback effect on the anterior pituitary, whereas activin has the opposite effect, stimulating follicle-stimulating hormone (FSH) secretion by the anterior pituitary. CNS, Central nervous system; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone.

before ovulation. This effect is demonstrated in **Figure 82-4**. The figure shows a much smaller preovulatory surge of FSH as well.

Experiments have shown that estrogen infusion into a female above a critical rate for 2 to 3 days during the latter part of the first half of the ovarian cycle will cause rapidly accelerating growth of the ovarian follicles, as well as rapidly accelerating secretion of ovarian estrogens. During this period, secretions of FSH and LH by the anterior pituitary gland are at first slightly suppressed. Secretion of LH then increases abruptly 6-fold to 8-fold, and secretion of FSH increases about 2-fold. The greatly increased LH secretion causes ovulation to occur.

The cause of this abrupt surge in LH secretion is not known. However, the following explanations are possible:

1. It has been suggested that at this point in the cycle, estrogen has a peculiar *positive feedback effect* of stimulating pituitary secretion of LH and, to a lesser extent, FSH (see **Figure 82-11**), which is in sharp contrast to the normal negative feedback effect of estrogen that occurs during the remainder of the female monthly cycle.
2. The granulosa cells of the follicles begin to secrete small but increasing quantities of progesterone a day or so before the preovulatory LH surge, and it has been suggested that this secretion might be the factor that stimulates the excess LH secretion.

Without this normal preovulatory surge of LH, ovulation will not occur.

FEEDBACK OSCILLATION OF THE HYPOTHALAMIC-PITUITARY-OVARIAN SYSTEM

Now that we have discussed the interrelations of the different components of the female hormonal system, we can explain the feedback oscillation that controls the rhythm of the female sexual cycle. It seems to operate in approximately the following sequence of three events.

1. *Postovulatory secretion of the ovarian hormones and depression of the pituitary gonadotropins.* Between ovulation and the beginning of menstruation, the corpus luteum secretes large quantities of progesterone and estrogen, as well as inhibin. All these hormones together have a combined negative feedback effect on the anterior pituitary gland and hypothalamus, causing suppression of FSH and LH secretion and decreasing them to their lowest levels about 3 to 4 days before the onset of menstruation. These effects are shown in **Figure 82-4.**
2. *Follicular growth phase.* Two to 3 days before menstruation, the corpus luteum has regressed to almost total involution and secretion of estrogen, progesterone, and inhibin from the corpus luteum decreases to a low ebb, which releases the hypothalamus and anterior pituitary from the negative feedback effect of these hormones. Therefore, a day or so later, at about the time that menstruation begins, pituitary secretion of FSH begins to increase again, as much as 2-fold; then, several days after menstruation begins, LH secretion increases slightly as well. These hormones initiate new ovarian follicle growth and a progressive increase in the secretion of estrogen, reaching a peak estrogen

secretion at about 12.5 to 13 days after the onset of the new female monthly sexual cycle. During the first 11 to 12 days of this follicle growth, the rates of pituitary secretion of the gonadotropins FSH and LH decrease slightly because of the negative feedback effect, mainly of estrogen, on the anterior pituitary gland. Then there is a sudden, marked increase in the secretion of LH and, to a lesser extent, FSH. This increased secretion is the preovulatory surge of LH and FSH, which is followed by ovulation.

3. *The preovulatory surge of LH and FSH causes ovulation.* About 11.5 to 12 days after the onset of the monthly cycle, the decline in FSH and LH secretion comes to an abrupt halt. The high level of estrogens at this time (or the beginning of progesterone secretion by the follicles) is believed to cause a positive feedback stimulatory effect on the anterior pituitary, as explained earlier, which leads to a large surge in the secretion of LH and, to a lesser extent, FSH. Whatever the cause of this preovulatory LH and FSH surge, the great excess of LH leads to both ovulation and subsequent development of and secretion by the corpus luteum. Thus, the hormonal system begins its new round of secretions until the next instance of ovulation.

Anovulatory Cycles—Sexual Cycles at Puberty

If the preovulatory surge of LH is not of sufficient magnitude, ovulation will not occur, and the cycle is said to be "anovulatory." The phases of the sexual cycle continue, but they are altered in the following ways:

1. Lack of ovulation causes failure of development of the corpus luteum, so there is almost no secretion of progesterone during the latter portion of the cycle.
2. The cycle is shortened by several days, but the rhythm continues.

Therefore, it is likely that progesterone is not required for maintenance of the cycle, although it can alter the cycle's rhythm.

The first few cycles after the onset of puberty are usually anovulatory, as are the cycles occurring several months to years before menopause, presumably because the LH surge is not potent enough at these times to cause ovulation.

PUBERTY AND MENARCHE

Puberty means the onset of adult sexual life, and *menarche* means the beginning of the cycle of menstruation. The period of puberty is caused by a gradual increase in gonadotropic hormone secretion by the pituitary, beginning in about the eighth year of life, as shown in **Figure 82-12**, and usually culminating in the onset of puberty and menstruation between ages 10 and 14 years in girls (average, 12 years).

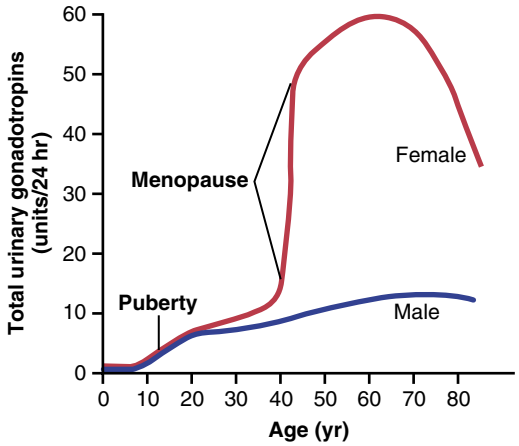

Figure 82-12. Total rates of secretion of gonadotropic hormones throughout the sexual lives of female and male human beings, showing an especially abrupt increase in gonadotropic hormones at menopause in the female.

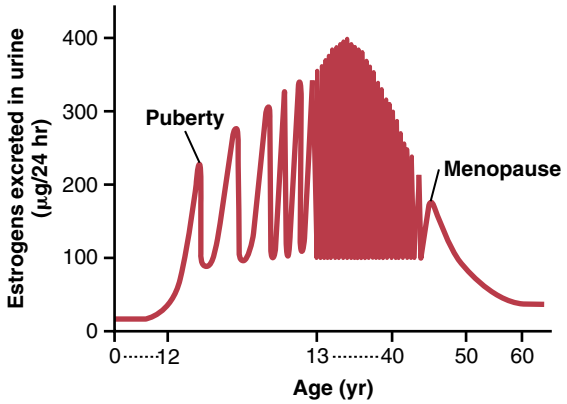

Figure 82-13. Estrogen secretion throughout the sexual life of the female human being.

In the female, as in the male, the infantile pituitary gland and ovaries are capable of full function if they are appropriately stimulated. However, as is also true in the male, and for reasons that are not understood, the hypothalamus does not secrete significant quantities of GnRH during childhood. Experiments have shown that the hypothalamus is capable of secreting this hormone, but the appropriate signal from some other area of the brain to cause secretion is lacking. Therefore, it is now believed that the onset of puberty is initiated by some maturation process that occurs elsewhere in the brain, perhaps somewhere in the limbic system.

Figure 82-13 shows (1) the increasing levels of estrogen secretion at puberty, (2) the cyclical variation during the monthly sexual cycle, (3) the further increase in estrogen secretion during the first few years of reproductive life, (4) the progressive decrease in estrogen secretion toward the end of reproductive life, and, finally, (5) almost no estrogen or progesterone secretion beyond menopause.

MENOPAUSE

At age 40 to 50 years, the sexual cycle usually becomes irregular, and ovulation often fails to occur. After a few

months to a few years, the cycle ceases altogether, as shown in **Figure 82-13**. The period during which the cycle ceases and the female sex hormones diminish to almost none is called *menopause.*

The cause of menopause is "burning out" of the ovaries. Throughout a woman's reproductive life, about 400 of the primordial follicles grow into mature follicles and ovulate, and hundreds of thousands of ova degenerate. At about age 45 years, only a few primordial follicles remain to be stimulated by FSH and LH and, as shown in **Figure 82-13**, the production of estrogens by the ovaries decreases as the number of primordial follicles approaches zero. When estrogen production falls below a critical value, the estrogens can no longer inhibit the production of FSH and LH. Instead, as shown in **Figure 82-12**, the gonadotropins FSH and LH (mainly FSH) are produced after menopause in large and continuous quantities, but as the remaining primordial follicles become atretic, production of estrogens by the ovaries falls virtually to zero.

At the time of menopause, a woman must readjust her life from one that has been physiologically stimulated by estrogen and progesterone production to one devoid of these hormones. The loss of estrogens often causes marked physiological changes in the function of the body, including (1) "hot flushes" characterized by extreme flushing of the skin, (2) psychic sensations of dyspnea, (3) irritability, (4) fatigue, (5) anxiety, and (6) decreased strength and calcification of bones throughout the body. These symptoms are of sufficient magnitude in about 15% of women to warrant treatment. Daily administration of estrogen in small quantities usually reverses the symptoms, and by gradually decreasing the dose, postmenopausal women may avoid severe symptoms.

Large clinical trials have provided evidence that administration of estrogen after menopause, although ameliorating many of the symptoms of menopause, may increase the risk for cardiovascular disease. As a result, hormone replacement therapy with estrogen is no longer routinely prescribed for postmenopausal women. Some studies, however, suggest that estrogen therapy may actually reduce the risk for cardiovascular disease if it is begun early in the postmenopausal years. Therefore, it is currently recommended that postmenopausal women who are considering hormone replacement therapy should discuss with their physicians whether the benefits outweigh the risks.

Abnormalities of Secretion by the Ovaries

Hypogonadism—Reduced Secretion by the Ovaries. Less than normal secretion by the ovaries can result from poorly formed ovaries, lack of ovaries, or genetically abnormal ovaries that secrete the wrong hormones because of missing enzymes in the secretory cells. When ovaries are absent from birth or when they become nonfunctional before puberty, *female eunuchism* occurs. In this condition the usual secondary sexual characteristics do not appear, and the sexual organs remain infantile. Especially characteristic of this condition is prolonged growth of the long bones because the epiphyses do not unite with the shafts as early as they do in a normal woman. Consequently, the female eunuch is essentially as tall as or perhaps even slightly taller than her male counterpart of similar genetic background.

When the ovaries of a fully developed woman are removed, the sexual organs regress to some extent so that the uterus becomes almost infantile in size, the vagina becomes smaller, and the vaginal epithelium becomes thin and easily damaged. The breasts atrophy and become pendulous, and the pubic hair becomes thinner. The same changes occur in women after menopause.

Irregularity of Menses, and Amenorrhea Caused by Hypogonadism. As pointed out in the preceding discussion of menopause, the quantity of estrogens produced by the ovaries must rise above a critical value to cause rhythmic sexual cycles. Consequently, in hypogonadism or when the gonads are secreting small quantities of estrogens as a result of other factors, such as *hypothyroidism,* the ovarian cycle often does not occur normally. Instead, several months may elapse between menstrual periods, or menstruation may cease altogether (amenorrhea). Prolonged ovarian cycles are frequently associated with failure of ovulation, presumably because of insufficient secretion of LH at the time of the preovulatory surge of LH, which is necessary for ovulation.

Hypersecretion by the Ovaries. Extreme hypersecretion of ovarian hormones by the ovaries is a rare clinical entity because excessive secretion of estrogens automatically decreases production of gonadotropins by the pituitary, which limits production of ovarian hormones. Consequently, hypersecretion of feminizing hormones is usually recognized clinically only when a feminizing tumor develops.

A rare *granulosa cell tumor* can develop in an ovary; development of this tumor occurs more often after menopause than before menopause. These tumors secrete large quantities of estrogens, which exert the usual estrogenic effects, including hypertrophy of the uterine endometrium and irregular bleeding from this endometrium. In fact, bleeding is often the first and only indication that such a tumor exists.

FEMALE SEXUAL ACT

Stimulation of the Female Sexual Act. As is true in the male sexual act, successful performance of the female sexual act depends on both psychic stimulation and local sexual stimulation.

Thinking sexual thoughts can lead to female sexual desire, and this aids greatly in the performance of the female sexual act. Such desire is based on psychological and physiological drive, although sexual desire does increase in proportion to the level of sex hormones secreted. Desire also changes during the monthly sexual cycle, reaching a peak near the time of ovulation, probably because of the high levels of estrogen secretion during the preovulatory period.

Local sexual stimulation in women occurs in more or less the same manner as in men because massage and other types of stimulation of the vulva, vagina, and other perineal regions can create sexual sensations. The glans of the *clitoris* is especially sensitive for initiating sexual sensations.

As in the male, the sexual sensory signals are transmitted to the sacral segments of the spinal cord through the pudendal nerve and sacral plexus. Once these signals have entered the spinal cord, they are transmitted to the cerebrum. Also, local reflexes integrated in the sacral and lumbar spinal cord are at least partly responsible for some of the reactions in the female sexual organs.

Female Erection and Lubrication. Located around the introitus and extending into the clitoris is erectile tissue almost identical to the erectile tissue of the penis. This erectile tissue, like that of the penis, is controlled by the parasympathetic nerves that pass through the nervi erigentes from the sacral plexus to the external genitalia. In the early phases of sexual stimulation, parasympathetic signals dilate the arteries of the erectile tissue, probably resulting from release of acetylcholine, nitric oxide, and vasoactive intestinal polypeptide at the nerve endings. This allows rapid accumulation of blood in the erectile tissue so that the introitus tightens around the penis, which aids the male in his attainment of sufficient sexual stimulation for ejaculation to occur.

Parasympathetic signals also pass to the bilateral Bartholin glands located beneath the labia minora and cause them to secrete mucus immediately inside the introitus. This mucus is responsible for much of the lubrication during sexual intercourse, although much lubrication is also provided by mucus secreted by the vaginal epithelium, and a small amount is provided from the male urethral glands. This lubrication is necessary during intercourse to establish a satisfactory massaging sensation rather than an irritative sensation, which may be provoked by a dry vagina. A massaging sensation constitutes the optimal stimulus for evoking the appropriate reflexes that culminate in both the male and female climaxes.

Female Orgasm. When local sexual stimulation reaches maximum intensity, and especially when the local sensations are supported by appropriate psychic conditioning signals from the cerebrum, reflexes are initiated that cause the female orgasm, also called the *female climax.* The female orgasm is analogous to emission and ejaculation in the male, and it may help promote fertilization of the ovum. Indeed, the human female is known to be somewhat more fertile when inseminated by normal sexual intercourse rather than by artificial methods, thus indicating an important function of the female orgasm. Possible reasons for this phenomenon are as follows.

First, during the orgasm, the perineal muscles of the female contract rhythmically, which results from spinal cord reflexes similar to those that cause ejaculation in the male. It is possible that these reflexes increase uterine and fallopian tube motility during the orgasm, thus helping to transport the sperm upward through the uterus toward the ovum; information on this subject is scanty, however. Also, the orgasm seems to cause dilation of the cervical canal for up to 30 minutes, thus allowing easy transport of the sperm.

Second, in many animals, copulation causes the posterior pituitary gland to secrete oxytocin; this effect is probably mediated through the brain amygdaloid nuclei and then through the hypothalamus to the pituitary. The oxytocin causes increased rhythmic contractions of the uterus, which may increase transport of the sperm. A few sperm have been shown to traverse the entire length of the fallopian tube in the cow in about 5 minutes, a rate at least 10 times as fast as that which the swimming motions of the sperm could possibly achieve. Whether this effect occurs in the human female is unknown.

In addition to possible effects of the orgasm on fertilization, the intense sexual sensations that develop during the orgasm also pass to the cerebrum and cause intense muscle tension throughout the body. After culmination of the sexual act, this tension gives way during the succeeding minutes to a sense of satisfaction characterized by relaxed peacefulness, an effect called *resolution.*

Female Fertility

Fertile Period of Each Sexual Cycle. The ovum remains viable and capable of being fertilized probably no longer than 24 hours after it is expelled from the ovary. Therefore, sperm must be available soon after ovulation if fertilization is to take place. A few sperm can remain fertile in the female reproductive tract for up to 5 days. Therefore, for fertilization to take place, intercourse must occur sometime between 4 and 5 days before ovulation up to a few hours after ovulation. Thus, the period of female fertility during each month is short, about 4 to 5 days.

Rhythm Method of Contraception. One commonly practiced method of contraception is to avoid intercourse near the time of ovulation. The difficulty with this method of contraception is predicting the exact time of ovulation. Yet, the interval from ovulation until the next succeeding onset of menstruation is almost always between 13 and 15 days. Therefore, if the menstrual cycle is regular, with an exact periodicity of 28 days, ovulation usually occurs within 1 day of the 14th day of the cycle. If, in contrast, the periodicity of the cycle is 40 days, ovulation usually occurs within 1 day of the 26th day of the cycle. Finally, if the periodicity of the cycle is 21 days, ovulation usually occurs within 1 day of the seventh day of the cycle. Therefore, it is usually stated that avoidance of intercourse for 4 days before the calculated day of ovulation and 3 days afterward prevents conception. However, such a method of contraception can be used only when the periodicity of the menstrual cycle is regular. The failure rate of this method of contraception, resulting in an unintentional pregnancy, may be as high as 20% to 25% per year.

Hormonal Suppression of Fertility—"The Pill"

Administration of either estrogen or progesterone, if given in appropriate quantities during the first half of the monthly cycle, can inhibit ovulation. The reason for this is that appropriate administration of either of these hormones can prevent the preovulatory surge of LH secretion by the pituitary gland, which is essential in causing ovulation.

It is not fully understood why administration of estrogen or progesterone prevents the preovulatory surge of LH

secretion. However, experimental work has suggested that immediately before the surge occurs, a sudden depression of estrogen secretion by the ovarian follicles probably occurs, which might be the necessary signal that causes the subsequent feedback effect on the anterior pituitary that leads to the LH surge. The administration of sex hormones (estrogens or progesterone) could prevent the initial ovarian hormonal depression that might be the initiating signal for ovulation.

The challenge in devising methods for the hormonal suppression of ovulation has been in developing appropriate combinations of estrogens and progestins that suppress ovulation but do not cause other, unwanted effects. For example, too much of either hormone can cause abnormal menstrual bleeding patterns. However, use of certain synthetic progestins in place of progesterone, especially the 19-norsteroids, along with small amounts of estrogens, usually prevents ovulation yet allows an almost normal pattern of menstruation. Therefore, almost all "pills" used for the control of fertility consist of some combination of synthetic estrogens and synthetic progestins. The main reason for using synthetic estrogens and progestins is that the *natural* hormones are almost entirely destroyed by the liver within a short time after they are absorbed from the gastrointestinal tract into the portal circulation. However, many of the *synthetic* hormones can resist this destructive propensity of the liver, thus allowing oral administration.

Two of the most commonly used synthetic estrogens are *ethinyl estradiol* and *mestranol.* Among the most commonly used progestins are *norethindrone, norethynodrel, ethynodiol,* and *norgestrel.* The drug is usually begun in the early stages of the monthly cycle and continued beyond the time that ovulation would normally occur. Then the drug is stopped, allowing menstruation to occur and a new cycle to begin.

The failure rate, resulting in an unintentional pregnancy, for hormonal suppression of fertility using various forms of the "pill" is about 8% to 9% per year.

Abnormal Conditions That Cause Female Sterility

About 5% to 10% of women are infertile. Occasionally, no abnormality can be discovered in the female genital organs, in which case the infertility is assumed to be due to either abnormal physiological function of the genital system or abnormal genetic development of the ova.

The most common cause of female sterility is failure to ovulate. This failure can result from hyposecretion of gonadotropic hormones, in which case the intensity of the hormonal stimuli is simply insufficient to cause ovulation, or it can result from abnormal ovaries that do not allow ovulation. For example, thick ovarian capsules occasionally exist on the outsides of the ovaries, making ovulation difficult.

Because of the high incidence of anovulation in sterile women, special methods are often used to determine whether ovulation occurs. These methods are based mainly on the effects of progesterone on the body because the normal increase in progesterone secretion usually does not occur during the latter half of anovulatory cycles. In the absence of progestational effects, the cycle can be assumed to be anovulatory.

One of these tests is simply to analyze the urine for a surge in pregnanediol, the end product of progesterone metabolism, during the latter half of the sexual cycle; the lack of this substance indicates failure of ovulation.

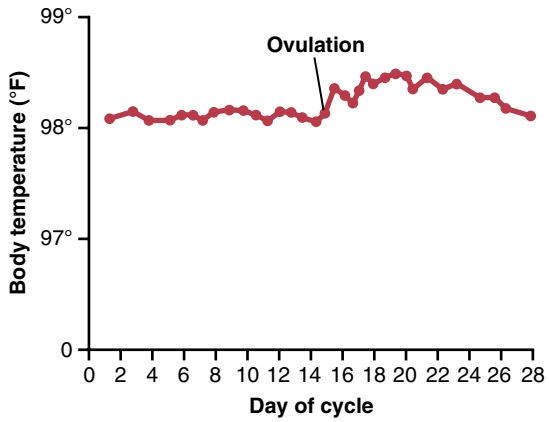

Figure 82-14. Elevation in body temperature shortly after ovulation.

Another common test is for the woman to chart her body temperature throughout the cycle. Secretion of progesterone during the latter half of the cycle raises the body temperature about 0.5°F, with the temperature rise coming abruptly at the time of ovulation. Such a temperature chart, showing the point of ovulation, is illustrated in **Figure 82-14**.

Lack of ovulation caused by hyposecretion of the pituitary gonadotropic hormones can sometimes be treated by appropriately timed administration of *human chorionic gonadotropin,* a hormone (discussed in Chapter 83) that is extracted from the human placenta. This hormone, although secreted by the placenta, has almost the same effects as LH and is therefore a powerful stimulator of ovulation. However, excess use of this hormone can cause ovulation from many follicles simultaneously, which results in multiple births, an effect that has caused as many as eight babies (stillborn in many cases) to be born to mothers treated for infertility with this hormone.

One of the most common causes of female sterility is *endometriosis,* a common condition in which endometrial tissue almost identical to that of the normal uterine endometrium grows and even menstruates in the pelvic cavity surrounding the uterus, fallopian tubes, and ovaries. Endometriosis causes fibrosis throughout the pelvis, and this fibrosis sometimes so enshrouds the ovaries that an ovum cannot be released into the abdominal cavity. Often, endometriosis occludes the fallopian tubes, either at the fimbriated ends or elsewhere along their extent.

Another common cause of female infertility is *salpingitis,* that is, *inflammation of the fallopian tubes;* this inflammation causes fibrosis in the tubes, thereby occluding them. In the past, such inflammation occurred mainly as a result of gonococcal infection. However, with modern therapy, salpingitis is becoming a less prevalent cause of female infertility.

Still another cause of infertility is secretion of abnormal mucus by the uterine cervix. Ordinarily, at the time of ovulation, the hormonal environment of estrogen causes secretion of mucus with special characteristics that allow rapid mobility of sperm into the uterus and actually guide the sperm up along mucous "threads." Abnormalities of the cervix, such as low-grade infection or inflammation, or abnormal hormonal stimulation of the cervix, can lead to a viscous mucous plug that prevents fertilization.

CHAPTER 83

UNIT XIV

Pregnancy and Lactation

In Chapters 81 and 82, the sexual functions of the male and female are described to the point of fertilization of the ovum. If the ovum becomes fertilized, a new sequence of events called *gestation* or *pregnancy* takes place, and the fertilized ovum eventually develops into a full-term fetus. The purpose of this chapter is to discuss the early stages of ovum development after fertilization and then to discuss the physiology of pregnancy. In Chapter 84, some special aspects of fetal and early childhood physiology are discussed.

MATURATION AND FERTILIZATION OF THE OVUM

While still in the ovary, the ovum is in the *primary oocyte* stage. Shortly before it is released from the ovarian follicle, its nucleus divides by meiosis and a *first polar body* is expelled from the nucleus of the oocyte (see **Figure 82-3**). The primary oocyte then becomes the *secondary oocyte.* In this process, each of the 23 pairs of chromosomes loses one of its partners, which becomes incorporated in a *polar body* that is expelled. This leaves 23 *unpaired* chromosomes in the secondary oocyte. It is at this time that the ovum, which is still in the secondary oocyte stage, is ovulated into the abdominal cavity. Then, almost immediately, it enters the fimbriated end of one of the fallopian tubes.

Entry of the Ovum Into the Fallopian Tube (Uterine Tube). When ovulation occurs, the ovum, along with a hundred or more attached granulosa cells that constitute the *corona radiata,* is expelled directly into the peritoneal cavity and must then enter one of the fallopian tubes (also called *uterine tubes*) to reach the cavity of the uterus. The fimbriated ends of each fallopian tube fall naturally around the ovaries. The inner surfaces of the fimbriated tentacles are lined with ciliated epithelium, and the *cilia* are activated by estrogen from the ovaries, which causes the cilia to beat toward the opening, or *ostium,* of the involved fallopian tube. One can actually see a slow fluid current flowing toward the ostium. By this means, the ovum enters one of the fallopian tubes.

Although one might suspect that many ova fail to enter the fallopian tubes, conception studies suggest that up to 98% of ova succeed in this task. Indeed, in some recorded cases, women with one ovary removed and the opposite fallopian tube removed have had several children with relative ease of conception, thus demonstrating that ova can even enter the opposite fallopian tube.

Fertilization of the Ovum. After the male ejaculates semen into the vagina during intercourse, a few sperm are transported within 5 to 10 minutes upward from the vagina and through the uterus and fallopian tubes to the *ampullae* of the fallopian tubes near the ovarian ends of the tubes. This transport of the sperm is aided by contractions of the uterus and fallopian tubes stimulated by prostaglandins in the male seminal fluid and also by oxytocin released from the posterior pituitary gland of the female during her orgasm. Of the almost half a billion sperm deposited in the vagina, a few thousand succeed in reaching each ampulla.

Fertilization of the ovum **(Figure 83-1)** normally takes place in the ampulla of one of the fallopian tubes soon after both the sperm and the ovum enter the ampulla. Before a sperm can enter the ovum, however, it must first penetrate the multiple layers of granulosa cells attached to the outside of the ovum (the *corona radiata*) and then bind to and penetrate the *zona pellucida* surrounding the ovum. The mechanisms used by the sperm for these purposes are presented in Chapter 81.

Once a sperm has entered the ovum (which is still in the secondary oocyte stage of development), the oocyte divides again to form the *mature ovum* plus a *second polar body* that is expelled (see **Figure 82-3**). The mature ovum still carries in its nucleus (now called the *female pronucleus*) 23 chromosomes. One of these chromosomes is the female chromosome, known as the *X chromosome.*

In the meantime, the fertilizing sperm has also changed. On entering the ovum, its head swells to form a *male pronucleus,* shown in **Figure 83-1*D***. Later, the 23 unpaired chromosomes of the male pronucleus and the 23 unpaired chromosomes of the female pronucleus align themselves to re-form a complete complement of 46 chromosomes (23 pairs) in the *fertilized ovum* or *zygote* (see **Figure 83-1*E***).

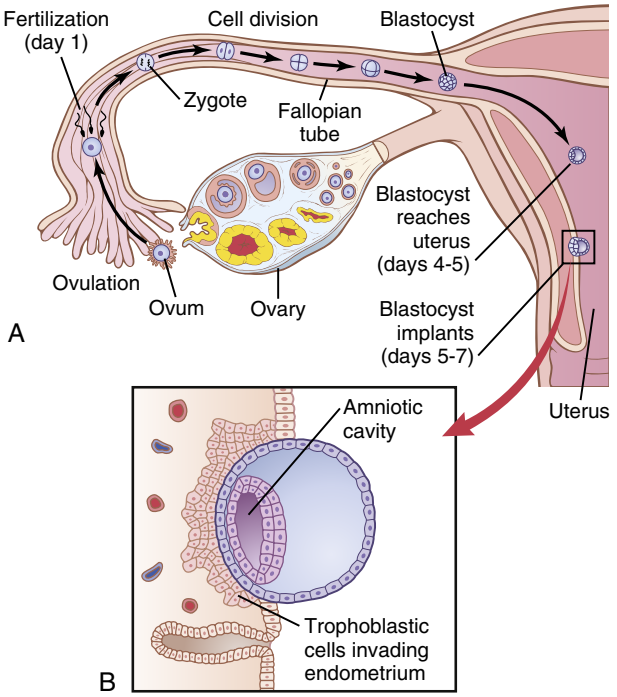

Figure 83-2. A, Ovulation, fertilization of the ovum in the fallopian tube, and implantation of the blastocyst in the uterus. **B,** The action of trophoblast cells in implantation of the blastocyst in the uterine endometrium.

WHAT DETERMINES THE SEX OF THE FETUS THAT IS CREATED?

Half of the mature sperm carry in their genome an X chromosome (the female chromosome) and half carry a Y chromosome (the male chromosome). Therefore, if an X chromosome from a sperm combines with an X chromosome from an ovum, giving an XX combination, a female child will be born, as explained in Chapter 81. If a Y chromosome from a sperm is paired with an X chromosome from an ovum, giving an XY combination, a male child will be born.

TRANSPORT OF THE FERTILIZED OVUM IN THE FALLOPIAN TUBE

After fertilization has occurred, an additional 3 to 5 days is normally required for transport of the fertilized ovum through the remainder of the fallopian tube into the cavity of the uterus (**Figure 83-2**). This transport is effected mainly by a feeble fluid current in the tube resulting from epithelial secretion plus action of the ciliated epithelium that lines the tube; the cilia always beat toward the uterus. Weak contractions of the fallopian tube may also aid passage of the ovum.

The fallopian tubes are lined with a rugged cryptoid surface that impedes passage of the ovum despite the fluid current. Also, the *isthmus* of the fallopian tube (the last 2 centimeters before the tube enters the uterus) remains spastically contracted for about the first 3 days after ovulation. After this time, the rapidly increasing progesterone secreted by the ovarian corpus luteum first promotes increasing progesterone receptors on the fallopian tube smooth muscle cells; then the progesterone activates the receptors, relaxing the tubules and allowing entry of the ovum into the uterus.

This delayed transport of the fertilized ovum through the fallopian tube allows several stages of cell division to occur before the dividing ovum—now called a *blastocyst,* with about 100 cells—enters the uterus. During this time, the fallopian tube secretory cells produce large quantities of secretions used for nutrition of the developing blastocyst.

IMPLANTATION OF THE BLASTOCYST IN THE UTERUS

After reaching the uterus, the developing blastocyst usually remains in the uterine cavity an additional 1 to 3 days before it implants in the endometrium; thus, implantation ordinarily occurs on about the fifth to seventh day after ovulation. Before implantation, the blastocyst obtains its nutrition from the uterine endometrial secretions, called "uterine milk."

Implantation results from the action of *trophoblast cells* that develop over the surface of the blastocyst. These cells secrete proteolytic enzymes that digest and liquefy the adjacent cells of the uterine endometrium. Some of the fluid and nutrients released are actively transported by the same trophoblast cells into the blastocyst, adding more sustenance for growth. **Figure 83-3** shows an early implanted human blastocyst with a small embryo. Once implantation has taken place, the trophoblast cells and other adjacent cells (from the blastocyst and the uterine

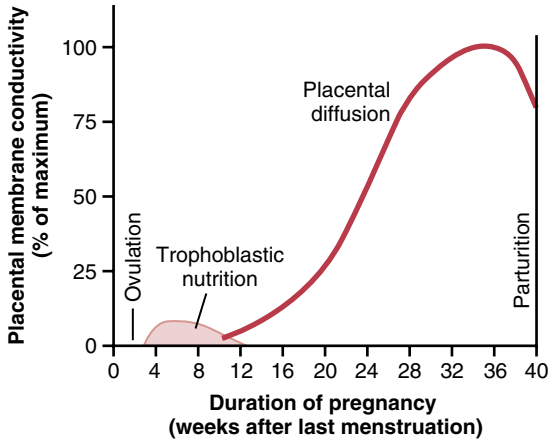

Figure 83-4. Nutrition of the fetus. Most of the early nutrition is due to trophoblastic digestion and absorption of nutrients from the endometrial decidua, and essentially all the later nutrition results from diffusion through the placental membrane.

endometrium) proliferate rapidly, forming the placenta and the various membranes of pregnancy.

EARLY NUTRITION OF THE EMBRYO

In Chapter 82, we pointed out that the progesterone secreted by the ovarian corpus luteum during the latter half of each monthly sexual cycle has an effect on the uterine endometrium, converting the endometrial stromal cells into large swollen cells containing extra quantities of glycogen, proteins, lipids, and even some minerals necessary for development of the *conceptus* (the embryo and its adjacent parts or associated membranes). Then, when the conceptus implants in the endometrium, continued secretion of progesterone causes the endometrial cells to swell further and to store even more nutrients. These cells are now called *decidual cells,* and the total mass of cells is called the *decidua.*

As the trophoblast cells invade the decidua, digesting and imbibing it, the stored nutrients in the decidua are used by the embryo for growth and development. During the first week after implantation, this is the only means by which the embryo can obtain nutrients; the embryo continues to obtain at least some of its nutrition in this way for up to 8 weeks, although the placenta also begins to provide nutrition after about the 16th day beyond fertilization (a little more than 1 week after implantation). **Figure 83-4** shows this trophoblastic period of nutrition, which gradually gives way to placental nutrition.

ANATOMY AND FUNCTION OF THE PLACENTA

While the trophoblastic cords from the blastocyst are attaching to the uterus, blood capillaries grow into the cords from the vascular system of the newly forming embryo. About 21 days after fertilization, blood also begins to be pumped by the heart of the human embryo. Simultaneously, *blood sinuses* supplied with blood from the mother develop around the outsides of the trophoblastic cords. The trophoblast cells send out more and more projections, which become *placental villi* into which fetal capillaries grow. Thus, the villi, carrying fetal blood, are surrounded by sinuses that contain maternal blood.

The final structure of the placenta is shown in **Figure 83-5**. Note that the blood of the fetus flows through two *umbilical arteries,* then into the capillaries of the villi, and finally back through a single *umbilical vein* into the fetus. At the same time, the mother's blood flows from her *uterine arteries* into large *maternal sinuses* that surround the villi and then back into the *uterine veins* of the mother. The lower part of **Figure 83-5** shows the relationship between the fetal blood of each fetal placental villus and the blood of the mother surrounding the outsides of the villus in the fully developed placenta.

The total surface area of all the villi of the mature placenta is only a few square meters—many times less than the area of the pulmonary membrane in the lungs. Nevertheless, nutrients and other substances pass through this placental membrane mainly by diffusion in much the same manner that diffusion occurs through the alveolar membranes of the lungs and the capillary membranes elsewhere in the body.

PLACENTAL PERMEABILITY AND MEMBRANE DIFFUSION CONDUCTANCE

The major function of the placenta is to provide for diffusion of foodstuffs and oxygen from the mother's blood into the fetus's blood and diffusion of excretory products from the fetus back into the mother.

In the early months of pregnancy, the placental membrane is still thick because it is not fully developed. Therefore, its permeability is low. Further, the surface area is small because the placenta has not grown significantly.

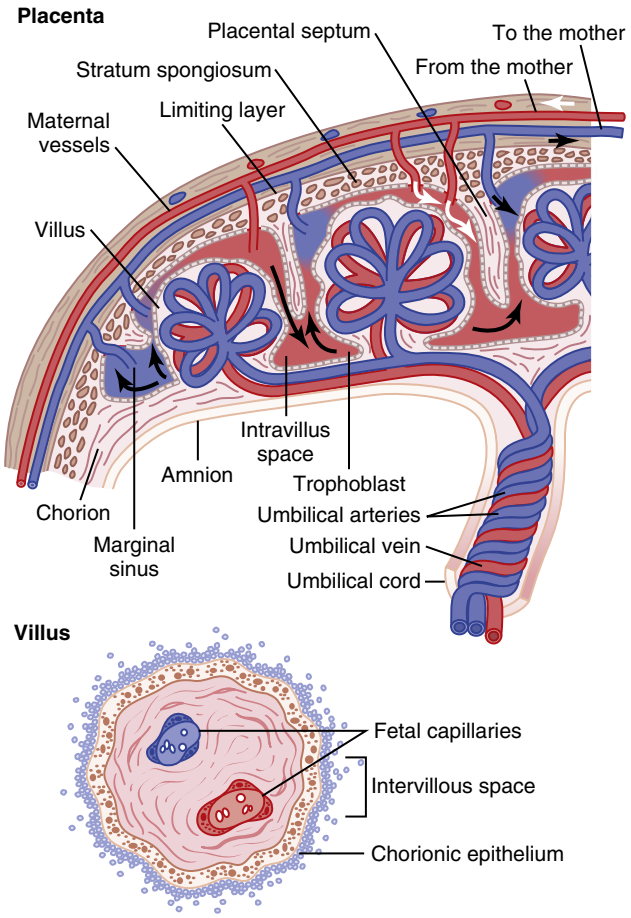

Figure 83-5. *Top,* Organization of the mature placenta. *Bottom,* Relationship of the fetal blood in the villus capillaries to the mother's blood in the intervillous spaces.

Therefore, the total diffusion conductance is minuscule at first. In later pregnancy, the permeability increases because of thinning of the membrane diffusion layers and because the surface area expands many times over, thus giving the tremendous increase in placental diffusion shown in **Figure 83-4**.

Rarely, "breaks" occur in the placental membrane, which allows fetal blood cells to pass into the mother or, even less commonly, the mother's cells to pass into the fetus. Fortunately, it is rare for the fetus to bleed severely into the mother's circulation because of a ruptured placental membrane.

