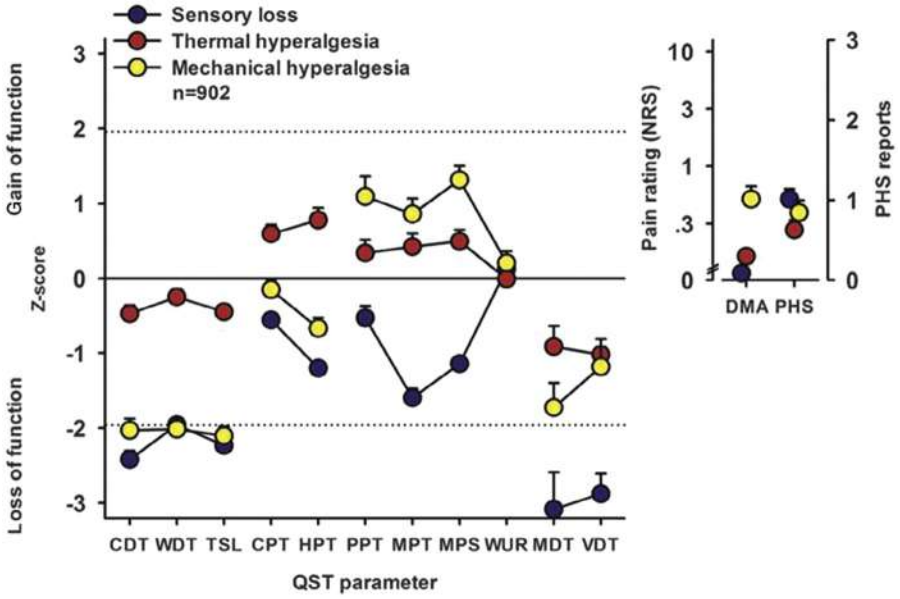
The correct interpretation of sensory abnormalities in pain patients requires a standardized testing protocol and comparison to reference data of healthy controls. In 2006, the German Research Network on Neuropathic Pain (DFNS) established a standardized QST protocol to analyze the exact somatosensory phenotype of neuropathic pain patients.[16] This protocol consists of seven tests to assess 13 thermal and mechanical parameters, i.e. cold and warm detection thresholds (CDT, WDT), thermal sensory limen (TSL), paradoxical heat sensations (PHS), cold and heat pain thresholds (CPT, HPT), mechanical detection threshold (MDT; von Frey filament 0.25-512 mN), mechanical pain threshold (MPT, pinprick stimulators, 8-512 mN), mechanical pain sensitivity and dynamic mechanical allodynia (MPS and DMA; pinprick stimulators, standardized brush, cotton wisp, cotton wool tip), wind-up ratio (WUR), vibration detection threshold (VDT; Rydel-Seiffer graded tuning fork, 64 Hz, 8/8 scale), pressure pain sensitivity (PPT; pressure gauge device) (Fig. 21.1).

A database with reference values for different body regions (face, dorsum of the foot, dorsum of the hand, trunk) was implemented[11,17] that allows direct comparison of patients with age- and sex-matched healthy controls. For this purpose, Z-transformation of every single parameter was performed (except for DMA, PHS), resulting in a QST profile where all parameters are presented as standard normal distribution independent of the different units. Z-values of zero represent a value corresponding to the mean of healthy controls. Z-values below zero indicate a loss of function, i.e. lower sensitivity compared to controls (hypoalgesia, hypoesthesia). Z-values above zero indicate a gain of function, i.e. higher sensitivity (hyperalgesia, hyperesthesia). A z-score of 0±1.96 represents the range that can be expected to include 95% of healthy control subject data (95% confidence interval). Z-values outside this 95% confidence interval are considered as absolute



• **Figure 21.1** Subgroup analysis of neuropathic pain. (Adapted from Baron et al.[19]). Sensory profiles of the three clusters presented as mean z-scores ± 95% confidence interval for the test data set (n = 902). Note that z-transformation eliminates differences because of test site, sex, and age. Positive z-scores indicate positive sensory signs (hyperalgesia), whereas negative z-values indicate negative sensory signs (hypoesthesia and hypoalgesia). *Dashed lines*: 95% confidence interval for healthy subjects (–1.96 < z < +1.96). Note that if the mean of a cluster is within the *shaded area*, this does not imply that it does not differ from a healthy cohort. Values are significantly different from those of healthy subjects if their 95% marked interval does not cross the zero line. *Insets* show numeric pain ratings for dynamic mechanical allodynia (DMA) on a logarithmic scale (0-100) and frequency of paradoxical heat sensation (PHS) (0-3). *Blue symbols:* cluster one "sensory loss" (42%). *Red symbols:* cluster two "thermal hyperalgesia" (33%). *Yellow symbols:* cluster three "mechanical hyperalgesia" (24%). *CDT*, cold detection threshold; *CPT*, cold pain threshold; *HPT*, heat pain threshold; *MDT*, mechanical detection threshold; *MPS*, mechanical pain sensitivity; *MPT*, mechanical pain threshold; *NRS*, Numerical Rating Scale; *PPT*, pressure pain threshold; *QST*, quantitative sensory testing; *TSL*, thermal sensory limen; *VDT*, vibration detection threshold; *WDT*, warm detection threshold; *WUR*, wind-up ratio.

abnormalities (<–1.96 abnormal loss, >1.96 abnormal gain).[18] Investigation of a large cohort of patients with different neuropathic pain symptoms revealed the presence of different combinations of loss and gain across all investigated pain etiologies.[18] QST cluster analysis in patients with peripheral neuropathic pain of different etiology revealed the presence of three subgroups of patients that were characterized by different sensory profiles (Fig. 21.1).[19] The first cluster, "sensory loss," was characterized by a loss of small and large fiber function in combination with PHS; the second cluster, "thermal hyperalgesia," showed preserved sensory functions in combination with heat and cold hyperalgesia and mild dynamic mechanical allodynia; and the third cluster, "mechanical hyperalgesia," was characterized by a loss of small fiber function in combination with pinprick hyperalgesia and dynamic mechanical allodynia. The three clusters were distributed across all included neuropathic pain etiologies. However, with different frequencies, e.g. the sensory loss cluster was the most frequent cluster in patients with polyneuropathy (about 51.8%), whereas patients with PHN were especially characterized by mechanical hyperalgesia, i.e. cluster three (46.6%). Interestingly, similar clusters were identified in human surrogate pain models,[20] which supports the concept of a mechanism-based stratification approach.

According to the updated grading system for neuropathic pain proposed by the International Association for the Study of Pain (IASP) Special Interest Group on Neuropathic Pain (NeuPSIG), a confirmation of sensory signs is necessary to raise the certainty of neuropathic pain presence from "possible" to "probable," which can be sometimes only obtained using QST.[21] However, only a few studies have examined the sensory profile in painful versus painless neuropathy so far.[22] As their results showed similar thermonociceptive impairment in both cases, QST seems limited in its ability to differentiate between neuropathy without pain and neuropathic pain.

Prognostic

There is evidence that QST has a prognostic value. For example, thermal deficits as indicative of small nerve fiber loss were associated with painfulness of diabetic neuropathy,[23] while mechanical deficits were shown to predict the development of foot ulcerations.[24] The prognostic value of QST was also demonstrated in a group of patients with colorectal cancer who were examined by QST before receiving oxaliplatin-based chemotherapy and were then followed up for 26 weeks.[25] Pretreatment touch sensation deficits were found to predict severity and painfulness of oxaliplatin-induced neuropathy.