Diffusion of Oxygen Through the Placental Membrane. Almost the same principles for diffusion of oxygen through the pulmonary membrane (discussed in detail in Chapter 40) are applicable for diffusion of oxygen through the placental membrane. The dissolved oxygen in the blood of the large maternal sinuses passes into the fetal blood by *simple diffusion,* driven by an oxygen pressure gradient from the mother's blood to the fetus's blood. Near the end of pregnancy, the mean partial pressure of oxygen (P_{O_2}) of the mother's blood in the placental sinuses is about 50 mm Hg, and the mean P_{O_2} in the fetal blood

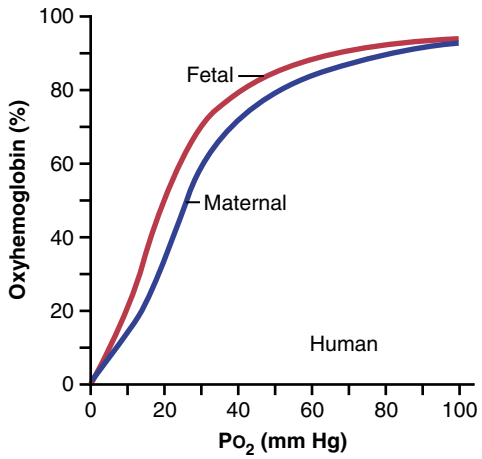

Figure 83-6. Oxyhemoglobin dissociation curves for maternal *(blue curve)* and fetal *(red curve)* blood, showing that fetal blood can carry a greater quantity of oxygen than can maternal blood for a given blood P_{O_2}. *(Data from Metcalfe J, Moll W, Bartels H: Gas exchange across the placenta. Fed Proc 23:775, 1964.)*

after it becomes oxygenated in the placenta is about 30 mm Hg. Therefore, the mean pressure gradient for diffusion of oxygen through the placental membrane is about 20 mm Hg.

One might wonder how it is possible for a fetus to obtain sufficient oxygen when the fetal blood leaving the placenta has a P_{O_2} of only 30 mm Hg. There are three reasons why even this low P_{O_2} is capable of allowing the fetal blood to transport almost as much oxygen to the fetal tissues as is transported by the mother's blood to her tissues.

First, the hemoglobin of the fetus is mainly *fetal hemoglobin,* which is a type of hemoglobin synthesized in the fetus before birth. **Figure 83-6** shows the comparative oxygen dissociation curves for maternal hemoglobin and fetal hemoglobin, demonstrating that the curve for fetal hemoglobin is shifted to the left of that for maternal hemoglobin. This means that at the low P_{O_2} levels in fetal blood, the fetal hemoglobin can carry 20% to 50% more oxygen than can maternal hemoglobin.

Second, the *hemoglobin concentration of fetal blood is about 50% greater than that of the mother,* which is an even more important factor in enhancing the amount of oxygen transported to the fetal tissues.

Third, the *Bohr effect,* which is explained in relation to the exchange of carbon dioxide and oxygen in the lung in Chapter 41, provides another mechanism to enhance the transport of oxygen by fetal blood. That is, hemoglobin can carry more oxygen at a low P_{CO_2} than it can at a high P_{CO_2}. The fetal blood entering the placenta carries large amounts of carbon dioxide, but much of this carbon dioxide diffuses from the fetal blood into the maternal blood. Loss of the carbon dioxide makes the fetal blood more alkaline, whereas the increased carbon dioxide in the maternal blood makes it more acidic.

These changes increase the capacity of fetal blood to combine with oxygen and decrease oxygen binding of maternal blood, which forces still more oxygen from the

maternal blood while enhancing oxygen uptake by the fetal blood. Thus, the Bohr shift operates in one direction in the maternal blood and in the other direction in the fetal blood. These two effects make the Bohr shift twice as important here as it is for oxygen exchange in the lungs; therefore, it is called the *double Bohr effect.*

By these three means, the fetus is capable of receiving more than adequate oxygen through the placental membrane, despite the fact that the fetal blood leaving the placenta has a P_{O_2} of only 30 mm Hg.

The total *diffusing capacity* of the entire placenta for oxygen at term is about 1.2 ml of oxygen per minute per mm Hg oxygen pressure difference across the membrane, which compares favorably with that of the lungs of the newborn baby.

Diffusion of Carbon Dioxide Through the Placental Membrane. Carbon dioxide is continually formed in the fetal tissues in the same way that it is formed in maternal tissues, and the only means for excreting the carbon dioxide from the fetus is through the placenta into the mother's blood. The partial pressure of carbon dioxide (P_{CO_2}) of the fetal blood is 2 to 3 mm Hg higher than that of the maternal blood. This small pressure gradient for carbon dioxide across the membrane is more than sufficient to allow adequate diffusion of carbon dioxide because the extreme solubility of carbon dioxide in the placental membrane allows carbon dioxide to diffuse about 20 times as rapidly as oxygen.

Diffusion of Foodstuffs Through the Placental Membrane. Other metabolic substrates needed by the fetus diffuse into the fetal blood in the same manner **as** oxygen. For example, in the late stages of pregnancy, the fetus often uses as much glucose as is used by the entire body of the mother. To provide this much glucose, the trophoblast cells lining the placental villi provide for *facilitated diffusion* of glucose through the placental membrane—that is, the glucose is transported by carrier molecules in the trophoblast cells of the membrane. Even so, the glucose level in fetal blood is 20% to 30% lower than that in maternal blood.

Because of the high solubility of fatty acids in cell membranes, these fatty acids also diffuse from the maternal blood into the fetal blood, but more slowly than glucose, so glucose is used more easily by the fetus for nutrition. Also, such substances as ketone bodies and potassium, sodium, and chloride ions diffuse with relative ease from the maternal blood into the fetal blood.

Excretion of Waste Products Through the Placental Membrane. In the same manner that carbon dioxide diffuses from the fetal blood into the maternal blood, other excretory products formed in the fetus also diffuse through the placental membrane into the maternal blood and are then excreted along with the excretory products of the mother. These products include especially the *nonprotein nitrogens* such as *urea, uric acid,* and *creatinine.* The level of urea in fetal blood is only slightly greater than that in maternal blood because urea diffuses through the placental membrane with great ease. However, creatinine, which does not diffuse as easily, has a fetal blood concentration considerably higher than that in the mother's blood. Therefore, excretion from the fetus depends mainly, if not entirely, on the diffusion gradients across the placental membrane and its permeability and surface area. Because there are higher concentrations of the excretory products in the fetal blood than in the maternal blood, there is continual diffusion of these substances from the fetal blood to the maternal blood.

HORMONAL FACTORS IN PREGNANCY

In pregnancy, the placenta forms especially large quantities of *human chorionic gonadotropin, estrogens, progesterone,* and *human chorionic somatomammotropin,* the first three of which, and probably the fourth as well, are all essential to a normal pregnancy.

HUMAN CHORIONIC GONADOTROPIN CAUSES PERSISTENCE OF THE CORPUS LUTEUM AND PREVENTS MENSTRUATION

Menstruation normally occurs in a nonpregnant woman about 14 days after ovulation, at which time most of the endometrium of the uterus sloughs away from the uterine wall and is expelled to the exterior. If this happens after an ovum has implanted, the pregnancy will terminate. However, this sloughing is prevented by secretion of *human chorionic gonadotropin* by the newly developing embryonic tissues.

Coincidental with the development of the trophoblast cells from the early fertilized ovum, human chorionic gonadotropin is secreted by the syncytial trophoblast cells into the fluids of the mother, as shown in **Figure 83-7**. Secretion of this hormone can first be measured in the blood 8 to 9 days after ovulation, shortly after the blastocyst implants in the endometrium. Then, the secretion rate rises rapidly to reach a maximum at about 10 to 12 weeks of pregnancy and decreases back to a lower value by 16 to 20 weeks. It continues at this level for the remainder of the pregnancy.

Function of Human Chorionic Gonadotropin. Human chorionic gonadotropin is a glycoprotein having a molecular weight of about 39,000 and much the same molecular structure and function as luteinizing hormone secreted by the pituitary gland. The most important function of human chorionic gonadotropin is to prevent involution of the corpus luteum at the end of the monthly female sexual cycle. Instead, it causes the corpus luteum to secrete even larger quantities of its sex hormones—progesterone and estrogens—for the next few months. These sex hormones prevent menstruation and cause the endometrium

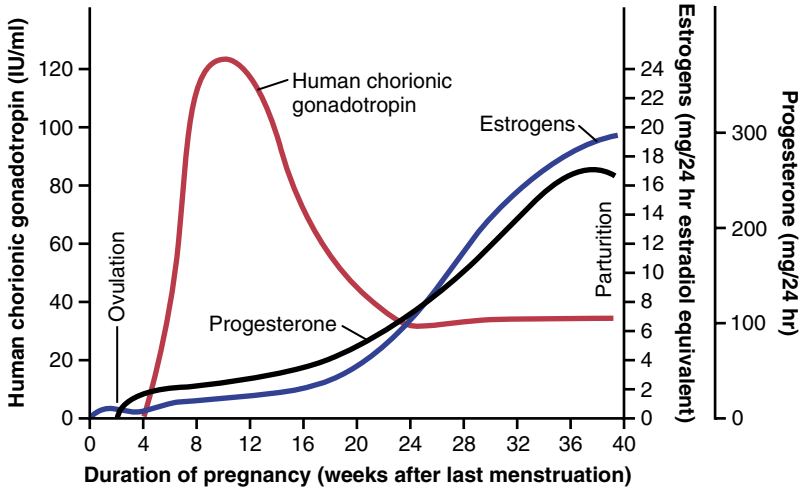

Figure 83-7. Rates of secretion of estrogens *(blue curve)* and progesterone *(black curve)* and concentration of human chorionic gonadotropin *(red curve)* at different stages of pregnancy.

to continue to grow and store large amounts of nutrients rather than being shed in the menstruum. As a result, the *decidua-like cells* that develop in the endometrium during the normal female sexual cycle become actual *decidual cells*—greatly swollen and nutritious—at about the time that the blastocyst implants.

Under the influence of human chorionic gonadotropin, the corpus luteum in the mother's ovary grows to about twice its initial size by a month or so after pregnancy begins. Its continued secretion of estrogens and progesterone maintains the decidual nature of the uterine endometrium, which is necessary for early development of the fetus.

If the corpus luteum is removed before approximately the seventh week of pregnancy, spontaneous abortion almost always occurs, sometimes even up to the 12th week. After that time, the placenta secretes sufficient quantities of progesterone and estrogens to maintain pregnancy for the remainder of the gestation period. The corpus luteum involutes slowly after the 13th to 17th week of gestation.

Human Chorionic Gonadotropin Stimulates the Male Fetal Testes to Produce Testosterone. Human chorionic gonadotropin also exerts an *interstitial cell*–stimulating effect on the testes of the male fetus, resulting in production of testosterone in male fetuses until the time of birth. This small secretion of testosterone during gestation is what causes the fetus to grow male sex organs instead of female organs. Near the end of pregnancy, testosterone secreted by the fetal testes also causes the testes to descend into the scrotum.

SECRETION OF ESTROGENS BY THE PLACENTA

The placenta, like the corpus luteum, secretes estrogens and progesterone. Histochemical and physiological studies show that these two hormones, like most other placental hormones, are secreted by the *syncytial trophoblast* cells of the placenta.

Figure 83-7 shows that toward the end of pregnancy, the daily production of placental estrogens increases to about 30 times the mother's normal level of production. However, secretion of estrogens by the placenta is quite different from secretion by the ovaries. Most important, the estrogens secreted by the placenta are not synthesized de novo from basic substrates in the placenta. Instead, they are formed almost entirely from androgenic steroid compounds, *dehydroepiandrosterone* and *16-hydroxydehydroepiandrosterone,* which are formed in the mother's adrenal glands and in the fetus's adrenal glands. These weak androgens are transported by the blood to the placenta and converted by the trophoblast cells into estradiol, estrone, and estriol. The cortices of the fetal adrenal glands are extremely large, and about 80% consists of a so-called *fetal zone,* the primary function of which seems to be to secrete dehydroepiandrosterone during pregnancy.

Function of Estrogen in Pregnancy. In Chapter 82, we pointed out that estrogens exert mainly a proliferative function on most reproductive and associated organs of the mother. During pregnancy, the extreme quantities of estrogens cause (1) enlargement of the mother's uterus, (2) enlargement of the mother's breasts and growth of the breast ductal structure, and (3) enlargement of the mother's female external genitalia.

The estrogens also relax the pelvic ligaments of the mother, so the sacroiliac joints become relatively limber, and the symphysis pubis becomes elastic. These changes allow easier passage of the fetus through the birth canal. There is reason to believe that estrogens also affect many general aspects of fetal development during pregnancy—for example, by affecting the rate of cell reproduction in the early embryo.

SECRETION OF PROGESTERONE BY THE PLACENTA

Progesterone is just as essential as estrogen for a successful pregnancy. In addition to being secreted in moderate

quantities by the corpus luteum at the beginning of pregnancy, progesterone is secreted later in tremendous quantities by the placenta, as shown in **Figure 83-7**.

The following special effects of progesterone are essential for the normal progression of pregnancy:

1. Progesterone causes decidual cells to develop in the uterine endometrium. These cells play an important role in nutrition of the early embryo.
2. Progesterone decreases contractility of the pregnant uterus, thus preventing uterine contractions from causing spontaneous abortion.
3. Progesterone contributes to development of the conceptus even before implantation because it specifically increases secretions of the mother's fallopian tubes and uterus to provide appropriate nutrition for the developing *morula* (the spherical mass of 16 to 32 blastomeres formed before the blastula) and *blastocyst.* Progesterone may also affect cell cleavage in the early developing embryo.
4. The progesterone secreted during pregnancy helps estrogen prepare the mother's breasts for lactation, which is discussed later in this chapter.

HUMAN CHORIONIC SOMATOMAMMOTROPIN

Human chorionic somatomammotropin, a protein hormone with a molecular weight of about 22,000, begins to be secreted by the placenta at about the fifth week of pregnancy. Secretion of this hormone increases progressively throughout the remainder of pregnancy in direct proportion to the weight of the placenta. Although the functions of chorionic somatomammotropin are uncertain, it is secreted in quantities several times greater than that of all the other pregnancy hormones combined. It has several possible important effects.

First, when administered to several types of animals, human chorionic somatomammotropin causes at least partial development of the animal's breasts and in some cases causes lactation. Because this was the first function of the hormone that was discovered, it was first named *human placental lactogen* and was believed to have functions similar to those of prolactin. However, attempts to use it to promote lactation in humans have not been successful.

Second, this hormone has weak actions similar to those of growth hormone, causing formation of tissue proteins in the same way that growth hormone does. It also has a chemical structure similar to that of growth hormone, but 100 times as much human chorionic somatomammotropin as growth hormone is required to promote growth.

Third, human chorionic somatomammotropin causes decreased insulin sensitivity and decreased utilization of glucose in the mother, thereby making larger quantities of glucose available to the fetus. Because glucose is the major substrate used by the fetus to energize its growth, the possible importance of such a hormonal effect is obvious. Further, the hormone promotes the release of free fatty acids from fat stores of the mother, thus providing this alternative source of energy for the mother's metabolism during pregnancy. Therefore, it appears that human chorionic somatomammotropin is a general metabolic hormone that has specific nutritional implications for the mother and the fetus.

Other Hormonal Factors in Pregnancy

Almost all the nonsexual endocrine glands of the mother also react markedly to pregnancy. This reaction results mainly from the increased metabolic load on the mother but also, to some extent, from the effects of placental hormones on the pituitary and other glands. The following effects are some of the most notable.

Pituitary Secretion. The anterior pituitary gland of the mother enlarges at least 50% during pregnancy and increases its production of *adrenocorticotropic hormone* (ACTH), *thyrotropin,* and *prolactin.* Conversely, pituitary secretion of follicle-stimulating hormone and luteinizing hormone is almost totally suppressed as a result of the inhibitory effects of estrogens and progesterone from the placenta.

Increased Corticosteroid Secretion. The rate of adrenocortical secretion of *glucocorticoids* is moderately increased throughout pregnancy. It is possible that these glucocorticoids help mobilize amino acids from the mother's tissues to be used for synthesis of fetal tissues.

Pregnant women usually have about a 2-fold increase in *aldosterone* secretion, reaching a peak at the end of gestation. This increase, along with the actions of estrogens, causes a tendency for even a normal pregnant woman to reabsorb excess sodium from her renal tubules and, therefore, to retain fluid.

Increased Thyroid Gland Secretion. The mother's thyroid gland ordinarily enlarges up to 50% during pregnancy and increases its production of thyroxine a corresponding amount. The increased thyroxine production is caused at least partly by a thyrotropic effect of *human chorionic gonadotropin* secreted by the placenta and by small quantities of a specific thyroid-stimulating hormone, *human chorionic thyrotropin,* also secreted by the placenta.

Increased Parathyroid Gland Secretion. The mother's parathyroid glands usually enlarge during pregnancy, especially if her diet is deficient in calcium. Enlargement of these glands causes calcium absorption from the mother's bones, thereby maintaining normal calcium ion concentration in the mother's extracellular fluid, even while the fetus removes calcium to ossify its own bones. This secretion of parathyroid hormone is even greater during lactation after the baby's birth because the growing baby requires many times more calcium than does the fetus.

Secretion of "Relaxin" by the Ovaries and Placenta. A hormone called *relaxin* is also secreted by the corpus luteum of the ovary and by placental tissues. Its secretion is increased by a stimulating effect of human chorionic gonadotropin at the same time that the corpus luteum and the placenta secrete large quantities of estrogens and progesterone.

Relaxin is a 48–amino acid polypeptide with a molecular weight of about 9000. This hormone, when injected, causes relaxation of the ligaments of the symphysis pubis

in the estrous rat and guinea pig. This effect is weak or possibly even absent in pregnant women. Instead, this role is probably played mainly by the estrogens, which also cause relaxation of the pelvic ligaments. It has also been claimed that relaxin softens the cervix of the pregnant woman at the time of delivery. Relaxin is also thought to serve as a vasodilator, contributing to increased blood flow in various tissues, including the kidneys, and increasing venous return and cardiac output in pregnancy.

Response of the Mother's Body to Pregnancy

Most apparent among the many reactions of the mother to the fetus and to the higher levels of pregnancy hormones is the increased size of the various sexual organs. For example, the uterus increases from about 50 to 1100 grams, and the breasts approximately double in size. At the same time, the vagina enlarges and the introitus opens more widely. Also, the various hormones can cause marked changes in a pregnant woman's appearance, sometimes resulting in the development of edema, acne, and masculine or acromegalic features.

Weight Gain in the Pregnant Woman

The average weight gain during pregnancy is about 25 to 35 pounds, with most of this gain occurring during the last two trimesters. Of this added weight, about 8 pounds is fetus and 4 pounds is amniotic fluid, placenta, and fetal membranes. The uterus increases about 3 pounds and the breasts another 2 pounds, still leaving an average weight increase of 8 to 18 pounds. About 5 pounds of this added weight is extra fluid in the blood and extracellular fluid, and the remaining 3 to 13 pounds is generally fat accumulation. The extra fluid is excreted in the urine during the first few days after birth—that is, after loss of the fluid-retaining hormones from the placenta.

During pregnancy, a woman often has a greatly increased desire for food, partly as a result of removal of food substrates from the mother's blood by the fetus and partly because of hormonal factors. Without appropriate prenatal control of diet, the mother's weight gain can be as great as 75 pounds instead of the usual 25 to 35 pounds.

Metabolism During Pregnancy

As a consequence of the increased secretion of many hormones during pregnancy, including thyroxine, adrenocortical hormones, and the sex hormones, the basal metabolic rate of the pregnant woman increases about 15% during the latter half of pregnancy. As a result, she frequently has sensations of becoming overheated. Also, owing to the extra load she is carrying, greater amounts of energy than normal must be expended for muscle activity.

Nutrition During Pregnancy

By far the greatest growth of the fetus occurs during the last trimester of pregnancy; its weight almost doubles during the last 2 months of pregnancy. Ordinarily, the mother does not absorb sufficient protein, calcium, phosphates, and iron from her diet during the last months of pregnancy to supply these extra needs of the fetus. However, in anticipation of these extra needs, the mother's body has already been storing these substances—some in the placenta, but most in the normal storage depots of the mother.

If appropriate nutritional elements are not present in a pregnant woman's diet, several maternal deficiencies can occur, especially in calcium, phosphates, iron, and the vitamins. For example, the fetus needs about 375 milligrams of iron to form its blood, and the mother needs an additional 600 milligrams to form her own extra blood. The normal store of nonhemoglobin iron in the mother at the outset of pregnancy is often only 100 milligrams and almost never more than 700 milligrams. Therefore, without sufficient iron in her food, a pregnant woman may develop *hypochromic anemia*. Also, it is especially important that she receive vitamin D, because although the total quantity of calcium used by the fetus is small, calcium is normally poorly absorbed by the mother's gastrointestinal tract without vitamin D. Finally, shortly before birth of the baby, vitamin K is often added to the mother's diet so the baby will have sufficient prothrombin to prevent hemorrhage, particularly brain hemorrhage, caused by the birth process.

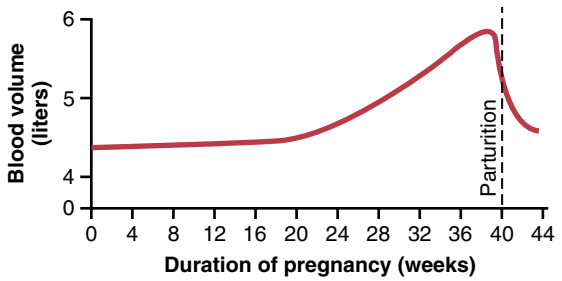

Figure 83-8. Effect of pregnancy on increasing the mother's blood volume.

Changes in the Maternal Circulatory System During Pregnancy

Blood Flow Through the Placenta and Maternal Cardiac Output Increase During Pregnancy. About 625 ml of blood flows through the maternal circulation of the placenta each minute during the last month of pregnancy. This flow, plus the general increase in the mother's metabolism, increases the mother's cardiac output to 30% to 40% above normal by the 27th week of pregnancy; then, for unexplained reasons, the cardiac output falls to only a little above normal during the last 8 weeks of pregnancy, despite the high uterine blood flow, indicating that blood flow in some other tissue(s) may be reduced.

Maternal Blood Volume Increases During Pregnancy. The maternal blood volume shortly before term is about 30% above normal. This increase occurs mainly during the latter half of pregnancy, as shown in **Figure 83-8**. The cause of the increased volume is likely due, at least in part, to aldosterone and estrogens, which are greatly increased in pregnancy, and to increased fluid retention by the kidneys. In addition, the bone marrow becomes increasingly active and produces extra red blood cells to go with the excess fluid volume. Therefore, at the time of the birth of the baby, the mother has about 1 to 2 liters of extra blood in her circulatory system. Only about one-fourth of this amount is normally lost through bleeding during delivery of the baby, thereby allowing a considerable safety factor for the mother.

Maternal Respiration Increases During Pregnancy. Because of the increased basal metabolic rate of a pregnant woman and because of her greater size, the total amount of oxygen used by the mother shortly before the birth of the baby

is about 20% above normal, and a commensurate amount of carbon dioxide is formed. These effects cause the mother's minute ventilation to increase. It is also believed that the high levels of progesterone during pregnancy increase the minute ventilation even more because progesterone increases the sensitivity of the respiratory center to carbon dioxide. The net result is an increase in minute ventilation of about 50% and a decrease in arterial P_{CO_2} to several mm Hg below that in a nonpregnant woman. Simultaneously, the growing uterus presses upward against the abdominal contents, which press upward against the diaphragm, so the total excursion of the diaphragm is decreased. Consequently, the respiratory rate is increased to maintain the extra ventilation.

Maternal Kidney Function During Pregnancy

The rate of urine formation by a pregnant woman is usually slightly increased because of increased fluid intake and increased load of excretory products. In addition, several special alterations of kidney function occur.

First, the renal tubules' reabsorptive capacity for sodium, chloride, and water is increased as much as 50% as a consequence of increased production of salt and water-retaining hormones, especially steroid hormones by the placenta and adrenal cortex.

Second, the renal blood flow and glomerular filtration rate increase up to 50% during normal pregnancy as a result of renal vasodilation. Although the mechanisms that cause renal vasodilation in pregnancy are still unclear, some studies suggest that increased levels of nitric oxide or the ovarian hormone *relaxin* may contribute to these changes. The increased glomerular filtration rate likely occurs, at least in part, as a compensation for increased tubular reabsorption of salt and water. Thus, the *normal* pregnant woman ordinarily accumulates only about 5 pounds of extra water and salt.

Amniotic Fluid and Its Formation

Normally, the volume of *amniotic fluid* (the fluid inside the uterus in which the fetus floats) is between 500 ml and 1 liter, but it can be only a few milliliters or as much as several liters. On average, the water in amniotic fluid is replaced once every 3 hours and the electrolytes sodium and potassium are replaced an average of once every 15 hours. A large portion of the fluid is derived from renal excretion by the fetus. Likewise, a certain amount of absorption occurs by way of the gastrointestinal tract and lungs of the fetus. However, even after in utero death of a fetus, some turnover of the amniotic fluid still occurs, which indicates that some of the fluid is formed and absorbed directly through the amniotic membranes.

Preeclampsia and Eclampsia

About 5% of all pregnant women experience *pregnancy-induced hypertension*, a rapid rise in arterial blood pressure to hypertensive levels during the last few months of pregnancy that may also be associated with leakage of large amounts of protein into the urine. This condition is called *preeclampsia* or *toxemia of pregnancy*. It is often characterized by excess salt and water retention by the mother's kidneys and by weight gain and development of edema and hypertension in the mother. In addition, function of the vascular endothelium is impaired, and arterial spasm occurs in many parts of the mother's body, most significantly in the kidneys, brain, and liver. Renal blood flow and the glomerular filtration rate are decreased, which is exactly opposite to the changes that occur in the normal pregnant woman. The renal effects also include thickened glomerular tufts that contain a protein deposit in the basement membranes.

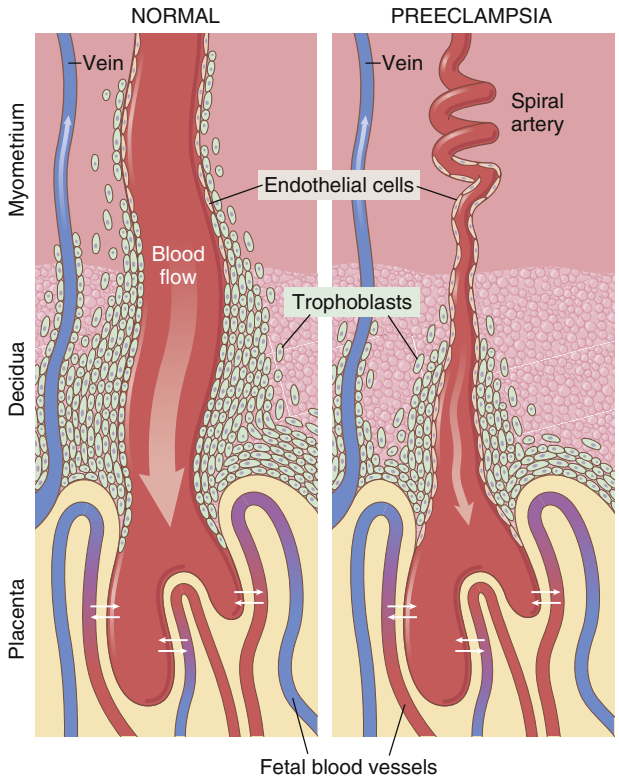

Figure 83-9. Remodeling of the spiral arteries of the uterine endometrium during normal pregnancy and failure of the spiral arteries to remodel adequately in preeclampsia. In normal pregnancy, the trophoblasts migrate into the maternal uterine spiral arteries and transform them into much larger, low-resistance, high-flow vessels. In preeclampsia, the trophoblasts fail to invade the endothelium of the spiral arteries adequately, resulting in narrow placental vessels and relative placental ischemia.

Various attempts have been made to prove that preeclampsia is caused by excessive secretion of placental or adrenal hormones, but proof of a hormonal basis is still lacking. Another theory is that preeclampsia results from some type of autoimmunity or allergy in the mother caused by the presence of the fetus. In support of this theory, the acute symptoms usually disappear within a few days after birth of the baby.

Evidence also indicates that preeclampsia is initiated by *insufficient blood supply to the placenta*, resulting in the placenta's release of substances that cause widespread dysfunction of the maternal vascular endothelium. During normal placental development, the trophoblasts invade the spiral arteries of the uterine endometrium and completely remodel the maternal arteries into much larger blood vessels with low resistance to blood flow (**Figure 83-9**). In women with preeclampsia, the maternal spiral arteries fail to undergo these adaptive changes, for reasons that are still unclear, and blood supply to the placenta is insufficient. This insufficient blood supply, in turn, causes the placenta to release various substances that enter the

mother's circulation and cause impaired vascular endothelial function, decreased blood flow to the kidneys, excess salt and water retention, and increased blood pressure.

Although the factors that link reduced placental blood supply with maternal endothelial dysfunction are still uncertain, some experimental studies suggest a role for increased levels of *inflammatory cytokines* such as *tumor necrosis factor-α and interleukin-6*. Placental factors that impede angiogenesis (blood vessel growth) have also been shown to contribute to increased inflammatory cytokines and preeclampsia. For example, the antiangiogenic proteins *soluble fms-related tyrosine kinase 1* (s-Flt1) and *soluble endoglin* are increased in the blood of women with preeclampsia. These substances are released by the placenta into the maternal circulation in response to ischemia and hypoxia of the placenta. Soluble endoglin and s-Flt1 have multiple effects that may impair function of the maternal vascular endothelium and cause hypertension, proteinuria, and the other systemic manifestations of preeclampsia. However, the precise role of the various factors released from the ischemic placenta in causing the multiple cardiovascular and renal abnormalities in women with preeclampsia is still uncertain.

Eclampsia is an extreme degree of preeclampsia characterized by vascular spasm throughout the body; clonic seizures in the mother, sometimes followed by coma; greatly decreased kidney output; malfunction of the liver; often extreme hypertension; and a generalized toxic condition of the body. It usually occurs shortly before the birth of the baby. Without treatment, a high percentage of mothers with eclampsia die. However, with optimal and immediate use of rapidly acting vasodilating drugs to reduce the arterial pressure to normal, followed by immediate termination of pregnancy—by cesarean section if necessary—the mortality even in mothers with eclampsia has been reduced to 1% or less.

PARTURITION

INCREASED UTERINE EXCITABILITY NEAR TERM

Parturition means birth of the baby. Toward the end of pregnancy, the uterus becomes progressively more excitable, until finally it develops such strong rhythmic contractions that the baby is expelled. The exact cause of the increased activity of the uterus is not known, but at least two major categories of effects lead up to the intense contractions responsible for parturition: (1) progressive hormonal changes that cause increased excitability of the uterine musculature and (2) progressive mechanical changes.

HORMONAL FACTORS THAT INCREASE UTERINE CONTRACTILITY

Increased Ratio of Estrogens to Progesterone. Progesterone inhibits uterine contractility during pregnancy, thereby helping to prevent expulsion of the fetus. Conversely, estrogens have tend to increase the degree of uterine contractility, partly because estrogens increase the number of gap junctions between the adjacent uterine smooth muscle cells, but also because of other poorly understood effects. Both progesterone and estrogen are secreted in progressively greater quantities throughout most of pregnancy, but from the seventh month onward, estrogen secretion continues to increase while progesterone secretion remains constant or perhaps even decreases slightly. Therefore, it has been postulated that the *estrogen-to-progesterone ratio* increases sufficiently toward the end of pregnancy to be at least partly responsible for the increased contractility of the uterus.

Oxytocin Causes Contraction of the Uterus. Oxytocin, a hormone secreted by the neurohypophysis, specifically causes uterine contraction (see Chapter 76). There are four reasons to believe that oxytocin is important in increasing the contractility of the uterus near term:

1. The uterine muscle increases its oxytocin receptors and therefore increases its responsiveness to a given dose of oxytocin during the latter few months of pregnancy.
2. Oxytocin secretion rate by the neurohypophysis is considerably increased at the time of labor.
3. Although hypophysectomized animals can still deliver their young at term, labor is prolonged.
4. Experiments in animals indicate that irritation or stretching of the uterine cervix, as occurs during labor, can cause a neurogenic reflex through the paraventricular and supraoptic nuclei of the hypothalamus that causes the posterior pituitary gland (the neurohypophysis) to increase its secretion of oxytocin.

Effect of Fetal Hormones on the Uterus. The fetus's pituitary gland secretes increasing quantities of oxytocin, which might play a role in exciting the uterus. Also, the fetus's adrenal glands secrete large quantities of cortisol, another possible uterine stimulant. In addition, the fetal membranes release prostaglandins in high concentration at the time of labor. These prostaglandins, too, can increase the intensity of uterine contractions.

Mechanical Factors That Increase Uterine Contractility

Stretch of the Uterine Musculature. Simply stretching smooth muscles usually increases their contractility. Further, intermittent stretch, which occurs repeatedly in the uterus because of fetal movements, can also elicit smooth muscle contraction. Note especially that twins are born, on average, *19 days earlier* than a single child, which emphasizes the importance of mechanical stretch in eliciting uterine contractions.

Stretch or Irritation of the Cervix. There is reason to believe that stretching or irritating the uterine cervix is particularly important in eliciting uterine contractions. For example, obstetricians frequently induce labor by rupturing the membranes so the head of the baby stretches the cervix more forcefully than usual or irritates it in other ways.

The mechanism whereby cervical irritation excites the body of the uterus is not known. It has been suggested that stretching or irritation of nerves in the cervix initiates reflexes to the body of the uterus, but the effect could also result simply from myogenic transmission of signals from the cervix to the body of the uterus.

ONSET OF LABOR—A POSITIVE FEEDBACK MECHANISM FOR ITS INITIATION

During pregnancy, the uterus undergoes periodic episodes of weak and slow rhythmic contractions called *Braxton Hicks contractions.* These contractions are usually not felt until the second or third trimester and become progressively stronger toward the end of pregnancy; then they change suddenly, within hours, to become exceptionally strong contractions that start stretching the cervix and later force the baby through the birth canal, thereby causing parturition. This process is called *labor,* and the strong contractions that result in final parturition are called *labor contractions.*

We do not know what suddenly changes the slow, weak rhythmicity of the uterus into strong labor contractions. However, the *positive feedback* theory suggests that stretching of the cervix by the fetus's head finally becomes great enough to elicit a strong reflex increase in contractility of the uterine body. This pushes the baby forward, which stretches the cervix more and initiates more positive feedback to the uterine body. Thus, the process repeats until the baby is expelled. This theory is shown in **Figure 83-10**, and the following observations support this theory.

First, labor contractions obey all the principles of positive feedback. That is, once the strength of uterine contraction becomes greater than a critical value, each contraction leads to subsequent contractions that become stronger and stronger until maximum effect is achieved. By referring to the discussion in Chapter 1 of positive feedback in control systems, one can see that this is the precise nature of all positive feedback mechanisms when the feedback gain becomes greater than a critical value.

Second, two known types of positive feedback increase uterine contractions during labor: (1) stretching of the cervix causes the entire body of the uterus to contract, and this contraction stretches the cervix even more because of the downward thrust of the baby's head, and (2) cervical stretching also causes the pituitary gland to secrete oxytocin, which is another means for increasing uterine contractility.

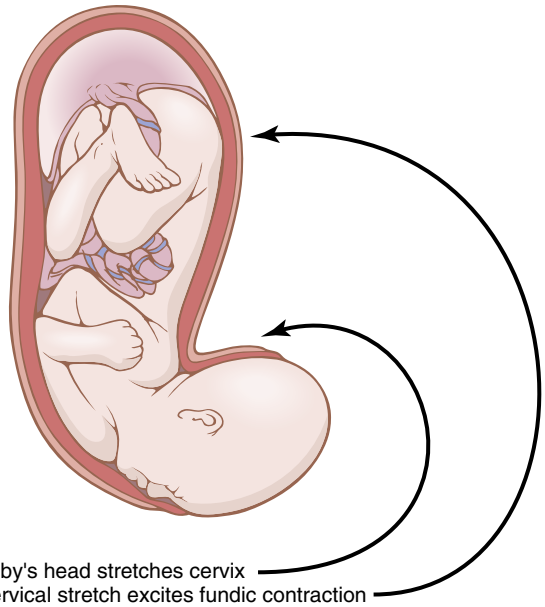

Figure 83-10. Theory for the onset of intensely strong contractions during labor.

To summarize, multiple factors increase the contractility of the uterus toward the end of pregnancy. Eventually a uterine contraction becomes strong enough to irritate the uterus, especially at the cervix, and this irritation increases uterine contractility still more because of positive feedback, resulting in a second uterine contraction stronger than the first, a third stronger than the second, and so forth. Once these contractions become strong enough to cause this type of feedback, with each succeeding contraction greater than the preceding one, the process proceeds to completion. One might ask about the many cases of false labor, in which the contractions become stronger and stronger and then fade away. Remember that for a positive feedback to continue, *each* new cycle of the positive feedback must be stronger than the previous one. If at any time after labor starts some contractions fail to re-excite the uterus sufficiently, the positive feedback could go into a retrograde decline, and the labor contractions would fade away.

ABDOMINAL MUSCLE CONTRACTIONS DURING LABOR

Once uterine contractions become strong during labor, pain signals originate both from the uterus and from the birth canal. These signals, in addition to causing suffering, elicit neurogenic reflexes in the spinal cord to the abdominal muscles, causing intense contractions of these muscles. The abdominal contractions add greatly to the force that causes expulsion of the baby.

Mechanics of Parturition

The uterine contractions during labor begin mainly at the top of the uterine fundus and spread downward over the body of the uterus. Also, the intensity of contraction is great in the top and body of the uterus but weak in the lower segment of the uterus adjacent to the cervix. Therefore, each uterine contraction tends to force the baby downward toward the cervix.

In the early part of labor, the contractions might occur only once every 30 minutes. As labor progresses, the contractions finally appear as often as once every 1 to 3 minutes and the intensity of contraction increases greatly, with only a short period of relaxation between contractions. The combined contractions of the uterine and abdominal musculature during delivery of the baby cause a downward force on the fetus of about 25 pounds during each strong contraction.

It is fortunate that the contractions of labor occur intermittently, because strong contractions impede or sometimes even stop blood flow through the placenta and would cause death of the fetus if the contractions were continuous. Indeed, overuse of various uterine stimulants, such as oxytocin, can cause uterine spasm rather than rhythmic contractions and can lead to death of the fetus.

In more than 95% of births, the head is the first part of the baby to be expelled and, in most of the remaining cases, the buttocks are presented first. Entering the birth canal with the buttocks or feet first is called a *breech* presentation.

The head acts as a wedge to open the structures of the birth canal as the fetus is forced downward. The first major obstruction to expulsion of the fetus is the uterine cervix. Toward the end of pregnancy, the cervix becomes soft, which allows it to stretch when labor contractions begin in the uterus. The so-called *first stage of labor* is a period of progressive cervical dilation, lasting until the cervical opening is as large as the head of the fetus. This stage usually lasts for 8 to 24 hours in the first pregnancy but often only a few minutes after many pregnancies.

Once the cervix has dilated fully, the fetal membranes usually rupture and the amniotic fluid is lost suddenly through the vagina. Then the head of the fetus moves rapidly into the birth canal, and with additional force from above, it continues to wedge its way through the canal until delivery occurs. This is called the *second stage of labor,* and it may last from as little as 1 minute after many pregnancies to 30 minutes or more in the first pregnancy.

Separation and Delivery of the Placenta. For 10 to 45 minutes after birth of the baby, the uterus continues to contract to a smaller and smaller size, which causes a *shearing* effect between the walls of the uterus and the placenta, thus separating the placenta from its implantation site. Separation of the placenta opens the placental sinuses and causes bleeding. The amount of bleeding is usually limited to an average of 350 ml by the following mechanism:

- The smooth muscle fibers of the uterine musculature are arranged in figures of eight around the blood vessels as the vessels pass through the uterine wall.
- Therefore, contraction of the uterus after delivery of the baby constricts the vessels that had previously supplied blood to the placenta.
- In addition, it is believed that vasoconstrictor prostaglandins formed at the placental separation site cause additional blood vessel spasm.

Labor Pains

With each uterine contraction, the mother experiences considerable pain. The cramping pain in early labor is probably caused mainly by hypoxia of the uterine muscle resulting from compression of the blood vessels in the uterus. This pain is not felt when the visceral sensory *hypogastric nerves,* which carry the visceral sensory fibers leading from the uterus, have been sectioned.

During the second stage of labor, when the fetus is being expelled through the birth canal, much more severe pain is caused by cervical stretching, perineal stretching, and stretching or tearing of structures in the vaginal canal. This pain is conducted to the mother's spinal cord and brain by somatic nerves instead of by the visceral sensory nerves.

Involution of the Uterus After Parturition

During the first 4 to 5 weeks after parturition, the uterus involutes. Its weight becomes less than half its immediate postpartum weight within 1 week, and in 4 weeks, if the mother lactates, the uterus may become as small as it was before pregnancy. This effect of lactation results from the suppression of pituitary gonadotropin and ovarian hormone secretion during the first few months of lactation, as discussed later. During early involution of the uterus, the placental site on the endometrial surface autolyzes, causing a vaginal discharge known as *lochia,* which is first bloody and then serous in nature and continues for a total of about 10 days. After this time, the endometrial surface becomes reepithelialized and ready for normal, nongravid sex life again.

LACTATION

DEVELOPMENT OF THE BREASTS

The breasts, shown in **Figure 83-11**, begin to develop at puberty. This development is stimulated by the estrogens of the monthly female sexual cycle; estrogens stimulate growth of the breasts' *mammary glands* plus the deposition of fat to give the breasts mass. In addition, far greater growth occurs during the high-estrogen state of pregnancy, and only then does the glandular tissue become completely developed for production of milk.

Estrogens Stimulate Growth of the Ductal System of the Breasts. All through pregnancy, the large quantities of estrogens secreted by the placenta cause the ductal system of the breasts to grow and branch. Simultaneously, the stroma of the breasts increases in quantity, and large quantities of fat are laid down in the stroma.

Also important for growth of the ductal system are at least four other hormones: *growth hormone, prolactin, adrenal glucocorticoids,* and *insulin.* Each of these

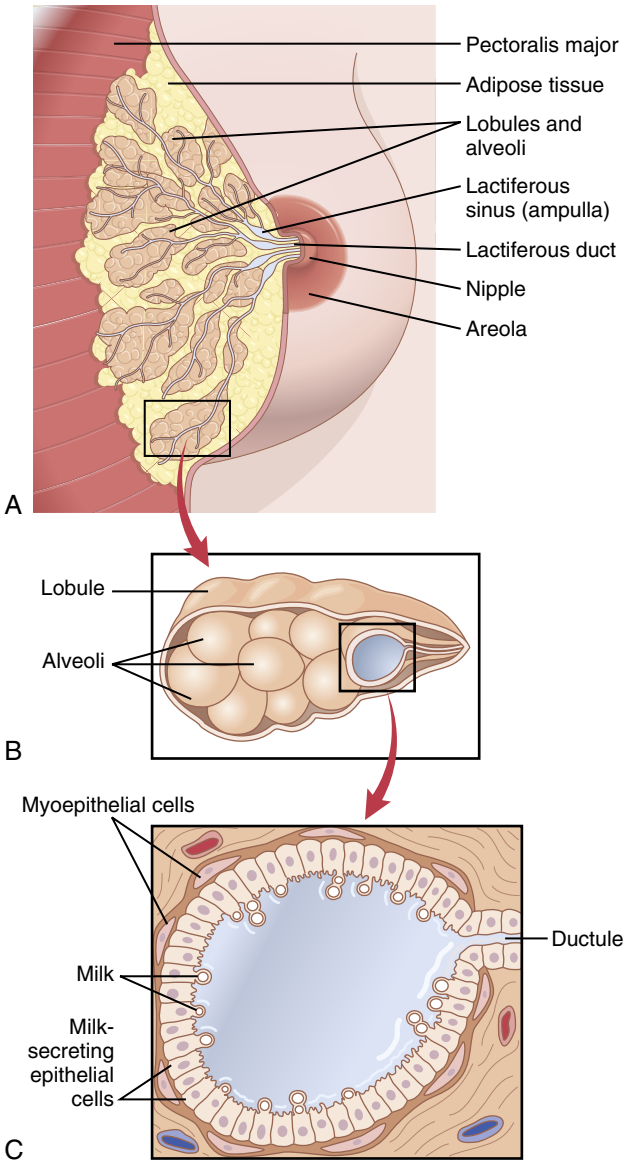

Figure 83-11. A, The breast and its secretory lobules, alveoli, and lactiferous ducts (milk ducts) that constitute its mammary gland. **B,** The enlargements show a lobule and milk-secreting cells (**C**) of an alveolus.

hormones is known to play at least some role in protein metabolism, which presumably explains their function in the development of the breasts.

Progesterone Is Required for Full Development of the Lobule-Alveolar System. Final development of the breasts into milk-secreting organs also requires *progesterone.* Once the ductal system has developed, progesterone—acting synergistically with estrogen, as well as with the other hormones just mentioned—causes additional growth of the breast lobules, with budding of alveoli and development of secretory characteristics in the cells of the alveoli. These changes are analogous to the secretory effects of progesterone on the endometrium of the uterus during the latter half of the female menstrual cycle.

PROLACTIN PROMOTES LACTATION

Although estrogen and progesterone are essential for physical development of the breasts during pregnancy, a specific effect of both these hormones is to inhibit *the actual secretion of milk.* Conversely, the hormone *prolactin* has the opposite effect and promotes milk secretion. Prolactin is secreted by the mother's anterior pituitary gland, and its concentration in her blood rises steadily from the fifth week of pregnancy until birth of the baby, at which time it has risen to 10 to 20 times the normal nonpregnant level. This high level of prolactin at the end of pregnancy is shown in **Figure 83-12**.

In addition, the placenta secretes large quantities of *human chorionic somatomammotropin,* which probably has lactogenic properties, thus supporting the prolactin from the mother's pituitary during pregnancy. Even so, because of the suppressive effects of estrogen and progesterone, no more than a few milliliters of fluid are secreted each day until after the baby is born. The fluid secreted during the last few days before and the first few days after parturition is called *colostrum;* it contains essentially the same concentrations of proteins and lactose as milk, but it has almost no fat, and its maximum rate of production is about 1/100 the subsequent rate of milk production.

Immediately after the baby is born, the sudden loss of both estrogen and progesterone secretion from the placenta allows the lactogenic effect of prolactin from the mother's pituitary gland to assume its natural milk-promoting role, and during the next 1 to 7 days, the breasts begin to secrete copious quantities of milk instead of colostrum. This secretion of milk requires an adequate background secretion of most of the mother's other hormones as well, but most important are *growth hormone, cortisol, parathyroid hormone,* and *insulin.* These hormones are necessary to provide the amino acids, fatty acids, glucose, and calcium required for the formation of milk.

After the birth of the baby, the *basal level* of prolactin secretion returns to the nonpregnant level during the next few weeks, as shown in **Figure 83-12**. However, each time the mother nurses her baby, nervous signals from the nipples to the hypothalamus cause a 10- to 20-fold surge in prolactin secretion that lasts for about 1 hour, which is also shown in **Figure 83-12**. This prolactin acts on the mother's breasts to keep the mammary glands secreting milk into the alveoli for the subsequent nursing periods. If this prolactin surge is absent or blocked as a result of hypothalamic or pituitary damage or if nursing does not continue, the breasts lose their ability to produce milk within 1 week or so. However, milk production can continue for several years if the child continues to suckle, although the rate of milk formation normally decreases considerably after 7 to 9 months.

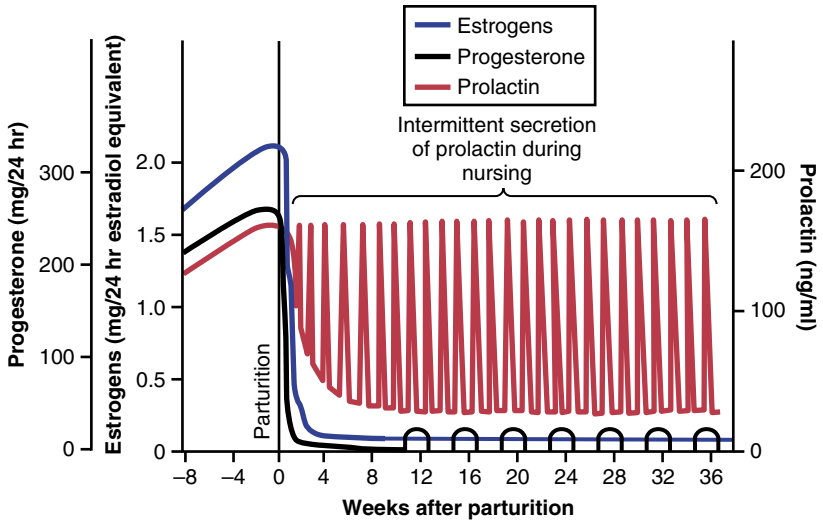

Figure 83-12. Changes in rates of secretion of estrogens, progesterone, and prolactin for 8 weeks before parturition and 36 weeks thereafter. Note especially the decrease of prolactin secretion back to basal levels within a few weeks after parturition, but also the intermittent periods of marked prolactin secretion (for about 1 hour at a time) during and after periods of nursing.

The Hypothalamus Secretes Prolactin Inhibitory Hormone. The hypothalamus plays an essential role in controlling prolactin secretion, as it does for almost all the other anterior pituitary hormones. However, this control is different in one aspect: The hypothalamus mainly *stimulates* production of all the other hormones, but it mainly *inhibits* prolactin production. Consequently, damage to the hypothalamus or blockage of the hypothalamic-hypophysial portal system often increases prolactin secretion while it depresses secretion of the other anterior pituitary hormones.

Therefore, it is believed that anterior pituitary secretion of prolactin is controlled either entirely or almost entirely by an inhibitory factor formed in the hypothalamus and transported through the hypothalamic-hypophysial portal system to the anterior pituitary gland. This factor is sometimes called *prolactin inhibitory hormone,* but it is almost certainly the same as the catecholamine *dopamine,* which is known to be secreted by the arcuate nuclei of the hypothalamus and can decrease prolactin secretion as much as 10-fold.

Suppression of the Female Ovarian Cycles in Nursing Mothers for Many Months After Delivery. In most nursing mothers, the ovarian cycle (and ovulation) does not resume until a few weeks after cessation of nursing. The reason seems to be that the same nervous signals from the breasts to the hypothalamus that cause prolactin secretion during suckling—either because of the nervous signals or because of a subsequent effect of increased prolactin—inhibit secretion of gonadotropin-releasing hormone by the hypothalamus. This inhibition, in turn, suppresses formation of the pituitary gonadotropic hormones—luteinizing hormone and follicle-stimulating hormone. However, after several months of lactation, in some mothers (especially those who nurse their babies only some of the time), the pituitary begins to secrete sufficient gonadotropic hormones to reinstate the monthly sexual cycle, even though nursing continues.

EJECTION (OR "LET-DOWN") PROCESS IN MILK SECRETION—FUNCTION OF OXYTOCIN

Milk is secreted continuously into the alveoli of the breasts, but it does not flow easily from the alveoli into the ductal system and, therefore, does not continually leak from the nipples. Instead, the milk must be *ejected* from the alveoli into the ducts before the baby can obtain it. This ejection is caused by a combined neurogenic and hormonal reflex that involves the posterior pituitary hormone *oxytocin*.

When the baby suckles, it receives virtually no milk for the first half minute or so. Sensory impulses must first be transmitted through somatic nerves from the nipples to the mother's spinal cord and then to her hypothalamus, where they cause nerve signals that promote *oxytocin* secretion at the same time that they cause prolactin secretion. The oxytocin is carried in the blood to the breasts, where it causes *myoepithelial cells* (which surround the outer walls of the alveoli) to contract, thereby expressing the milk from the alveoli into the ducts at a pressure of +10 to 20 mm Hg. Then the baby's suckling becomes effective in removing the milk. Thus, within 30 seconds to 1 minute after a baby begins to suckle, milk begins to flow. This process is called *milk ejection* or *milk let-down.*

Suckling on one breast causes milk flow not only in that breast but also in the opposite breast. It is especially interesting that fondling of the baby by the mother or hearing the baby crying often gives enough of an emotional signal to the hypothalamus to cause milk ejection.

Table 83-1 Composition of Milk

Constituent	Human Milk (%)	Cow's Milk (%)
Water	88.5	87.0
Fat	3.3	3.5
Lactose	6.8	4.8
Casein	0.9	2.7
Lactalbumin and other proteins	0.4	0.7
Ash	0.2	0.7

Inhibition of Milk Ejection. A particular problem in nursing a baby comes from the fact that many psychogenic factors or even generalized sympathetic nervous system stimulation throughout the mother's body can inhibit oxytocin secretion and consequently depress milk ejection. For this reason, many mothers must have an undisturbed period of adjustment after childbirth if they are to be successful in nursing their babies.

MILK COMPOSITION AND THE METABOLIC DRAIN ON THE MOTHER CAUSED BY LACTATION

Table 83-1 lists the approximate composition of human milk and cow's milk. The concentration of lactose in human milk is about 50% greater than in cow's milk, but the concentration of protein in cow's milk is ordinarily two or more times greater than in human milk. Finally, only one-third as much ash, which contains calcium and other minerals, is found in human milk compared with cow's milk.

At the height of lactation in the human mother, 1.5 liters of milk may be formed each day (and even more if the mother has twins). With this degree of lactation, great quantities of energy are drained from the mother; approximately 650 to 750 kilocalories per liter (or 19 to 22 kilocalories per ounce) are contained in breast milk, although the composition and caloric content of the milk depends on the mother's diet and other factors such as the fullness of the breasts.

Large amounts of metabolic substrates are also lost from the mother. For example, about 50 grams of fat enter the milk each day, as well as about 100 grams of lactose, which must be derived by conversion from the mother's glucose. Also, 2 to 3 grams of calcium phosphate may be lost each day; unless the mother is drinking large quantities of milk and has an adequate intake of vitamin D, the output of calcium and phosphate by the lactating mammae will often be much greater than the intake of these substances. To supply the needed calcium and phosphate, the parathyroid glands enlarge greatly, and the bones become progressively decalcified. The mother's bone decalcification is usually not a big problem during pregnancy, but it can become more important during lactation.

Antibodies and Other Anti-infectious Agents in Milk. Not only does milk provide the newborn baby with needed nutrients, but it also provides important protection against infection. For example, multiple types of *antibodies* and other anti-infectious agents are secreted in milk along with nutrients. Also, several different types of white blood cells are secreted, including both *neutrophils* and *macrophages,* some of which are especially lethal to bacteria that could cause deadly infections in newborn babies. Particularly important are antibodies and macrophages that destroy *Escherichia coli* bacteria, which can cause lethal diarrhea in newborns.

When cow's milk is used to supply nutrition for the baby in place of mother's milk, the protective agents in it are usually of little value because they are normally destroyed within minutes in the internal environment of the human being.

CHAPTER 84

UNIT XIV

Fetal and Neonatal Physiology

A complete discussion of fetal development, physiology of the child immediately after birth, and growth and development through the early years of life lies within the province of formal courses in obstetrics and pediatrics. However, many physiological principles are peculiar to the infant, and this chapter discusses the more important of these principles.

Growth and Development of the Fetus

The placenta and fetal membranes initially develop far more rapidly than does the fetus. In fact, during the first 2 to 3 weeks after implantation of the blastocyst, the fetus remains almost microscopic, but thereafter, as shown in **Figure 84-1**, the length of the fetus increases almost in proportion to age. At 12 weeks, the length is about 10 centimeters; at 20 weeks, 25 centimeters; and at term (40 weeks), 53 centimeters (≈21 inches). Because the weight of the fetus is approximately proportional to the cube of length, the weight increases almost in proportion to the cube of the age of the fetus.

Note in **Figure 84-1** that the weight remains minuscule during the first 12 weeks and reaches 1 pound only at 23 weeks (5.5 months) of gestation. Then, during the last trimester of pregnancy, the fetus gains weight rapidly, so that 2 months before birth, the weight averages 3 pounds; 1 month before birth, the average is 4.5 pounds; and at birth, the average is 7 pounds, with the final birth weight varying from as low as 4.5 pounds to as high as 11 pounds in normal infants with normal gestational periods.

Development of the Organ Systems

Within 1 month after fertilization of the ovum, the gross characteristics of all the different organs of the fetus have already begun to develop, and during the next 2 to 3 months, most of the details of the different organs are established. Beyond month 4, the organs of the fetus are grossly the same as those of the neonate. However, cellular development in each organ is usually far from complete and requires the full remaining 5 months of pregnancy for complete development. Even at birth, certain structures lack full development, particularly in the nervous system, the kidneys, and the liver, as discussed later in this chapter.

Circulatory System. The human heart begins beating during the fourth week after fertilization, contracting at a rate of about 65 beats/min. This rate increases steadily to about 140 beats/min immediately before birth.

Formation of Blood Cells. Nucleated red blood cells begin to be formed in the yolk sac and mesothelial layers of the placenta at about the third week of fetal development. This is followed 1 week later (at 4–5 weeks) by formation of non-nucleated red blood cells by the fetal mesenchyme and also by the endothelium of fetal blood vessels. At 6 weeks, the liver begins to form blood cells, and in the third month, the spleen and other lymphoid tissues of the body begin forming blood cells. Finally, from the third month on, the bone marrow gradually becomes the principal source of red blood cells, as well as most of the white blood cells, except for continued lymphocyte and plasma cell production in lymphoid tissue.

Respiratory System. Respiration cannot occur during fetal life because there is no air to breathe in the amniotic cavity. However, attempted respiratory movements do take place beginning at the end of the first trimester of pregnancy. Tactile stimuli and fetal asphyxia especially cause these attempted respiratory movements.

During the last 3 to 4 months of pregnancy, the respiratory movements of the fetus are mainly inhibited, for reasons unknown, and the lungs remain almost completely deflated. The inhibition of respiration during the later months of fetal life prevents filling of the lungs with fluid and debris from the *meconium* excreted by the fetus's gastrointestinal tract into the amniotic fluid. Also, small amounts of fluid are secreted into the lungs by the alveolar epithelium up until the moment of birth, thus keeping only clean fluid in the lungs.

Nervous System. Most of the reflexes of the fetus that involve the spinal cord and even the brain stem are present by the third to fourth months of pregnancy. However, nervous system functions that involve the cerebral cortex are still only in the early stages of development, even at birth. Indeed, myelinization of some major tracts of the brain becomes complete only after about 1 year of postnatal life.

Gastrointestinal Tract. By midpregnancy, the fetus begins to ingest and absorb large quantities of amniotic fluid, and during the last 2 to 3 months, gastrointestinal function approaches that of the normal neonate. By that time, small quantities of *meconium* are continually formed in the gastrointestinal tract and excreted from the anus into the amniotic fluid. Meconium is composed partly of residue from swallowed amniotic fluid and partly of *mucus,*

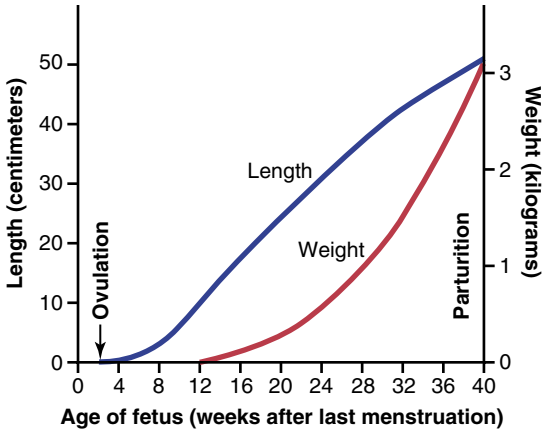

Figure 84-1. Growth of the fetus.

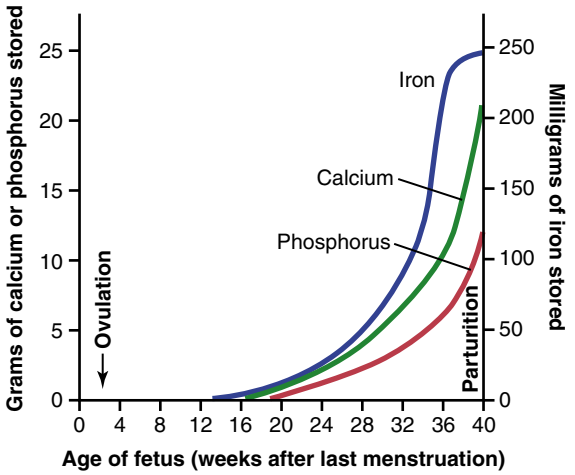

Figure 84-2. Iron, calcium, and phosphorus storage in the fetus at different stages of gestation.

epithelial cells, and other residues of excretory products from the gastrointestinal mucosa and glands.

Kidneys. The fetal kidneys begin to excrete urine during the second trimester, and fetal urine accounts for about 70% to 80% of the amniotic fluid. Abnormal kidney development or severe impairment of kidney function in the fetus greatly reduces formation of amniotic fluid (*oligohydramnios*) and can lead to fetal death.

Although fetal kidneys form urine, the renal control systems for regulating fetal extracellular fluid volume and electrolyte balances, and especially acid–base balance, are almost nonexistent until late fetal life and do not reach full development until a few months after birth.

Fetal Metabolism

The fetus mainly uses glucose for energy. The fetus has a high capability of storing fat and protein, with much if not most of the fat being synthesized from glucose rather than being absorbed directly from the mother's blood. In addition to these generalities, there are special problems of fetal metabolism related to calcium, phosphate, iron, and some vitamins.

Metabolism of Calcium and Phosphate

Figure 84-2 shows the rates of calcium and phosphate accumulation in the fetus, demonstrating that about 22.5 grams of calcium and 13.5 grams of phosphorus are accumulated in the average fetus during gestation. About one-half of these accumulate during the last 4 weeks of gestation, which is coincident with the period of rapid ossification of the fetal bones and with the period of rapid weight gain of the fetus.

During the earlier part of fetal life, the bones are relatively unossified and have mainly a cartilaginous matrix. Ossification usually does not occur until after the fourth month of pregnancy.

Note especially that the total amounts of calcium and phosphate needed by the fetus during gestation represent only about 2% of the quantities of these substances in the mother's bones, and thus the drain of these substances from the mother is minimal. A much greater drain occurs after birth during lactation.

Accumulation of Iron

Figure 84-2 also shows that iron accumulates in the fetus even more rapidly than does calcium and phosphate. Most of the iron is in the form of hemoglobin, which begins to be formed as early as the third week after fertilization of the ovum.

Small amounts of iron are concentrated in the mother's uterine progestational endometrium even before implantation of the ovum; this iron is ingested into the embryo by the trophoblastic cells and is used to form the very early red blood cells. About one-third of the iron in a fully developed fetus is normally stored in the liver. This iron can then be used by the neonate to form additional hemoglobin for several months after birth.

Utilization and Storage of Vitamins

The fetus needs vitamins equally as much as the adult and in some instances to a far greater extent. In general, the vitamins function the same in the fetus as in the adult, as discussed in Chapter 72. Special functions of several vitamins should be mentioned, however.

The B vitamins, especially vitamin B_{12} and folic acid, are necessary for the formation of red blood cells and nervous tissue, as well as for overall growth of the fetus.

Vitamin C is necessary for appropriate formation of intercellular substances, especially the bone matrix and fibers of connective tissue.

Vitamin D is necessary for normal bone growth in the fetus, but even more important, the mother needs it for adequate absorption of calcium from her gastrointestinal tract. If the mother has plenty of vitamin D in her body fluids, large quantities of the vitamin will be stored by the fetal liver to be used by the neonate for several months after birth.

The mechanisms of the functions of vitamin E are not entirely clear, but it is necessary for normal development of the early embryo. In its absence in laboratory animals, spontaneous abortion usually occurs at an early stage of pregnancy.

Vitamin K is used by the fetal liver for formation of Factor VII, prothrombin, and several other blood coagulation factors. When vitamin K is insufficient in the mother, Factor VII and prothrombin become deficient in the fetus and the mother. Because most vitamin K is formed by bacterial action in the mother's colon, the neonate has no adequate

source of vitamin K for the first week or so of life after birth until normal colonic bacterial flora become established in the newborn infant. Therefore, prenatal storage in the fetal liver of at least small amounts of vitamin K derived from the mother is helpful in preventing fetal hemorrhage, particularly hemorrhage in the brain when the head is traumatized by squeezing through the birth canal.

Adjustments of the Infant to Extrauterine Life

Onset of Breathing. The most obvious effect of birth on the baby is loss of the placental connection with the mother and, therefore, loss of metabolic support. One of the most important immediate adjustments required of the infant is to begin breathing.

Cause of Breathing at Birth. After normal delivery from a mother whose system has not been depressed by anesthetics, the child ordinarily begins to breathe within seconds and has a normal respiratory rhythm within less than 1 minute after birth. The promptness with which the fetus begins to breathe indicates that breathing is initiated by sudden exposure to the exterior world, probably resulting from a slightly asphyxiated state that is incident to the birth process and from sensory impulses that originate in the suddenly cooled skin. In an infant who does not breathe immediately, the body becomes progressively more hypoxic and hypercapnic, which provides additional stimulus to the respiratory center and usually causes breathing within an additional minute after birth.

Delayed or Abnormal Breathing at Birth—Danger of Hypoxia. If the mother's system has been depressed by a general anesthetic during delivery, which at least partially anesthetizes the fetus as well, the onset of respiration is likely to be delayed for several minutes, thus demonstrating the importance of using as little anesthesia as feasible. Also, many infants who have had head trauma during delivery or who undergo prolonged delivery are slow to breathe or sometimes do not breathe at all. This can result from two possible effects: (1) in a few infants, intracranial hemorrhage or brain contusion causes a concussion syndrome, with a greatly depressed respiratory center; (2) probably much more important, prolonged fetal hypoxia during delivery can cause serious depression of the respiratory center.

Hypoxia may occur during delivery because of (1) compression of the umbilical cord; (2) premature separation of the placenta; (3) excessive contraction of the uterus, which can cut off the mother's blood flow to the placenta; or (4) excessive anesthesia of the mother, which depresses oxygenation even of her blood.

Degree of Hypoxia That an Infant Can Tolerate. In adults, failure to breathe for only 4 minutes often causes death, but neonates may survive as long as 10 minutes without breathing after birth. Permanent and serious brain impairment often ensues if breathing is delayed more than 8 to 10 minutes. Indeed, actual lesions develop mainly in the thalamus, in the inferior colliculi, and in other brain stem areas, thus permanently affecting many of the motor functions of the body.

Expansion of the Lungs at Birth. At birth, the walls of the alveoli are at first collapsed because of the surface tension of the viscid fluid that fills them. More than 25 mm Hg of negative inspiratory pressure in the lungs is usually required

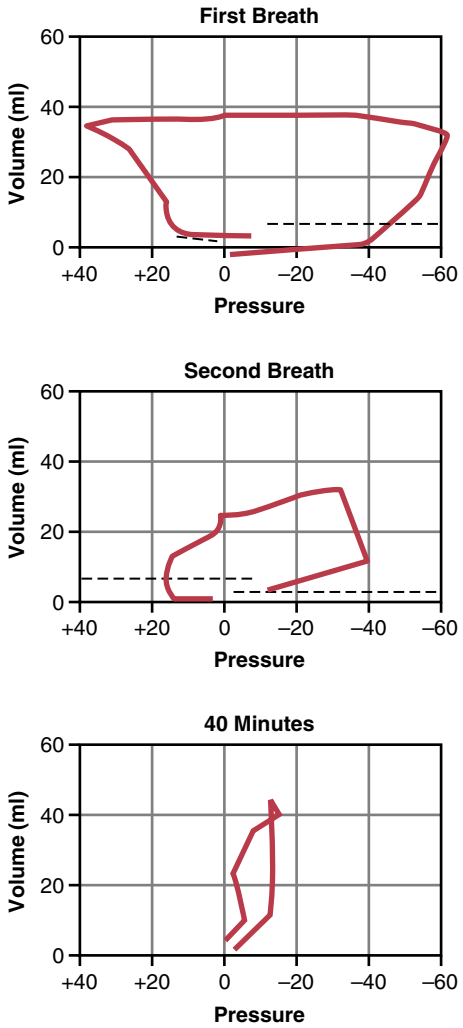

Figure 84-3. Pressure-volume curves of the lungs ("compliance" curves) of a neonate immediately after birth, showing the extreme forces required for breathing during the first two breaths of life and development of a nearly normal compliance curve within 40 minutes after birth. *(Modified from Smith CA: The first breath. Sci Am 209:32, 1963. Copyright 1963 by Scientific American, Inc.)*

to oppose the effects of this surface tension and to open the alveoli for the first time. Once the alveoli open, however, further respiration can be effected with relatively weak respiratory movements. Fortunately, the first inspirations of the normal neonate are extremely powerful; they are usually capable of creating as much as 60 mm Hg negative pressure in the intrapleural space.

Figure 84-3 shows the tremendous negative intrapleural pressures required to open the lungs at the onset of breathing. At the top of the figure, the pressure-volume curve ("compliance" curve) for the first breath after birth is shown. Observe, first, that the lower part of the curve *begins at the zero pressure point* and moves to the right. The curve shows that the volume of air in the lungs remains almost exactly zero until the negative pressure has reached –40 centimeters of water (–30 mm Hg). Then, as the negative pressure increases to –60 centimeters of water, about 40 ml of air enters the lungs. To deflate the

lungs, considerable positive pressure, about +40 centimeters of water, is required because of viscous resistance offered by the fluid in the bronchioles.

Note that the second breath is much easier, requiring far less negative and positive pressures. Breathing does not become completely normal until about 40 minutes after birth, as shown by the third compliance curve, the shape of which compares favorably with that for the normal adult, as shown in Chapter 38.

Respiratory Distress Syndrome Occurs When Surfactant Secretion Is Deficient. In a small number of infants, especially premature infants and infants born of mothers with diabetes mellitus, severe respiratory distress develops in the early hours to the first several days after birth, and some infants die within the next day or so. The alveoli of these infants at death contain large quantities of proteinaceous fluid, almost as if pure plasma had leaked out of the capillaries into the alveoli. The fluid also contains desquamated alveolar epithelial cells. This condition is called *hyaline membrane disease* because microscopic slides of the lung show that the material filling the alveoli looks like a hyaline membrane.

A characteristic finding in respiratory distress syndrome is failure of the respiratory epithelium to secrete adequate quantities of *surfactant,* a substance normally secreted into the alveoli that decreases the surface tension of the alveolar fluid, therefore allowing the alveoli to open easily during inspiration. The surfactant-secreting cells (type II alveolar epithelial cells) do not begin to secrete surfactant until the last 1 to 3 months of gestation. Therefore, many premature babies and a few full-term babies are born without the capability to secrete sufficient surfactant, which causes both a collapse tendency of the alveoli and development of pulmonary edema. The role of surfactant in preventing these effects is discussed in Chapter 38.

Circulatory Readjustments at Birth

Equally as essential as the onset of breathing at birth are immediate circulatory adjustments that allow adequate blood flow through the lungs. In addition, circulatory adjustments during the first few hours of life cause more and more blood flow through the baby's liver, which up to this point has had little blood flow. To describe these readjustments, we first consider the anatomical structure of the fetal circulation.

Specific Anatomical Structure of the Fetal Circulation

Because the lungs are mainly nonfunctional during fetal life and because the liver is only partially functional, it is not necessary for the fetal heart to pump much blood through either the lungs or the liver. However, the fetal heart must pump large quantities of blood through the placenta. Therefore, special anatomical arrangements cause the fetal circulatory system to operate much differently from that of the newborn baby.

First, as shown in **Figure 84-4**, blood returning from the placenta through the umbilical vein passes through the *ductus venosus,* mainly bypassing the liver. Then most of the blood entering the right atrium from the inferior vena cava is directed in a straight pathway across the posterior aspect of the right atrium and through the *foramen ovale* directly into the left atrium. Thus, the well-oxygenated blood from the placenta enters mainly the left side of the heart, rather than the right side, and is pumped by the left ventricle mainly into the arteries of the head and forelimbs.

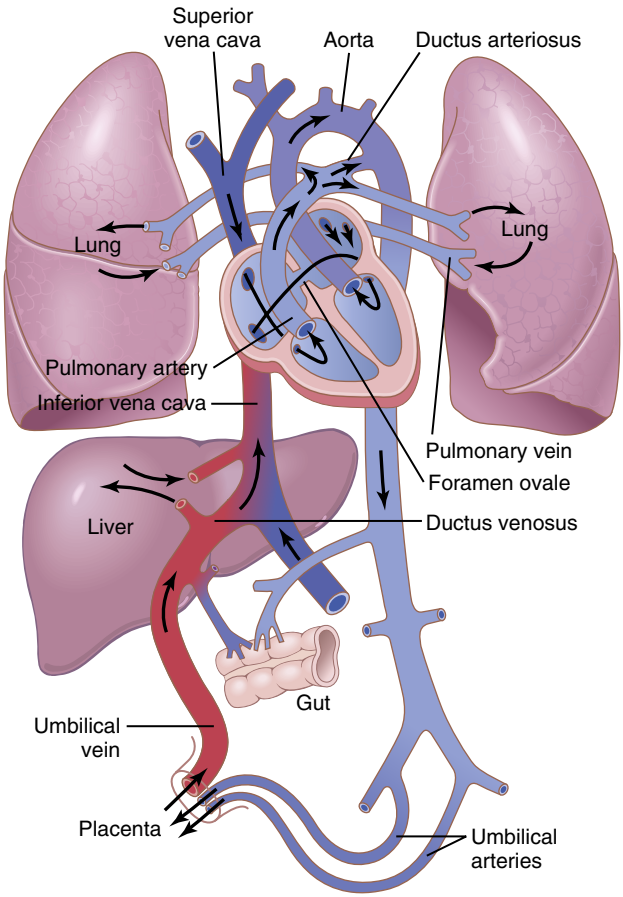

Figure 84-4. Organization of the fetal circulation.

The blood entering the right atrium from the superior vena cava is directed downward through the tricuspid valve into the right ventricle. This blood is mainly deoxygenated blood from the head region of the fetus. It is pumped by the right ventricle into the pulmonary artery and then mainly through the *ductus arteriosus* into the descending aorta, then through the two umbilical arteries into the placenta, where the deoxygenated blood becomes oxygenated.

Figure 84-5 shows the relative percentages of the total blood pumped by the heart that pass through the different vascular circuits of the fetus. Approximately 55% of all the blood goes through the placenta, leaving only 45% to pass through all the tissues of the fetus. Furthermore, during fetal life, only 12% of the blood flows through the lungs, whereas immediately after birth, virtually all the blood flows through the lungs.

Changes in Fetal Circulation at Birth

The basic changes in fetal circulation at birth are discussed in Chapter 23 in relation to congenital anomalies of the ductus arteriosus and foramen ovale that persist throughout life in a few persons. These changes are briefly described in the following sections.

Decreased Pulmonary and Increased Systemic Vascular Resistances at Birth. The primary changes in the circulation at birth are, first, loss of the tremendous blood flow through the placenta, which approximately doubles

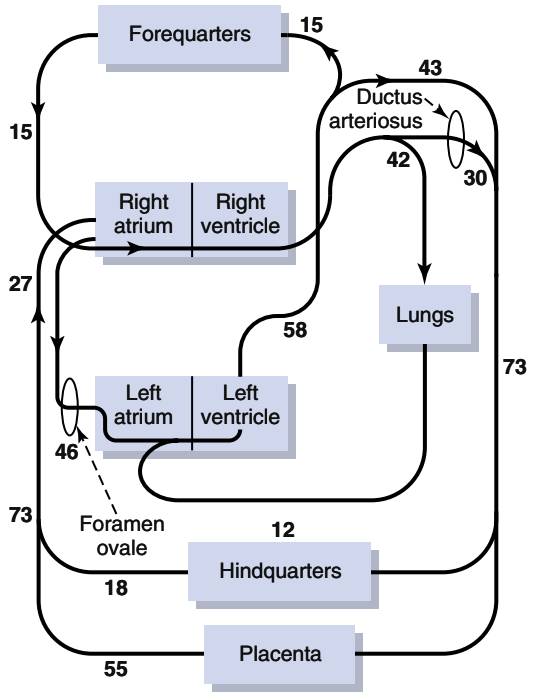

Figure 84-5. Diagram of the fetal circulatory system, showing relative distribution of blood flow to the different vascular areas. The numerals represent the percentage of the total output from both sides of the heart flowing through each particular area.

the systemic vascular resistance at birth. This doubling of the systemic vascular resistance increases the aortic pressure, as well as the pressures in the left ventricle and left atrium.