Susceptibility/Predictive

In addition, QST seems to be a promising susceptibility and predictive biomarker for chronic pain (for definition, see Table 21.2). A recent prospective study aimed to identify potential risk factors

TABLE 21.2 Quantitative Sensory Testing Parameters and Suspected Location of the Underlying Pathophysiologic Mechanisms

QST Parameter	QST Testing Device	Suspected Location of an Underlying Pathophysiologic Mechanism: Peripheral	Suspected Location of an Underlying Pathophysiologic Mechanism: Central	QST Finding
Thermal				
Detection threshold for innocuous thermal stimuli (cold, warm)	Thermotest	Aδ (cold) C (warm)	Spinothalamic	Increased thermal detection threshold, i.e. cold/warm hypoesthesia Decreased thermal detection threshold, i.e. cold/warm hyperesthesia
Detection of the threshold for noxious thermal stimuli (cold, heat)	Thermotest	(Aδ) C	Spinothalamic	Increased thermal pain threshold, i.e. cold/heat hypoalgesia/analgesia Decreased thermal pain threshold, i.e. cold/heat hyperalgesia
Paradoxical heat sensations	Thermotest		Central disinhibition	Heat sensation as a response to a cold stimulus
Mechanical				
Detection threshold for innocuous mechanical stimuli (static light touch)	Calibrated von Frey hairs	Aβ	Lemniscal	Increased mechanical detection threshold, i.e. mechanical hypoesthesia Decreased mechanical detection threshold, i.e. mechanical hyperesthesia
Detection threshold for innocuous vibration	Graduated tuning fork	Aβ	Lemniscal	Increased vibration detection threshold
Detection threshold for noxious mechanical stimuli (pinprick)	Calibrated needles, e.g. pinprick stimulators	Aδ	Spinothalamic	Increased mechanical pain threshold, i.e. pinprick hypoalgesia/analgesia Decreased mechanical pain threshold, i.e. pinprick hyperalgesia
Pain rating suprathreshold stimulation	Calibrated needles, e.g. pinprick stimulators	Aδ	Spinothalamic	Decreased pain/absent pain, i.e. pinprick hypoalgesia/analgesia Increased pain, i.e. hyperalgesia
Dynamic mechanical allodynia	Cotton wool, Q-tip, brush	Aβ	Lemniscal	Allodynia, i.e. pain because of a normally non-painful stimulus
Pain induced by repetitive stimulation (wind-up ratio)	Calibrated needles, e.g. pinprick stimulator		Spinothalamic	Temporal summation
Blunt pressure	Algometer	Aδ, C	Spinothalamic	Increased pressure pain threshold, i.e. pressure hypoalgesia Decreased pressure pain threshold, i.e. pressure hyperalgesia

for PHN via characterization of the sensory profile and physical and psychosocial functioning during acute herpes zoster.[26] The sensory profile at the affected site and a distal contralateral control site (four dermatomes above or rostral) of 74 patients with acute herpes zoster was compared to 20 healthy controls. Patients with PHN at the six-month follow-up point, defined as persisting pain in the affected area (22.4%), were then compared to those without PHN. Besides older age, higher pain intensity, reduced quality of life, and physical functioning during acute herpes zoster, the development of PHN seems to be predicted by sensory alterations. The authors concluded that mechanical hyposthesia and/or hyperalgesia/mechanical allodynia combined with preserved thermal detection, especially at body sites distal to the acute herpes zoster area, may be potential risk factors for PHN.

A priori stratification of patients according to their sensory profile could help to predict treatment response in clinical trials and clinical practice. Consequently, the Committee for Medicinal Products for Human Use (CHMP) of the European Medicines Agency (EMA) has acknowledged the sensory subgrouping of patients by use of standardized QST, an adequate stratification tool for determination of specific sensory phenotypes of patients in clinical trials on neuropathic pain.[27] Although no analgesic drug has been developed based on the prediction by sensory testing, several studies have reported promising results. In a Phase 2a proof of concept study with retrospective phenotyping of patients with painful diabetic neuropathy, a novel selective TRPA1 antagonist (GRC 17536) was shown to be effective, especially in patients with preserved sensory function (irritable nociceptor).[28] A retrospective analysis of a randomized

controlled trial investigating the effect of pregabalin vs. placebo in patients with painful human immunodeficiency virus (HIV) neuropathy showed significant pain reduction only in a subgroup of patients with marked pinprick hyperalgesia (corresponding to QST cluster three). In contrast, there was no difference in the entire patient cohort.[29] In a first placebo-controlled trial with *a priori* phenotype-stratification, oxcarbazepine was more effective for relief of neuropathic pain in patients with the "irritable nociceptor" phenotype defined as hypersensitivity and preserved small nerve fiber function (corresponding to QST cluster two) compared to the "non-irritable phenotype" (NNT for 50% pain relief: 3.9 vs. 13).[30] However, the same authors failed to show a phenotype-dependent treatment effect of 5% lidocaine patch in patients with peripheral neuropathic pain because of PHN or peripheral nerve injury using the same patient stratification (irritable vs. non-irritable phenotype).[31] An additional prospective crossover study investigated the effect of pregabalin versus placebo in patients with painful chemotherapy induced neuropathy.[32] At baseline, all study participants received sensory testing on the dorsum of the feet, assuming that patients with increased mechanical pain sensitivity would more likely respond to treatment with pregabalin. Since there was no correlation of the MPT with the analgesic response, the authors concluded that the MPT was not a useful treatment predictor in this specific case.

To examine the value of predictive sensory testing, future trials of drug development will need to include a prospective stratification of patients according to their somatosensory profile.

Besides the above-mentioned advantages, several limitations should be kept in mind when performing and interpreting QST (Table 21.3). One major limitation is that QST only assesses stimulus-evoked negative and positive sensory phenomena, whereas spontaneous pain is not detectable. Since the whole somatosensory pathways are assessed, QST cannot determine the exact localization of the lesion, i.e. peripheral versus central. Finally, as a psychophysical method, QST depends on the patient's cooperation and may be influenced by psychological factors that may result in false-negative findings. Therefore it is even more important to use a standardized testing protocol with standardized stimuli and instructions and reference values of healthy controls. Because of high commitments of time and costs and the need for a good training to ensure standardization, the DFNS QST protocol is only used by certain centers. To overcome these limitations, easy-to-use bedside protocols have recently been presented that enables increased applicability of sensory testing in clinical practice and clinical trials of drug development.[33,34]

TABLE 21.3 Advantages and Limitation of QST

Advantages	Limitations
Non-invasive	Psychophysical method
Examination of large and small fibers	No information about the localization of the lesion (central versus peripheral)
Assessment of gain and loss of function	No information about the extent of the lesion (predefined testing area)
Characterization of sensory phenotypes	Only stimulus-evoked phenomena, not spontaneous pain
Standardized German Research Network on Neuropathic Pain (DFNS) protocol with reference values	Standardized DFNS protocol needs training, is time-consuming, and cost intensive
Subgrouping of patients	

Conditioned Pain Modulation

Endogenous descending inhibitory and facilitatory pathways originating in the brain can modulate the function of nociceptive neurons in the dorsal horn of the spinal cord. One important descending inhibitory pathway that suppresses the firing of convergent second-order neurons, i.e. wide-dynamic range neurons in the dorsal horn of the spinal cord, by a noxious stimulus has been first described by Le Bars et al. as diffuse noxious inhibitory controls (DNIC) in rats.[35] An expert opinion consensus has recommended the term "CPM" as the human counterpart of DNIC to describe the psychophysical paradigm in which a conditioning stimulus is used to affect a test stimulus."[36] In contrast to QST, which focuses mainly on static parameters (except for temporal summation), CPM is a dynamic measurement.

In general, CPM paradigms consist of the evaluation of a painful test stimulus first alone and afterwards during (parallel paradigm) or immediately after a painful conditioning stimulus (sequential paradigm). An intact CPM effect describes a reduction in pain intensity of the test stimulus induced by the conditioning stimulus (pain inhibits pain phenomenon).

Numerous different CPM protocols exist using different test and conditioning stimuli. Hot or cold water immersion is the most commonly used conditioning stimulus, whereas a variety of thermal, mechanical, and electrical stimuli is used as test stimulus.[37] A schematic of a possible CPM protocol is shown in Fig. 21.2.