Second, the *pulmonary vascular resistance greatly decreases* as a result of expansion of the lungs. In the unexpanded fetal lungs, the blood vessels are compressed because of the small volume of the lungs. Immediately on expansion, these vessels are no longer compressed, and the resistance to blood flow decreases severalfold. Also, in fetal life, the hypoxia of the lungs causes considerable tonic vasoconstriction of the lung blood vessels, but vasodilation takes place when aeration of the lungs eliminates the hypoxia. All these changes together reduce the resistance to blood flow through the lungs as much as 5-fold, which *reduces the pulmonary arterial pressure, right ventricular pressure,* and *right atrial pressure.*

Closure of the Foramen Ovale. The *low right atrial pressure* and the *high left atrial pressure* that occur secondarily to the changes in pulmonary and systemic resistances at birth cause blood to now attempt to flow backward through the foramen ovale, from the left atrium into the right atrium, rather than in the other direction, as occurred during fetal life. Consequently, the small valve that lies over the foramen ovale on the left side of the atrial septum closes over this opening, thereby preventing further flow through the foramen ovale.

In two-thirds of all people, the valve becomes adherent over the foramen ovale within a few months to a few years and forms a permanent closure. However, even if permanent closure does not occur—a condition called *patent foramen ovale*—throughout life the left atrial pressure normally remains 2 to 4 mm Hg greater than the right atrial pressure, and the backpressure keeps the valve closed.

Closure of the Ductus Arteriosus. The ductus arteriosus also closes, but for different reasons. First, the increased systemic resistance elevates the aortic pressure while the decreased pulmonary resistance reduces the pulmonary arterial pressure. As a consequence, after birth, blood begins to flow backward from the aorta into the pulmonary artery through the ductus arteriosus, rather than in the other direction, as in fetal life. However, after only a few hours, the muscle wall of the ductus arteriosus constricts markedly and, within 1 to 8 days, the constriction is usually sufficient to stop all blood flow. This is called *functional closure* of the ductus arteriosus. Then, during the next 1 to 4 months, the ductus arteriosus ordinarily becomes anatomically occluded by growth of fibrous tissue into its lumen.

The cause of ductus arteriosus closure relates to the increased oxygenation of the blood flowing through the ductus, as well as loss of the vascular relaxing effects of *prostaglandin E2* (PGE2). In fetal life, the partial pressure of oxygen (P_{O_2}) of the ductus blood is only 15 to 20 mm Hg, but it increases to about 100 mm Hg within a few hours after birth. Furthermore, experiments have shown that the degree of contraction of the smooth muscle in the ductus wall is highly related to this availability of oxygen.

In one of several thousand infants, the ductus fails to close, resulting in a *patent ductus arteriosus,* the consequences of which are discussed in Chapter 23. The failure of closure has been postulated to result from excessive ductus dilation caused by vasodilating prostaglandins, especially PGE2, in the ductus wall. In fact, administration of the drug *indomethacin,* which blocks synthesis of prostaglandins, often leads to closure.

Closure of the Ductus Venosus. In fetal life the portal blood from the fetus's abdomen joins the blood from the umbilical vein, and these together pass by way of the *ductus venosus* directly into the vena cava immediately below the heart but above the liver, thus bypassing the liver.

Immediately after birth, blood flow through the umbilical vein ceases, but most of the portal blood still flows through the ductus venosus, with only a small amount passing through the channels of the liver. However, within 1 to 3 hours the muscle wall of the ductus venosus contracts strongly and closes this avenue of flow. As a consequence, the portal venous pressure rises from near 0 to 6 to 10 mm Hg, which is enough to force portal venous blood flow through the liver sinuses. Although the ductus venosus rarely fails to close, the mechanisms that cause its closure are uncertain.

Nutrition of the Neonate

Before birth, the fetus derives almost all its energy from glucose obtained from the mother's blood. After birth, the amount of glucose stored in the infant's body in the form of liver and muscle glycogen is sufficient to supply the infant's needs for only a few hours. The liver of the neonate is still far from functionally adequate at birth, which prevents significant gluconeogenesis. Therefore, the infant's blood glucose concentration frequently falls the first day to as low as 30 to 40 mg/dl of plasma, which is less than half the normal value. Fortunately, appropriate mechanisms are available that allow the infant to use its stored fats and proteins

for metabolism until mother's milk can be provided 2 to 3 days later.

Special problems are also frequently associated with getting an adequate fluid supply to the neonate because the infant's rate of body fluid turnover averages seven times that of an adult, and the mother's milk supply requires several days to develop. Ordinarily, the infant's weight decreases 5% to 10% and sometimes as much as 20% within the first 2 to 3 days of life. Most of this weight loss is loss of fluid rather than of body solids.

Special Functional Problems in the Neonate

An important characteristic of the neonate is instability of the various hormonal and neurogenic control systems. This instability results partly from immature development of the different organs of the body and partly from the fact that the control systems simply have not become adjusted to the new way of life.

Respiratory System

The normal rate of respiration in a neonate is about 40 breaths per minute, and tidal air with each breath averages 16 ml, which results in a total minute respiratory volume of 640 ml/min—about twice as great in relation to the body weight as that of an adult. *The functional residual capacity of the infant's lungs is only one-half that of an adult in relation to body weight.* This difference causes excessive cyclical increases and decreases in the newborn baby's blood gas concentrations if the respiratory rate becomes slowed, because it is the residual air in the lungs that smooths out the blood gas variations.

Circulation

Blood Volume. The blood volume of a neonate immediately after birth averages about 300 ml, but if the infant is left attached to the placenta for a few minutes after birth or if the umbilical cord is stripped to force blood out of its vessels into the baby, an additional 75 ml of blood enters the infant, to make a total of 375 ml. Then, during the ensuing few hours, fluid is lost into the neonate's tissue spaces from this blood, which increases the hematocrit but returns the blood volume once again to the normal value of about 300 ml. Some pediatricians believe that this extra blood volume that results from stripping the umbilical cord can lead to mild pulmonary edema with some degree of respiratory distress, but the extra red blood cells may also be valuable to the infant.

Cardiac Output. The cardiac output of the neonate averages 500 ml/min, which, like respiration and body metabolism, is about twice as much in relation to body weight as in the adult. Occasionally a child is born with an especially low cardiac output caused by hemorrhage of much of its blood volume from the placenta at birth.

Arterial Pressure. The arterial pressure during the first day after birth averages about 70 mm Hg systolic and 50 mm Hg diastolic and increases slowly during the next several months to about 90/60 mm Hg. A much slower rise then occurs during the subsequent years until the adult pressure of 115/70 mm Hg is attained at adolescence.

Blood Characteristics. The red blood cell count in the neonate averages about 4 million per cubic millimeter. If blood is stripped from the cord into the infant, the red blood cell count rises an additional 0.5 to 0.75 million during the first few hours of life, giving a red blood cell count of about 4.75 million per cubic millimeter, as shown in Figure 84-6. Subsequently, however, few new red blood cells are formed in the infant during the first few weeks of life, presumably because the hypoxic stimulus of fetal life is no longer present to stimulate red blood cell production. Thus, as shown in Figure 84-6, the average red blood cell count falls to less than 4 million per cubic millimeter by about 6 to 8 weeks of age. From that time on, increasing activity by the baby provides the appropriate stimulus for the red blood cell count to return to normal within another 2 to 3 months. Immediately after birth, the white blood cell count of the neonate is approximately 45,000 per cubic millimeter, which is about five times as great as that of the normal adult.

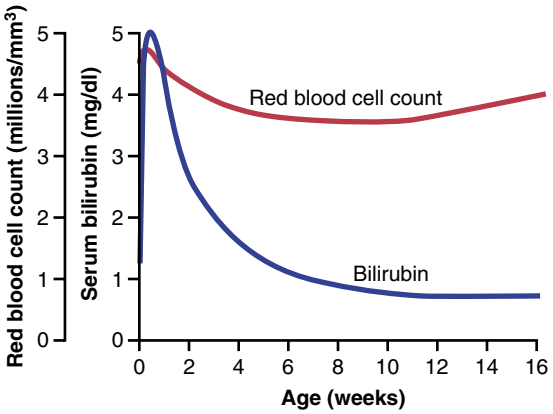

Figure 84-6. Changes in the red blood cell count and in serum bilirubin concentration during the first 16 weeks of life, showing physiological anemia at 6 to 12 weeks of life and physiological hyperbilirubinemia during the first 2 weeks of life.

Neonatal Jaundice and Erythroblastosis Fetalis. Bilirubin formed in the fetus can cross the placenta into the mother and be excreted through the liver of the mother. Immediately after birth, the only means for ridding the neonate of bilirubin is through the neonate's own liver, which for the first week or so of life functions poorly and is incapable of conjugating significant quantities of bilirubin with glucuronic acid for excretion into the bile. Consequently, the plasma bilirubin concentration rises from a normal value of less than 1 mg/dl to an average of 5 mg/dl during the first 3 days of life and then gradually falls back to normal as the liver becomes functional. This effect, called *physiological hyperbilirubinemia,* is shown in Figure 84-6, and it is associated with mild *jaundice* (yellowness) of the infant's skin and especially of the sclerae of its eyes for a week or two.

However, by far the most important abnormal cause of serious neonatal jaundice is *erythroblastosis fetalis,* which is discussed in detail in Chapters 33 and 36 in relation to Rh factor incompatibility between the fetus and mother. Briefly, the *erythroblastotic baby* inherits Rh-positive red blood cells from the father, while the mother is Rh-negative. The mother then becomes immunized against the Rh-positive factor (a protein) in the fetus's blood cells, and her antibodies destroy fetal red blood cells, releasing extreme quantities of bilirubin into the fetus's plasma and often causing

fetal death because of a lack of adequate red blood cells. Before the advent of modern obstetrical therapeutics, mild or serious cases of this condition occurred in 1 of every 50 to 100 neonates.

Fluid Balance, Acid–Base Balance, and Renal Function

The rate of fluid intake and fluid excretion in the newborn infant is seven times as great in relation to weight as in the adult, which means that alteration of even a slight percentage in fluid intake or fluid output can cause rapidly developing abnormalities.

The rate of metabolism in the infant is also twice as great in relation to body mass as in the adult, which means that twice as much acid is normally formed, creating a tendency toward acidosis in the infant. Functional development of the kidneys is not complete until the end of about the first month of life. For example, the kidneys of the neonate can concentrate urine to only 1.5 times the osmolality of the plasma, whereas the adult can concentrate the urine to three to four times the plasma osmolarity. Therefore, considering the immaturity of the kidneys, together with the marked fluid turnover in the infant and the rapid formation of acid, one can readily understand that among the most important problems of infancy are acidosis, dehydration, and, more rarely, overhydration.

Liver Function

During the first few days of life, liver function in the neonate may be quite deficient, as evidenced by the following effects:

1. The liver of the neonate conjugates bilirubin with glucuronic acid poorly and therefore excretes only a slight amount of bilirubin during the first few days of life.
2. Because the liver of the neonate is deficient in forming plasma proteins, the plasma protein concentration falls during the first weeks of life to 15% to 20% less than that for older children. Occasionally the protein concentration falls so low that hypoproteinemic edema develops.
3. The gluconeogenesis function of the neonate's liver is particularly deficient. As a result, the blood glucose level of the unfed neonate falls to about 30 to 40 mg/dl (≈40% of normal), and the infant must depend mainly on its stored fats for energy until sufficient feeding can occur.
4. The liver of the neonate usually also forms too little of the blood factors needed for normal blood coagulation.

Digestion, Absorption, and Metabolism of Energy Foods and Nutrition

In general, the ability of the neonate to digest, absorb, and metabolize foods is no different from that of the older child, with the following three exceptions:

1. *Secretion of pancreatic amylase in the neonate is deficient*, so the neonate uses starches less adequately than do older children.
2. *Absorption of fats from the gastrointestinal tract is somewhat less than that in the older child.* Consequently, milk with a high fat content, such as cow's milk, is often inadequately absorbed.
3. Because the liver functions imperfectly during at least the first week of life, *glucose concentration in the blood is unstable and low.*

The neonate is especially capable of synthesizing and storing proteins. Indeed, with an adequate diet, up to 90% of the ingested amino acids is used for formation of body proteins, which is a much higher percentage than in adults.

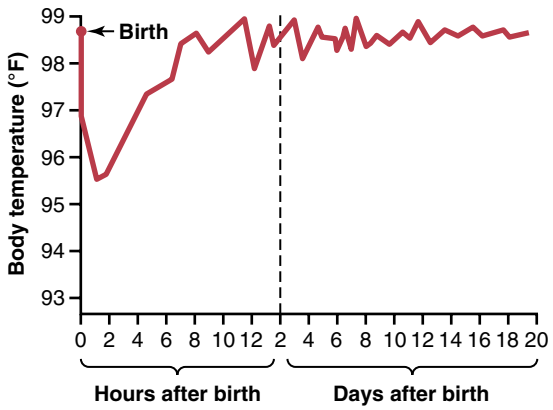

Figure 84-7. Fall in body temperature of the neonate immediately after birth, and instability of body temperature during the first few days of life.

Increased Metabolic Rate and Poor Body Temperature Regulation. The normal metabolic rate of the neonate in relation to body weight is about twice that of the adult, which also accounts for the fact that cardiac output and minute respiratory volume are twice as great in relation to body weight in the infant.

Because the body surface area is large in relation to body mass, heat is readily lost from the body. As a result, the body temperature of the neonate, particularly of premature infants, falls easily. Figure 84-7 shows that the body temperature of even a normal infant often falls several degrees during the first few hours after birth but returns to normal in 7 to 10 hours. Still, the body temperature regulatory mechanisms remain poor during the early days of life, allowing marked deviations in temperature, which are also shown in Figure 84-7.

Nutritional Needs During the Early Weeks of Life

At birth, a neonate is usually in complete nutritional balance, provided the mother has had an adequate diet. Furthermore, the function of the gastrointestinal system is usually more than adequate to digest and assimilate all the nutritional needs of the infant if appropriate nutrients are provided in the diet. However, three specific problems occur in the early nutrition of the infant.

Need for Calcium and Vitamin D. Because the neonate is in a stage of rapid ossification of its bones at birth, a ready supply of calcium throughout infancy is necessary. This is ordinarily supplied adequately by the usual diet of milk. However, absorption of calcium by the gastrointestinal tract is poor in the absence of vitamin D. Therefore, within only a few weeks, severe rickets can develop in infants who have vitamin D deficiency. This is particularly true in premature babies because their gastrointestinal tracts absorb calcium even less effectively than do those of normal infants.

Need for Iron in the Diet. If the mother has had adequate amounts of iron in her diet, the infant's liver usually has stored enough iron to keep forming blood cells for 4 to 6 months after birth. However, if the mother has had insufficient iron in her diet, severe anemia is likely to occur in the infant after about 3 months of life. To prevent this

possibility, early feeding of the infant with egg yolk, which contains reasonably large quantities of iron, or the administration of iron in some other form is desirable by the second or third month of life.

Vitamin C Deficiency in Infants. Ascorbic acid (vitamin C) is not stored in significant quantities in the fetal tissues, yet it is required for proper formation of cartilage, bone, and other intercellular structures of the infant. However, adequate amounts of vitamin C are normally provided in the mother's breast milk unless the mother has severe vitamin C deficiency. Cow's milk has only one-fourth as much vitamin C as human milk. In some cases, orange juice or other sources of ascorbic acid are prescribed for infants with vitamin C deficiency.

Immunity

The neonate inherits a great degree of immunity from the mother because many protein antibodies diffuse from the mother's blood through the placenta into the fetus. However, the neonate does not form antibodies of its own to a significant extent. By the end of the first month, the baby's gamma globulins, which contain the antibodies, have decreased to less than half the original level, with a corresponding decrease in immunity. Thereafter, the baby's own immune system begins to form antibodies, and the gamma globulin concentration returns essentially to normal by the age of 12 to 20 months.

Despite the decrease in gamma globulins soon after birth, the antibodies inherited from the mother protect the infant for about 6 months against most major childhood infectious diseases, including diphtheria, measles, and polio. Therefore, immunization against these diseases before 6 months is usually not necessary. However, the inherited antibodies against whooping cough are normally insufficient to protect the neonate; therefore, for full safety, the infant requires immunization against this disease beginning the second month or so of life. Health care professionals recommend that children receive five "shots" that combine vaccines for diphtheria, tetanus, and pertussis (DTaP) at 2, 4, 6, and 15 to 18 months, and then at 4 to 6 years of age.

Allergy. Newborn infants are seldom subject to allergies. Several months later, however, when the infant's own antibodies first begin to form, extreme allergic states can develop, sometimes resulting in serious eczema, gastrointestinal abnormalities, and even anaphylaxis. As the child grows older and still higher degrees of immunity develop, these allergic manifestations usually disappear. This relation of immunity to allergy is discussed in Chapter 35.

Endocrine Problems

Ordinarily, the endocrine system of the infant is highly developed at birth, and infants seldom exhibit any immediate endocrine abnormalities. However, the endocrinology of infancy is important in the following special circumstances:

1. If a pregnant mother bearing a female child is treated with an androgenic hormone or if an androgenic tumor develops during pregnancy, the child will be born with a high degree of masculinization of her sexual organs, thus resulting in a type of *hermaphroditism.*
2. The sex hormones secreted by the placenta and by the mother's glands during pregnancy occasionally cause the neonate's breasts to form milk during the first days of life. Sometimes the breasts then become inflamed, or *infectious mastitis* develops.
3. An infant born of an untreated diabetic mother will have considerable hypertrophy and hyperfunction of the islets of Langerhans in the pancreas. As a consequence, the infant's blood glucose concentration may fall to lower than 20 mg/dl shortly after birth. Fortunately, in the neonate—unlike in the adult—insulin shock or coma from this low level of blood glucose concentration only rarely develops. Maternal type 2 diabetes is the most common cause of large babies. Type 2 diabetes in the mother is associated with resistance to the metabolic effects of insulin and compensatory increases in plasma insulin concentration. The high levels of insulin are believed to stimulate fetal growth and contribute to increased birth weight. An increased supply of glucose and other nutrients to the fetus may also contribute to increased fetal growth. However, most of the increased fetal weight is due to increased body fat; there is usually little increase in body length, although the size of some organs may be increased *(organomegaly).* When a mother has uncontrolled type 1 diabetes (caused by lack of insulin secretion), fetal growth may be stunted because of metabolic deficits in the mother, and growth and tissue maturation of the neonate are often stunted. Also, there is a high rate of intrauterine mortality. Among the fetuses who do come to term, there is still a high mortality rate. Two-thirds of the infants who die succumb to *respiratory distress syndrome,* which is described earlier in this chapter.
4. Occasionally a child is born with hypofunctional adrenal cortices, often resulting from *agenesis* of the adrenal glands or *exhaustion atrophy*, which can occur when the adrenal glands have been vastly overstimulated.
5. If a pregnant woman has hyperthyroidism or is treated with excess thyroid hormone, the infant is likely to be born with a temporarily hyposecreting thyroid gland. Conversely, if before pregnancy a woman has had her thyroid gland removed, her pituitary gland may secrete great quantities of thyrotropin during gestation, and the child might be born with temporary hyperthyroidism.
6. In a fetus lacking thyroid hormone secretion, the bones grow poorly, and there is mental retardation, resulting in the condition called *cretin dwarfism,* which is discussed in Chapter 77.

Special Problems of Prematurity

All the problems in neonatal life just noted are severely exacerbated in prematurity. They can be categorized under the following two headings: (1) immaturity of certain organ systems and (2) instability of the different homeostatic control systems. Advances in medical care have greatly improved outcomes for preterm babies in recent years. The survival rate for "extremely preterm" (born at less than 28 weeks of gestation) infants is about 80% to 90% with modern medical care. However, with each week of shortened gestation below 28 weeks, the survival rate declines; at 22 weeks or less gestational age, the preterm baby rarely survives.

Immature Development of the Premature Infant

Almost all the organ systems of the body are immature in the premature infant and require particular attention if the life of the premature baby is to be saved.

Respiration. The respiratory system is especially likely to be underdeveloped in the extremely premature infant. The vital capacity and the functional residual capacity of the lungs are especially small in relation to the size of the infant. In addition, surfactant secretion is depressed or absent. As a consequence, *respiratory distress syndrome* is a common cause of death. Also, the low functional residual capacity in the premature infant is often associated with periodic breathing of the Cheyne-Stokes type.

Gastrointestinal Function. Another major problem of the premature infant is ingesting and absorbing adequate food. In infants who are more than 2 months premature, the digestive and absorptive systems are almost always inadequate. The absorption of fat is so poor that the premature infant must have a low-fat diet. Furthermore, because the absorption of calcium is unusually difficult in premature infants, severe rickets can develop before the difficulty is recognized. For this reason, special attention to adequate calcium and vitamin D intake is necessary.

Function of Other Organs. Immaturity of other organ systems that frequently causes serious difficulties in the premature infant includes (1) immaturity of the liver, which results in poor intermediary metabolism and often a bleeding tendency as a result of poor formation of coagulation factors; (2) immaturity of the kidneys, which are particularly deficient in their ability to rid the body of acids, thereby predisposing the infant to acidosis and to serious fluid balance abnormalities; (3) immaturity of the blood-forming mechanism of the bone marrow, which allows rapid development of anemia; and (4) depressed formation of gamma globulin by the lymphoid system, which often leads to serious infection.

Instability of the Homeostatic Control Systems in Premature Infants

Immaturity of the different organ systems in the premature infant creates a high degree of instability in the homeostatic mechanisms of the body. For example, the acid–base balance can vary tremendously, particularly when the rate of food intake varies from time to time. Likewise, the blood protein concentration is usually low because of immature liver development, often leading to *hypoproteinemic edema.* Inability of the infant to regulate its calcium ion concentration may bring on hypocalcemic tetany. Also, the blood glucose concentration can vary between the extremely wide limits of 20 to more than 100 mg/dl, depending principally on the regularity of feeding.

Instability of Body Temperature. One important problem of the premature infant is the inability to maintain a normal body temperature. The premature infant's temperature tends to approach that of its surroundings. At normal room temperature, the infant's temperature (in degrees Fahrenheit) may stabilize in the low 90s or even in the 80s. Studies show that a body temperature maintained below 96°F (35.5°C) is associated with a particularly high incidence of death, which explains the almost mandatory use of the incubator when treating prematurity.

Danger of Blindness Caused by Excess Oxygen Therapy in the Premature Infant

Because premature infants frequently experience respiratory distress, oxygen therapy has often been used to treat these infants. However, excess use of oxygen in treating premature infants, especially in early prematurity, can lead to blindness because too much oxygen stops the growth of new blood vessels in the retina. Then, when oxygen therapy is stopped, the blood vessels try to make up for lost time and burst forth with a great mass of vessels that grow all through the vitreous humor, blocking light from the pupil to the retina. Later, the vessels are replaced with a mass of fibrous tissue where the eye's clear vitreous humor should be located.

This condition, known as *retrolental fibroplasias,* causes permanent blindness. For this reason, it is particularly important to avoid treatment of premature infants with high concentrations of respiratory oxygen. Physiological studies indicate that premature infants are usually safe with up to 40% oxygen in the air breathed, but some child physiologists believe that complete safety can be achieved only at normal oxygen concentration in the air breathed.

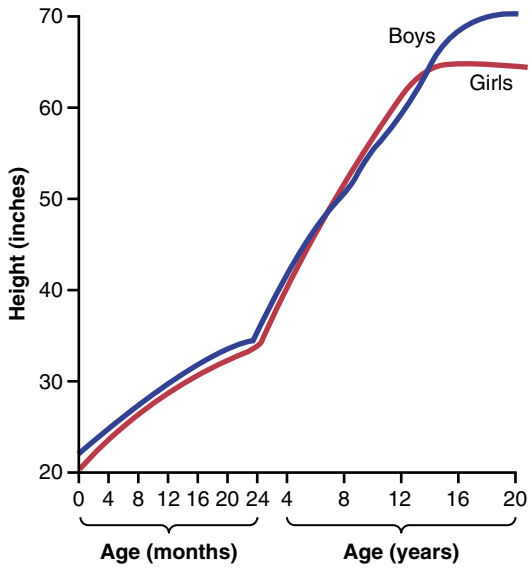

Figure 84-8. Average height of boys *(blue curve)* and girls *(red curve)* from infancy to 20 years of age.

Growth and Development of the Child

The major physiological problems of the child beyond the neonatal period are related to special metabolic needs for growth, which have been fully covered in the sections of this book on metabolism and endocrinology.

Figure 84-8 shows the changes in heights of boys and girls from the time of birth until the age of 20 years. Note especially that these heights parallel each other almost exactly until the end of the first decade of life. Between the ages of 11 and 13 years, the female estrogens begin to be formed and cause rapid growth in height but early uniting of the epiphyses of the long bones at about the 14th to 16th year of life, so growth in height then ceases. In contrast, the effect of testosterone in the male causes extra growth at a slightly later age—mainly between ages 13 and 17 years. The male, however, undergoes more prolonged growth because of delayed uniting of the epiphyses, so his final height is considerably greater than that of the female.

Behavioral Growth

Behavioral growth is principally related to maturity of the nervous system. It is difficult to dissociate maturity of the anatomical structures of the nervous system from maturity caused by training. Anatomical studies show that certain major tracts in the central nervous system are not completely myelinated until the end of the first year of life. For this reason, it is frequently stated that the nervous system is not fully functional at birth. The brain cortex and its associated functions, such as vision, seem to require several months after birth for final functional development to occur.

At birth, the infant brain mass is only 26% of the adult brain mass and 55% at 1 year, but it reaches almost adult proportions by the end of the second year. This process is also associated with closure of the fontanels and sutures of the skull, which allows only 20% additional growth of the brain beyond the first 2 years of life. **Figure 84-9** shows a normal progress chart for the infant during the first year of life. Comparison of this chart with the baby's actual development is used for clinical assessment of mental and behavioral growth.

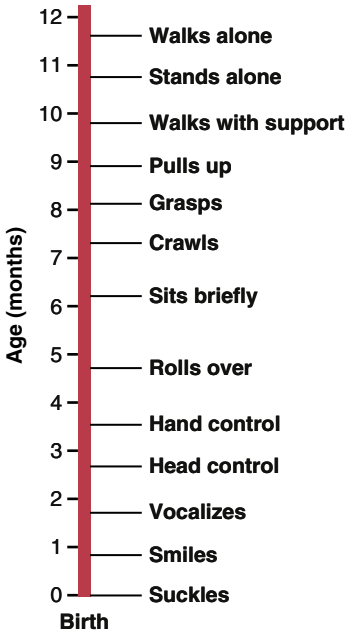

Figure 84-9. Behavioral development of the infant during the first year of life.

CHAPTER 85

UNIT XV

Sports Physiology

There are few stresses to which the body is exposed that approach the extreme stresses of heavy exercise. In fact, if some of the extremes of exercise were continued for even moderately prolonged periods, they might be lethal. Therefore, sports physiology is mainly a discussion of the ultimate limits to which several of the bodily mechanisms can be stressed. To give one simple example: In a person who has extremely high fever approaching the level of lethality, the body metabolism increases to about 100% above normal. By comparison, the metabolism of the body during a marathon race may increase to 2000% above normal.

Female and Male Athletes

Most of the quantitative data that are given in this chapter are for the young male athlete, not because it is desirable to know only these values, but because it is only in young male athletes that relatively complete measurements have been made. Measurements in older athletes and in females are much less complete. However, for measurements that have been made in the female athlete, similar basic physiological principles apply, except for quantitative differences caused by differences in body size, body composition, and the presence or absence of the male sex hormone testosterone.

In general, most quantitative values for women—such as muscle strength, pulmonary ventilation, and cardiac output, all of which are related mainly to the muscle mass—vary between two-thirds and three-quarters of the values recorded in men, although there are many exceptions to this generalization. When measured in terms of strength per square centimeter of cross-sectional area, the female muscle can achieve almost exactly the same maximal force of contraction as that of the male muscle—between 3 and 4 kg/cm^2. Therefore, most of the difference in total muscle performance lies in the extra percentage of the male body that is muscle, which is caused partly by endocrine differences that we will discuss later.

The performance capabilities of the female versus male athlete are illustrated by the relative running speeds for a marathon race. In a comparison, the top female performer had a running speed that was 11% less than that of the top male performer. For other events, however, women have at times held records faster than men—for example, for the two-way swim across the English Channel, for which the availability of extra fat seems to be an advantage for heat insulation, buoyancy, and extra long-term energy.

Testosterone secreted by the male testes has a powerful *anabolic effect* in causing greatly increased deposition of protein everywhere in the body, but especially in the muscles. In fact, even a male who participates in very little sports activity but who nevertheless has a normal level of testosterone will have muscles that grow about 40% larger than those of a comparable female without the testosterone.

The female sex hormone *estrogen* probably also accounts for some of the difference between female and male performance, although not nearly so much as testosterone. Estrogen increases the deposition of fat in the female, especially in the breasts, hips, and subcutaneous tissue. At least partly for this reason, the average young (age 16–19 years) nonathletic female has about 34% body fat composition, in contrast to the nonathletic young male (age 16–19 years), who has about 23% (**Figure 85-1**). The average percentages for body fat are higher in older men and women and have increased substantially over the past 20 to 30 years as the prevalence of obesity has risen in populations of most developed countries. In the United States, for example, the prevalence of obesity in now approximately 37% of the adult population. Increased body fat composition is a detriment to the highest levels of athletic performance in events in which performance depends on speed or on the ratio of total body muscle strength to body weight.

Muscles in Exercise

Strength, Power, and Endurance of Muscles

The final common determinant of success in athletic events is what the muscles can do for you—that is, what strength they can give when it is needed, what power they can achieve in the performance of work, and how long they can continue their activity.

The strength of a muscle is determined mainly by its size, with a *maximal contractile force between 3 and 4 kg/cm^2* of muscle cross-sectional area. Thus, a person who has enlarged his or her muscles through an exercise training program will have correspondingly increased muscle strength.

To give an example of muscle strength, a world-class male weight lifter might have a quadriceps muscle with a cross-sectional area as great as 150 square centimeters. This measurement would translate into a maximal contractile strength of 525 kilograms (or 1155 pounds), with all this force applied to the patellar tendon. Therefore, one

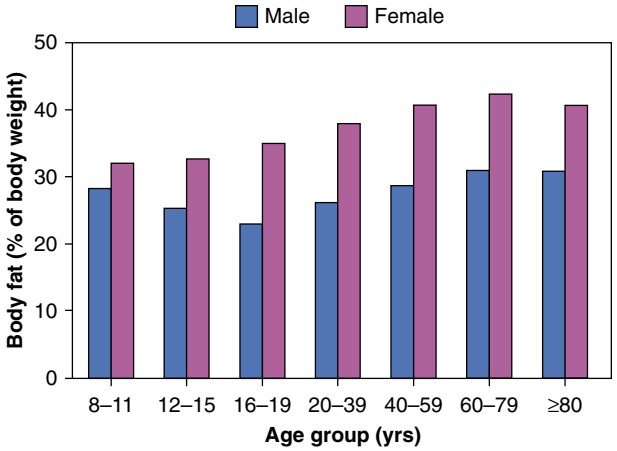

Figure 85-1 Average percentage body fat in males and females at different ages. *(Data from the National Health and Nutrition Examination Survey, United States, 1999–2004*).

can readily understand how it is possible for this tendon at times to be ruptured or actually to be avulsed from its insertion into the tibia below the knee. Also, when such forces occur in tendons that span a joint, similar forces are applied to the surfaces of the joint or sometimes to ligaments spanning the joints, thus accounting for such happenings as displaced cartilages, compression fractures about the joint, and torn ligaments.

The *holding strength* of muscles is about 40% greater than the contractile strength. That is, if a muscle is already contracted and a force then attempts to stretch out the muscle, as occurs when landing after a jump, this action requires about 40% more force than can be achieved by a shortening contraction. Therefore, the force of 525 kilograms previously calculated for the patellar tendon during muscle contraction becomes 735 kilograms (1617 pounds) during holding contractions, which further compounds the problems of the tendons, joints, and ligaments. It can also lead to internal tearing in the muscle. In fact, forceful stretching of a maximally contracted muscle is one of the surest ways to create the highest degree of muscle soreness.

Mechanical work performed by a muscle is the amount of force applied by the muscle multiplied by the distance over which the force is applied. The *power* of muscle contraction is different from muscle strength because power is a measure of the total amount of work that the muscle performs in a unit period of time. Power is therefore determined not only by the strength of muscle contraction but also by its *distance of contraction* and the *number of times that it contracts each minute.* Muscle power is generally measured in *kilogram meters (kg-m) per minute.* That is, a muscle that can lift 1-kilogram weight to a height of 1 meter or that can move some object laterally against a force of 1 kilogram for a distance of 1 meter in 1 minute is said to have a power of 1 kg-m/min. The maximal power achievable by all the muscles in the body of a highly trained athlete with all the muscles working together is approximately the following:

	kg-m/min
First 8 to 10 seconds	7000
Next 1 minute	4000
Next 30 minutes	1700

Thus, it is clear that a person has the capability of extreme power surges for short periods, such as during a 100-meter dash that is completed entirely within 10 seconds, whereas for long-term endurance events, the power output of the muscles is only one-fourth as great as during the initial power surge.

This does not mean that one's athletic performance is four times as great during the initial power surge as it is for the next 30 minutes, because the *efficiency* for translation of muscle power output into athletic performance is often much less during rapid activity than during less rapid but sustained activity. Thus, the velocity of the 100-meter dash is only 1.75 times as great as the velocity of a 30-minute race, despite the 4-fold difference in short-term versus long-term muscle power capability.

Another measure of muscle performance is *endurance.* Endurance, to a great extent, depends on the nutritive support for the muscle—more than anything else, it depends on the amount of glycogen that has been stored in the muscle before the period of exercise. A person who consumes a high-carbohydrate diet stores far more glycogen in muscles than does a person who consumes either a mixed diet or a high-fat diet. Therefore, endurance is enhanced by a high-carbohydrate diet. When athletes run at speeds typical for the marathon race, their endurance (as measured by the time that they can sustain the race until complete exhaustion) is approximately the following:

	Minutes
High-carbohydrate diet	240
Mixed diet	120
High-fat diet	85

The corresponding amounts of glycogen stored in the muscle before the race started explain these differences. The amounts stored are approximately the following:

	g/kg Muscle
High-carbohydrate diet	40
Mixed diet	20
High-fat diet	6

Muscle Metabolic Systems in Exercise

The same basic metabolic systems are present in muscle as in other parts of the body; these systems are discussed in detail in Chapters 68 through 74. However, special quantitative measures of the activities of three metabolic systems are exceedingly important in understanding the limits of physical activity. These systems are (1) *the phosphocreatine-creatine system,* (2) *the glycogen–lactic acid system,* and (3) *the aerobic system.*

Adenosine Triphosphate. The source of energy actually used to cause muscle contraction is adenosine triphosphate (ATP), which has the following basic formula:

$$\text{Adenosine} - PO_3 \sim PO_3 \sim PO_3^{-}$$

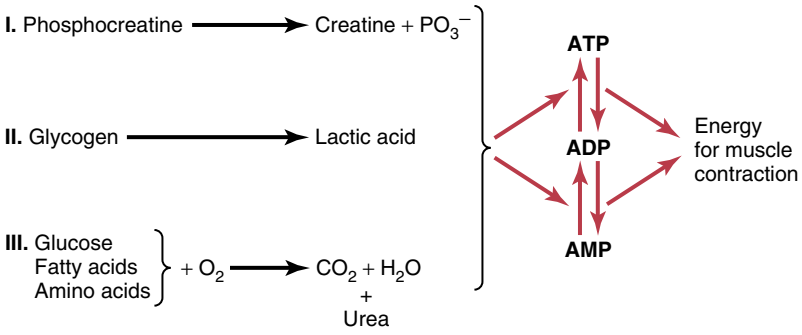

Figure 85-2 Important metabolic systems that supply energy for muscle contraction.

The bonds attaching the last two phosphate radicals to the molecule, designated by the symbol ~, are *high-energy phosphate bonds.* Each of these bonds stores 7300 calories of energy per mole of ATP under standard conditions (and even slightly more than this under the physical conditions in the body, which is discussed in detail in Chapter 68). Therefore, when one phosphate radical is removed, more than 7300 calories of energy are released to energize the muscle contractile process. Then, when the second phosphate radical is removed, still another 7300 calories become available. Removal of the first phosphate converts the ATP into *adenosine diphosphate* (ADP), and removal of the second converts this ADP into *adenosine monophosphate* (AMP).

The amount of ATP present in the muscles, even in a well-trained athlete, is sufficient to sustain maximal muscle power for only about 3 seconds, which might be enough for one half of a 50-meter dash. Therefore, except for a few seconds at a time, it is essential that new ATP be formed continuously, even during the performance of short athletic events. **Figure 85-2** shows the overall metabolic system, demonstrating the breakdown of ATP first to ADP and then to AMP, with release of energy to the muscles for contraction. The left-hand side of the figure shows the three metabolic systems that provide a continuous supply of ATP in the muscle fibers.

Phosphocreatine-Creatine System

Phosphocreatine (also called *creatine phosphate*) is another chemical compound that has a high-energy phosphate bond, with the following formula:

$$\text{Creatine} \sim PO_3^-$$

Phosphocreatine can decompose to *creatine* and *phosphate ion,* as shown in **Figure 85-2**, and in doing so releases large amounts of energy. In fact, the high-energy phosphate bond of phosphocreatine has more energy than the bond of ATP: 10,300 calories per mole compared with 7300 for the ATP bond. Therefore, phosphocreatine can easily provide enough energy to reconstitute the high-energy bond of ATP. Furthermore, most muscle cells have two to four times as much phosphocreatine as ATP.