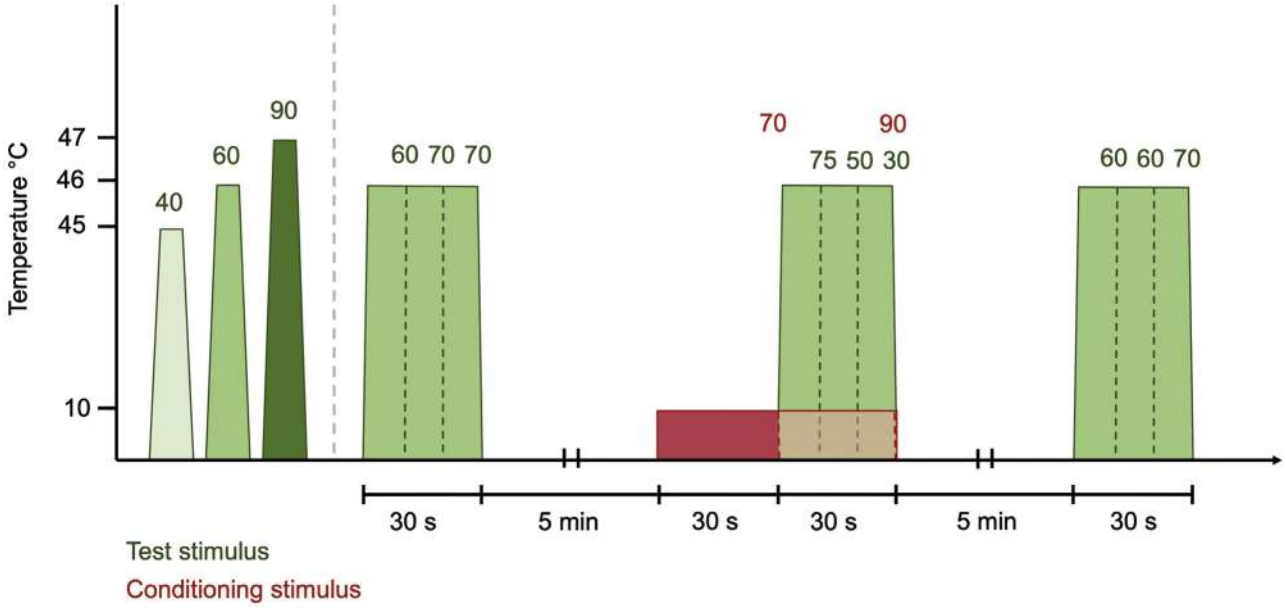
Diagnostic

Many different chronic pain syndromes are characterized by less sufficient CPM, e.g. fibromyalgia syndrome, irritable bowel syndrome, migraine, and osteoarthritis.[38] In a study investigating 96 fibromyalgia patients and 71 healthy controls, heat stimulation was used as the test stimulus and the cold pressor test as the conditioning stimulus.[39] Patients showed reduced CPM compared to controls with a good specificity (78.9%) but low sensitivity (45.7%), suggesting impaired CPM in a subgroup of fibromyalgia patients. Patients with irritable bowel syndrome were also shown to exhibit less sufficient CPM than healthy controls in several studies. For example, a study that used phasic heat as a test stimulus on the one hand and painful cold water as a conditioning stimulus on the other one showed smaller CPM in 27 premenopausal females compared to 21 age-matched controls.[40] Another study used rectal distension as a test stimulus and cold water (foot) as a conditioning stimulus.[41] However, abnormal CPM effects must be interpreted with caution as no normative values have been published so far, and a high inter-individual variability is even present in healthy subjects (see below).

Susceptibility/Predictive

CPM may also serve as a potential susceptibility biomarker for the development of chronic pain. A less efficient CPM was shown to be associated with a higher risk of chronic postoperative pain after thoracotomy[42] and abdominal surgery.[43]

Like QST, CPM may predict the treatment response of chronic pain patients via the identification of subgroups with altered endogenous pain modulation. The pharmacologic basis of CPM is not



• **Figure 21.2** Schematic of a conditioned pain modulation protocol with heat as the test stimulus and cold water immersion as the conditioning stimulus. Examples of pain intensity ratings (0–100 NRS, 0 = no pain, 100 = worst imaginable pain) are shown above the stimuli. The temperature of the heat stimulus is selected by applying three heat stimuli of 45°C, 46°C, and 47°C to the dominant volar forearm. The subject is asked to rate the pain intensity of each stimulus on a 0–100 NRS. The temperature with an intensity of 60 ± 5 is used as the test stimulus (here: 46°C). The test stimulus is applied for 30 s with pain ratings every 10 s. After 5 min, a 60 s conditioning stimulus (spread-fingered non-dominant hand in 10°C cold water immersion) is delivered and rated after 30 and 60 s. During the last 30 s the test stimulus is applied and rated again every 10 s. The application of the test stimulus is repeated after 5 min.

yet completely understood. However, investigation of DNIC in animals suggests the involvement of noradrenergic and serotonergic pathways.[44] In a study by Yarnitsky et al. baseline CPM was shown to be correlated with the efficacy of duloxetine, a serotonin-noradrenalin reuptake inhibitor, in patients with painful diabetic neuropathy.[45] Less efficient CPM at baseline predicted better duloxetine efficacy, i.e. self-reported effect of the drug on pain and greater pain reduction. Another study investigated the predictive effect of CPM and QST (dynamic mechanical allodynia, pressure, and thermal pain thresholds, temporal summation) on response to spinal cord stimulation.[46] A reduced CPM, as well as less enhanced central sensitization (pain hypersensitivity), predicted less self-reported pain three months after implantation. In patients with knee osteoarthritis, the combination of preoperative impaired CPM and facilitated temporal pain summation was associated with less postoperative pain relief 12 months after total knee replacement.[47]

Pharmacodynamic

Different studies indicate a role of CPM as a potential pharmacodynamic biomarker, i.e. to measure and monitor treatment effect. In a study by Yarnitsky et al. CPM was shown to be modified in response to duloxetine treatment, i.e. a greater improvement of CPM (baseline compared to posttreatment) was associated with greater drug efficacy. However, these results were not compared to placebo. The potential pharmacodynamic role of CPM was also shown in a placebo-controlled study of tapentadol, a μ-Opioid receptor agonist and noradrenaline reuptake inhibitor, in painful diabetic neuropathy.[48] At baseline, patients did not show significant CPM response. However, after four weeks of treatment, the tapentadol group developed significant CPM together with greater pain relief than the placebo group.

The CPM effect is affected by several factors.[49] It is dependent on age and sex, i.e. a stronger CPM effect was observed in younger adults (reduction starting in middle-age from about 40 years[50]) and in men. In women, it is influenced by the menstrual cycle phase. Attention and positive expectation are positively correlated with the CPM effect. Finally, the CPM magnitude is influenced by the paradigm itself. Higher evoked pain intensities and longer duration of the conditioning stimulus cause a stronger CPM. The modality of the conditioning stimulus is also relevant, e.g. a cold pressor test was shown to induce a stronger CPM effect than cuff-pressure and heat pain stimulation.[51]