A special characteristic of energy transfer from phosphocreatine to ATP is that it occurs within a small fraction of a second. Therefore, all the energy stored in muscle phosphocreatine is almost instantaneously available for muscle contraction, just as is the energy stored in ATP.

The combined amounts of cell ATP and cell phosphocreatine are called the *phosphagen energy system.* These substances together can provide maximal muscle power for 8 to 10 seconds, almost enough for the 100-meter run. *Thus, the energy from the phosphagen system is used for maximal short bursts of muscle power.*

Glycogen–Lactic Acid System. The stored glycogen in muscle can be split into glucose, and the glucose can then be used for energy. The initial stage of this process, called *glycolysis,* occurs without use of oxygen and, therefore, is said to be *anaerobic metabolism* (see Chapter 68). During glycolysis, each glucose molecule is split into two *pyruvic acid molecules,* and energy is released to form four ATP molecules for each original glucose molecule, as explained in Chapter 68. Ordinarily, the pyruvic acid then enters the mitochondria of muscle cells and reacts with oxygen to form still many more ATP molecules. However, when there is insufficient oxygen for this second stage (the oxidative stage) of glucose metabolism to occur, most of the pyruvic acid then is converted into *lactic acid,* which diffuses out of the muscle cells into the interstitial fluid and blood. Therefore, much of the muscle glycogen is transformed to lactic acid, but in doing so, considerable amounts of ATP are formed entirely without consumption of oxygen.

Another characteristic of the glycogen–lactic acid system is that it can form ATP molecules about 2.5 times as rapidly as can the oxidative mechanism of mitochondria. Therefore, when large amounts of ATP are required for short to moderate periods of muscle contraction, this anaerobic glycolysis mechanism can be used as a rapid source of energy. However, it is only about one-half as rapid as the phosphagen system. Under optimal conditions, the glycogen–lactic acid system can provide 1.3 to 1.6 minutes of maximal muscle activity in addition to the 8 to 10 seconds provided by the phosphagen system, although at somewhat reduced muscle power.

Aerobic System. The aerobic system is the oxidation of foodstuffs in the mitochondria to provide energy. As shown to the left in **Figure 85-2**, glucose, fatty acids, and amino acids from the foodstuffs—after some intermediate processing—combine with oxygen to release tremendous amounts of energy that are used to convert AMP and ADP into ATP, as discussed in Chapter 68.

In comparing this aerobic mechanism of energy supply with the glycogen–lactic acid system and the phosphagen system, the relative *maximal rates of power generation* in terms of moles of ATP generation per minute are the following:

	Moles of ATP/min
Phosphagen system	4
Glycogen–lactic acid system	2.5
Aerobic system	1

Table 85-1 Energy Systems Used in Various Sports

Aerobic System
10,000-meter skating
Cross-country skiing
Marathon run (26.2 miles, 42.2 kilometers)
Jogging

When comparing the same systems for endurance, the relative values are the following:

	Time
Phosphagen system	8-10 seconds
Glycogen–lactic acid system	1.3-1.6 minutes
Aerobic system	Unlimited time (as long as nutrients last)

Thus, one can readily see that the phosphagen system is used by the muscle for power surges of a few seconds, and the aerobic system is required for prolonged athletic activity. In between is the glycogen–lactic acid system, which is especially important for providing extra power during such intermediate races as 200- to 800-meter runs.

What Types of Sports Use Which Energy Systems? By considering the vigor of a sports activity and its duration, one can estimate closely which of the energy systems is used for each activity. Various approximations are presented in Table 85-1.

Recovery of Muscle Metabolic Systems After Exercise. In the same way that energy from phosphocreatine can be used to reconstitute ATP, energy from the glycogen–lactic acid system can be used to reconstitute phosphocreatine and ATP. Energy from the oxidative metabolism of the aerobic system can then be used to reconstitute all the other systems—the ATP, phosphocreatine, and glycogen–lactic acid systems.

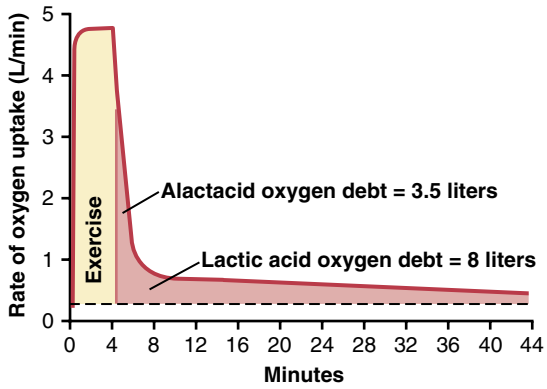

Figure 85-3 Rate of oxygen uptake by the lungs during maximal exercise for 4 minutes and then for about 40 minutes after the exercise is over. This figure demonstrates the principle of *oxygen debt*.

Reconstitution of the lactic acid system means mainly the removal of the excess lactic acid that has accumulated in the body fluids. Removal of the excess lactic acid is especially important because buildup of lactic acid contributes to fatigue and the "burning" sensation in active muscles during intense exercise. When adequate amounts of energy are available from oxidative metabolism, removal of lactic acid is achieved in two ways: (1) A small portion of it is converted back into pyruvic acid and then metabolized oxidatively by the body tissues, and (2) the remaining lactic acid is reconverted into glucose mainly in the liver, and the glucose in turn is used to replenish the glycogen stores of the muscles.

Recovery of the Aerobic System After Exercise. Even during the early stages of heavy exercise, a portion of one's aerobic energy capability is depleted. This depletion results from two effects: (1) the so-called *oxygen debt* and (2) *depletion of glycogen stores* of the muscles.

Oxygen Debt. The body normally contains about 2 liters of stored oxygen that can be used for aerobic metabolism even without breathing any new oxygen. This stored oxygen consists of the following: (1) 0.5 liter in the air of the lungs, (2) 0.25 liter dissolved in the body fluids, (3) 1 liter combined with the hemoglobin of the blood, and (4) 0.3 liter stored in the muscle fibers, combined mainly with myoglobin, an oxygen-binding chemical similar to hemoglobin.

In heavy exercise, almost all this stored oxygen is used within a minute or so for aerobic metabolism. Then, after the exercise is over, this stored oxygen must be replenished by breathing extra amounts of oxygen over and above the normal requirements. In addition, about 9 liters more oxygen must be consumed to reconstitute the phosphagen system and the lactic acid system. All this extra oxygen that must be "repaid," about 11.5 liters, is called *the oxygen debt.*

Figure 85-3 shows this principle of oxygen debt. During the first 4 minutes, as depicted in the figure, the person exercises heavily, and the rate of oxygen uptake increases more than 15-fold. Then, even after the exercise is over, the oxygen uptake still remains above normal; at first it is very high while the body is reconstituting the phosphagen system and repaying the stored oxygen portion of the oxygen debt, and then it is still above normal although at a lower level for another 40 minutes while the lactic acid

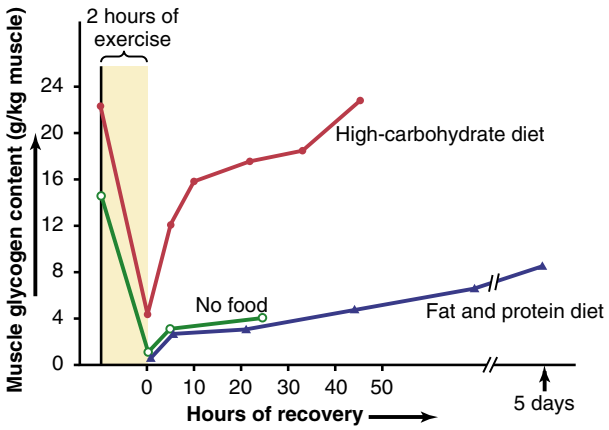

Figure 85-4 The effect of diet on the rate of muscle glycogen replenishment after prolonged exercise. *(Modified from Fox EL: Sports Physiology. Philadelphia: Saunders College Publishing, 1979.)*

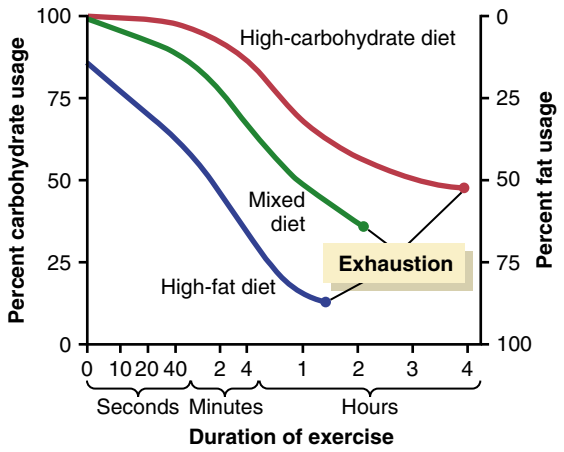

Figure 85-5 The effect of duration of exercise, as well as type of diet, on relative percentages of carbohydrate or fat used for energy by muscles. *(Data from Fox EL: Sports Physiology. Philadelphia: Saunders College Publishing, 1979.)*

is removed. The early portion of the oxygen debt is called the *alactacid oxygen debt* and amounts to about 3.5 liters. The latter portion is called the *lactic acid oxygen debt* and amounts to about 8 liters.

Recovery of Muscle Glycogen. Recovery from exhaustive muscle glycogen depletion is not a simple matter. This process often requires days, rather than the seconds, minutes, or hours required for recovery of the phosphagen and lactic acid metabolic systems. Figure 85-4 shows this recovery process under three conditions: (1) in people who consume a high-carbohydrate diet; (2) in people who consume a high-fat, high-protein diet; and (3) in people who consume no food. Note that for persons who consume a high-carbohydrate diet, full recovery occurs in about 2 days. Conversely, people who consume a high-fat, high-protein diet or no food at all show very little recovery, even after as long as 5 days. The messages of this comparison are (1) it is important for athletes to consume a high-carbohydrate diet before a grueling athletic event and (2) athletes should not participate in exhaustive exercise during the 48 hours preceding the event.

Nutrients Used During Muscle Activity

In addition to the use of a large amount of carbohydrates by the muscles during exercise, especially during the early stages of exercise, muscles use large amounts of fat for energy in the form of *fatty acids* and *acetoacetic acid* (see Chapter 69), as well as (to a much less extent) proteins in the form of *amino acids.* In fact, even under the best conditions, in endurance athletic events that last longer than 4 to 5 hours, the glycogen stores of the muscle become almost totally depleted and are of little further use for energizing muscle contraction. Instead, the muscle now depends on energy from other sources, mainly from fats.

Figure 85-5 shows the approximate relative usage of carbohydrates and fat for energy during prolonged exhaustive exercise under three dietary conditions: a high-carbohydrate diet, a mixed diet, and a high-fat diet. Note that most of the energy is derived from carbohydrates during the first few seconds or minutes of the exercise, but at the time of exhaustion, as much as 60% to 85% of the energy is being derived from fats rather than carbohydrates.

Not all the energy from carbohydrates comes from the stored *muscle* glycogen. In fact, almost as much glycogen is stored in the *liver* as in the muscles, and this glycogen can be released into the blood in the form of glucose and then taken up by the muscles as an energy source. In addition, glucose solutions given to an athlete to drink during the course of an athletic event can provide as much as 30% to 40% of the energy required during prolonged events such as marathon races.

Therefore, if muscle glycogen and blood glucose are available, they are the energy nutrients of choice for intense muscle activity. Even so, for a long-term endurance event, one can expect fat to supply more than 50% of the required energy after about the first 3 to 4 hours.

Effect of Athletic Training on Muscles and Muscle Performance

Maximal Resistance Training Increases Muscle Strength. One of the cardinal principles of muscle development during athletic training is the following: Muscles that function under no load, even if they are exercised for hours on end, increase little in strength. At the other extreme, muscles that contract at more than 50% maximal force of contraction will develop strength rapidly even if the contractions are performed only a few times each day. Using this principle, experiments on muscle building have shown that *six nearly maximal muscle contractions performed in three sets 3 days a week give approximately optimal increase in muscle strength without producing chronic muscle fatigue.*

The upper curve in Figure 85-6 shows the approximate percentage increase in strength that can be achieved in a previously untrained young person by this resistive training program, demonstrating that the muscle strength increases about 30% during the first 6 to 8 weeks but almost plateaus after that time. Along with this increase in strength is an approximately equal percentage increase in muscle mass, which is called *muscle hypertrophy.*

In old age, many people become so sedentary that their muscles atrophy tremendously. In these cases, however, muscle training may increase muscle strength more than 100%.

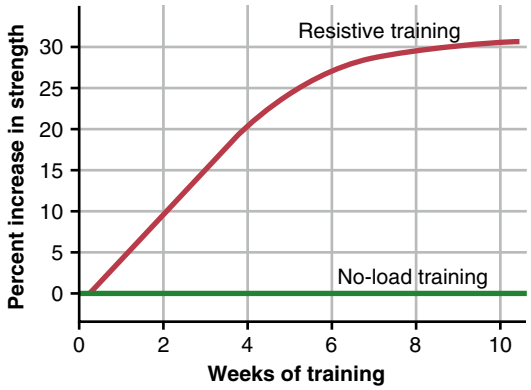

Figure 85-6 Approximate effect of optimal resistive exercise training on increase in muscle strength over a training period of 10 weeks.

Muscle Hypertrophy. The average size of a person's muscles is determined to a great extent by heredity plus the level of testosterone secretion, which, in men, causes considerably larger muscles than in women. With training, however, the muscles can become hypertrophied perhaps an additional 30% to 60%. Most of this hypertrophy results from increased diameter of the muscle fibers rather than increased numbers of fibers. However, a very few greatly enlarged muscle fibers are believed to split down the middle along their entire length to form entirely new fibers, thus increasing the number of fibers slightly.

The changes that occur inside the hypertrophied muscle fibers include (1) increased numbers of myofibrils, proportionate to the degree of hypertrophy; (2) up to 120% increase in mitochondrial enzymes; (3) as much as 60% to 80% increase in the components of the phosphagen metabolic system, including ATP and phosphocreatine; (4) as much as 50% increase in stored glycogen; and (5) as much as 75% to 100% increase in stored triglyceride (fat). Because of all these changes, the capabilities of both the anaerobic and the aerobic metabolic systems are increased, especially increasing the maximum oxidation rate and efficiency of the oxidative metabolic system as much as 45%.

Fast-Twitch and Slow-Twitch Muscle Fibers. In the human being, all muscles have varying percentages of *fast-twitch* and *slow-twitch muscle fibers.* For example, the gastrocnemius muscle has a higher preponderance of fast-twitch fibers, which gives it the capability of forceful and rapid contraction of the type used in jumping. In contrast, the soleus muscle has a higher preponderance of slow-twitch muscle fibers, and therefore is used to a greater extent for prolonged lower leg muscle activity.

The basic differences between the fast-twitch and the slow-twitch fibers are the following:

1. Fast-twitch fibers are about twice as large in diameter compared with slow-twitch fibers.
2. The enzymes that promote rapid release of energy from the phosphagen and glycogen–lactic acid energy systems are two to three times as active in fast-twitch fibers as in slow-twitch fibers, thus making the maximal power that can be achieved for very short periods by fast-twitch fibers about twice as great as that of slow-twitch fibers.
3. Slow-twitch fibers are mainly organized for endurance, especially for generation of aerobic energy. They have far more mitochondria than do the fast-twitch fibers. In addition, they contain considerably more *myoglobin*, a hemoglobin-like protein that combines with oxygen within the muscle fiber; the extra myoglobin increases the rate of diffusion of oxygen throughout the fiber by shuttling oxygen from one molecule of myoglobin to the next. In addition, the enzymes of the aerobic metabolic system are considerably more active in slow-twitch fibers than in fast-twitch fibers.
4. The number of capillaries is greater in the vicinity of slow-twitch fibers than in the vicinity of fast-twitch fibers.

In summary, fast-twitch fibers can deliver extreme amounts of power for a few seconds to a minute or so. Conversely, slow-twitch fibers provide endurance, delivering prolonged strength of contraction over many minutes to hours.

Hereditary Differences Among Athletes for Fast-Twitch Versus Slow-Twitch Muscle Fibers. Some people have considerably more fast-twitch than slow-twitch fibers, and others have more slow-twitch fibers; this factor could determine to some extent the athletic capabilities of different individuals. Athletic training may change the relative proportions of fast-twitch and slow-twitch fibers as much as 10%. However, the relative proportions of fast-twitch and slow-twitch fibers seem to be determined to a great extent by genetic inheritance, which in turn helps determine which area of athletics is most suited to each person: some people appear to be born to be marathoners, whereas others are born to be sprinters and jumpers. For example, the following values are recorded percentages of fast-twitch versus slow-twitch fiber in the quadriceps muscles of different types of athletes:

	Fast-Twitch Fiber	Slow-Twitch Fiber
Marathoners	18	82
Swimmers	26	74
Average male	55	45
Weight lifters	55	45
Sprinters	63	37
Jumpers	63	37

Respiration in Exercise

Although one's respiratory ability is of relatively little concern in the performance of sprint types of athletics, it is critical for maximal performance in endurance athletics.

Oxygen Consumption and Pulmonary Ventilation in Exercise. Normal oxygen consumption for a young man at rest is about 250 ml/min. However, under maximal conditions, this consumption can be increased to approximately the following average levels:

	ml/min
Untrained average male	3600
Athletically trained average male	4000
Male marathon runner	5100

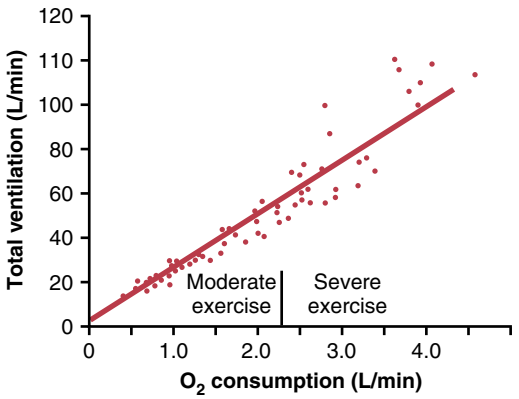

Figure 85-7 Effect of exercise on oxygen consumption and ventilatory rate. *(Modified from Gray JS: Pulmonary Ventilation and Its Physiological Regulation. Springfield, IL: Charles C Thomas, 1950.)*

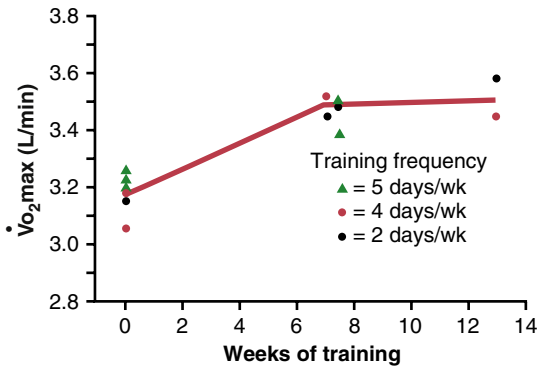

Figure 85-8 Increase in $\dot{V}O_2$max over a period of 7 to 13 weeks of athletic training. *(Modified from Fox EL: Sports Physiology. Philadelphia: Saunders College Publishing, 1979.)*

Figure 85-7 shows the relation between *oxygen consumption* and *total pulmonary ventilation* at different levels of exercise. As would be expected, there is a linear relation. Both oxygen consumption and total pulmonary ventilation increase about 20-fold between the resting state and maximal intensity of exercise *in the well-trained athlete.*

Limits of Pulmonary Ventilation. How severely do we stress our respiratory systems during exercise? This question can be answered by the following comparison for a normal young man:

	L/min
Pulmonary ventilation at maximal exercise	100–110
Maximal breathing capacity	150–170

Thus, the maximal breathing capacity is about 50% greater than the actual pulmonary ventilation during maximal exercise. This difference provides an element of safety for athletes, giving them extra ventilation that can be called on in such conditions as (1) exercise at high altitudes, (2) exercise under very hot conditions, and (3) abnormalities in the respiratory system.

The important point is *that the respiratory system is not normally the most limiting factor in the delivery of oxygen to the muscles during maximal muscle aerobic metabolism.* We shall see shortly that the ability of the heart to pump blood to the muscles is usually a greater limiting factor.

Effect of Training on $\dot{V}O_2$max. The abbreviation for the rate of oxygen usage (in L/min) under maximal aerobic metabolism is $\dot{V}O_2$max . Figure 85-8 shows the progressive effect of athletic training on $\dot{V}O_2$max recorded in a group of subjects beginning at the level of no training and then while pursuing the training program for 7 to 13 weeks. In this study, it is surprising that the $\dot{V}O_2$max increased only about 10%. Furthermore, the frequency of training, whether two times or five times per week, had little effect on the increase in $\dot{V}O_2$max. Yet, as pointed out earlier, the $\dot{V}O_2$max of a marathoner is about 45% greater than that of an untrained person. Part of this greater $\dot{V}O_2$max of the marathoner may be genetically determined; that is, people who have greater chest sizes in relation to body size and stronger respiratory muscles may select themselves to become marathoners. However, it is also likely that many years of training increase the marathoner's $\dot{V}O_2$max by values considerably greater than the 10% that has been recorded in short-term experiments such as that in Figure 85-8.

Oxygen-Diffusing Capacity of Athletes. The *oxygen-diffusing capacity* is a measure of the rate at which oxygen can diffuse from the pulmonary alveoli into the blood. This capacity is expressed in terms of *milliliters of oxygen that will diffuse each minute for each millimeter of mercury difference between alveolar partial pressure of oxygen and pulmonary blood oxygen pressure.* That is, if the partial pressure of oxygen in the alveoli is 91 mm Hg and the oxygen pressure in the blood is 90 mm Hg, the amount of oxygen that diffuses through the respiratory membrane each minute is equal to the diffusing capacity. The following values are measured values for different diffusing capacities:

	ml/min
Nonathlete at rest	23
Nonathlete during maximal exercise	48
Speed skater during maximal exercise	64
Swimmer during maximal exercise	71
Oarsman during maximal exercise	80

The most startling fact about these results is the severalfold increase in diffusing capacity between the resting state and the state of maximal exercise. This finding results mainly from the fact that blood flow through many of the pulmonary capillaries is sluggish or even dormant in the resting state, whereas in maximal exercise, increased blood flow through the lungs causes all the pulmonary capillaries to be perfused at their maximal rates, thus providing a far greater surface area through which oxygen can diffuse into the pulmonary capillary blood.

It is also clear from these values that athletes who require greater amounts of oxygen per minute have higher diffusing capacities. Is this the case because people with naturally greater diffusing capacities choose these types of sports, or is it because something about the training procedures increases the diffusing capacity? The answer is uncertain, but it is very likely that training, particularly endurance training, does play an important role.

Blood Gases During Exercise. Because of the great oxygen usage by the muscles in exercise, one might expect the oxygen pressure of the arterial blood to decrease markedly during strenuous athletics and the carbon dioxide pressure of the venous blood to increase far above normal. However, this normally is not the case. Both of these values remain nearly normal, demonstrating the extreme ability of the respiratory system to provide adequate aeration of the blood, even during heavy exercise.

This demonstrates another important point: *The blood gases do not always have to become abnormal for respiration to be stimulated in exercise.* Instead, respiration is stimulated mainly by neurogenic mechanisms during exercise, as discussed in Chapter 42. Part of this stimulation results from direct stimulation of the respiratory center by the same nervous signals that are transmitted from the brain to the muscles to cause the exercise. An additional part is believed to result from sensory signals transmitted into the respiratory center from the contracting muscles and moving joints. All this extra nervous stimulation of respiration is normally sufficient to provide the necessary increase in pulmonary ventilation required to keep the blood oxygen and carbon dioxide very near to normal.

Effect of Smoking on Pulmonary Ventilation in Exercise. It is widely known that smoking can decrease an athlete's "wind." This is true for many reasons:

1. One effect of nicotine is constriction of terminal bronchioles of the lungs, which increases the resistance of airflow into and out of the lungs.
2. The irritating effects of smoke cause increased fluid secretion into the bronchial tree, as well as some swelling of the epithelial linings.
3. Nicotine paralyzes the cilia on the surfaces of respiratory epithelial cells that normally beat continuously to remove excess fluids and foreign particles from the respiratory passageways. As a result, much debris accumulates in the passageways and adds further to the difficulty of breathing.

After putting all these factors together, even a light smoker often feels respiratory strain during maximal exercise, and the level of performance may be reduced.

Much more severe are the effects of chronic smoking. There are few chronic smokers in whom some degree of emphysema does not develop. In this disease, the following mechanisms occur: (1) chronic bronchitis, (2) obstruction of many of the terminal bronchioles, and (3) destruction of many alveolar walls. In persons with severe emphysema, as much as four-fifths of the respiratory membrane can be destroyed; then even the slightest exercise can cause respiratory distress. In fact, many such patients cannot even perform the simple feat of walking across the floor of a single room without gasping for breath.

Cardiovascular System in Exercise

Muscle Blood Flow. A key requirement of cardiovascular function in exercise is to deliver the required oxygen and other nutrients to the exercising muscles. For this purpose, the muscle blood flow increases drastically during exercise. **Figure 85-9** shows a recording of muscle blood flow in the calf of a person for a period of 6 minutes during moderately strong intermittent contractions. Note not only the great increase in flow—about 13-fold—but also the flow decrease during each muscle contraction. Two points can be made from this study:

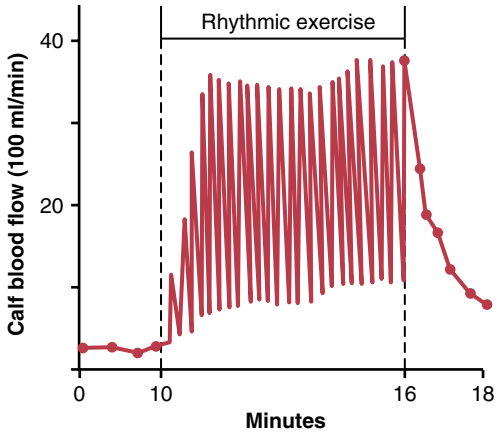

Figure 85-9 Effects of muscle exercise on blood flow in the calf of a leg during strong rhythmic contractions. The blood flow was much less during contraction than between contractions. *(Modified from Barcroft J, Dornhorst AC: The blood flow through the human calf during rhythmic exercise, J Physiol 109:402, 1949.)*

1. The actual contractile process itself temporarily decreases muscle blood flow because the contracting skeletal muscle compresses the intramuscular blood vessels; therefore, strong *tonic* muscle contractions can cause rapid muscle fatigue because of lack of delivery of enough oxygen and other nutrients during the continuous contraction.
2. The blood flow to muscles during exercise increases markedly. The following comparison shows the maximal increase in blood flow that can occur in a well-trained athlete:

	ml/100 g Muscle/min
Resting blood flow	3.6
Blood flow during maximal exercise	90

Thus, muscle blood flow can increase a maximum of about 25-fold during the most strenuous exercise. Almost one-half this increase in flow results from intramuscular vasodilation caused by the direct effects of increased muscle metabolism, as explained in Chapter 21. The remaining increase results from multiple factors, the most important of which is probably the moderate increase in arterial blood pressure that occurs in exercise, which is usually about a 30% increase. The increase in pressure not only forces more blood through the blood vessels but also stretches the walls of the arterioles and further reduces vascular resistance. Therefore, a 30% increase in blood pressure can often more than double the blood flow, which multiplies the great increase in flow already caused by the metabolic vasodilation at least another 2-fold.

Work Output, Oxygen Consumption, and Cardiac Output During Exercise. **Figure 85-10** shows the interrelations among work output, oxygen consumption, and cardiac output during exercise. It is not surprising that all these factors are directly related to one another, as shown by the linear functions, because the muscle work output increases oxy-

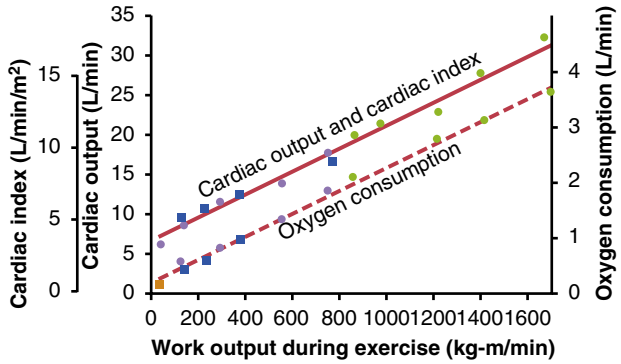

Figure 85-10 Relation between cardiac output and work output *(solid line)* and between oxygen consumption and work output *(dashed line)* during different levels of exercise. The different *colored dots* and *squares* show data derived from different studies in humans. *(Modified from Guyton AC, Jones CE, Coleman TB: Circulatory Physiology: Cardiac Output and Its Regulation. Philadelphia: WB Saunders, 1973.)*

gen consumption, and increased oxygen consumption in turn dilates the muscle blood vessels, thus increasing venous return and cardiac output. Typical cardiac outputs at several levels of exercise are as follows:

	L/min
Cardiac output in a young man at rest	5.5
Maximal cardiac output during exercise in a young untrained man	23
Maximal cardiac output during exercise in an average male marathoner	30

Thus, the normal untrained person can increase cardiac output a little over 4-fold, and the well-trained athlete can increase output about 6-fold. Cardiac outputs as great as 35 to 40 L/min, or seven to eight times normal resting output, have been measured in individual marathoners.

Effect of Training on Heart Hypertrophy and on Cardiac Output. From the foregoing data, it is clear that marathoners can achieve maximal cardiac outputs that are about 40% greater than those achieved by untrained persons. This results mainly from the fact that the heart chambers of marathoners enlarge about 40%; along with this enlargement of the chambers, the heart mass also increases 40% or more. Therefore, not only do the skeletal muscles hypertrophy during athletic training, but so does the heart. However, heart enlargement and increased pumping capacity occur mainly in the endurance types, not in the sprint types, of athletic training.

Even though the heart of the marathoner is considerably larger than that of the normal person, resting cardiac output is almost exactly the same as that in a normal person. However, this normal cardiac output is achieved by a large stroke volume at a reduced heart rate. Table 85-2 compares stroke volume and heart rate in the untrained person and the marathoner.

Thus, the heart-pumping effectiveness of each heartbeat is 40% to 50% greater in the highly trained athlete than in the untrained person, but there is a corresponding decrease in the heart rate at rest.

Table 85-2 Comparison of Cardiac Function Between Marathoner and Nonathlete

Type of Athlete	Stroke Volume (ml)	Heart Rate (beats/min)
Resting		
Nonathlete	75	75
Marathoner	105	50
Maximum		
Nonathlete	110	195
Marathoner	162	185

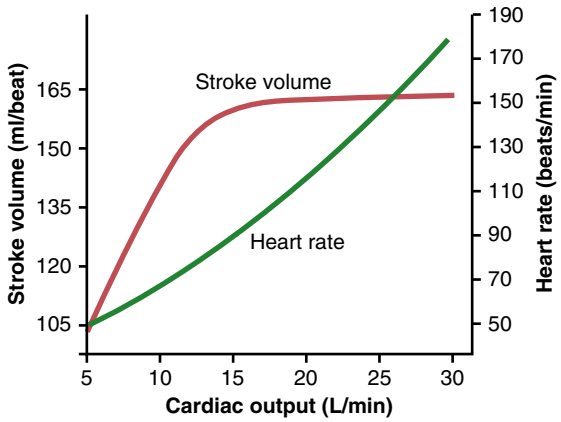

Figure 85-11 Approximate stroke volume output and heart rate at different levels of cardiac output in a marathon athlete.

Role of Stroke Volume and Heart Rate in Increasing Cardiac Output. Figure 85-11 shows the approximate changes in stroke volume and heart rate as the cardiac output increases from its resting level of about 5.5 L/min to 30 L/min in the marathon runner. The *stroke volume* increases from 105 to 162 ml, an increase of about 50%, whereas the heart rate increases from 50 to 185 beats/min, an increase of 270%. Therefore, the heart rate increase by far accounts for a greater proportion of the increase in cardiac output than does the increase in stroke volume during sustained strenuous exercise. The stroke volume normally reaches its maximum by the time the cardiac output has increased only halfway to its maximum. Any further increase in cardiac output must occur by increasing the heart rate.

Relation of Cardiovascular Performance to $\dot{V}o_2max$. During maximal exercise, both the heart rate and stroke volume are increased to about 95% of their maximal levels. Because the cardiac output is equal to stroke volume *times* heart rate, the cardiac output is about 90% of the maximum that the person can achieve, which is in contrast to about 65% of maximum for pulmonary ventilation. Therefore, one can readily see that the cardiovascular system is normally much more limiting on $\dot{V}o_2max$ than is the respiratory system because oxygen utilization by the body can never be more than the rate at which the cardiovascular system can transport oxygen to the tissues.

For this reason, it is frequently stated that the level of athletic performance that can be achieved by the marathoner mainly depends on the performance capability of his or

her heart, because this is the most limiting link in the delivery of adequate oxygen to the exercising muscles. Therefore, the 40% greater cardiac output that the marathoner can achieve over the average untrained male is probably the single most important physiological benefit of the marathoner's training program.

Effect of Heart Disease and Old Age on Athletic Performance. Because of the critical limitation that the cardiovascular system places on maximal performance in endurance athletics, one can readily understand that any type of heart disease that reduces maximal cardiac output will cause an almost corresponding decrease in achievable total body muscle power. Therefore, a person with congestive heart failure frequently has difficulty achieving even the muscle power required to climb out of bed, much less to walk across the floor.

The maximal cardiac output of older people also decreases considerably; there is as much as a 50% decrease between ages 18 and 80 years. Also, there is even more of a decrease in maximal breathing capacity. For these reasons, as well as because of reduced skeletal muscle mass, the maximal achievable muscle power is greatly reduced in old age.

Body Heat in Exercise

Almost all the energy released by the body's metabolism of nutrients is eventually converted into body heat. This applies even to the energy that causes muscle contraction for the following reasons: First, the maximal efficiency for conversion of nutrient energy into muscle work, even under the best of conditions, is only 20% to 25%; the remainder of the nutrient energy is converted into heat during the course of the intracellular chemical reactions. Second, almost all the energy that does go into creating muscle work still becomes body heat because all but a small portion of this energy is used for (1) overcoming viscous resistance to the movement of the muscles and joints, (2) overcoming the friction of the blood flowing through the blood vessels, and (3) other, similar effects, all of which convert the muscle contractile energy into heat.

Now, recognizing that the oxygen consumption by the body can increase as much as 20-fold in the well-trained athlete and that the amount of heat liberated in the body is almost exactly proportional to the oxygen consumption (as discussed in Chapter 73), one quickly realizes that tremendous amounts of heat are injected into the internal body tissues when performing endurance athletic events. Next, with a vast rate of heat flow into the body, on a very hot and humid day that prevents the sweating mechanism from eliminating the heat, an intolerable and even lethal condition called *heatstroke* can develop in the athlete.

Heatstroke. During endurance athletics, even under normal environmental conditions, the body temperature often rises from its normal level of 98.6°F to 102°F or 103°F (37°C to 40°C). With very hot and humid conditions or excess clothing, the body temperature can rise to 106°F to 108°F (41°C to 42°C). At this level, the elevated temperature becomes destructive to tissue cells, especially the brain cells. When this phenomenon occurs, multiple symptoms begin to appear, including extreme weakness, exhaustion, headache, dizziness, nausea, profuse sweating, confusion, staggering gait, collapse, and unconsciousness.

This entire complex is called *heatstroke,* and failure to treat it immediately can lead to death. In fact, even though the person has stopped exercising, the temperature does not easily decrease, partly because at these high temperatures, the temperature-regulating mechanism often fails (see Chapter 74). A second reason is that in heatstroke, the very high body temperature approximately doubles the rates of all intracellular chemical reactions, thus liberating still more heat.

The treatment of heatstroke is to reduce the body temperature as rapidly as possible. The most practical way to reduce the body temperature is to remove all clothing, maintain a spray of cool water on all surfaces of the body or continually sponge the body, and blow air over the body with a fan. Experiments have shown that this treatment can reduce the temperature either as rapidly or almost as rapidly as any other procedure, although some physicians prefer total immersion of the body in water containing a mush of crushed ice, if available.

Body Fluids and Salt in Exercise

As much as a 5- to 10-pound weight loss has been recorded in athletes in a period of 1 hour during endurance athletic events under hot and humid conditions. Essentially all this weight loss results from loss of sweat. Loss of enough sweat to decrease body weight only 3% can significantly diminish a person's performance, and a 5% to 10% rapid decrease in weight can often be serious, leading to muscle cramps, nausea, and other adverse effects. Therefore, it is essential to replace fluid as it is lost.

Replacement of Sodium Chloride and Potassium. Because sweat contains a large amount of sodium chloride, it has long been stated that all athletes should take salt (sodium chloride) tablets when performing exercise on hot and humid days. However, overuse of salt tablets has often done as much harm as good. Furthermore, if an athlete becomes acclimatized to the heat by progressive increase in athletic exposure over a period of 1 to 2 weeks rather than performing maximal athletic feats on the first day, the sweat glands also become acclimatized, so the amount of salt lost in the sweat becomes only a small fraction of that lost before acclimatization. This sweat gland acclimatization results mainly from increased aldosterone secretion by the adrenal cortex. The aldosterone in turn has a direct effect on the sweat glands, increasing reabsorption of sodium chloride from the sweat before the sweat issues forth from the sweat gland tubules onto the surface of the skin. Once the athlete is acclimatized, only rarely do salt supplements need to be considered during athletic events.

Exercise-associated *hyponatremia (low plasma sodium concentration)* can sometimes occur after sustained physical exertion. In fact, severe hyponatremia can be an important cause of fatalities in endurance athletes. As noted in Chapter 25, severe hyponatremia can cause tissue edema, especially in the brain, which can be lethal. In persons who experience life-threatening hyponatremia after heavy exercise, the main cause is not simply the loss of sodium due to sweating; instead, the hyponatremia is often due to ingestion of hypotonic fluid (water or sports drinks that usually have a sodium concentration of less than 18 mmol/L) in excess of sweat, urine, and insensible (mainly respiratory)

fluid losses. This excess fluid consumption can be driven by thirst but also may be due to conditioned behavior that is based on recommendations to drink fluid during exercise to avoid dehydration. Copious supplies of water are also generally available in marathons, triathlons, and other endurance athletic events.

Experience by military units exposed to heavy exercise in the desert has demonstrated still another electrolyte problem—the loss of potassium. Potassium loss results partly from the increased secretion of aldosterone during heat acclimatization, which increases the loss of potassium in the urine, as well as in the sweat. As a consequence of these findings, some of the supplemental fluids for athletics contain properly proportioned amounts of potassium along with sodium, usually in the form of fruit juices.

Drugs and Athletes

Without belaboring this issue, let us list some of the effects of drugs in athletics.

First, some persons believe that *caffeine* increases athletic performance. In one experiment performed by a marathon runner, running time for the marathon was improved by 7% through judicious use of caffeine in amounts similar to those found in one to three cups of coffee. Yet experiments by other investigators have failed to confirm any advantage, thus leaving this issue in doubt.

Second, use of *male sex hormones (androgens)* or other anabolic steroids to increase muscle strength undoubtedly can increase athletic performance under some conditions, especially in women and even in men. However, anabolic steroids also greatly increase the risk of cardiovascular disease because they often cause hypertension, decreased high-density blood lipoproteins, and increased low-density lipoproteins, all of which promote heart attacks and strokes.

In men, any type of male sex hormone preparation also leads to decreased testicular function, including both decreased formation of sperm and decreased secretion of the person's own natural testosterone, with residual effects sometimes lasting at least for many months and perhaps indefinitely. In a woman, even more significant effects such as facial hair, a bass voice, ruddy skin, and cessation of menses can occur because she is not normally adapted to the male sex hormone.

Other drugs, such as *amphetamines* and *cocaine,* have been reputed to increase athletic performance. It is equally true that overuse of these drugs can lead to deterioration of performance. Furthermore, experiments have failed to prove the value of these drugs except as a psychic stimulant. Some athletes have been known to die during athletic events because of interaction between such drugs and the norepinephrine and epinephrine released by the sympathetic nervous system during exercise. One of the possible causes of death under these conditions is overexcitability of the heart, leading to ventricular fibrillation, which is lethal within seconds.

Body Fitness Prolongs Life

Multiple studies have shown that people who maintain appropriate body fitness, using judicious regimens of exercise and weight control, have the additional benefit of prolonged life. Especially between the ages of 50 and 70 years, studies have shown mortality to be three times less in the most fit people than in the least fit people.

Why does body fitness prolong life? The following reasons are some of the most important.

Body fitness and weight control greatly reduce cardiovascular disease. This results from (1) maintenance of moderately lower blood pressure and (2) reduced blood cholesterol and low-density lipoprotein along with increased high-density lipoprotein. As pointed out earlier, these changes all work together to reduce the number of heart attacks, brain strokes, and kidney disease.

The athletically fit person has more bodily reserves to call on when he or she does become sick. For example, an 80-year-old, nonfit person may have a respiratory system that limits oxygen delivery to the tissues to no more than 1 L/min; this means a *respiratory reserve of no more than 3-fold to 4-fold.* However, an athletically fit old person may have twice as much reserve. This extra reserve is especially important in preserving life when the older person experiences conditions such as pneumonia that can rapidly require all available respiratory reserve. In addition, the ability to increase cardiac output in times of need (the "cardiac reserve") is often 50% greater in the athletically fit old person than in the nonfit old person.

Exercise and overall body fitness also reduce the risk for several chronic metabolic disorders associated with obesity, such as insulin resistance and type 2 diabetes. Moderate exercise, even in the absence of significant weight loss, has been shown to improve insulin sensitivity and reduce, or in some cases eliminate, the need for insulin treatment in patients with type 2 diabetes.

Improved body fitness also reduces the risk for several types of cancers, including breast, prostate, and colon cancer. Much of the beneficial effects of exercise may be related to a reduction in obesity. However, studies in animals used in experiments and in humans have also shown that regular exercise reduces the risk for many chronic diseases through mechanisms that are, at least to some extent, independent of weight loss or decreased adiposity.

  renal excretion and, 399
  renal reabsorption and, 360
Atrial paroxysmal tachycardia, 162–163, 163f
Atrial premature contractions, 160–161, 160f
Atrial pressure
  in cardiac cycle, 118f
  ventricular function curves, 123–124, 124f
Atrial reflexes, in arterial pressure regulation, 224
Atrial syncytium, 113–114
Atrial T wave, 136, 136f
  vectorial analysis of, 147–148, 147f
Atrial tachycardia, paroxysmal, 162–163, 163f
Atrioventricular (A-V) block, 158
  ectopic pacemaker and, 131
  ischemia of, 158
  first-degree, 158–160, 159f
  second-degree, 159, 159f
  third-degree, 159, 159f
  incomplete, 158–160
Atrioventricular (A-V) bundle, 128f
  ectopic pacemaker and, 131
  one-way conduction through, 130
  premature contractions, 160–161
  sympathetic effects of, 132
Atrioventricular (A-V) nodal paroxysmal tachycardia, 163
Atrioventricular (A-V) nodal premature contractions, 160–161, 160f
Atrioventricular (A-V) node, 128f–129f, 129
  as ectopic pacemaker, 131
  inflammation of, 158
  ischemia of, 158
Atrioventricular (A-V) node *(Continued)*
  parasympathetic stimulation and, 132
  premature contractions and, 160–161
  sympathetic effects of, 132
Atrioventricular (A-V) valves, 120, 120f
  first heart sound and, 121, 283–284
Atrophy, of skeletal muscle, 90–92
Atropine, parasympathetic constriction of bronchioles and, 499
Attenuation reflex, 664
Audiogram
  of conduction deafness, 673, 673f
  in nerve deafness, 672–673, 673f
Audiometer, 672
Auditory association cortex, 670, 671f
Auditory cortex, language and, 729
Auditory nervous pathways, 669–670, 670f
  firing rates at different levels of, 670
Auditory receptive aphasia, 734
Auscultation, of heart sounds, 284, 284f
Auscultatory method, of blood pressure measurement, 186–188, 187f–188f
Autocrines, 915
Autografts, 475
Autoimmune diseases, tolerance mechanism causes, failure of, 468–469
Autolysis, 22
Automated oscillometric method, 187
Automaticity, of body, 10
Autonomic ganglia
  nicotinic receptors in, 767
  peripheral sympathetic, 763
  prevertebral, 763
  sympathetic chains and, 763, 764f
Autonomic nervous system, 569, 763–776
  basic characteristics of, 765–772
    cholinergic and adrenergic fibers in, 765–767
    excitation and inhibition in, 768–770, 769t
    receptors on effector organs and, 767–768
    specific organs and, 768–770, 769t
    stimulus rate and, 771
    "tone" in, 771–772
  brain stem control of, 774
  dysfunction of, 985
  general organizations of, 763–765, 764f–765f
  hypothalamus and, 774, 774f
  insulin secretion and, 981
  medullary, pontine, and mesencephalic control of, 773–774, 774f
  pharmacology of, 774
  rapidity and intensity on visceral functions, 763
  in regulating the circulation, 217–220
  sweating and, 904–905
Autonomic reflexes, 763, 772
  bowel activity and, 806
  local, 773
  in spinal cord, 695
Autonomic system, 6
Autophagy, 22, 23f
Autoregulation of blood flow, 179–181, 208–209, 208f, 233
  cerebral, 779, 779f
  renal, 337–342, 339f
"Autoregulatory escape," gastrointestinal blood flow and, 796
Aviation
  acceleratory forces on the body in, 557–559
  acute hypoxia in, 554
  breathing air *vs.* breathing oxygen in, 554
  deceleratory forces in parachuting in, 559
Axis deviation, 149–150, 149f
Axon, 573
Axoneme, 28
Azathioprine, for immunosuppression, in transplantation, 476

B

B lymphocytes, 459–460, 460f, 466
  attributes of, 462
  helper T cells and, 462
  memory cells of, 463
  preprocessing of, 461
  role of T cells in activation of, 462
  specifically against specific antigens, 461
Bacteria
  caries and, 1008
  in colon, 832, 891
  in feces, 832
  fever and, 910
  phagocytosis and, 22
Bainbridge reflex, 224–225, 245
Baldness, male pattern, testosterone and, 1020
Ballistic movements, cerebellar control of, 718
Barometric pressures, at different altitudes, 553, 554t
Baroreceptor reflexes, 221–225, 772
  in cardiac failure, acute, 271, 272f
  in hypovolemic shock, 295
  oscillation of, 227
  renal sodium and water excretion and, 396–397
Baroreceptor system, as rapidly acting control mechanism, 7, 7f
Baroreceptors
  acute neurogenic hypertension and, 241
  anatomy and innervation of, 221–222, 221f
  buffer function of, 223, 223f
  circulatory reflex initiated by, 222, 222f
  in integrated arterial pressure control mechanism, 243, 243f
  in long-term regulation of arterial pressure, 223–224
  posture and, 222
  response to arterial pressure of, 222, 222f
Bartter syndrome, 433
Basal ganglia, 720–724
  as accessory motor system, 720
  anatomical relations of, 720, 721f
  associated functions of, 725
  clinical syndromes resulting from damage to, 723–724
    Huntington's disease, 724
    Parkinson's disease, 723–724
  dopamine system and, 743, 743f
  function of, 720–722
    intensity of movements, 722–723
  gamma efferent system and, 689
  in integrated control system, 725
  motor pattern sequences and, 722
  neglect syndrome and, 722–723, 723f
  neuronal circuitry of, 720, 721f
    caudate circuit, 722, 722f
    putamen circuit, 720, 721f
  neurotransmitter substances in, 723, 723f
  overall motor control by, 711–726
  scaling of movements and, 723
  timing of movements and, 723
Basal metabolic rate (BMR), 897–898, 897f–898f
  increased, 947
  testosterone and, 1021
  thyroid hormones and, 947f
Basal metabolism, autonomic control of, 769t
Basement membrane
  of capillaries, 193
  gastrointestinal secretions and, 807f
Bases
  definition of, 403–404
  strong and weak, 403–404
Basilar fibers, of cochlea, 665
  traveling wave and, 666

Basilar membrane, of cochlea, 665, 665f
  pattern of vibration of, sound frequencies and, 665–666, 666f
    amplitude of, 666, 666f
  traveling wave along, 666, 666f
Basket cells, 715
Basophil cells, heparin produced by, 484
Basophil erythroblasts, 441, 441f
Basophils, 457
  activation of, by complement system, 465
  eosinophil chemotactic factor, 457
Bathorhodopsin, 641–642
Becker muscular dystrophy (BMD), 92
Beriberi, 547, 888
  cardiac failure associated with, 280f, 281, 889
  cardiac output in, 248
  peripheral vascular blood flow and, 207–208
  peripheral vasodilation in, 889
Beta adrenergic receptors, 499, 767–768, 768t
  drugs blocking, 774
  drugs stimulating, 774
Beta-aminoisobutyricaciduria, 432
Beta-amyloid peptide, in Alzheimer's disease, 761
Beta blockers, for angina pectoris, 269
Beta-oxidation of fatty acids, 857, 857f, 873
Beta receptors, in coronary vessels, 264
Beta waves, 754f, 756, 756f
Betz cells, 699–700
Bicarbonate
  in bile, 818, 820
  diarrhea-related loss of, 417
  dissociation of carbonic acid into, 528
  in extracellular fluid, normal range of, 8t
  gastric acid secretion and, 812, 812f
  intestinal absorption of, 829
  intestinal secretion of
    in large intestine, 821, 829, 832
    in small intestine, 821, 829
  in mucus, duodenal, 820
  pancreatic secretion of, 815–816, 816f
    cellular mechanism of, 815, 816f
    mucus protection and, 834
  in plasma, carbon dioxide transport and, 439
  ratio in renal tubular fluid, acidosis decreases, 415–416
  reabsorbed by interaction with H^+ in tubules, 411
  renal excretion of, 414
    in alkalosis, 417
  renal reabsorption of, 352–354, 353f, 410–412, 410f
    carbonic anhydrase inhibitors and, 422–423
    factors affecting, 415, 415t
  in saliva, 808f, 809
  titrated against H^+, 411
  transport of CO_2 in, 528–529
Bicarbonate buffer system, 405–407, 406f
  extracellular buffer and, 407
  quantitative dynamics of, 405–407
  titration curve, 406
Bicarbonate-chloride carrier protein, 528
Bile, 817
  composition of, 818–819, 819t
  in duodenum, 818
  excretion of hormones in, 920
  functions of, 817–818
  secretion of, 818
    secretin and, 818f, 820
  storage and concentration of, 818–819
Bile acids
  cholesterol and, 861, 864
  function of, 817–818
Bile canaliculi, 818, 871, 872f
Bile ducts, 818
  autonomic control of, 769t
Bile salts
  cholic acid for, 862
  concentration in bile, 818–819, 819t
  enterohepatic circulation of, 819–820
  in fat digestion, 826
    and absorption, 819–820
Biliary secretion, physiologic anatomy of, 818–819, 818f
Bilirubin, 445, 818
  concentration in bile, 818–819, 819t
  conjugated, 875
  fecal color and, 832
  in fetus, 1066
  formation and excretion of, 875f
  jaundice and, 875–876
  measurement of, 874–876
  unconjugated, 874
Biliverdin, 874
Binocular vision, 635, 635f
Bipolar cells, 640–641, 646
  depolarizing and hyperpolarizing, 648–649
Bipolar disorder, 760
Bipolar limb leads, 138–141
  increased voltage in standard, 150–151
  vectorial analysis
    atrial T wave, 147–148, 147f
    axis for, 143–144, 144f
Bitter taste, 675–677, 676t
Bladder
  anatomy of, physiologic, 325–327, 326f
  atonic, 328
  autonomic control of, 769t
  external sphincter of, 325–326, 326f, 328
  innervation of, 326–327, 326f
  irritation of, intestinal activity and, 806
  pressure changes in, 327, 327f
Blastocyst, 1046
  implantation of, 1046–1047
Bleeding
  excessive, 484–486
  in thrombocytopenia, 485
Bleeding tendencies, in vitamin K deficiency, 484
Bleeding time, 487
Blindness, in premature infant, 1069
Blood
  amino acids in, 865–867
  arterial, transport of oxygen in, 522, 522f
  autonomic control of, 769t
  characteristics of, in neonates, 1066
  cleansing of, by spleen, 192
  reservoirs, 191
  transport of CO_2 in, 528–530
  viscosity of, 175
    anemia and, 446
    hematocrit and, 179, 179f
    plasma loss and, 299
    in polycythemia, 447
    vascular resistance and blood flow, 178–179
Blood-brain barrier, 783
Blood cells, 437–448
  in fetus, 1061
  genesis of, 440–441, 440f, 449–450, 450f
Blood-cerebrospinal fluid barrier, 783
Blood clot
  dissolution of, 478–479
  formation of, 480–481
  in normal vascular system, intravascular anticoagulants prevent, 483–484
  plasmin causes lysis of, 484
Blood-clotting factors, 484
Blood coagulation
  clotting factors in, 479t
  hemophilia and, 485
  initiation of, 481–484
  mechanism of, 479–484
Blood coagulation *(Continued)*
  in neonate, 1067
  outside the body, 487
  pressure difference and, 173
  in ruptured vessel, 478, 478f
  tests of, 487–488
  thrombocytopenia and, 485–486
Blood flow, 174–176
  arterial pressure and, 179–181
  autoregulation of, arterial pressure and, 233
  cardiac output and, 173
  definition of, 174
  in different tissues and organs, 205, 206t
  interstitial fluid PCO_2 and, 523, 524f
  interstitial fluid PO_2 and, 522–523, 522f
  laminar, 175
    parabolic velocity profile during, 175
  local, cardiac output and, 246–248, 246f
  on metabolic use of oxygen, 527
  methods for measuring, 174–176
  needs of tissues for, 205
  pressure difference and, 173, 174f
  rate of, 171
  reduced oxygen availability, 206
  in skin, heat loss and, 902, 902f
  thyroid hormones and, 947
  in total circulation, 174
  turbulent, 175–176, 175f
  units of, 177
  vascularity determined by maximum, 212
  velocities of
    cross-sectional areas and, 172
    parabolic profile for, 175
Blood flow control, 205–216
  endothelium-derived relaxing or constricting factors, 210–211
  humoral, 214–215
  local
    acute, 206–211, 206f
    acute metabolic control of, 208
    autoregulation in, 208–209, 208f
    importance of, 205
    long-term, 205, 211–214
    possible role of other nutrients besides oxygen, 207–208
    in response to tissue needs, 205
  mechanisms of, 205–214
  tissue needs, 173
Blood gases
  during exercise, 1080
    respiration and, 1080
  study of, for respiratory abnormalities, 541
Blood glucose, 852
  dehydration and, 985
  in diabetes mellitus, 984
  glucagon and, 982–984, 983f
  gluconeogenesis and, 873
  hunger and, 883
  hypoglycemia and, 984
  insulin and, 980, 980f, 983–984
  liver in
    concentration of, 873
    release from, 976
  in neonates, 1065–1066
    of diabetic mother, 1068
    of premature, 1069
  normal, 852
  regulation of, 983–989
    importance of, 984
  renal blood flow and, 341–342
  urine and, 984
Blood loss anemia, 446
Blood matching, 472–473

Blood pressure, 176
antidiuretic hormone and, 939
blood flow and, 174f
definition of, 176
in different portions of circulatory system, 172f
measuring, high-fidelity methods for, 176, 176f
standard units of, 176
Blood reservoirs, specific, 191
Blood transfusion, 301
agglutination process in, 472
blood types in, 471–472, 472t
reactions, Rh transfusion, 473–474
Blood trauma, 482
Blood types, 471–476, 472t
frequencies of, 471–472
mismatched, transfusion reactions resulting from, 474–475
O-A-B, 471–472
Rh, 473–474
Blood typing, 472–473, 473t
Blood vessels
autonomic control of, 763, 764f, 769t, 770
adrenal medulla in, 770
intrinsic tone of, 771–772
sympathetic innervation of, 217, 218f
Blood volume, 307
antidiuretic hormone and, 377, 377f, 939
atrial natriuretic peptide and, 399
atrial reflexes and, 224, 225f
cardiac output and, 249, 254–256, 254f
conditions causing large increases in, 400
and extracellular fluid volume, 396f
hemorrhagic shock and, compensatory mechanisms, 295
in lungs, 171, 504
mean circulatory filling pressure and, 252, 252f
measurement of, 309–310
mitral valvular disease and, 288
in neonates, 1066
regulation of, 395–396, 395f
valvular heart disease and, 287
venous return and, 254, 254f
Blue weakness, 646
BMD. *See* Becker muscular dystrophy
BMI. *See* Body mass index
BMR. *See* Basal metabolic rate
Body functions, regulation of, 6
Body mass index (BMI), 884
Bohr effect, 526, 526f
double, 1048–1049
fetal blood and, 1048
Bone, 991–1010
broken, muscle spasm from, 694
calcification, mechanism of, 994–995
calcium and, 993–997
buffer function of, 1003–1004
extracellular fluid, exchange between, 995
precipitation and absorption of, 994–995
cortical, 993f
"deconditioning," weightlessness and, 559–560
deposition of, 995–997, 995f
and resorption, equilibrium with, 995f
disease of, 1004–1006
in hypoparathyroidism, 1004
in fetus, 1062
growth hormone and, 934–935
matrix, testosterone and, 1020
organic matrix of, 994
disease of, 1006
osteolysis, 1000–1001
phosphate and, 993–997
precipitation and absorption of, 994–995
remodeling of, 995–997
continual, value of, 996
resorption of, 995–996, 996f
Bone *(Continued)*
and deposition, equilibrium in, 996
slow phase of, 1001
rickets and, 1005
salts of, 994
stress, 996–997
structure of, 997f
tensile and compressional strength of, 994
trabecular, 993f
transmission of sound through, 664
vitamin D and, 999
Bone fluid, 1000
Bone marrow
B lymphocyte processing in, 461
leukopenia and, 457
lymphocyte preprocessing in, 468–469
macrophages of, 453–454
Bone marrow aplasia, 446
Bony labyrinth, 664, 704
Botulinum toxin, 95–96
Bowman's capsule, 323, 324f, 329, 329f, 331, 332f–333f
pressure in, 333–334, 333f
Boyle's law, 561, 562f
Bradycardia, sinus, 157, 158f
vagal stimulation causes, 157
Bradykinin, 214–215
glomerular filtration rate and, 338
in gut wall, 795
from mast cells and basophils, 457
in salivary glands, 810
tissue damage and, 614
Brain
activating-driving systems of, 741–744
neurohormonal systems, 742–744, 743f
reticular excitatory area, 741–742, 742f
blood flow control in, 209
capillaries of, tight junctions, 194
carbon dioxide in blood and, 215
childhood development of, 1070
effect of circulatory arrest on, 302
glucose and, 984
uptake and usage of, insulin and, 977
growth and development of, thyroid hormone and, 946
higher, 572
intellectual functions of, 727–740
interstitial fluid pressure, 198
lower, 571
metabolism of, 783–784
pain suppression (analgesia) system in, 616–618, 617f
reticular inhibitory area and, 742, 742f
vegetative functions of, 744
Brain activity, 753–762
Brain cell edema, hyponatremia with, 314
Brain damage, neurogenic shock caused by, 300
Brain edema, 783
measures for, 783
Brain ischemia, vasomotor paralysis caused by, 300
Brain stem
activating-driving systems of, neurohormonal systems, 742–744, 743f
afferent tracts in, 713
autonomic control centers of, 774, 774f
basal ganglia and, 723, 723f
cerebellar signals to, 716
cerebral activation by, continuous excitatory signals in, 741–742, 742f
chewing and, 797
dual pain pathways in, 615–616
gastrointestinal reflexes and, 791
hypothalamus and, 745
limbic system and, 745
motor functions and, 703–704, 704f
Brain stem *(Continued)*
anencephaly and, 708
gamma efferents in, 689
stretch reflex and, 688–689
neospinothalamic tract in, termination of, 615
salivatory nuclei in, 810
slow-chronic pain signals into, 616
swallowing and, 798–799
taste reflexes integrated in, 678
vestibular nuclei in, 707
vestibulocerebellum functions and, 717
vomiting center in, 837–838, 837f
Brain stem nuclei, functions of controlling subconscious, stereotyped movements, 708
Brain's opiate system, 617–618
Braxton Hicks contractions, 1055
Breasts
development of, 1056–1057, 1057f
ductal system of, estrogen and, 1056–1057
estrogen and, 1035, 1056–1057
of neonates, 1068
progesterone and, 1036
Breathing
cardiac output curve and, 250
Cheyne-Stokes, 538–539
work of, 494
Broca's area, 698f, 699, 729f, 730
Brodmann's areas, 603, 603f
Bronchi, 499
autonomic control of, 769t
muscular wall of, 499
Bronchial vessels, 503
Bronchiolar constriction, local secretory factors, 499
Bronchioles, 499
muscular wall of, 499
parasympathetic constriction of, 499
spasmodic contraction of smooth muscles in, 546
sympathetic dilation of, 499
Brown fat, 907
sympathetic nervous stimulation, 899
Brown-Séquard syndrome, 620–621, 620f
Brunner's glands, 820, 834

  blood coagulation and, prevention of, 487
  bone and, 993–997
  buffer function of, 1003–1004
  calcitonin and, 1003
    weak effect of, 1003
  in cardiac muscle, excitation-contraction coupling, 116–117, 117f
  control of, 390–391, 390f
  in dentin, 1006–1007
  effect of, 125
  exchange of, between bone and extracellular fluid, 995
  exocytosis and, 24
    of gastrointestinal secretions, 808
  in extracellular fluid, 105
    excess of, 391–392
    normal range of, 8, 8t
    parathyroid hormone and, 1000–1001, 1000f
    regulation of, 991–993
    summary of, 1003–1006
  fecal excretion of, 390, 992–993
  in gastrointestinal smooth muscle
    action potential and, 788–789
    tonic contraction and, 789
  hormonal control of, 1003–1004
  intestinal absorption of, 830, 992–993, 993f
    parathyroid hormone and, 830, 1001
    vitamin D and, 830, 890, 999
  ion concentration of, 991
  metabolism of, 991–1010
    in fetus, 1062, 1062f
  need for, in neonates, 1067
  parathyroid secretion control by, 1001–1002, 1002f
  peptide hormone secretion and, 916
  in plasma and interstitial fluid, 991, 991f
  plasma protein binding of, 331
  at postganglionic nerve endings, 766
  precipitation of, in nonosseous tissues, 995
  primary active transport of, 60
  renal excretion of, 390–391, 392t, 993
    parathyroid hormone and, 1001
    vitamin D and, 999
  renal reabsorption of, 360, 391, 391f
  role of, in intrinsic and extrinsic pathways, 483
  in skeletal muscle, 83–84
  in smooth muscle, 101, 104f–105f
    regulation of contraction by, 103–105
  sodium channels and, 71
  sodium counter-transport of, 61, 61f
  source of, cause contraction, 104–105
Calcium ATPase, 344
Calcium-ATPase pump, renal, 391, 391f
Calcium carbonate, of macula, 705
Calcium ion channels
  of cardiac muscle, 115
  excitatory "pulse" of, 98
  memory system of *Aplysia* and, 737, 737f
  myofibrillar fluid after contraction, 97–98
  release of, by sarcoplasmic reticulum, 97–98
  voltage-gated, 70–71
    at neuromuscular junction, 93, 94f
    at presynaptic terminal, 574
Calcium ions, 494
Calcium pump, of smooth muscle, 105
Calcium release channels, 97, 99f
Calcium-sensing receptor, 1001–1002
Calcium-sodium channels
  in cardiac muscle, 115
  in gastrointestinal smooth muscle, 788–789
Callus, on bone, 997
Calmodulin, 104, 105f, 925
Calorie, 896

Dentin, of teeth, 1006–1007
Dentinal tubules, 1007
Deoxyhemoglobin, 778–779
Deoxyribonucleic acid (DNA), 31
basic building blocks of, 31–33, 32f
code, in cell nucleus, 33–37
methylation, 40
replication of, 41–43, 42f
structure of, 31–33, 33f
Deoxyribose, 31
Depolarization stage, action potential, 68
Depolarization waves, 135–136, 136f
slow conduction of, T wave, 156
Depression, mental, psychosis, 760
Depth perception, 635, 660
Dermatomes, 610, 610f
Desmopressin, 374
Desynchronized sleep, 753
Detoxification, enzymes for, 23
Detrusor muscle, 325, 326f, 327
autonomic control of, 769t
micturition reflex and, 328
parasympathetic fibers to, 326
Deuteranope, 646
Dexamethasone, 956
test, 970
Dextran solution, 301
α-Dextrinase, 824
DHEA. *See* Dehydroepiandrosterone
Diabetes insipidus, 315
"central," 374
nephrogenic, 374, 432
Diabetes mellitus, 973–990
acidosis in, 417
atherosclerosis and, 863
blood glucose and, 984
dehydration and, 985
tissue injury and, 985
urine and, 984
brain metabolism in, 784
end-stage renal disease caused by, 427
enzyme concentration and, 895
fats, utilization of, 985
Diabetes mellitus *(Continued)*
fatty acids in blood in, 854
with gigantism, 937
glomerular filtration rate in, 341
hyperkalemia in, 384
insulinoma and, 988–989
ketosis in, 858
maternal, 1068
metabolic acidosis and, 985, 985f
metabolic utilization of nutrients in, 879
physiology of diagnosis, 987–988, 987t
protein depletion and, 985
treatment of, 984–989
and arteriosclerosis, 988
triglycerides in liver in, 856
type 1, 984–986
fetal morbidity in mothers with, 1068
type 2
acromegaly and, 986
Cushing syndrome and, 986
development of, 986–987
insulin resistance and, 986, 986t
large babies of mothers with, 1068
metabolic syndrome and, 986
obesity and, 986–987
polycystic ovary syndrome and, 986
urinary glucose excretion in, 347
urine output in, 421
Diacylglycerol (DAG), 924–925
Dialysis, renal, 433–434, 434f
hypertension associated with, 235–236
principles of, 433–434
Dialyzing fluid, 434, 434t
Diapedesis, 441, 455
by lymphocytes, 450
by monocytes, 451
by neutrophils, 451, 451f
Diarrhea, 836–837
hyponatremia caused by, 314
intestinal absorption capacity and, 832
lethal, 832
metabolic acidosis caused by, 417
psychogenic, 836
as response to irritation, 821
Diastole, 118–123, 118f
ventricles fill with blood during, 119
Diastolic dysfunction, heart failure with, 280
Diastolic pressure, measurement of, 186–188
Diastolic pressure curve, 121, 121f
Dicer enzyme, 36–37
Diet
carbohydrate foods of, 823–824
fats of, 825–827
proteins of, 824–825
Differentiation, cell, 45
Differentiation inducers, of hematopoietic stem cells, 440–441
Diffusion
of gases, physics of, 511–513
osmosis and, 310
of oxygen and carbon dioxide, through respiratory membrane, 511–520
through respiratory membrane, 511–520
Diffusion across capillary walls, 5f
Diffusion potential, 63, 64f
Diffusion through cell membrane, 52–53, 52f
versus active transport, 52
facilitated, 55–56, 55f
in glucose reabsorption, 346f
in sodium reabsorption, 345
in pores and channels, 53–55
rate of, 56–57
simple, 52, 55f
of water, 52–53, 57f

Digestion, 823–827
of carbohydrates, 823–824, 824f
enzymes for, 823
pancreatic enzymes in, 815
of fats, 825–827, 825f
end products of, 826
of proteins, 824–825, 825f
enterogastric reflexes and, 801–802
pancreatic proteolytic enzymes in, 825
of proteins, pancreatic enzymes in, 815
Digestive enzymes, 807
intestinal, 821, 824
pancreatic, 815
carbohydrates and, 815, 824
cholecystokinin and, 817
fats and, 815, 826, 826f
loss of, 835
optimal pH for, 817
phases of secretion, 816
proteins and, 815, 825, 825f
regulation of, 816, 817f
salivary, 807f, 809, 824
Digestive vesicle, 22, 22f, 452
Digitalis
in cardiac failure, 274
with acute pulmonary edema, 277
decompensated, 279–280, 279f
in cardiogenic shock, 275
diuresis caused by, 279
toxicity, T wave, 156, 156f
ventricular tachycardia causing, 163
Dihydropyridine receptors, 97
Dihydrotestosterone, 1018, 1021
chemical structure of, 1018f
1,25-dihydroxycholecalciferol, 997f, 998
calcium ion and, 998, 998f
treatment with, in hypoparathyroidism, 1004
1,25-dihydroxyvitamin D_3, production of, regulation of, 322
Diisopropyl fluorophosphate, 96
Diopter, 629, 630f
Dipalmitoyl phosphatidylcholine, 494
Dipeptidases, 825
Dipeptidyl peptidase 4 (DPP-4), 987
Direct calorimetry, 896–897
Disaccharides
absorption of, 821
in diet, 823
hydrolysis of, 823–824
Discharge zone, 593, 593f
Disease, defined, 4
Disseminated intravascular coagulation, 486
in septic shock, 300
Dissociation constant, 405
Distal tubules, 323–324, 324f
calcium reabsorption in, 391
diluting segment of, 351
potassium secretion by, 385, 388f–389f
transport characteristics of, 351, 352f–353f
urine concentration and, 366, 368t, 369–370, 370f, 372f, 373
Distensibility, vascular, 183–184
units of, 183
Diuretics, 421–436, 422f, 422t
for essential hypertension, 243
in heart failure, 274
with acute pulmonary edema, 277
hyponatremia caused by, 314
metabolic alkalosis caused by, 417
DMD. *See* Duchenne muscular dystrophy
DNA. *See* Deoxyribonucleic acid

Excitatory stimulus, 593
Excitatory transmitter, 575
Excited zone, 593
Excretion rate, calculation of, 361t
Exercise
aerobic system and, recovery after, 1076
anaerobic glycolysis in, 894–895
arterial pressure increase in, 248
blood flow regulation in skeletal muscle and, 259–262
blood gases during, 1080
body heat in, 1082
cardiac output during, 246, 246f, 248, 261–262, 261f, 1080–1081, 1081f
athletic training and, 1081, 1081t
cardiovascular system in, 1080–1082
and muscle blood flow, 1080–1082, 1080f
circulatory readjustments in, 260–262
coronary blood flow during, 262
diffusing capacity during, increased oxygen, 517
energy expenditure in, 898, 899t
fat utilization in, 860
gastrointestinal vasoconstriction during, 796
glucagon and, 983
glucose and, 975
growth hormone and, 935, 935f
hyperkalemia caused by, 384
increase in, body temperature, 901
lactic acid release in, 850
lymphatic pump during, 203
muscle metabolic systems in, 1074–1075, 1075f, 1076t
recovery after, 1076
neurogenic control of ventilation during, 537–538
oxygen consumption during, 1080–1081, 1081f
oxygen debt and, 895
oxygen transport during, 524f
regulation of respiration during, 536–540, 537f
respiration in, 1078–1080
rightward shift of oxygen-hemoglobin dissociation curve during, 526
sweat glands in, 904
sympathetic activation and, effects of, 260
transport of oxygen during, 524–525
uptake of oxygen, by pulmonary blood during, 521
valvular heart lesions and, 288
work output during, 1080–1081, 1081f
Exercise test, cardiac reserve and, 277–278
Exhaustion atrophy, 1068
Exocytosis, 22, 24, 938
of gastrointestinal secretions, 808
stimulus for, 916
Exons, 35
Exonuclease, 42
Exophthalmos, hyperthyroidism and, 951, 951f
Expanded tip tactile receptors, 599–600
Expiratory reserve volume, 495
Expired air, 515
External work, cardiac, 123
Exteroceptive information, 708
Exteroreceptive sensations, 599
Extracellular fluid, 306–307, 306f
in chronic kidney disease, 430, 430f
composition of, 51f, 307, 307f, 308t
constituents, normal ranges and physical characteristics of, 7–8, 8t
control of, 392–394
EExtracellular fluid *(Continued)*
distribution between interstitium and vascular system, 396, 396f
effect of adding saline solution to, 312–313, 312f
as internal environment, 3–4
intracellular fluid and, 3–4
exchange between compartments, 310–312
osmotic equilibrium of, 311–312
measurement of, 309, 309t
mixing system, 4–5
nutrients in, origin of, 5–6
osmolality, in abnormal states, 312–313
pH of, 8, 404t
potassium concentration in, 386–389, 386f–388f
regulation of
carbon dioxide concentrations, 7
oxygen concentration, 7
transport, 4–5
Extracellular fluid osmolarity
potassium distribution and, 384
regulation of, 365, 375
angiotensin II and aldosterone in, 379–380, 380f
by osmoreceptor-ADH feedback system, 375, 375f, 379–380
by osmoreceptor-ADH system, 939
by thirst, 377–380, 378t, 379f
Extracellular fluid volume
in abnormal states, 312–313
aldosterone and, 959–960
antidiuretic hormone and, 398–399
arterial blood pressure and, 232–233, 233f
angiotensin II and, 237–238, 398
conditions causing large increases in, 400–401
depletion of, alkalosis secondary to, 415
diuretics and, 421, 422f
hypertension and, 235–236, 235f
regulation of, 392–393, 395–396
salt and, 233
salt appetite and, 380
thirst and, 378
Extracorporeal circulation, in cardiac surgery, 291
Extrafusal muscle fibers, 687, 687f
Extravasation, 455
Extrinsic pathway, for initiating clotting, 481–483, 481f
Eye movements, 657–660
fixation, 658–660
muscular control of, 657–658, 658f
neural pathways for, 657–658, 658f
saccadic, 659
"voluntary," premotor area and, 699
Eyes
accommodation control of, 661
autonomic control of, 768, 769t
autonomic nerves to, 660–661, 661f
disorders, headache caused by, 622
emmetropic, 632
equilibrium maintenance and, 707
fluid system of, 635–637, 636f
optics of, 630–635
as camera, 630f
"depth of focus," 632, 632f
"depth perception," 635
pupillary diameter, 631–634
refractive surfaces of, 630–631
visual acuity, 634, 635f
outflow of aqueous humor from, 636, 636f
protruding, in hyperthyroidism, 951f
pupillary diameter of, 631–634
receptor of, 639–652
vestibular mechanisms for stabilizing, 707