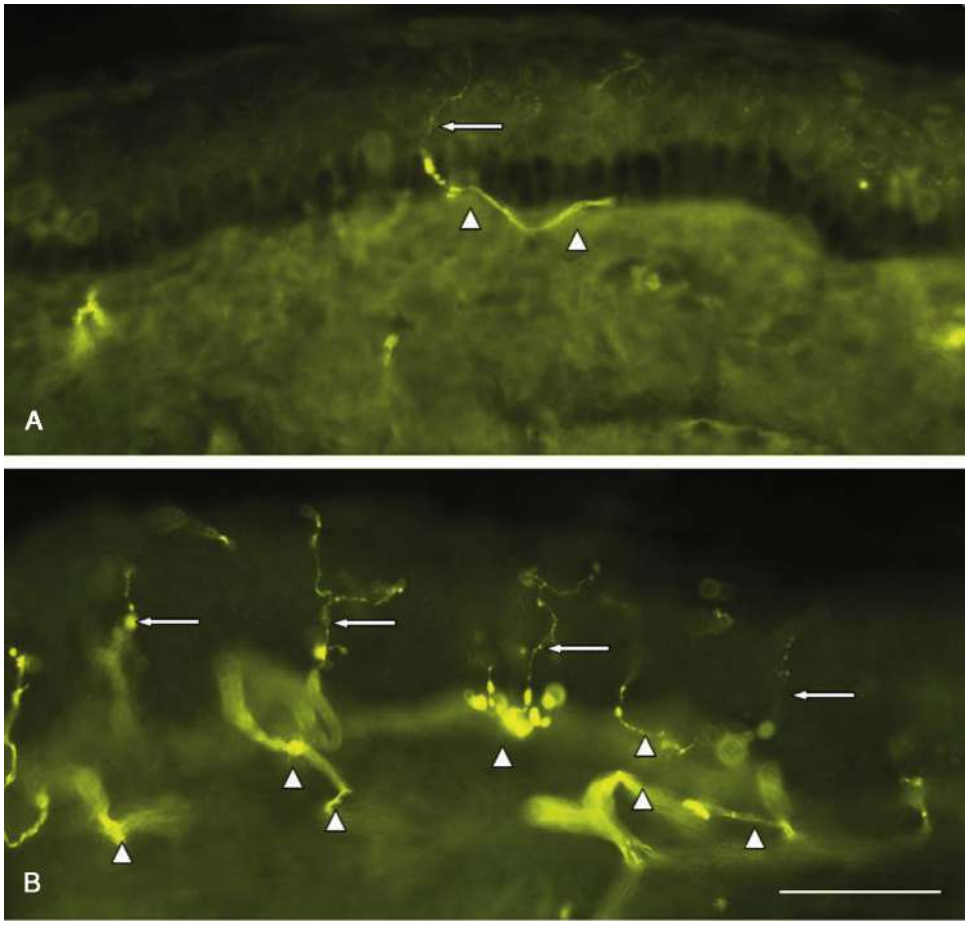
These factors can complicate the interpretation of CPM in chronic pain states. While some of them are difficult to influence, e.g. patients' expectations, standardization of the testing protocol would enable the conduction of meta-analyses with a comparison of data from different studies and thus could improve reliability. Because of the current lack of a "gold standard" CPM protocol, an expert forum has proposed recommendations regarding the practice of CPM,[52] i.e. use of an additional test stimulus or an additional standard CPM protocol. It has also been discussed that a sequential protocol is superior to a parallel one as it provides a cleaner representation of pain modulation, although this consideration has been questioned in a review by Kennedy et al. who declared that there is insufficient evidence for a greater reliability of one paradigm over another at present.[53] However, standardization of the CPM protocol is a prerequisite for its use as a biomarker and the subject of current research.

Skin Punch Biopsy

In contrast to sensory testing, skin punch biopsies are an objective measurement that can be used to investigate the nervous system and may serve as a potential biomarker, especially because they are less invasive than nerve biopsies, safe, and almost painless. Skin punch biopsies can be obtained from the hairy skin to assess the unmyelinated and thinly myelinated nerve fibers, as well as from the glabrous skin to assess large myelinated fibers. While a punch of 3–4 mm is sufficient to examine the epidermal nerve fibers, deeper biopsies of approximately 5–6 mm are required to examine sweat glands or hair follicles. To quantify the intraepidermal nerve fiber density (IENFD), sections of the biopsy are immunohistochemically labeled with the protein gene product (PGP) 9.5 antibody, a pan-axonal marker directed against ubiquitin carboxy-terminal hydrolase and highly specific in neurons.

Diagnostic

In neuropathies affecting small caliber nerve fibers, skin punch biopsies with the determination of the IEFND can serve as a diagnostic biomarker to identify neuronal loss. In small fiber neuropathies, neuronal denervation occurs in a length-dependent manner, which can be detected by a skin biopsy (Fig. 21.3). IENFD normative values exist for different biopsy techniques and different body sites. In a large multicenter study of 550 healthy participants, age and sex-dependent normative IENFD reference values at the distal leg were established for use in clinical practice and research.[54] It was shown that the IENFD declines with age and may be lower in men than in women. McArthur et al. performed skin biopsies in 98 healthy controls and 20 patients with neuropathy.[55] An IENFD below the 5th percentile of healthy controls was defined as abnormal. At the distal leg, this cutoff value results in an overall diagnostic accuracy, i.e. patients that were correctly classified via IENFD, of 88%, with a positive predictive value of 75%, a negative predictive value of 90%, a sensitivity of 45%, and a specificity of 97%. The relatively low sensitivity indicates that a normal IENFD does not exclude the presence of sensory neuropathy. For example, IENFD was within the normal range in about 10% of patients diagnosed with small fiber neuropathy based on clinical findings plus abnormal thermal thresholds at the foot.[56] In general, data on sensitivity and specificity of skin punch biopsies vary in different studies depending on the definition of small fiber neuropathy. Furthermore, altered IENFD was detected in conditions other than small fiber neuropathies, i.e. widespread pain conditions like fibromyalgia.[14] A recent study by Devigili et al. re-investigated the criteria for the diagnosis of small fiber neuropathy.[57] The authors concluded that the combination of clinical examination, QST, and IENFD is a reliable diagnostic tool in clinical practice and research. They further showed a higher diagnostic



• **Figure 21.3** Sections from 50 µm skin punch biopsies of the lower leg immunoreacted for PGP 9.5 with Cy3 as a chromophore. *Arrows* indicate examples of intraepidermal nerve fibers. *Arrowheads* show parts of the subepidermal nerve plexus. **A,** from a patient with small fiber neuropathy, only one intraepidermal nerve fiber visible. **B,** from a healthy control person. Bar = 50 µm. (Figure provided by Prof. Dr. Claudia Sommer.)

accuracy of IENFD compared to QST, depicted by a higher area under the receiver operating characteristic curve (0.90 vs. 0.58). In 2010, the European Federation of Neurological Societies (EFNS) and Peripheral Nerve Society (PNS) declared that skin biopsy with IENFD quantification is a reliable technique to confirm the diagnosis of small fiber neuropathy.[58] It has been recommended to perform a skin punch biopsy at the distal leg, i.e. 10 cm above the malleolus lateralis, which may be accompanied by an additional biopsy from the proximal thigh (20 cm below the anterior iliac spine) to evaluate the length dependency of the neuropathy.

Besides diagnosis of pure small fiber neuropathies, skin biopsies may be used as a potential biomarker for the early diagnosis of neuropathies, where damage of small fibers may precede large fiber loss.[6] Furthermore, in PHN, cutaneous innervation is usually reduced in the affected skin compared to the mirror-image area.[59] However, a significant proportion of PHN patients have similar fiber densities in both the affected and the mirror-image skin, suggesting that the symptoms of pain and sensory dysfunction are not because of a mere loss in overall innervation density.[60] Using simple counts of anti-PGP labeled fibers, Oaklander and colleagues demonstrated that the average cutaneous fiber density was lower in subjects with established PHN than in those who had recovered without PHN after herpes zoster. Furthermore, mirror-image skin had lower fiber densities than distant control skin in subjects with established PHN.[60] Using a combination of results from a skin biopsy and testing of sensory function has helped characterize phenotypical subtypes in PHN.