F

F-actin, 83, 83f
Facial recognition areas, 730, 731f
Facilitated diffusion, 55–56, 56f
  in glucose reabsorption, 346f
  placental, 1049
  in sodium reabsorption, 345
Facilitated zone, 593, 593f
Facilitation of neurons, 583, 593
  memory and, 571, 737–738
Factor V, role of, 483
Factor VII, 484–485
Factor VIII
  abnormality/deficiency of, 485
  role of, 483
Factor IX, 484–485
  activation of, by activated Factor XI, 483
Factor X, 484–485
  action of, 483
  activation of, 481–483
Factor XI, activation of, 482–483
Factor XII, activated of, 482
FAD. *See* Flavin adenine dinucleotide
Fainting
  acute venous dilation in, 249
  emotional, 220
  in long QT syndromes, 162
  in Stokes-Adams syndrome, 159–160
Fallopian tube, 1028f
  entry of ovum into, 1045
  estrogen and, 1035
  fertilized ovum, transport in, 1046, 1046f
  inflammation of, 1043
  progesterone and, 1036
  relaxation of, 1046
  transport of sperm in, 1045
Familial hypercholesterolemia, 862–863
Fanconi syndrome, 433
Farsightedness, 632, 632f
Fast muscle fibers, 88
Fast pain, 613
  capability of nervous system to localize, 615
  neospinothalamic tract for, 615
Fast-sharp pain signals, 614, 615f
Fast sodium channels, 71
  in cardiac muscle, 115
Fast-twitch muscle fibers, 1078
  athletes and, hereditary differences in, 1078
Fastigial nucleus, 713, 714f
Fasting blood glucose, 987
Fat cells, autonomic control of, 769t
Fatigue
  of neuromuscular junction, 96
  of skeletal muscle, 89–90
  synaptic, 597, 597f
  of synaptic transmission, 584–585
Fats, 877
  absorption of, 831
    bile salts and, 819–820
    impaired, 836
    in neonates, 1067
  deposits of, 856
    estrogen and, 1035, 1073
  dietary, gallstones and, 820
  digestion of, 825–827, 825f
    bile acids and, 819
    bile salts and, 819
    end products of, 826
    gallbladder emptying and, 819
    pancreatic enzymes for, 815
    in stomach, 826
  emulsification of, 826, 826f
  as energy source
    for athletes, 1077
    growth hormone and, 934
Extracellular fluid *(Continued)*
    with high-fat diet, 858
    hormonal regulation of, 860
    liver and, 856
  excess usage of, 978
  in feces, 832
  in foods
    energy from, 877
    metabolic utilization of, 878–879
  glucose conversion to, 851
  glucose storage as, 851
  hydrolysis of, 823
  as insulation, 902
  metabolism of
    cortisol and, 963–964
    insulin and, 977–978
    liver in, 873–876
    thyroid hormones and, 946
  mobilization of, in Cushing's syndrome, 970
  oxidation of, 878
  as protein sparer, 878
  stomach emptying and, 802
  storage of, 884
    insulin and, 977
  synthesis of, insulin and, 977
  use of hydrogen to synthesize, 851
  utilization of, diabetes mellitus and, 985
Fatty acids, 826
  absorption of
    bile salts and, 819
    direct, 831
  beta-oxidation of, 857, 857f
  in blood, as energy source
    form of, 854
    transport of, 854
  for cardiac muscle, 264
  cholecystokinin stimulus and, 819
  chylomicron and, 853, 855f
  combustion of, 893
  degradation of, 856–857
    in liver, 857
  as energy source, 856
  entry to mitochondria, 856
  mobilization of, cortisol and, 963–964
  nonesterified, 854
  placental diffusion of, 1049
  in plasma, protein binding of, 331
  synthesis of, from carbohydrate excess, 859
  from triglyceride hydrolysis, 823, 826
  triglyceride synthesis from, in intestinal epithelium, 831, 853
  typical, 853
Fatty streak, 862
Febrile conditions, characteristics of, 910
Feces
  composition of, 832
  formation of, 831–832
  intestinal mucus and, 821
  nitrogen in, 879
  water loss in, 305, 306t
Feedback
  enzyme inhibition, 40
  gain of, 8
  negative, 8–9, 9f
    delayed, 10
    in hormone systems, 919
  positive, 9, 9f
    in hormone systems, 919
Feedback gain, body temperature and, 908
Feed-forward control, 10
Feeding center, hypothalamic, 879
Female fertility, 1042
  hormonal suppression of, 1042–1043
Female hormonal system, 1027–1028
Female orgasm, 1042
Female sexual act, 1041–1043
  erection and lubrication in, 1042
  stimulation of, 1041–1043
Female sexual organs, physiologic anatomy of, 1027, 1028f
Female sterility, 1043
Fenestrated capillaries, glomerular, 331
Fenn effect, 84
Ferritin, 444f, 445, 874
Fertilization, 1045, 1046f
Fetal dopamine cells, transplantation of, for Parkinson disease, 724
Fetal zone, of adrenal cortex, 1050
Fetus
  blood cells in, 1061
  blood flow of, 1047
  circulation in, 1064, 1064f–1065f
    changes in, at birth, 1064–1065
  circulatory system in, 1061–1062
  gastrointestinal tract in, 1061–1062
  growth and development of, 1061–1070, 1062f
  hemoglobin of, 1048, 1048f
  hormones of, uterine contractility and, 1054
  kidneys in, 1062
  metabolism in, 1062–1063
  nervous system in, 1061
  nutrition of, human chorionic somatomammotropin and, 1051
  organ systems in, 1061–1062
  respiratory system in, 1061
Fever, 909–910, 909f

Hypoeffective heart, 247–248, 247f
Hypogastric nerves, bladder and, 326–327
Hypogastric plexus, 764f
Hypoglycemia
growth factor and, 935, 936f
insulin shock and, 988–989
Hypoglycemic shock, 977

Hypogonadism
female, 1041
male, 1023
Hypokalemia, 383
acidosis secondary to, 415
aldosterone excess and, 960
Hyponatremia, 314–316, 314t, 315f, 1082–1083
Hypo-osmotic solutions, 311
Hypoparathyroidism, 1004
bone disease in, 1004
hypercalcemia and, 1004
kidney stone formation in, 1005
primary, 1004–1005
secondary, 1005
treatment of, 1004
Hypophosphatemia, renal, 432
Hypophysis, 929
Hypoproteinemic edema, 1067, 1069
Hypothalamic-hypophysial portal blood vessels, 931–932
Hypothalamic-hypophysial portal vessels, 930, 931f
Hypothalamic inhibitory hormones, 930
and anterior pituitary secretion, 932t
Hypothalamic-pituitary-ovarian system, feedback oscillation of, 1039–1040
Hypothalamic releasing hormones, 930
and anterior pituitary secretion, 932t
Hypothalamus, 744–749, 744f–746f, 881t
amygdala and, 750
anterior pituitary gland and, 747
autonomic control by, 774f
behavioral functions of, 748
blood-brain barrier and, 783
control of male sexual functions and, 1021–1023
gonadotropin-releasing hormone secretion by, 1038
pulsatile, 1038, 1038f
hunger and satiety centers of, 879–882, 880f, 881t
anorexia and, 887
leptin and, 883
neurons and neurotransmitters in, 880–882, 881f
obesity and, 886
and hypothalamic releasing and inhibitory hormones, control of, 932
lesions in, 748
osmoreceptors in, 376f, 939
pituitary gland and
anterior, 931–932, 931f
posterior, 930, 938–940, 939f
secretion and, 930–932, 931f
prolactin inhibitory hormone and, 1058
"reward" and "punishment" functions of, 748–749
sleep and, 754
vasodilator system and, 220
vasomotor center controlled by, 219
vegetative and endocrine control functions of, 745–748
Hypothermia
artificial, 911
deep body temperature receptors and, 906
Hypothyroidism, 951–953
cardiac output in, 250
diagnostic tests for, 952
physiological characteristics of, 952
treatment of, 952–953
Hypotonia
deep cerebellar nuclei and, 720
motor cortex lesions with, 702–703
Hypotonic solution, 311, 311f
Hypoventilation hypoxia, 547
Hypovolemic shock, 294
arterial pressure and, 294–295, 294f
Hypovolemic shock *(Continued)*
bleeding volume and, 294–295, 294f
cardiac output and, 294–295, 294f

mechanism for cleansing, 637
Intraocular pressure, 636–637
measurement of, by tonometry, 636–637, 637f
regulation of, 637
Intrapleural pressure, cardiac output curves and, 250, 250f–251f
Intrarenal acute kidney injury, 423–425, 424t
Intraventricular block, partial, 160, 160f
Intrinsic factor, 443, 446, 834
secretion of, 811–812
Intrinsic pathway, for initiating clotting, 482–483, 482f
Introns, 35
Inulin, water reabsorption and, 355
Inulin clearance, 360–361, 361t, 362f, 363–364
Inulin space, 309
Involuntary fixation mechanism, of eyes, 658
Inward eutrophic remodeling, blood flow and, 213, 213f
Iodide
in high concentrations, 950
ingested, 941
ion, oxidation of, 943
Iodide trapping, 941–942, 942f, 948
thiocyanate ions and, 950
Iodine, 891
radioactive, for hyperthyroidism, 951
for thyroxine, 941
Ion channels
of adrenergic or cholinergic receptors, 767
concentration differences of, across neuronal somal membrane, 579–580
of interstitial cells of Cajal, 788
in postsynaptic membrane, 574–576
receptors linked to, 921–923
Ionizing radiation, cancer caused by, 46
Ionotropic receptors, 574
Ions
in cell, 13
transport of, thyroid hormones and, 946
vascular control by, 215
Iron, 444–445, 891
absorption of, 445
accumulation of, in fetus, 1062
atherosclerosis and, 864
daily loss of, 445
intestinal absorption of, 830
in liver, 874
metabolism of, 444–445
need for, in diet, 1067–1068
transport and storage of, 444–445, 444f
Iron-lung, 548–549
Iron sulfide proteins, 848–849
Irritant receptors, in airways, 538
IRS. *See* Insulin-receptor substrates
Ischemia, as pain stimulus, visceral, 618
Ischemic heart disease, 264–266
Ischemic tissue, release of toxins by, 297
Islets of Langerhans, 815, 973
beta cells of, 973
cell-to-cell communication and, 973
Isocitrate, 977
Isografts, 475
Isohydric principle, 408
Isomaltase, 821

Isometric contraction
of skeletal muscle, 87–88, 87f
of ventricles, 119
Isometric relaxation, period of isovolumic, 119
Isosmotic solutions, 311
Isosthenuria, 430, 430f
Isotonic contraction, of skeletal muscle, 87, 87f
Isotonic solutions, 311, 311f
Isovolumic contraction, 119
Isovolumic relaxation, 119
Itch detection, 601
scratch reflex and, 694

J

J point, 153–154, 153f
J receptors, 538
Jacksonian march, 758
Janus kinase (JAK) family, leptin receptor and, 922
Jaundice, 875–876
in neonates, 1066–1067
in transfusion reactions, 474
JG cells. *See* Juxtaglomerular cells
Joint receptors
of neck, 707–708
Ruffini's endings as, 600
Joint spaces, effusion in, 320
Juxtaglomerular apparatus, 209
Juxtaglomerular cells (JG cells), 236, 339–340, 340f
Juxtaglomerular complex, 339, 340f, 351
Juxtamedullary nephrons, 324, 325f
countercurrent multiplier mechanism and, 368

K

Kallidin, 214–215, 795
Kallikrein, 214–215
in salivary glands, 810
Keratoconus, 634
Kernicterus, 474
Keto acid, in amino acid synthesis, 868
Ketogenesis, 869
Ketone bodies, 858, 978
in starvation, 887
Ketosis, 858
hormonally induced, by growth hormone, 934
insulin deficiency and, 978
in starvation, 887
Kidney(s)
anatomy of, physiologic, 322–324
artificial, volume-loading hypertension and, 235–236
atrial reflex in, 224
autonomic control of, 769t
blood flow control in, 209
blood supply of, 323, 324f
drugs and, 350
in fetus, 1062
filtration by, 330
functions of, 321–322
general organization of, 322, 323f
glomerular capillaries of, 194
gluconeogenesis in, 851
irritation of, intestinal activity and, 806
metabolic end product removal in, 6
oxygen consumption by, 336, 336f
reabsorption by, 329f, 330, 343, 344f
calculation from renal clearance, 361t
of different substances, 343, 344t
glomerulotubular balance and, 355
mechanisms of, 343–348
transport maximum for, 346–347, 347f
secretion by, 329f, 330, 343
of hydrogen ions, 330
of organic acids and bases, 350
Kidney(s) *(Continued)*
of potassium, 330
shock-related lesions in, 298
water loss by, 305–306
Kidney diseases, 421–436
anemia in, 322
edema in, 317
hypertension and, 431–432
in end-stage renal disease, 427
as nephrosclerosis, 427
nephrotic syndrome in, 428
tubular disorders, 432–433
Kidney stone, in hyperparathyroidism, 1005
Kidney transplantation, 433
Killer cells, 467–468
Kilocalorie, 896
Kinesiology, 90
Kinesthesia, 608
Kinetic energy, of blood flow, work output, 121
Kinocilium, 705, 705f
Klüver-Bucy syndrome, 751
Knee jerk, 690, 690f
Korotkoff sounds, 186
Kupffer cells, 453, 453f, 871, 873
Kwashiorkor, 877–878, 889
growth hormone in, 935–936
Kyphosis, 542, 937

L

"Labeled line" principle, 587
Labor
abdominal muscle contractions during, 1055–1056
onset of, 1055, 1055f
positive feedback theory of, 1055
pains in, 1056
Lacrimal glands, autonomic control of, 768, 769t
Lactase, 821, 824
Lactation, 1045–1060
metabolic drain on mother by, 1059, 1059t
oxytocin and, 940
parathyroid glands and, 1001
prolactin and, 1057–1058, 1058f
Lactic acid
from anaerobic glycolysis, 846f, 850, 894–895
as energy for heart, 850
from muscle glycogen, 1075
reconversion to pyruvic acid, 850
removal of, 1076
shock and, 298
in skeletal muscle, 86
as vasodilator, 260
in sweat, 904
Lactic acid oxygen debt, 1076–1077, 1076f
Lactic dehydrogenase, zinc in, 892
Lactose, 823
Lactotropes, 930, 931t
Lagging strand, 42
Laminar flow, 175
of blood, 175
Language, 729f, 730, 732
Large intestine (colon)
absorption in, 831–832
of chloride, 829, 832
maximum capacity of, 832
of sodium, 828, 832
bacterial action in, 832, 838
disorders of, 836–837
functions of, 804
gas in, 832, 838
movements of, 804, 804f–805f
obstruction of, 838
secretions of
bicarbonate in, 829
Large intestine (colon) *(Continued)*
mucus in, 821
storage function of, 831
Larynx, 500, 501f
Lateral geniculate body, 653, 653f
Lateral inhibition
in cerebellum, 715
effect of, 607
in motor system, 686
in retina
to enhance visual contrast, 648, 648f
role of, 650, 651f
Lateral lemniscus, 669
Lateral motor system of cord, 701
Lateral olfactory area, 682
Law of the gut, 793
LDLs. *See* Low-density lipoproteins
Leading strand, 42
Learned patterns of movement, 725
Learning
hippocampus in, 750
theoretical function of, 750
intellectual functions of, 727–740
neuronal connectivity and, 738
reflexive, 739
reward or punishment and, 749
Lecithin
in bile, 818–820, 819t, 826
chemical formula of, 860–861, 860f
Left atrial, pressures in, 504
Left bundle branch block, axis deviation in, 149f–150f, 150
Left-to-right shunt, 289–290
Left ventricles, volume-pressure curves, 121
Left ventricular hypertrophy
electrocardiogram, 149
valvular heart disease and, 286–287, 287f
Lengthening reaction, 691
Lenses, of eye
accommodation by, loss of, 631
combination of two cylindrical, 628, 629f
concave, 628, 628f
convex, 627–628, 627f
formation of an image by, 629, 630f
correction of myopia and hyperopia through, 633, 633f
cylindrical, 628, 628f
focal length of, 628–629, 629f
focus of, autonomic control of, 768
opaque areas in, 634
pupillary diameter and, 632
refractive errors in, 632–634
refractive power of, measurement of, 629, 630f
refractive principles to, application of, 627
spherical, 628, 628f
Leptin, 883
obesity and, 885, 899
receptors of, 922, 922f
stimulation of, 883
resistance to, 883
Leukemias, 457–458
effect on body, 458
Leukocyte pyrogen, 910
Leukocytes, 449–458
Leukopenia, 457
Leukorrhea, during menstruation, 1037
Lever systems, of skeletal muscle, 90, 90f

  as smooth muscle neurotransmitter, 106
  sweat glands and, 904
  sympathetic effect of, 132
  as sympathomimetic drug, 774
  synthesis of, 918–919
    removal and duration of action of, 766–767
  as vasoconstrictor, 214, 219–220
    in skeletal muscle, 260
Norepinephrine system, in brain, 742, 743f
Nose, filtration function of, 500
NPP1. *See* Nucleotide pyrophosphatase phosphodiesterase 1
NPY. *See* Neuropeptide Y
NTS. *See* Nucleus tractus solitarius
Nuclear bag muscle fibers, 687–688, 687f
Nuclear chain muscle fibers, 687–688, 687f
Nuclear membrane, 13, 20
Nuclear pores, 20
Nuclear receptors, activation of, thyroid hormones and, 944–946
Nucleoli, 20, 36
Nucleotide pyrophosphatase phosphodiesterase 1 (NPP1), 995
Nucleotides, 31–33, 33f
  activated, RNA chain assembly from, 34–35
  deoxyribose, 31–33, 33f
  formation of RNA, 34
Nucleus, 19–20
  genes in, control protein synthesis, 31–33, 32f
  structure of, 20f
Nucleus accumbens, Parkinson disease and, 724
Nucleus ambiguus, 532
Nucleus parabrachialis, 532
Nucleus reticularis paragigantocellularis, 616
Nucleus retroambiguus, 532
Nucleus tractus solitarius (NTS), 531
  carotid baroreceptors and, 222
  energy expenditure and, 880
  sleep and, 754
Nutrient demand theory, for local blood flow control, 207
Nystagmus, cerebellar, 720

O

Oat bran, 864
Obesity, 884–887
  atherosclerosis and, 863
  causes of, 884–886
    abnormal feeding behavior as, 885
    childhood overnutrition and, 885
    neurogenic abnormalities as, 886
    sedentary lifestyle as, 884–885
  cortisol and, 964
  end-stage renal disease associated with, 427
  fat storage in, 860
  genetic factors in, 885
    leptin and, 885
    in rodents, 860
  hypertension and, 242
  nonshivering thermogenesis and, 899
  results from greater intake than energy expenditure, 884
  through epigenetic mechanisms, 885–886, 885f
  treatment of, 886–887
  type II diabetes and, 986
Obstructive jaundice, 875–876
Obstructive sleep apnea, 539
Occipital headache, 621
Occlusion, of teeth, 1006
Oddi, sphincter of, 814–815, 818f, 819
Odontoblasts, 1006
Odor blindness, 680
Ohm's law, 174, 246
Okazaki fragments, 42
Oleic acid, 853
Olfaction, amygdala and, 751
Olfactory bulb, 679f, 681, 681f
  granule cells in, 680, 682
Olfactory cells, 679, 679f, 681
  stimulation of, 679–681, 679f
Olfactory cilia, 679, 679f
Olfactory cortex, hippocampus and, 750
Olfactory membrane, 679, 679f, 681
Olfactory nerve, 679–680
Oligohydramnios, 1062
Oligomenorrhea, 948
Oliguria, 424
Olivocerebellar fibers, 700
Olivocerebellar tract, 713
Oncoviruses, cancer caused by, 47
Oocyte, 1027
  primary, 1045
  secondary, 1045
Oogenesis, 1027, 1029f
OPG. *See* Osteoprotegerin
OPGL. *See* Osteoprotegerin ligand
Opposite limbs, reciprocal stepping of, 694
Opsonization, 22, 451
  phagocytosis and, 465
Optic chiasm, 653, 653f
Optic nerves, 653, 653f
Optic radiation, 653, 653f
Optic tracts, 653, 653f
  interruption of, 657
Opticokinetic movements, 659
Optics
  of eye, 630–635
  physical principles of, 627–629
Orexigenic substances, 881t, 886
Orexin neurons, 755
Organ of Corti, 664
  function of, 666–668, 667f
  retrograde pathways in, 672
Organic substances, secretion of, 808–809
Organum vasculosum, 939
Orgasm
  female, 1042
  male, 1017

Orlistat, 886
Oscillatory methods, normal arterial pressures measured by, 187
Oscilloscope, measurement of membrane potentials, 65
Osmolality, 58, 310–311
of chyme, 801
Osmolar activity, of body fluids, 311
Osmolar clearances, 374
Osmolarity, 58, 310–311
of body fluids, 308t, 310–311
plasma, 308t, 312–313
estimated from sodium concentration, 314, 375
Osmoles, 58, 310
Osmoreceptor cells, 375
Osmoreceptors, 939
Osmosis, 57, 57f, 310–312
across selectively permeable membranes, 57–58
active transport combined with, 62
Na^+-K^+ pump, 60
renal reabsorption and, 344, 347–348
of water, in small intestine, 829
Osmotic coefficient, 310
Osmotic diuresis, 985
Osmotic diuretics, 421–423, 422t
Osmotic equilibrium, of intracellular and extracellular fluids, 311–312
Osmotic pressure, 57–58, 58f, 310
of cerebrospinal fluid, 781
importance of number of, 58
Ossicular system, 663–664, 663f
impedance matching by, 664
Osteitis fibrosa cystica, 1004
Osteoblasts, 934–935
deposition of bone by, 995–997, 995f
fracture repair and, 997
Osteoclastogenesis inhibitory factor, 996
Osteoclasts, 934–935
activation of, 1001
bone resorption and, 995–996, 996f
Osteocytes, 994
Osteocytic membrane system, 1000
Osteoid, 994
Osteolysis, 1000–1001
Osteomalacia, 1005
in renal disease, 431, 1005–1006
Osteon, 996, 997f
Osteoporosis, 1006, 1035
Osteoprogenitor cells, 997
Osteoprotegerin (OPG), 996
Osteoprotegerin ligand (OPGL), 996
Otosclerosis, 673
Outward hypertrophic remodeling, blood flow and, 213–214, 213f
Outward remodeling, blood flow and, 213–214, 213f
Oval window, 663, 663f
Ovarian cycle, 1028–1032
follicular phase of, 1029–1031, 1030f
luteal phase of, 1031–1032
ovulation in, 1031
suppression of, during nursing, 1058
Ovarian follicles
atretic, 1031
growth, 1029–1031, 1030f
Ovarian hormones, 915
Ovaries
anatomy of, 1027, 1028f
cholesterol used by, 862
follicular development in, 1027
hypersecretion by, 1041
relaxin secretion and, 1051–1052
secretion by, abnormalities in, 1041
hypogonadism-reduced, 1041
Overdistention, visceral pain and, 619
Overdrive suppression, 159
Overflow incontinence, 328
Overhydration
hypernatremia causing, 314t, 315
hyponatremia in, 314, 314t
Ovulation, 1027, 1031, 1031f, 1045
failure of, 1043
gonadotropic hormones and, 1028–1029
hypothalamic-pituitary hormones and, 1037–1041
initiation of, 1031
luteinizing hormone in, 1031
Ovum, 1027
entry into fallopian tube, 1045
fertilization of, 1045, 1046f
capacitation of spermatozoa and, 1014–1015
maturation of, 1045–1047
penetration of, acrosome enzymes and, 1015
Oxalate, as anticoagulant, 487
Oxalate ion, 483
Oxaloacetate, in citric acid cycle, deficiency of, 858
Oxaloacetic acid, in citric acid cycle, 847, 847f
fatty acids and, 857
Oxidases, of peroxisomes, 18
Oxidative metabolism, in skeletal muscle, 86
Oxidative phosphorylation, 848–849, 848f
pentose phosphate pathway and, 850–851
uncoupled, 899
Oxygen
in alveoli, concentration of, 514, 514f–515f
in blood flow control, in skeletal muscle, 259–260
brain special requirement for, 784
breathing pure and, 553–554
of cardiac muscle, 266
coronary blood flow and, 263
deficiency
cerebral blood flow and, 778
chemoreceptors by, 535, 535f
diffusing capacity for, 517
diffusion of
from peripheral capillaries to interstitial fluid, 522–523, 522f
from peripheral capillaries to tissue cells, 523
through cell membranes of capillary endothelium, 195
through placenta, 1048–1049, 1048f
through the respiratory membrane, 511–520
displacement of, 527f
energy equivalent of, 897
in extracellular fluid
normal range of, 8t
regulation of, 7
in heart failure, with acute pulmonary edema, 277
with hemoglobin, 529, 529f
reversible combination of, 524–525
high pressures of, 561–563
inadequate tissue capability to use, 547
lipid solubility, 52
in local blood flow control
acute, 206–211, 206f
long-term, 211–212
local tissues, of smooth muscle, 108
low, chronic breathing of, 536
maximum amount of, with hemoglobin of blood, 524
metabolic use of, by cells, 526–528
poisoning, acute, 562
released from hemoglobin, systemic arterial blood flows and, 524, 524f
respiratory control by, 534–536, 534f
transport of
in dissolved state, 527
hemoglobin and, 524–526
Oxygen *(Continued)*
importance of, 525–526, 526f
in lungs, to body tissues, 521–528
during strenuous exercise, 524–525, 524f
utilization of, BMR and, 897
Oxygen consumption
cardiac output and, 246, 246f
in cellular metabolism, interstitial fluid PO_2 and, 522–523, 522f
during exercise, 1078–1080, 1079f
work output and, 1080–1081, 1081f
by heart, 123
Oxygen debt, 895, 1076–1077, 1076f
Oxygen demand theory, for local blood flow control, 207, 207f
Oxygen-diffusing capacity, 1079
Oxygen free radicals, 562
Oxygen-hemoglobin dissociation curve, 524, 524f
factors that shift, 525–526, 526f
at high pressures, 561, 562f
for high-altitude residents, 556, 556f
increased delivery of oxygen to tissues, CO_2 and H^+ shift, 526, 526f
rightward shift of
effect of 2, 3-biphosphoglycerate to cause, 526
during exercise, 526
Oxygen partial pressure (PO_2)
alveolar
during exercise, 1079
high altitude and, 553
ventilation, composite effects of, 536, 536f
arterial, low, effect of, 535–536, 536f
blood, determination of, 541
expired air and, 515, 515f
hemoglobin and, 525
high level of, on blood oxygen transport, 561–563
intracellular, oxygen usage and, 526–527, 527f
in tissues
cerebral blood flow and, 778
high alveolar PO_2 and, 562, 562f
Oxygen saturation, arterial
at different altitudes, 554t
in local blood flow and, 206, 206f
Oxygen therapy
in different types of hypoxia, 547, 547f
hyperbaric, 566
in premature infant, 1069
for respiratory abnormalities, 546–548
for shock, 301
Oxygen toxicity, at high pressures, 561–563
Oxyhemoglobin, 778–779
Oxyhemoglobin dissociation curves, 1048, 1048f
Oxyntic (gastric) glands, 807, 811–813, 811f
peptic cells of, 811–813, 811f
typical, 811, 811f
Oxyphil cells, 999, 1000f
Oxytocin, 929, 938
chemical structure of, 938
contractions of the uterus and, 1042
fertilization and, 1045
labor and, 940
milk ejection and, 1058–1059
physiological functions of, 940
and milk ejection, 940
uterus, pregnant, contraction of, 940
uterus and, contraction of, 1054
Oxytocin, hypothalamus and, 746

P

P ganglion cells, 649–650
P wave, 135
atrial contraction and, 135
cardiac cycle and, 118

Pacemaker
  cardiac, 131
    arrhythmias, 157
    ectopic, 131
    in paroxysmal tachycardia, 162
  gastrointestinal smooth muscle, 788
Pacinian corpuscles, 600
  receptor potentials of, 589, 589f
  vibrations detected by, 600–601
PAF. *See* Platelet-activating factor
Paget's disease, calcitonin and, 1003
PAH. *See* Para-aminohippuric acid
Pain
  abdominal and thoracic, parietal pathway for transmission of, 619–620, 620f
  analgesia system of brain and spinal cord, 616–618, 617f
  brain stem excitatory area and, 741
  Brown-Séquard syndrome and, 620–621, 620f
  clinical abnormalities of, 620–622
  in coronary heart disease, 268–269
  dual pathways for transmission of, 614–616
    surgical interruptions of, 616
  by electrical stimulation, 618
  fast and slow, 613
  of headache, 621
  of herpes zoster, 620
  hyperalgesia and, 620
  hypersensitivity and, 620
  of labor, 1056
  muscle spasm and, 614
  parietal, 619
  referred, 618–619
    headache as, 621
  surgical interruption of, 616
  by tactile sensory signals, 617–618
  of tic douloureux, 620
  tissue damage and, 613–614, 614f
  tissue ischemia and, 614
  types and qualities of, 613
  visceral, 618
Pain fibers, peripheral, "fast" and "slow," 614
Pain receptors
  nonadapting nature of, 613
  stimulation of, 613–614
  thermal excitation of, 622–623
  types of stimuli excite, 613
Pain reflex, 691
Pain sense, 599
Pain signals, arousal, pain excitability and, 616
Pain suppression (analgesia) system, in brain and spinal cord, 616–618, 617f
Paleocortex, 745
Paleospinothalamic pathway
  into brain stem and thalamus, 616
  for transmitting slow-chronic pain, 615–616
Paleospinothalamic tract, 615–616
Palmitic acid, 853
Pancreas
  acini of, 807, 814–815
  beta cells of, insulin deficiency and, 984–986
  digestive enzymes of, 815
  islets, 981
  physiologic anatomy of, 973, 973f
Pancreatic duct, 814–815
Pancreatic failure, 835
Pancreatic gland, autonomic control of, 769t
Pancreatic polypeptide, 973
Pancreatic secretions, 814–816, 816f–817f
  alkalinity of, 834
  amylase, 815, 824
    in neonates, 1067
  basic stimuli causing, 816
  lack of, 835
  lipases, 815, 826, 826f
  proteolytic enzymes, 815, 825, 825f
Pancreatitis, 835
  acute, 815
Panhypopituitarism, 936–937
  in adults, 936–937
    with gigantism, 937
  in dwarfism, 936
Panting, 905
Pantothenic acid, 847, 889
Papilla of Vater, 814–815
  blockage at, 835
Papillary muscles, 120, 120f
Para-aminohippuric acid (PAH), 350
  renal plasma flow and, 362–363, 363f
Paracellular pathway, 344
Paracellular route, 343–344
Parachute jumps, deceleratory forces in, 559
Paracrines, 915
Paradoxical sleep, 753
Parafollicular cells, 1002
Parallax, moving, determination of distance by, 635
Parallel fibers, of cerebellum, 715
Parallel vascular circuits, resistance to blood flow in series and, 178
Paralysis, of swallowing mechanism, 833
Parasympathetic nervous system
  anatomy of, physiologic, 764–765, 765f
  cardiac, 124f–125f, 125
  control of heart by, 124–125
  denervation sensitivity of, 772
  erection and
    in female, 1042
    penile, 1017, 1017f
  eye and, 765
  gastric secretions and, 812
  gastrointestinal regulation by
    defecation and, 772
    large intestine mucus and, 821
    psychogenic diarrhea and, 836
  gastrointestinal secretions and, 808
  gastrointestinal stimulation by, 790–791
    blood flow and, 796
    defecation and, 791
    peristalsis and, 793
  localized responses of, 773
  lubrication and, 1017
  salivary glands and, 810, 810f
Parasympathetic tone, 771–772
Parasympathomimetic drugs, 774–775
Parathyroid gland, physiologic anatomy of, 999, 1000f
Parathyroid hormone (PTH), 991–1010
  bone resorption and, 995–996
  calcium and, 390, 390f
    absorption of, 1001, 1004
    excretion of, 1001
    intestinal absorption of, 830
    phosphate mobilization and, 1000–1001
  chemistry of, 999
  control of secretion of, 1001–1002, 1002f
  and cyclic adenosine monophosphate (cAMP), 1001
  1,25-dihydroxycholecalciferol and, 997f, 998
  disease of, 1004–1006
  effect of, on calcium and phosphate concentrations, 1000–1001, 1000f
  excess of, in chronic kidney disease, 431
  lactation and, 1057
  osteolysis and, 1000
  phosphate and, 392
    absorption, 1001
    excretion of, 1001
  renal reabsorption in, 360
  summary of effects of, 1002, 1002f
  treatment with, in hypoparathyroidism, 1004
  vitamin D and, 999
Parathyroid poisoning, 1004–1005
Paraventricular nuclei
  food intake and, 880
  pituitary hormones and, 938
Parietal (oxyntic) cells, 811, 811f
  hydrochloric acid secretion by, 812f, 813, 814f
    stimulation of, 812–813
  intrinsic factor secretion by, 812
Parietal lobe, somatosensory signals and, 603
"Parietal pain," by visceral disease, 619
Parieto-occipitotemporal association area, 729–730, 729f
  prefrontal association area and, 730
Parieto-occipitotemporal cortex, in nondominant hemisphere, 732
Parkinson's disease, 723–724, 761
Parotid glands, 809, 823–824
  autonomic control of, 769t
Paroxysmal tachycardia, 162–163
  atrial, 162–163, 163f
  ventricular, 163, 163f
Pars intermedia, 929
Partial intraventricular block, 160, 160f
Partial pressures
  of gas, 511–513
  net diffusion and, 512
Parturition, 1054–1056
  involution of uterus after, 1056
  mechanics of, 1056
Parvocellular layers, 654, 655f
Passive immunity, 469
Passive vascular beds, pressure-flow relationship in, 180, 180f
Past pointing, 719
Patch-clamp method, 54–55, 55f
Patent ductus arteriosus, 289–290, 289f, 1065
  abnormal pressure pulse contours and, 185
  circulatory dynamics in, 289–290
  murmur of, 285f, 289
Pathophysiology, defined, 4
Pathway sensitivity, automatic short-term adjustment of, 597
Pellagra, 889
Pelvic nerves
  bladder and, 326–328
  parasympathetic fibers in, defecation reflex and, 805–806, 805f
  parasympathetic innervation to, to intestine, 821
  sacral parasympathetics and, to intestine, 791
Pelvis, testosterone and, 1020
Pendrin, 942
Pendular movements, 718
Penetrating arteries and arterioles, of brain, 777, 777f
Penile erection, 210, 772, 1017, 1017f
Penis, autonomic control of, 769t
Pentagastrin, 814
Pentose phosphate pathway, 850–851, 851f
Pepsin, 812, 824–825, 825f
  diminished secretion of, 834
  excess of, 834–835
Pepsinogen, 811–812
  regulation of secretion of, 813–814
Peptic (chief) cells, 811–813, 811f
Peptic ulcer, 814, 820, 834–835, 834f
  basic cause of, 834–835
  obstruction caused by, 838
  specific causes of, 835
  treatment of, 835
Peptidases
  of enterocytes, 821, 825
  zinc in, 892
Peptide bonds, 38
Peptide chains, amino acids and, 865
Peptide linkages, 823–824
  amino acids and, 865
  ATP and, 893, 896
  formation of, 38

Peptide YY (PYY), 882
Peptidyl transferase, 38
Peptones, 817, 817f, 825
Perforins, 467–468
Periaqueductal gray region, pain signals and, 616
Perilymph, 668
Perimetry, 657, 657f
Periodic breathing, respiration and, 538, 538f
Periodontal membrane, 1007
Peripheral cell membrane protein, 16
Peripheral chemoreceptor system, 534–536, 534f
Peripheral circulation, 171
Peripheral resistance unit (PRU), 177
Peripheral venous pressure, high right atrial pressure on, 188–189
Perisinusoidal spaces, 871
Peristalsis, 793, 793f
  of colon, 805
  control of, by nervous and hormonal signals, 803
  of esophagus, 798f, 799
  of ileum, 804, 804f
  of pharynx, 798–799
  of rectum, 805
  of small intestine, 803
  of stomach, 799
    emptying and, 802
Peristaltic reflex, 793
Peristaltic rush, 803
Peristaltic waves, in small intestine, 803
Peritoneointestinal reflex, 806
Peritonitis
  abdominal muscle spasm in, 694
  intestinal paralysis and, 806
  septic shock secondary to, 300
Peritubular capillaries, 323–324, 324f, 329–330, 329f
  reabsorption and, 343–344, 344f
    physical forces and, 355–357, 356f–357f, 357t
Perivascular spaces, of brain, lymphatic function of, 782–783, 782f
Pernicious anemia, 443, 446, 812, 834, 890
Peroxidases, 562
  iodide oxidation and, 943
Peroxide radical, high alveolar PO_2 and, 562
Peroxisomes, 18, 452
Petechiae, 478
Petit mal seizures, 759–760, 759f

SCN. *See* Suprachiasmatic nucleus
Scoliosis, 542
Scotomata, 657
Scotopsin, 641
Scratch reflex, 694
Scurvy, 888
Second-degree heart block, 159, 159f

Second heart sound, 283
duration and pitch of, 283–284
"Second messenger" enzymes, 767
Second messengers, 16
adenylyl cyclase-cAMP, 923–924, 924f, 924t
adrenergic or cholinergic receptors and, 767
aldosterone and, 961
calcium-calmodulin, 925
cell membrane phospholipid, 924–925, 924t, 925f
postsynaptic neuron in, 575–576, 575f
in smooth muscle, 108–109
transmitter substances, in taste cells, 677
Secondary active transport, 344–346
Secondary visual areas, of cortex, 654–655, 654f
Secretin, 792, 792t
bile secretion and, 818, 818f
chemical composition of, 814
duodenal mucous glands and, 820
gastric secretion and, 814
pancreatic secretions and, 816–817, 834
small intestine motility and, 803
stomach emptying and, 802
Secretory vesicles, 18f, 24, 24f
of gastrointestinal glands, 808
of polypeptide and protein hormones, 916–918
Segmentation contractions
of colon, 804
of small intestine, 802–803, 802f
Seizures, 757–760
brain, in acute oxygen poisoning, 562
epileptic, 597
hippocampal, 750
neuronal circuits, 597
Selectins, 455
Self-antigens, 461, 468
Self-contained underwater breathing apparatus (SCUBA) diving, 565, 565f
Sella turcica, 929
Semen, 1014–1016
ejaculation of, 1017
Semicircular canals, 704–705, 704f
Semicircular ducts, 705–706, 706f–707f
flocculonodular lobes and, 708, 720
Semilunar valves, 120
second heart sound and, 283
Seminal vesicles, function of, 1014
Seminiferous tubules, 1011, 1012f
Sensations
modality of, 587
segmental fields of, 610, 610f
transmission of changing and repetitive, 607
Sensitization, memory and, 736
Sensitizing antibodies, 469
Sensory antennae, 28
Sensory areas, 219
of cerebral cortex, 727, 729f
Sensory pathways, for transmitting somatic signals, into central nervous system, 601
Sensory reception, tremendous intensity range of, 607–608
Sensory receptors, 569, 570f
adaptation of, 589–591, 590f
mechanism by, 590–591
classification of, 588t
differential sensitivity of, 587
maximum receptor potential amplitude, 588
position, 608
receptor potentials of, 587–589
relation of receptor potential to action potentials, 588–589, 589f
types of, 587, 588f
Sensory sensitivity, cortical control of, 610
Sensory signals
brain stem excitatory area and, 741–742
hippocampus and, 750
Sensory stimulus
intensity
interpretation of, 607–608
judgment of, 608
transduction of, into nerve impulses, 587–592
Septic shock, 300
Septicemia, 486
Septicemic shock, disseminated intravascular coagulation in, 486
Sequential movements
planning of, 719
timing function for, 719
Serotonin
in basal ganglia, 723f
depression and, 760–761
from mast cells and basophils, 457
memory and, 737
neurotransmitters in, 723
reticular inhibitory area and, 742
sleep and, 754–755
small intestine peristalsis and, 803
as small-molecule transmitter, 578
Serotonin system, in brain, 742, 743f
Serous secretion, 809–810
Sertoli cells, 1012
Serum, expression of, 480–481
Sex chromosomes, 1012–1013
Sex determination, 1046
Sex-determining region Y (SRY) gene, 1019
Sex hormone-binding globulin, 1018
Sexual activities, amygdala and, 751
Sexual drive, hypothalamus and, 748
Sexual function, thyroid hormones and, 948
Sexual life, male, 1023
Sexual reflexes, 772
Sexual sensation, 1016
"Shaken baby syndrome," 781
Shingles, 620
Shivering
hypothalamic stimulation of, 907
primary motor center for, 907, 909f
Shock lung syndrome, 298
Short interfering RNA, 37
Shunt, congenital, 289–290
Sibutramine, for weight loss, 886
Sickle cell anemia, 441f, 446
hemoglobin in, 444
Sickle cell disease crisis, 446
Signal averaging function, of muscle spindle reflex, 689
Signal transducer and activator of transcription (STAT) proteins, 922
Silencing RNA (siRNA), 37
Siliconized containers, 487
Silicosis, 542
Simple cells, of visual cortex, 656
Simple spike, 715
Sinoatrial block, 158, 158f
Sinus arrhythmia, 157–158, 158f
Sinus bradycardia, 157, 158f
Sinus node, 127
action potentials in, 129
atrial stretch and, 245
as pacemaker, 131
parasympathetic stimulation and, 132
rhythmicity, mechanism of, 127–129, 128f
self-excitation of fibers in, 128–129
Sinus node rhythm, autonomic control of, 769t
Sinus tachycardia, 157, 158f
Size principle, 89
Skeletal muscle
atrophy, 90–92
autonomic control of, 769t
blood flow in, 259–262
control of, 259–260
during exercise, 1080–1082
nervous control of, 260
rate of, 259
during rhythmic muscular exercise, 259
during rhythmical contractions, 259f, 1080f
BMR and, 897–898
capillary pores, permeability of, 195, 196t
contraction of, 79–92
characteristics of, 87–92
energetics of, 85–87
mechanics of, 88–90
molecular mechanism of, 81–82
contracture of, 91
decreased mass of, cardiac output and, 250
denervation in, 91
efficiency of, 86–87
end plate potential and excitation of, 95–96
energy sources for, 84, 86
excitation of, 93–100
excitation-contraction coupling in, 97–100
fatigue, 89–90
fibers in, 79–81
fast *versus* slow, 88
force, 85, 85f
velocity of contraction, 86f
glycogen in, 86
hyperplasia of, 91
hypertrophy of, 90–92
length, adjustment of, 91
lever systems of, 90, 90f
maximum strength of, 89
motor units of, 89
organization of, 80f
physiologic anatomy of, 79–81
in poliomyelitis, 91
remodeling of, 90–92
to match function, 90–92
sequential steps, 81
versus smooth muscle, 102–103
staircase effect, 89
summation of contractions, 88–89, 89f
tension developed in, 85, 85f
tetanization in, 89
tone of, 89
transverse tubules, 97
velocity of contraction to load on, 85, 86f
work output of, 85–87
Skill learning, 739
Skill memory, 736
Skin
autonomic control of, 769t
blood flow control in, 209
as body protection, 6
cholecalciferol formation and, 997–998
cholesterol in, 862
in defense against infection, 459
estrogen and, 1035
heat loss through, 902–903
physics of, 902–903, 903f
insensible water loss through, 305, 306t
thickening of, testosterone and, 1020
tissue macrophages in, 453–454
Skin temperature, 901
blood vessels in, vasodilation of, 906
local reflexes of, 909
normal, 901
set point and, 908, 908f–909f
vasoconstriction and, 906
SLE. *See* Systemic lupus erythematosus

Sleep, 753–756
basic theories of, 754–755
brain waves in, 754f, 756–757, 756f
cycle between wakefulness and, 755
growth hormone and, 935, 935f
metabolic rate and, 898
physiological functions of, 755–756
possible transmitter substances related to, 755
-promoting centers, lesions in, 754–755
rapid eye movement, 743, 753
brain waves in, 754f, 757
deprivation of, 755
possible cause of, 755
slow-wave, 753–754
delta waves in, 757
thyroid hormones and, 948
Sleep apnea, 539
"central," 539
Slit pores, of glomerular capillary, 331–332, 332f
Slow calcium channels, 71
in cardiac muscle, 115
Slow-chronic pain signals, 614, 615f
Slow conduction, cause of, 129
Slow ejection, period of, 119
Slow muscle fibers, 88
Slow pain, 613
Slow-reacting substance of anaphylaxis, 470
Slow sodium-calcium channels, cardiac muscle, 128
ventricular action potential, 128
Slow-twitch muscle fibers, 1078
athletes and, hereditary differences in, 1078
Slow waves
of gastrointestinal smooth muscle, 787–788, 788f
in small intestine, 802–803
in stomach, 800
Sludged blood
in circulatory shock, 297
in septic shock, 300
Small interfering RNA (siRNA), 36–37
Small intestine
abnormal digestion of food in, 835
absorption in, 828–831
anatomical basis of, 827–828, 827f–828f
capacity of, 828
of ions, 829f
of nutrients, 830–831
total absorptive area of, 828
carbohydrate digestion in, 824
digestive enzymes of, 821
disorders of, 835–836
enzymes of, 824
isosmotic absorption in
of ions, 828–830
of water, 828
malabsorption by, 835–836
movements of, 802–803, 802f, 804f
obstruction of, 838, 838f
peptic ulcer of, 834
protein digestion in, 825f
secretions of, 820–821
regulation of, 821
secretory cells of, 807
Small-molecule, rapidly acting transmitters, 577–578, 577t
Small nuclear RNA (snRNA), 35
Smaller arteries, pressure pulses in, 186, 186f
Smell, 679–682
adaptation of, 680
affective nature of, 680–681
intensities of, gradations of, 681
olfactory cell stimulation in, 679–681, 679f
olfactory membrane in, 679, 679f
primary sensations of, 680–681
signal transmission into central nervous system, 681–682, 681f
Smell *(Continued)*
taste and, 675
threshold for, 681
Smoking
atherosclerosis and, 863
peptic ulcer and, 835
pulmonary ventilation in exercise and, 1080
Smooth endoplasmic reticulum, 17, 24f
Smooth muscle
calcium channels and, 107
calcium ions and, 789
contractile mechanism in, 101–103
calcium ions, 101
contraction of, 101–110
chemical basis for, 101–102
hormones on, 108
local tissue chemical factors, 108
nervous and hormonal control of, 105–109
physical basis for, 102, 102f
without action potentials, 108–109
energy requirement of, 103
excitation, 101–110
of visceral, 108
"latch" mechanism of, 103, 105
latent period of, 104
maximum force of contraction, 103
membrane potentials in, 106–108
of metarterioles, 193, 207
multi-unit, 101, 102f
neuromuscular junctions of, 106
peristalsis in, 793
of precapillary sphincters, 193, 207
versus skeletal muscle, 102–103
slowness of onset of contraction, 103
stimulatory factors for, 108
stress-relaxation of, 103
reverse, 103
types of, 101
vascular
autoregulation of blood flow and, 209
intrinsic tone of, 771–772
Sneeze reflex, 500
Social responses, inappropriate, 733
Sodium, 828–830
in bone, 994
in cerebrospinal fluid, 781
dietary
potassium intake and, 389
recommendation for, 389
diffusion, through cell membranes of capillary endothelium, 195
extracellular fluid, regulation of, 365, 375
angiotensin II and aldosterone in, 379–380, 380f
by osmoreceptor-ADH system, 375, 379–380
salt appetite and, 380
by thirst, 377–380, 378t, 379f
extracellular fluid volume and, 393
extreme secretion of, 830
integrated responses to, 399
intestinal absorption of, 828, 829f, 832
in colon, 832
intestinal secretion of, 820
in nerve conduction, 893–894
in neuronal somal membrane, 579–580, 579f
normal range of, in extracellular fluid, 8t
plasma concentration of
aldosterone and, 959–960
with reduced GFR, 429, 429f
postsynaptic potential of, 581
renal adaptation to intake of, 321, 322f
renal excretion of
angiotensin II and, 398
control of, 393–394
diuretics and, 421, 422f
intake and, 393
Sodium *(Continued)*
renal reabsorption of, 344–345, 345f
aldosterone and, 347, 358–360, 398
angiotensin II and, 237, 359, 359f
arterial pressure and, 357t
atrial natriuretic peptide and, 360
chloride ions and, 348, 348f
with gradient-time transport, 347
hydrogen ions and, 346, 351f, 352, 415
oxygen consumption and, 336, 336f
by principal cells, 352–354
sympathetic activation and, 360
with transport maximum, 347
urine concentration and, 373
water reabsorption and, 347–348
in saliva, 808f, 809–810
salty taste of ions of, 675
Sodium bicarbonate
for acidosis, 417
metabolic alkalosis caused by, 417
Sodium-calcium counter-transporter, renal, 391, 391f
Sodium-calcium exchange pump, in cardiac muscle, digitalis activity and, 274
Sodium-calcium exchanger, in cardiac muscle, 117
Sodium channel blockers, 352, 353f, 422t, 423
Sodium channel proteins, epithelial, aldosterone and, 961
Sodium channels, 53–54
acetylcholine-gated, 81
in olfactory cilium, 679–680, 679f
voltage-gated, 81
action potential and, 68–70
activation of, 68
calcium ion concentration and, 70–71
characteristics of, 68f
inactivation of, 68
positive-feedback cycle, 71
Sodium chloride
active transport of, urine concentration and, 368–369, 368t, 373
diarrheal loss of, 830
mineralocorticoid deficiency and, 958–959
renal transport of, in distal tubule, 351, 352f
replacement of, 1082–1083
in sweat, 905
tubuloglomerular feedback and, 339, 340f
Sodium-chloride co-transporter, 351
thiazide diuretics and, 421–422
Sodium-chloride-potassium co-transport, loop diuretics and, 422
Sodium co-transport
of amino acid, 61
of amino acids and peptides, 831
of glucose, 61, 61f, 829f–830f, 830–831, 845
Sodium counter-transport, 61, 61f
Sodium gluconate, for acidosis, 418
Sodium glucose co-transporters, 345, 346f
Sodium-hydrogen counter-transport, renal, 410–411, 411f
Sodium-hydrogen exchanger, 346
Sodium-hydrogen exchanger protein, 410
Sodium-iodide symporter, 941–942, 942f
Sodium lactate, for acidosis, 418
Sodium-loading renal function curves, 242, 242f
Sodium-potassium adenosine triphosphatase (Na^+-K^+ ATPase) pump, 961
in cardiac muscle, 117
digitalis activity and, 274
gastric acid secretion and, 812, 812f
intestinal absorption of, 828–829
potassium secretion and, 384, 385f, 386, 389
renal reabsorption and, 344, 345f, 347
of bicarbonate, 410–411, 412f
in collecting tubule, 353f, 358

Sodium-potassium adenosine triphosphatase (Na^+-K^+ ATPase) pump *(Continued)*
in distal tubule, 351, 352f–353f
in loop of Henle, 351, 351f
thyroid hormones and, 941–942
Sodium-potassium (Na^+-K^+) pump
contribution of, 67
in re-establishing ionic gradients, 72, 72f
resting membrane potential and, 66–67, 66f
Sodium-potassium pump transports, 59–60, 59f
electrogenic nature of, 60
Sodium space, 309
Soma of neuron, 573
uniform distribution of, electrical potential inside, 580
Somatic senses
classification of, 599
definition of, 599
thalamus in, function of, 610
Somatomedin C, 935
prolonged action of, 935
Somatosensory area I, 603–604, 604f
functions of, 605
spatial orientation of signals from, 604, 604f
Somatosensory area II, 603–604, 604f
Somatosensory association area, 606
effect of removing, 606
Somatosensory cortex, 603–605, 603f
basal ganglia and, 722f
cerebellum and, 712–713
layers and function of, 604–605, 605f
motor cortex and, 697, 697f
vertical columns and, 605
Somatostatin, 936, 973
gastric secretion and, 814
glucagon and, 983
insulin secretion and, 983
Somatotropes, 930, 931t
Sour taste, 675–676, 676t
salivation and, 810
Spacecraft
acceleratory forces in, 557–559, 558f
sealed, "artificial climate" in, 559
weightlessness in, 559–560
Spaces of Disse, 871
Spasm
of coronary artery, 265
visceral pain and, 618
Spatial coordinates of body
posterior parietal cortex and, 722–723, 729, 729f
prefrontal cortex and, 730
Spatial summation
of impulses, auditory, 669
in neurons, 582
in sensory fibers, 592, 592f
thermal, 623
Special senses, definition of, 599
Speech
articulation in, 734
Broca's area and, 698f, 699, 732, 734, 734f
Sperm
count, 1016
formation of, 1013, 1013f
maturation of, 1013–1014
morphology and motility of, 1016, 1016f
and oocyte, 1015
physiology of, 1014
storage of, in testes, 1013–1014
Spermatogenesis, 1011–1016
abnormal, 1015–1016
hormonal factors stimulating, 1013
meiosis in, 1012–1013, 1012f
regulation of, 1022–1023
sex chromosomes in, 1012–1013
Spermatogenesis *(Continued)*
steps of, 1011–1014

Spinoreticular pathway, 713
Spiral ganglion of Corti, 665f, 666, 667f
Spirometer, forced vital capacity in, 543
Spirometry, 495–496, 495f
Spironolactone, 352, 353f, 423
Splanchnic circulation, 794–796, 794f
vasoconstriction in, in exercise or shock, 796
Spleen
as blood reservoirs, 191–192
macrophages of, 453–454, 454f
Splenectomy, 485–486
Splenic pulp, 454
Sports physiology, 1071–1084
body fluids and salt in, 1082–1083
cardiovascular system in, 1080–1082
and muscle blood flow, 1080–1082, 1080f
drugs and, 1083
female and male athletes in, 1073–1083, 1074f
muscles in, 1073–1078
endurance of, 1073–1074
metabolic system in, 1074–1075, 1075f, 1076t
power of, 1073–1074
strength of, 1073–1074
training effect on, 1077–1078
respiration in, 1078–1080
Sprue, 835, 889
anemia in, 836
Staircase effect (Treppe), 89
Standard bipolar limb leads, 139–140, 139f
Stapedius muscle, 664
Stapes, 663, 663f
Starch
digestion of, 824, 824f
in non-animal foods, 823
Starling equilibrium, for capillary exchange, 200
Starling forces, 197
Starvation, 887–888
fatty acids in blood in, 854
food stores, depletion of, 887, 887f
growth hormone secretion and, 935
ketosis in, 858
triglycerides in liver in, 856
vitamin deficiencies in, 887–888
Static position sense, 608
Static response, of spindle receptor, 687–688
Static stretch reflexes, 689
Statins, 864
Statoconia, 704f, 705
Stearic acid, 853
ATP from oxidation of, 857
Steatohepatitis, nonalcoholic, 871
Steatorrhea
rickets and, 1005
in sprue, 836
Stellate cells, of cerebellum, 715
Stem cells, multipotential hematopoietic, 440–441, 440f, 449–450
Stents, coronary artery, 269
Stepping movements, 694–695
Stercobilin, 875, 875f
Stereocilia, 667
of vestibular apparatus, 705, 705f
Stereopsis
determination of distance by, 635
neural mechanism of, 660
Steroid hormones, 916
cholesterol and, 861, 916, 918f
protein synthesis and, 925
Steroids, 916
adrenal, 958t
synthetic pathways for, 956, 957f
Stimulatory field, 593
Stimuli, multiplicative effects of, 816
Stokes-Adams syndrome, 131, 159–160
Stomach
absorption in, 827
anatomy of, 799–800, 800f
disorders of, 833–834
fat digestion in, 826
gastrin secretion by, 792, 792t
mixing and propulsion of food in, 800
motilin secretion by, 792–793
motor functions of, 799–801
peristalsis of, 799
emptying and, 802

Stomach *(Continued)*
protein digestion in, 824–825
receptive relaxation of, 799
starch digestion in, 824
storage function of, 800
Stomach emptying, 800–801
regulation of, 801
slowing, 814
Stools, fat in, 836
Storage colon, 831
Strabismus, 660, 660f
Streamline flow, 175
Streptococcal infection, glomerulonephritis secondary to, 424–425
Streptococcus mutans, caries and, 1008
Streptokinase, 275
Stress
cortisol and, 964–966, 964f
fat utilization in, 860
Stress relaxation, of blood vessels, 244
"Stress" response, of sympathetic nervous system, 773
Stress-relaxation
of blood vessels, 184, 184f, 243f
increased blood volume and, 254
reverse, in hypovolemic shock, 295
of smooth muscle, 103
reverse, 103
Stretch receptors, 399
of lungs, 532
Stria vascularis, 668
Stroke
cerebral vessels and, blocked, 780
hypertension and, 234
reduced brain blood supply caused by, 702
volume, and cardiac output, 1081, 1081f
Stroke volume output, 119–120, 286
arterial pressure pulsations, 184
Stroke work output, 121
curve, 123–124, 124f
Strychnine, 585
Stumble reflex, 694
Subarachnoid space, 781, 782f
Subcallosal gyri, 751
Subcortical level, of nervous system, 571
Subcutaneous tissues, macrophages in, 453–454
Subendocardial infarction, 266
Subliminal zone, 593
Sublingual glands, 809
Submandibular glands, 808f, 809
autonomic control of, 769t
Submarines
escape from, 565–566
internal environment, health problems in, 565–566
Submucosal plexus, 789–790, 790f
parasympathetic neurons in, 791
of small intestine, 803
Subneural clefts, 93, 94f
Substance P, 616
Substantia nigra, 720, 722f
dopamine system and, 743, 743f
Huntington disease and, 724
neurotransmitters in, 723, 723f
Parkinson disease and, 722, 724
Subthalamus, 721f–722f, 722
lesion in, 722–723
Subthreshold stimulus, 593
Subthreshold zone, 593
Sucrase, 821, 824
Sucrose, 823
Sulfonylurea drugs, 980
Summation
of inhibitory and excitatory postsynaptic potentials, 583
Summation *(Continued)*
in neuronal pools, 594
of skeletal muscle contractions, 88–89, 89f
Superior colliculus
involuntary locking fixation and, 659–660
visual disturbance and, 659–660
visual fibers to, 653, 653f
Superior salivatory nuclei, 678
Superoxide (O_2-), of neutrophils and macrophages, 452
Superoxide dismutases, high alveolar PO_2 and, 562
Supplementary motor area, 697f, 698–699, 728, 729f
basal ganglia and, 722
Suppressor genes, 46
Suppressor T cells, 466–468
Suprachiasmatic nucleus (SCN), 747–748, 747f
visual fibers to, 653
Supraoptic nucleus, pituitary hormones and, 930, 938
Suprathreshold stimulus, 593
Supraventricular tachycardias, 163
Surface mucous cells, 813
Surface receptor proteins, 462
Surface tension, 493–494
principle of, 493
Surface tension elastic force, 493
Surfactant, 493–494
as cause of lung collapse, 545
effect on surface tension, 493–494
neonatal respiratory distress and, 1064
Surfactant apoproteins, 494
Surround inhibition, 607
Sustentacular cells
of olfactory membrane, 679, 679f
of taste bud, 676
Swallowing, 797–799, 798f
disorders of, 833
esophageal secretions and, 811
involuntary pharyngeal stage of, 798
nervous initiation of, 798
paralysis of, 833
voluntary stage of, 797–799
Swallowing center, 798, 798f
Swallowing reflex, 798–799
Sweat
composition of, 904
evaporation of, 903
secretion of, mechanism of, 904–905, 904f
as temperature-decreasing mechanism, 906, 907f
water loss in, 305, 306t
Sweat glands
aldosterone and, 960
autonomic control of, 763, 764f, 768–770, 769t
congenital absence of, 903
Sweating
acclimatization to, 905
autonomic control of, 763
hypothalamus and, set point and, 908f
local, 909
regulation of, autonomic nervous system and, 904–905
and skin receptors, 909
Sweet taste, 675–677, 676t
Sympathetic chains, 763, 764f
Sympathetic nerves
activity, obesity and, 242
cardiac, 124f–125f, 125
control of heart by, 124–125
emission and ejaculation and, 1017
mechanisms of excitation of, 124
Sympathetic nervous, salivary glands and, 810
Sympathetic nervous reflexes
in cardiac failure
acute, 271–272, 272f, 278
decompensated, 279
Sympathetic nervous reflexes *(Continued)*
in hypovolemic shock
compensations in, 294
greater effect of, 294
value of, 294
Sympathetic nervous system
"alarm" or "stress" response of, 773
anatomy of, physiologic, 763–764, 764f
in cardiac failure, fluid retention and, 276–277
cerebral blood flow and, 779
circulatory control by, 217, 218f
in circulatory shock, vasomotor failure and, 297
control of heat conduction by, 902
denervation sensitivity of, 772
fatty acid mobilization caused by, 860
function of, value of adrenal medullae to, 771
gastrointestinal regulation by
duodenal mucus and, 820
glandular secretions and, 808
gastrointestinal stimulation by, 791
reflexes in, 791
vasoconstriction in, 796
glomerular filtration rate and, 337
glucose availability and, 846
mass discharge of, 773–774
nonshivering thermogenesis and, 898–899
renal function and, 396–397
reservoir for storing red blood cells, 191–192
segmental distribution of fibers in, 764
sodium reabsorption in, 360
stimulation
cardiac output and, 254–255, 255f
mean circulatory filling pressure and, 252, 252f
sweat glands and, 763, 764f, 768–770, 769t
tachycardia and, 157
Sympathetic tone, 771–772
Sympathetic vasoconstrictor nerves, 260
Sympathetic vasoconstrictor tone, 219, 219f
Sympathetic vasodilator system, 220
Sympathomimetic drugs, 774
for shock, 301
Synapses
in central nervous system, 572–584
chemical, "one-way" conduction at, 573
greater excitatory (or inhibitory) effect by, 583, 583f
memory and, 571, 738
long-term, 738
physiologic anatomy of, 573–576, 574f
role of, 570
transmission and, 584–585
types of, 572–573, 573f
Synaptic after discharge, 595–596
Synaptic body, 640–641
Synaptic cleft, 573–574
of neuromuscular junction, 93
Synaptic delay, 585
Synaptic fatigue, 597, 597f
Synaptic sensitivity, long-term changes in, by automatic down-regulation or up-regulation of synaptic receptors, 597
Synaptic space, 93
Synaptic transmitters, chemical substances, 576–579
Synaptic trough, 93, 94f
Synaptic vesicles, of neuromuscular junction, 93, 94f
Syncope, vasovagal, 220
Syncytium, of gastrointestinal smooth muscle, 787–789
Systemic arterioles, autonomic control of, 769t
Systemic circulation, 171
blood volumes in, 171f, 172
pressures in different portions of, 172, 173f
Systemic lupus erythematosus (SLE), 468–469
chronic glomerulonephritis in, 427–428

Systole, 118–123, 118f
backflow of blood during, 120
outflow of blood from ventricles during, 119–120
Systolic blood pressure, 186–188
Systolic pressure curve, 121
Systolic stretch, 266–267, 266f

T

T lymphocytes (T cells), 459–460, 460f
activated, 466
delayed-reaction allergy caused by, 469
release of, formation of memory cells, 466
in activation of B lymphocytes, role of, 462
antigen-presenting cells, MHC proteins, and antigen receptors on, 466, 466f
clone selection during preprocessing, 468–469
memory cells of, 466
preprocessing of, 461
special attributes of, 466
specifically against specific antigens, 461
types and functions of, 466–468
T vectorcardiogram, 148f
T wave, 135
abnormalities, 156
atrial, 136, 136f
cardiac muscle and, 116, 118f
monophasic action potential and, 135–136, 136f
vectorial analysis of, 147, 147f
Tabes dorsalis, 328
Tabetic bladder, 328
Tachycardia
incomplete intraventricular block, 160
paroxysmal, 162–163
atrial, 162–163, 163f
ventricular, 163, 163f
sinus, 157
Tacrolimus, for immunosuppression, in transplantation, 476
Tactile receptors, 599–600
feedback to motor cortex, 701
transmission of, in peripheral nerve fibers, 600
Tactile senses, detection and transmission of, 599–601
Tactile stimuli, salivation and, 810
Tameness, placidity and, 749
Tamponade, cardiac, cardiac output curves and, 250, 250f
Tandem pore domain potassium channel, 66
Tank decompression, 564
Tank respirator, 548–549, 549f
Taste, 675–679
adaptation of, 678
diet control and, 678–679
preference in, 678–679
primary sensations of, 675–676
threshold for, 676, 676t
salivation and, 810
signal transmission into central nervous system, 678, 678f
taste buds and its function and, 676–678, 677f
Taste blindness, 676
Taste bud
function of, 676–678, 677f
location of, 676–677
nerve impulses from, 677–678
specificity of, for primary taste stimulus, 677
stimulation of, mechanism of, 677–678
Taste cells, 676–677, 677f
Taste hairs, 676
Taste pore, 676, 677f
TATA box, 39–40, 39f
Tectorial membrane, 667, 667f
Tectospinal tracts, 702f
Teeth, 991–1010
abnormalities in, 1008
cementum, 1007
deciduous, 1007
dentin, 1006–1007
dentition in, 1007
development of, metabolic factors influencing, 1007
enamel, 1006–1008
eruption of, 1007
formation of, 1007, 1007f
function of, 1006–1008
mineral exchange in, 1007–1008
permanent, development of, 1007
physiology of, 1006–1008, 1006f
pulp, 1007
wisdom, 1007
Telomerase, 45
Telomere, 44–45, 44f
Telophase, 41f, 44
Temperature, body
abnormalities of, 909–911
behavioral control of, 909
blood flow and, 902, 902f
core temperature, 901
normal, 901
range of, 901f
set point for, 908, 908f–909f
decreasing mechanisms, 906
gain of system controlling, 9
heart function and, 125
heart rate and, 157
heat loss and, 902–905
heat production and, 901
hypothalamic regulation of, 746, 905–909, 905f, 910f
anterior hypothalamic-preoptic area and, 905–906
neuronal effector mechanisms and, 906–908
posterior hypothalamus, 906
set point for, 907f, 908
by skin receptors and deep body tissues, 906
increasing mechanisms for, 906–908
normal, 901
normal range of, 8t
in premature infants, 1069
rectal, 901, 901f
regulation of
at low temperatures, 909f
in neonates, 1067, 1067f
and spinal cord, cutting of, 909
skin temperature, 901
blood vessels in, vasodilation of, 906
core temperature control and, 908, 908f–909f
vasoconstriction and, 906
Temporal field of vision, 657
Temporal summation
in neurons, 582–583
in sensory fibers, 592, 592f
Tendon reflex
to equalize contractile force among muscle fibers, 691
Golgi, 690–691, 691f
prevents excessive tension on muscle, 691
Teniae coli, 804
Tension-time index, 123
Tensor tympani muscle, 663
Teratoma, 1024
Testis(es), 1011
cholesterol used by, 862
descent of, 1019–1020
fetal, human chorionic gonadotropin and, 1023, 1050
storage of sperm in, 1013–1014
tumors of, 1024
Testosterone, 1018–1025, 1032
acne and, development of, 1020
basal metabolic rate and, 1021
basic intracellular mechanism of action, 1021
bone matrix and, 1020
calcium retention and, 1020
chemical structure of, 1018f
conversion of, to dihydrotestosterone, 1018, 1021
degradation and excretion of, 1018
descent of testes and, 1019–1020
effect of
on body hair, distribution of, 1020
on development of adult primary and secondary sexual characteristics, 1020–1021
on electrolyte and water balance, 1021
on voice, 1020
in fetal development, 1050
functions of, 1019–1021, 1019f
during fetal development, 1019–1020
metabolism of, 1018
muscle development and, 1020
nongenomic effects of, 1021
protein deposition in tissues and, 870, 1073
protein formation and, 1020
red blood cells and, 1021
regulation of, by luteinizing hormone, 1022
secretion of, 1018–1019, 1018f
testosterone-negative feedback control of, 1022, 1022f
skin and, thickening of, 1020
spermatogenesis and, 1013
regulation of, 1022–1023
Tetanization, 89
Tetany, 992, 992f
hypocalcemic, 390
muscle, 71
in premature infant, 1069
in rickets, 1005
Tetracaine, 76
Tetraethylammonium ion, 69
Tetralogy of Fallot, 290, 290f
Tetrodotoxin, 69
Thalamic neurons, 608, 609f
Thalamocortical system, 728
alpha waves and, 757
petit mal seizures and, 759–760
Thalamus
alpha waves and, 757
basal ganglia and, 721f, 725
in Parkinson disease, 725
cerebral cortex and, 728, 728f, 742
function of, in pain, 616
memory and, 739
neospinothalamic tract in, termination of, 615
pain signals into, slow-chronic, 616
reticular excitatory signals and, 742, 742f
sleep and, 754
in somatic sensation, function of, 610
taste signals and, 678
Theca, 1030
Theca externa, 1030–1031
Theobromine, 584–585
Theophylline, 584–585
Thermal pain stimuli, 613
Thermal receptors, stimulation of, 622f, 623
Thermal sensations, 622–623
Thermogenesis (heat production), 907
chemical, 907
increase in, 907
nonshivering, 907
sympathetic "chemical" excitation of, 907
thyroxine output and, increased, 907–908
Thermogenin, 907
Thermoreceptive senses, 599
localization of, 605

Thermoreceptors, 587, 588t
Theta waves, 754f, 756, 756f
Thiamine (vitamin B_1), 888–889
  colon bacteria and, 832
  deficiency, 888
    central and peripheral nervous systems, lesions in and, 888
    gastrointestinal tract disturbances and, 889
    peripheral vasodilation and, 889
Thiazide diuretics, 351, 352f, 422, 422t
Thiazolidinediones, 987
Thiocyanate ions
  iodide trapping and, 950
  in saliva, 810
Third heart sound, 284
Thirst
  extracellular fluid osmolarity and, 377–380, 378t, 379f
  hypothalamic regulation of, 746
  stimuli for, 378
Thirst center, 378, 746
Thoracic cage
  expansion and contraction of, 492f
  on lung expansibility, 494
Thoracic duct, 201, 853
  lymph, 202
Thoracic electrical bioimpedance method, 257
Thought, 735–739
  elaboration of, 730, 733
  holistic theory of, 735–736
  prefrontal association area and, 730, 733
  Wernicke's area and, 731, 734
Threshold, for drinking, 378–379
Threshold stimulus, 593
Thrill, in aortic stenosis, 286
Thrombi, 486
Thrombin, 480
  prothrombin to, conversion of, 479–480, 479f–480f
Thrombocytes, 450, 477
Thrombocytopenia, 483, 485–486
Thrombocytopenic purpura, 485
Thromboembolic conditions, 486
  cause of, 486
Thrombomodulin, 483
Thrombosthenin, 477
Thromboxane A_2, 477
Thymine, 31, 33
Thymus gland, 461, 468–469
Thyroglobulin, 916–918, 941
  formation and secretion of, 942–943, 942f
  organification of, 943
  proteolysis of, 948
  storage of, 943
  thyroid cells and, 942f, 948
Thyroid cartilage, 500
Thyroid gland, 941
  adenoma of, 950
  endemic colloid goiter, 951–952
  hyperthyroidism, 950
  hypothyroidism, 951–953
  idiopathic nontoxic colloid goiter, 952
  physiologic anatomy of, 941, 942f
  release of thyroxine and triiodothyronine from, 943–944
Thyroid hormones
  excitatory effects of, on central nervous system, 947–948
  fat mobilization and, 860
  feedback effect of, 949–950
  formation of, 943
  gene transcription and, increase in, 925–926
  genes and, transcription of, 944–946, 945f
  long duration of action of, 944, 944f
  metabolic rate and, 898
Thyroid hormones *(Continued)*
  muscle and, function of, 947–948
  muscle tremor and, 948
  nongenomic cellular effects of, 945–946
  nuclear receptors and, 944–946
  other endocrine glands and, 948
  physiological functions of, 944–948
  propylthiouracil and, 950
  secretion of, regulation of, 948–953, 949f
  sexual function and, 948
  sleep and, 948
  slow onset of, 944
  synthesis and secretion of, and antithyroid substances, 950
Thyroid metabolic hormones, synthesis and secretion of, 941–944
Thyroid-stimulating hormone (TSH), 929, 941
  anterior pituitary secretion of, 949
  cold and neurogenic stimuli, effect on, 949
  cyclic adenosine monophosphate (cAMP) and, 948–949
  in iodide trapping, 942
  thyroid hormone and, feedback effect on, 949–950, 949f
  thyroid secretion and, 948–949
Thyroid-stimulating immunoglobulins (TSIs), 950
Thyroiditis, 951
Thyrotropes, 930, 931t
Thyrotropin, 948
Thyrotropin-releasing hormone (TRH), 907, 932, 932t, 949
  cold and neurogenic stimuli, effect on, 949
Thyroxine, 891, 898, 915, 941, 943
  converted to triiodothyronine, 944–946
  daily rate of secretion of, 944
  iodine for, 941
  long latent period of, 944, 944f
  in protein metabolism, 870
  release of, from thyroid gland, 943–944
  slow release of, 944
  transcription and, 925–926
  transport of, 944
Thyroxine-binding globulin, 916–918, 944
Thyroxine-binding prealbumin, 944
Tic douloureux, 620
Tidal volume, 495
Tissue(s)

Normal Values for Selected Common Laboratory Measurements

Substance	Average ("Normal" Value)	Range	Comment/Unit of Measure
Electrolytes			
Sodium (Na^+)	142 mmol/L	135-145 mmol/L	mmol/L = millimoles per liter
Potassium (K^+)	4.2 mmol/L	3.5-5.3 mmol/L	
Chloride (Cl^-)	106 mmol/L	98-108 mmol/L	
Anion gap	12 mEq/L	7-16 mEq/L	mEq/L = milliequivalents per liter Anion gap = $Na^+ - Cl^- - HCO_3^-$
Bicarbonate (HCO_3^-)	24 mmol/L	22-29 mmol/L	
Hydrogen ion (H^+)	40 nmol/L	30-50 nmol/L	nmol/L = nanomoles per liter
pH, arterial	7.4	7.25-7.45	
pH, venous	7.37	7.32-7.42	
Calcium ion (Ca^{2+})	5.0 mg/dL	4.65-5.28 mg/dL	mg/dL = milligrams/deciliter Average normal value can also be expressed as approximately 1.2 mmol/L or 2.4 mEq/L
Calcium, total	10.0 mg/dL	8.5-10.5 mg/dL	
Magnesium ion (Mg^{2+})	0.8 mEq/L	0.6-1.1 mEq/L	
Magnesium, total	1.8 mEq/L	1.3-2.4 mEq/L	
Phosphate, total	3.5 mg/dL	2.5-4.5 mg/dL	In plasma, $HPO_4^=$ is ~1.05 mmol/L and $H_2PO_4^-$ is 0.26 mmol/L
Nonelectrolyte Blood Chemistries			
Albumin	4.5 g/dL	3.5-5.5 g/dL	g/dL = grams per deciliter
Alkaline phosphatase		M: 38-126 U/L F: 70-230 U/L	U/L = units per liter
Bilirubin, total		0.2-1.0 mg/dL	
Bilirubin, conjugated		0-0.2 mg/dL	
Blood urea nitrogen (BUN)	14 mg/dL	10-26 mg/dL	
Creatinine	1.0 mg/dL	0.6-1.3 mg/dL	Varies depending on muscle mass, age, and sex
Glucose	90 mg/dL	70-115 mg/dL	
Osmolarity	282 mOsm/L	275-300 mOsm/L	mOsm/L = milliosmoles per liter Osmolality is expresses as mOsm/kg of water
Protein, total	7.0 g/dL	6.0-8.0 g/dL	
Uric acid		M: 3.0-7.4 mg/dL F: 2.1-6.3 mg/dL	
Blood Gases			
O_2 sat, arterial	98%	95%-99%	Percentage of hemoglobin molecules saturated with oxygen
PO_2, arterial	90 mm Hg	80-100 mm Hg	PO_2 = partial pressure of oxygen in millimeters of mercury
PO_2, venous	40 mm Hg	25-40 mm Hg	
PCO_2, arterial	40 mm Hg	35-45 mm Hg	PCO_2 = partial pressure of carbon dioxide in millimeters of mercury
PCO_2, venous	45 mm Hg	41-51 mm Hg	
Hematology			
Hematocrit (Hct)	M: 42% F: 38%	M: 39%-49% F: 35%-45%	
Hemoglobin (Hgb)	M: 15 g/dL F: 14 g/dL	M: 13.5-17.5 g/dL F: 12-16 g/dL	
Red blood cells (RBCs)	M: $5.5 \times 10^8/\mu L$ F: $4.7 \times 10^8/\mu L$	$4.3\text{-}5.7 \times 10^8/\mu L$ $4.3\text{-}5.7 \times 10^8/\mu L$	Number of cells per microliter of blood
Mean corpuscular (RBC) volume (MCV)	90 fl	80-100 fl	fl = femtoliters
Prothrombin time (PT)		10-14 seconds	Time required for the plasma to clot during a special test
Platelets		$150\text{-}450 \times 10^3/\mu L$	
White blood cells, total Neutrophils Lymphocytes Monocytes Eosinophils Basophils		$4.5\text{-}11.0 \times 10^3/\mu L$ 57%-67% 23%-33% 3%-7% 1%-3% 0%-1%	
Lipids			
Total cholesterol		<200 mg/dL	
Low-density lipoprotein (LDL)		<130 mg/dL	
High-density lipoprotein (HDL)		M: >29 mg/dL F: >35 mg/dL	
Triglycerides		M: 40-160 mg/dL F: 35-135 mg/dL	

This table is not an exhaustive list of common laboratory values. Most of these values are approximate reference values used by the University of Mississippi Medical Center Clinical Laboratories; normal ranges may vary among different clinical laboratories. Average "normal" values and units of measure may also differ slightly from those cited in the *Guyton and Hall Textbook of Medical Physiology*, 14th edition.

F, female; M, male.