It should be noted that the IENFD has been used in particular to diagnose peripheral neuropathies, whereas the possibility to distinguish between painful and painless neuropathies remains controversial. While patients with painful diabetic neuropathy were shown to have lower IENFD than those without pain in one study,[61] an observational study comparing 191 patients with painful and painless diabetic neuropathies showed a reduced IENFD in all patients without distinction between the two groups.[62] In this study, reduction of IENFD did not correlate with pain intensity. Future studies are necessary to elucidate the relationship between IENFD and pain, focusing on other protein and RNA analysis parameters. For example, different microRNA patterns were shown for painful versus painless neuropathies.[63]

Prognostic

There is some evidence that disease progression can be evaluated with skin biopsies. A prospective longitudinal study of HIV-infected patients showed that a lower nerve fiber density in the distal leg was associated with the development of a symptomatic neuropathy six to 12 months after baseline examination.[64] Beside the count of epidermal nerve fibers, skin biopsies allow the quantification of nerve fiber morphology, i.e. axon swelling, which seems to be a pre-degenerative change preceding IEFND reduction.[65] More pronounced swellings were shown to be associated with a decline in nerve fiber density and a higher probability to develop neuropathic symptoms over time in patients with neuropathy.[66]

Predictive

Only a few studies have investigated the role of skin biopsies as a potential biomarker to predict treatment response in pain. Herrmann and colleagues performed a retrospective study of patients with a painful distal sensory polyneuropathy who have been treated with a 5% lidocaine patch.[67] There was no association of the degree of epidermal or subepidermal fiber denervation at the distal leg with self-reported treatment response, implying that skin biopsy cannot predict response to the lidocaine patch. In addition, some patients exhibited a pain reduction in response to the lidocaine patch, although they were shown to have a complete nerve fiber loss. The authors concluded that the epidermal nerve innervation is not an essential substrate for the therapeutic response to lidocaine. In contrast, a retrospective study by Saperstein et al. demonstrated that patients with confirmed small fiber neuropathy (i.e. abnormal skin biopsy) were more likely to exhibit pain and to respond to standard neuropathic pain medications compared to patients with normal skin biopsies.[68] The regeneration potential of nerve fibers (spontaneous or treatment-induced) further indicates that skin biopsy can be used as an outcome parameter in clinical trials to investigate the effect of neuroprotective agents. Application of capsaicin, an ingredient of hot chili pepper and agonist of the vanilloid one receptor (TRPV1), to the skin induces short-term nerve fiber degeneration followed by spontaneous regeneration of epidermal nerve fibers with the restoration of evoked pain sensation after approximately three weeks.[69] Nerve fiber regeneration was also shown in patients with prediabetic neuropathy after one year following lifestyle interventions.[70]

Pharmacologic treatment of neuropathic pain with first-line drugs (anti-depressants, gabapentin, pregabalin) is often limited because of the systemic side effects such as dizziness or sedation.[5] Therefore topical agents have become an alternative treatment option, especially in elderly patients with localized peripheral neuropathic pain and a higher risk of fall. The application of capsaicin 8% patches can reduce neuropathic pain that lasts up to 12 weeks. To realize the concept of individualized pain therapy, current research focuses on identifying biomarkers to predict treatment response to high dose capsaicin patches. Anand et al. assessed the effect of capsaicin 8% patch in 16 patients with painful chemotherapy induced neuropathy comparing baseline and three months follow-up data of conventional neurophysiology, QST parameters, and different skin biopsy markers, among others, against PGP 9.5, TRPV1, and GAP-43 for regenerative nerve fibers.[71] Posttreatment skin biopsies showed a normalization of PGP 9.5 fibers and TRPV1 and GAP-43 fibers indicating that capsaicin application can induce nerve fiber regeneration. These results support the role of skin biopsies as a prognostic biomarker and can also be used to investigate further the predictive value of different skin biopsy markers for treatment with capsaicin.

Overall, however, there is currently insufficient data about the evidence of skin biopsy as a predictor of treatment response.

Similar to sensory testing, there are several caveats of skin biopsy techniques that should be considered. Skin biopsies predominantly provide information about the pathology in the skin, whereas changes in the afferent innervation of deep somatic structures and central changes cannot be assessed. It further remains to be determined whether the pathology in a single biopsy is representative of the entire affected area.

Summary

To date, no valid biomarkers have been identified for pain. However, there are some hints for potential candidates: sensory testing including QST and CPM as well as skin punch biopsy. Each of these methods provides both advantages as well as limitations. QST allows for the subgrouping of patients according to their pathophysiologic mechanism and may thus be helpful in realizing the concept of a mechanism-based therapy, although its validity may be limited because of its psychophysiologic character. In

contrast, a skin punch biopsy is an objective measurement. Nevertheless, its role as a diagnostic biomarker is limited since there is insufficient information about the differentiation of painful and painless neuropathies. In this chapter, we concentrated only on selected measures. However, other tools, such as electrophysiology, brain imaging, or omic assays (for example, genomic, epigenomic, metabolomic), may serve as potential pain biomarkers as well. Composite biomarkers, i.e. the combination of different methods that incorporate biologic and behavioral testing procedures, is a promising approach that may further help improving pain diagnosis and therapy.

The establishment of biomarkers in the pain field is essential for the correct diagnosis, monitoring, and treatment of pain and should therefore be increasingly the focus of scientific research.

Key Points

- Standardized and validated biomarkers are needed to improve the diagnosis of pain, predict treatment response, and monitor disease progression; promising tools are sensory testing, i.e. QST and CPM, and skin biopsy.
- A prerequisite for the establishment of a biomarker is the definition of its objective and the pain condition that should be addressed.
- The psychophysiologic character of sensory testing should be considered when using it as a biomarker for pain.
- A standardized QST protocol with reference values exists that enables direct comparison of pain patients with healthy controls
- QST allows the stratification of pain patients according to their sensory profile reflecting the underlying pathophysiologic pain mechanism.
- CPM is a dynamic measurement of the endogenous pain-inhibitory control system.
- A standardized protocol is needed to explore further the potential role of CPM as a pain biomarker.
- Skin biopsies, including quantification of intraepidermal nerve fiber density and morphologic changes, are an objective measurement for the evaluation of the peripheral nervous system.
- Further studies on skin biopsies are needed to clarify the possibility to distinguish between painful and painless neuropathies.
- Future studies should focus on composite biomarkers, i.e. combination of different measurements.

Psychological and Behavioral Assessment

JESSICA KRUSE, ROBERT D. KERNS, ELIZABETH K. SENG

Psychological and Behavioral Assessment

Chronic pain presents two broad challenges to proper assessment: 1) pain is personal and subjective, and 2) chronic pain impacts a wide range of patient functioning. These challenges necessitate a systematic approach to the standardized assessment of multiple domains of functioning using several assessment techniques, including interviews, questionnaires, behavioral observation, psychophysiologic measurement, diary data, and reports of significant others. This chapter will begin with a brief discussion of the clinical goals of psychological and behavioral assessment of patients with persistent pain, provide a rationale and context for the use of psychological assessment in the practice of pain management, articulate recommendations for the core domains of assessment, and provide an overview of the psychological assessment process. The chapter will then provide specific information about some of the most commonly employed psychological and behavioral assessment strategies for general use across chronic pain conditions. Finally, the chapter will provide information about the assessment of chronic pain in specific populations (e.g. pediatrics, older adults, and patients with mild cognitive impairment). Disease-specific measures may also be of interest to the clinician but are not specifically covered in this chapter. Examples include the Oswestry disability questionnaire (lower back pain),[1] Western Ontario and McMaster Universities osteoarthritis index (osteoarthritis),[2] and the neuropathic pain scale (neuropathic pain).[3]

Clinical Objectives

A multidimensional psychological and behavioral assessment of patients with pain can assist a multi-disciplinary pain team or treating clinician in several ways. Multidimensional assessment serves as a foundation for treatment planning and subsequent evaluation of treatment outcomes. An important outcome of the assessment process is the development of specific, measurable, achievable, relevant, and time-based patient-centered goals for treatment.[4] Data gathered in the assessment process provide important information about patients' pain experiences, pain treatment history, current, and past emotional and physical functioning, and beliefs about pain. Assessment allows the clinician to identify patients' strengths and weaknesses and the factors that contribute to the development and maintenance of problems in physical, social, and emotional functioning. Psychological and behavioral assessment may also reveal the need for adjunctive psychological treatment of preexisting or emerging psychosocial difficulties that may interfere with treatment. Psychological assessment can provide information about patients' motivation and readiness to engage in treatment and the patients' treatment preferences. Psychological assessment can also provide data about a patients' suitability for surgical or other invasive procedures under consideration.

A thorough assessment of a patient's pain complaint and functioning at baseline provides an important benchmark against which the efficacy of future treatments can be measured. Assessment should not stop after the initial visit but should be ongoing throughout the treatment process. This allows for the identification of new problems, quantifies progress across domains, and facilitates the refinement or revision of treatment if necessary. Posttreatment assessment is imperative to evaluate the overall success of the treatment and the differential success of the treatment across various domains of functions such as pain intensity, social, emotional, and physical functioning.

When making a request for a psychological and behavioral assessment, it is necessary to explicitly state the reasons for the request or pose a question about the patient or his/her treatment. It is helpful for the psychologist or behavioral specialist to understand the specific question the clinician or team is trying to answer about a patient to do a thorough evaluation and provide meaningful feedback. Although any psychological or behavioral assessment should be multidimensional and include all relevant domains of function, the specific measures used and the areas of most intense focus will differ depending on the consultation question. For example, an assessment to inform a decision about appropriateness for surgical intervention would have a different focus than an assessment to determine appropriateness for psychological pain treatment.

Overview of the Psychological and Behavioral Assessment Process

Ideally, psychological and behavioral assessment of patients with chronic pain should follow a hypothesis generating and testing approach. The assessment should begin broadly; as problems are identified, the clinician can hypothesize contributing and maintaining mechanisms. The assessment process will be increasingly focused and behaviorally oriented as the hypothesized mechanisms are investigated. Generally, the assessment process begins with a standardized interview that assesses the pain complaint and

patients' physical, emotional, social, and occupational functioning. This allows for the assessment of patients' past and present levels of functioning and the temporal association of any changes in functioning to the pain complaint. Besides the information gained in the interview, questionnaires, diaries, behavioral observations, significant other reports, and medical record information may be used as adjunct sources of information. The use of multiple adjunct measures helps avoid the biases or error associated with reliance on a single assessment strategy. Hypotheses about the factors that initiated and maintain adjustment and functioning problems are generated and refined throughout the assessment process. Ultimately, the validity of hypotheses is tested by examining patients' response to treatment.

For example, anxiety and fear of pain have been shown to contribute to unfavorable outcomes for persons with chronic pain complaints.[5] Significant functional disability can be associated with fear of pain and further injury, such as behavioral avoidance, muscle deconditioning because of reduced activity, muscle hyperreactivity to stress, negative and distorted cognitions about the adverse effects of activity, and psychological distress secondary to restricted access to pleasant and rewarding activities. Thus when an initial interview provides evidence of a significant decline in physical functioning and anxiety is present as described above, it becomes a reasonable hypothesis and avenue for more targeted assessment through the use of specific questionnaires, diaries, or reports from significant others (e.g. spouses or partners) to determine the extent to which anxiety is present and interacting with the pain experience. Ultimately, the assessment process should result in a model that describes the patient's specific pain experience, explicates how that patient's beliefs, experiences, strengths, and weaknesses have resulted in their current level of functioning across domains and provide an individualized treatment plan that uses these hypotheses to target specific factors for intervention.

Domains of Functioning

The multidimensional nature of chronic pain necessitates a broad assessment of multiple domains of functioning to provide a valid snapshot of a patient's unique pain experience and meaningfully guide intervention strategies. A useful guide for the assessment process is the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) group consensus statement regarding the core outcome domains that should be assessed and recommended instruments for measuring those domains when evaluating the efficacy of a pain treatment.[6–8]

Although originally generated to aid researchers in increasing comparability across randomized controlled studies of pain treatments, these recommendations can be useful to the clinician in guiding assessment. The IMMPACT group, which consists of recognized experts drawn from academia, government agencies, and the pharmaceutical industry, recommend assessing the following chronic pain domains: pain, physical functioning, emotional functioning, patient ratings of improvement and satisfaction with treatment, treatment-related symptoms, and adverse events, and patient disposition. Additionally, through literature review and expert consensus, the group has provided recommendations regarding specific assessment instruments within each domain applicable across various pain complaints. This same group has also developed recommendations for the future development of patient-oriented outcome measures that may provide a more sensitive and efficient assessment of the key outcome domains relevant to a comprehensive assessment of patients with pain.[8]

Overview of Assessment Strategies

Multiple assessment strategies such as interviews, standardized questionnaires, diaries, behavioral observation, psychophysiologic assessment, and assessment of family members and significant others are commonly used to investigate and quantify the pain experience and concomitant physical and emotional functioning. Multiple, standardized assessment measures are encouraged to obtain comprehensive, valid, and reliable information.

The well-conducted clinical interview can be a rich source of information regarding a patient's pain and pain treatment history as well as the resulting physical, emotional, behavioral, and cognitive responses.[9,10] The interview also provides an opportunity for clinicians to interact with a patient, to establish rapport, and to develop an impression of that patient's receptivity to rehabilitation and treatment efforts. Interviews may be standardized or unstandardized. Even when conducting an unstandardized interview, it is useful to systematically investigate a pre-specified set of domains. (Table 22.1 is an example of an interview structure used in the author's [RK] comprehensive pain management clinic.)

Questionnaires and inventories provide opportunities for focused assessment of specific domains of functioning and quantifying patient responses. Because published questionnaires have typically met standards for reliability and validity, greater confidence can be placed in the information provided by these measures. Questionnaires typically permit quantification of important dimensions of the experience of pain and allow for evaluation of within-person change over time. The concurrent administration of measures of multiple domains of functioning can assist in the identification of patient relative strengths and weaknesses across these domains, such as the identification of patients who report low levels of disability and distress despite an apparently severe level of pain intensity. Questionnaires with normative data offer the added benefit of providing a comparison point for evaluating the status of the respondent relative to others with similar painful conditions or within similar demographic (i.e. age, race/ethnicity, gender) groups. Ultimately, they may provide a more efficient and cost-effective option for more intensive and time consuming interviews. Following this brief overview of psychological and behavioral assessment strategies, several questionnaires and inventories frequently employed in assessing patients with pain in the clinical setting are reviewed.

Ecologic momentary assessment (EMA) is an umbrella term for measurement tools ranging from pen and paper diaries to smartphone apps and wearable technologies that sample biomarkers and physiologic parameters.[11] Across these different tools, EMA measures seek to measure behaviors, perceptions, and physiologic markers in real-world contexts and offer many advantages over other assessment methods. They allow for information about pain, sleep, and physical and emotional functioning to be recorded prospectively and once or more times a day, eliminating distortions associated with memory and retrospective recall.[12] EMA measures are also thought to increase the ecologic validity of assessments, as observations and ratings occur in patients' natural environment during real (vs. contrived) situations.[11] Additionally, EMA measures allow for recording the temporal association between pain and other factors. For example, many sleep diaries and smartphone applications collect information about pain intensity scores prior to sleep as well as sleep quality and duration.[13] This allows for the investigation of the relationship between pain and functioning instead of examining either factor in isolation. The composition of EMA measures can vary from those designed to assess a single

TABLE 22.1 Comprehensive Pain Interview

Demographics:

Age, gender, race/ethnicity, family/marital status.

Referral Source:

Referring MD and service, the reason for referral.

Behavioral Observations:

Noteworthy pain behaviors or behaviors indicative of psychiatric disturbance, otherwise, state "unremarkable."

Pain Complaints and Treatment History:

Please ask the patient the location of pain sites, then copy and paste questions one through seven for each pain site. If the patient describes a pain site as running through the leg, knee, and foot, check all sites below but evaluate as one pain site. Thus for the patient who identifies three pain sites: lower back, right hip and leg, and hands, record three pain sites here, then complete one to seven three times, each time identifying a different pain location "lower back," "hip and leg," and "hand." Qualify when necessary (e.g. left leg only, write this in).

1. LOCATION OF PAIN

[ ] head/face [ ] neck [ ] shoulder [ ] arm [ ] hands

[ ] stomach/abdomen [ ] upper back [ ] lower back [ ] hip [ ] leg

[ ] knee [ ] foot [ ] anal [ ] genital

[ ] whole body [ ] other sites (specify)

2. INTENSITY OF PAIN

The patient rates their average level of pain over the past week as follows:

0——1——2——3——4——5——6——7——8——9——10

No Worst Possible

Pain

Worst pain gets: Best pain gets: Average pain rating:

3. <u>QUALITY OF PAIN</u> (Do not prompt; use patient's own words when possible):

[ ] dull [ ] stabbing [ ] hot-burning [ ] shooting [ ] aching

[ ] piercing [ ] tingling [ ] numb [ ] squeezing [ ] throbbing

[ ] pulling [ ] sharp [ ] cramping [ ] gnawing [ ] heavy

[ ] tender [ ] radiating [ ] deep

[ ] other (specify)

4. ONSET/DURATION:

Approximate time pain started:

5. VARIATIONS/PATTERNS/RHYTHMS:

The pain is [ ] constant [ ] intermittent [ ] episodic/recurring

[ ] other (specify)

6. WHAT RELIEVES THE PAIN?

[ ] sitting [ ] lying down [ ] standing [ ] heat [ ] cold [ ] rest

[ ] distraction [ ] exercises [ ] movement

[ ] other (specify)

7. WHAT CAUSES OR INCREASES PAIN?

[ ] sitting [ ] lying down [ ] standing [ ] heat [ ] cold [ ] rest [ ] exercises

[ ] movement

[ ] other (specify)

domain, such as pain intensity to those that are much more comprehensive and multidimensional. Patients may already engage in self-monitoring and recording and might be using pen and paper measures, smartphone applications, or a combination of modalities. It can be useful to ask patients about self-monitoring habits and consider the implantation of EMA technologies in routine patient assessment. The use of innovative technologies such as mobile telephone apps, web-based diaries, and interactive voice response systems are increasingly being promoted as more efficient strategies for the collection of prospective information.[14]

Advances in wearable technologies also provide an efficient and powerful strategy for collecting EMA data. Consumer grade devices (e.g. AppleWatch and FitBit) and research grade devices (e.g. SenseWear Armbands, Step-Watch 3) can measure a range of biometric data, including steps taken per day, heart rate, and duration and intensity of physical activity.[15] Steps taken per day, and other measures of physical activity and energy expenditure, can be particularly useful metrics to capture in patients with chronic pain, as reduced physical activity levels can cause worsening of comorbidities. Additionally, evidence suggests that routine physical activity can reduce pain severity and improve quality of life and physical functioning.[16] Subsequently, wearable technologies can provide both clinicians and patients with objective measures of important modifiable health behaviors.

Behavioral observation is a useful adjunctive to self-report. Although pain is a private, subjective experience, it is possible to observe signs that patients are experiencing pain by direct behavioral observation. Patients can communicate that they are experiencing pain and the intensity of the pain through facial expressions, crying, moaning, limping, guarding, and rubbing affected areas. Behavioral observation of patients with chronic pain can provide valuable adjunct information beyond that gathered using a self-report format and is crucial to the evaluation of patients with cognitive or physical limitations that interfere with verbal communication. Behavioral observation methods have been developed to assess patients with a range of painful medical conditions, including cancer pain,[17] rheumatoid arthritis,[18] osteoarthritis,[19] and low back pain.[20] Prkachin and his colleagues[21] reported on a method for assessment of pain behaviors in the context of a clinical evaluation of patients with low back pain. These methods have also been developed and used in studies of pain-relevant communication in partner dyads.[22] To obtain reliable and valid behavioral observation data, it is necessary to have a systematic plan for behavioral observation, coding, and interpretation of the data; thus the use of these methods requires considerable technological sophistication and expense.[23] The use of behavioral observation methods is commonly limited to the clinical research setting because of the time-intensive and costly nature of these methods.

The reports of families and significant others in the assessment of pain have been strongly encouraged in contemporary models of pain, particularly Fordyce's operant conditioning model,[24] and Turk's cognitive behavioral model,[25] which have specifically encouraged this focus given hypothesized roles of social contingencies in the perpetuation, if not etiology, of persistent pain and disability and the awareness of the frequent negative impact of persistent pain on significant others. In particular, the role of solicitousness in the development and maintenance of pain related disability has been a topic of a great deal of research. Operant principles specify that when spouses provide solicitous responses to pain behaviors, the pain behaviors are more likely to be emitted in the future, even in the absence of continued nociception. Positive or solicitous responses from spouses and family members, contingent on pain behaviors, may reinforce these maladaptive behaviors and encourage the development and maintenance of pain and pain related disability. Examples of solicitous behavior examined in the literature include expressions of sympathy or concern for the spouse, physical assistance or performance of a task, and encouraging rest and discouraging activity. In general, spouse solicitousness is significantly related to greater pain intensity, greater frequency of pain behaviors, higher levels of disability,[26–28] and increased help-seeking behaviors.[27,28] Distracting responses from significant others, meaning responses that are intended to cue engagement in other behaviors in an effort to distract from pain, have been found to be positively related to poor outcomes despite the likely intent of these responses to encourage adaptive coping with pain.[26] In addition to global measures of family and marital relationships, numerous questionnaires and inventories,[29–31] diaries,[32] and behavioral observation methods[22] have been developed specifically for the assessment of pain-relevant communication and the impact of pain on family members and significant others.

Psychophysical measures are primarily used to demonstrate the influence of psychological factors on the initiation and maintenance of pain symptoms.[33] For clinicians, psychophysical measures provide evidence that psychological factors are influencing biologic reactions in an individual patient and provide information regarding the utility of certain types of interventions (e.g. biofeedback). For patients, evidence that psychological factors are influencing physical responses related to pain can provide direct feedback regarding the successful use of behavioral strategies to manage a pain disorder and increase confidence to engage in these behavioral strategies.[34]

The most common clinical use of psychophysical measures in the treatment of pain primarily occurs during biofeedback treatments. Biofeedback treatments utilize psychophysical measures to train patients in voluntary modifications of bodily reactions through the provision of feedback of physiologic processes.[33] Surface electromyographic (EMG) recordings are the most widely used psychophysical measure in biofeedback for pain disorders because muscle tension is implicated in most musculoskeletal pain disorders. EMG readings typically target specific muscle groups associated with the patient's pain disorder (e.g. trapezius muscle for patients with upper back pain and the erector spinae muscle for patients with lower back pain). Additionally, abnormal blood flow is linked to several chronically painful conditions, including migraine headaches and Raynaud's disease. For these conditions, measures of blood flow and peripheral skin temperature (a proxy for peripheral circulation) can be used in biofeedback treatments.

In recent years, heart rate variability (HRV) has risen in prominence as a well validated psychophysical biofeedback measure. HRV, a measure of the duration of time between consecutive heartbeats, is an important indicator of autonomic nervous system functioning and reflects the balance in the parasympathetic and sympathetic nervous systems.[35–38] Increased HRV generally indicates more adaptive physiologic reactions to environmental stressors. However, it should be noted that pathologic abnormalities in the heart's conduction system can also increase HRV. Assuming healthy cardiac functioning, HRV provides a powerful biofeedback measure, especially for patients with chronic pain, as multiple chronic pain conditions including fibromyalgia, chronic lower back pain, and migraine have been associated with reduced HRV in the literature.[35,38,39] Preliminary pilot studies have suggested that HRV biofeedback is an effective biofeedback treatment for chronic pain.[35,38,40]

Specific Psychological and Behavioral Assessment Strategies

Standardized assessment instruments, often in the form of questionnaires or inventories, are frequently used in the assessment of patients with pain (Table 22.2). Questionnaires allow for a focused examination of a specific domain such as pain intensity,

TABLE 22.2 Overview of Assessment Measures

Measure	Domain	Measure Details	Advantage/Disadvantages
Numerical rating scale (NRS)[44,*]	Pain intensity	Single item, written or oral	Demonstrated validity, easy to administer, high completion rate; single item hinders reliability
Verbal rating scale (VRS)[44]		Collection of pain descriptors	Demonstrated validity, easy to administer, high completion rate; may be difficult for persons with poor command of English
Visual analog scale (VAS)[44]		10 cm line with descriptive endpoints	Demonstrated validity, easy to administer; more likely to be incomplete than NRS or VRS, and single item hinders reliability
McGill pain questionnaire (MPQ)[49,*]		Collection of pain descriptors. Also assesses the location of pain and exacerbating and ameliorating factors	Demonstrated validity; not consistently associated with pain intensity but more consistently associated with psychological distress
Brief pain inventory (BPI)[64,*]	Pain interference	32 items, short form has 15 items, ultra-brief version (PEG) has three items	Widely used, demonstrated validity and reliability, easy to administer, brief versions appropriate for multiple clinical settings; PEG has demonstrated good validity and is shorter and easier to administer
Graded chronic pain scale-revised (GCPS-R)[67]		Six item scale includes PEG	Short and easily interpretable, it provides clinically meaningful gradation of patients with chronic pain
West Haven-Yale multidimensional pain inventory (WHYMPI - interference scale)[68,*]	Psychosocial impact	52 items, assesses multiple domains	Demonstrated validity and reliability, useful with a variety of pain complaints, widely used; relatively high response burden, scoring time consuming
Pain disability index (PDI)[1]	Physical/social role function	49 items, assesses perceived disability in seven areas	Demonstrated validity and reliability, can identify specific areas of perceived disability; relatively high response burden, scoring time consuming
Patient-reported outcomes measurement information system (PROMIS pain interference and pain behaviors item banks)[79,80]		Item banks (Interference = 41 items; Behaviors = 39 items)	Standardized bank of items developed by National Institutes of Health (NIH), demonstrated reliability and initial validity, available in short forms; good demonstrated validity and reliability
Sickness impact scale (SIP)[89]		136 items and 24 items brief version for persons with chronic back pain	Demonstrated validity and reliability, responsive to change; full version has high response burden
Minnesota multiphasic personality inventory 2 - restructured form (MMPI-2-RF)[92]	Personality	567 true-false items	Most widely used personality measure, uses normative data in scoring; high response burden, difficult to score, requires training to interpret, restructured clinical scales have demonstrably improved discriminant validity in patients with chronic pain
Millon behavioral health inventory (MBHI)[97]		150 true-false items	Developed specifically for use with persons with medical conditions, demonstrated validity and reliability; high response burden, scoring time consuming, not predictive of outcomes in treatment studies of persons with chronic pain
Beck depression inventory (BDI)[101,*]	Emotional function	21 items, measures depression	Demonstrated reliability and reliability, sensitive to change; somatic items may be associated with pain rather than mood, a possible bias for certain populations
Center for Epidemiological Studies depression scale (CES-D)[110]		20 items, measures depression	Demonstrated reliability and validity in a wide variety of ethnic populations, non-English version available; lacks sensitivity and specificity without psychiatric interview
Geriatric depression scale (GDS)[118]		30 yes-no questions, measures depression in older adults	Demonstrated reliability and validity, good sensitivity and specificity; has not yet been widely used in chronic pain samples

TABLE 22.2 Overview of Assessment Measures—cont'd

Measure	Domain	Measure Details	Advantage/Disadvantages
Patient health questionnaire-9 (PHQ-9)[121]		Nine items, measures depression	Demonstrated reliability and validity across multiple populations, translated into several languages; does not specifically assess for mania and therefore underdiagnoses bipolar disorder
General anxiety disorder-7 (GAD-7)[126]		Seven items, measures generalized anxiety	Demonstrated validity and reliability in patients with chronic pain, easy to use, assesses for anxiety-related interference
Beck anxiety inventory (BAI)[129]		21 items, assesses anxiety symptoms	Good validity and reliability, normed on multiple clinical populations and translated into several languages, provides an indication of anxiety symptom severity
Pain anxiety symptom scale (PASS)[137]		53 items, assesses pain related fear	Demonstrated validity; poor prediction of pain related disability, relatively high response burden
Spielberger state-trait anxiety Inventory (STAI)[141]		Two 20 item measures of state and trait anxiety	Acceptable psychometric properties, widely used, sensitive to change
Medical outcomes study short form health survey (SF-36)[144]		36 item measure of perceived physical and emotional health	Psychometrically sound, widely used; concerns regarding measure's sensitivity and validity in discriminating dimensions of functional limitations in patients with pain
Survey of pain attitudes (SOPA)[154]	Pain beliefs and coping	57 item measure of pain related beliefs, brief forms are also available	Psychometrically sound, scores correlated with treatment outcomes and physical and emotional functioning
Pain stages of change questionnaire (PSOCQ)[161]		30 item measure of readiness to change	Demonstrated reliability and validity, predicts completion of treatment, changes in PSOCQ predict changes in "readiness"; may not be predictive of treatment outcomes
Chronic pain coping inventory (CPCI)[168]		64 item measure to assess the use of pain coping strategies	Psychometrically sound, patient coping strategies found to be associated with outcomes; high response burden
Pain catastrophizing scale (PCS)[172]		13 item measure of pain related catastrophic thoughts	Psychometrically sound, associated with treatment outcomes, demonstrated reliability and validity across different clinical populations, translated into several languages; further evaluation across racial groups is warranted
Chronic pain acceptance questionnaire (CPAQ)[188]		20 item measure of pain acceptance; eight item brief form also available	Demonstrated reliability and cross-sectional validity; associated with treatment outcomes, measure is specific to a single type of pain treatment, and further information regarding predictive validity is warranted
Revised American Pain Society pain outcomes questionnaire (APS-POQ-R)[199]	Quality of care	12 item measure of perceived quality of pain treatment	Commissioned by the American Pain Society and demonstrated reliability and internal validity

* = Measure was selected by the IMMPACT panel as the preferred measure within a domain.

pain interference, or coping beliefs and provide quantitative data that can be used to understand the patient's functioning relative to the general population or other patients experiencing pain.

Pain Intensity

Historically, change in pain intensity from baseline to posttreatment has been the primary outcome measure used in evaluating the efficacy of a given pain treatment.[41] However, pain intensity should not be used as a primary, unitary pain outcome measure as it does not directly correlate with pain related disability, and its measurement does not improve the quality of patient pain management.[42, 43] This section briefly outlines pain intensity measures. However, clinicians should not consider these to be sufficient nor comprehensive assessment measures of pain in patients.

Measures that attempt to quantify the private experience of perceived pain intensity include the numeric rating scale (NRS), the verbal rating scale (VRS), and the visual analog scale (VAS).[44]

The NRS is a single item rating scale of pain intensity that can be administered in an oral or written format. Patients are asked to specify their pain on a scale of zero to ten, with zero representing "no pain" and ten representing "the worst pain imaginable" The ease of administration and scoring advantage the NRS.[44,45] The VRS contains a list of pain descriptors that typically range in intensity from "No pain" to "Severe pain." Patients select the descriptor that best characterizes their level of pain. The descriptors are then assigned a numeric value based on intensity level (i.e. no pain = zero, mild = one, moderate = two, and severe = three).[44] While the VRS is easy to administer, patients with limited vocabularies or command of English may have difficulty discriminating among the descriptor words.[44] The VAS uses a 10 cm long line with endpoints denoting the absence of pain (e.g. "no pain") at one end and extreme pain at the other: Respondents mark the point that best characterizes their pain intensity, and a score is calculated based on the distance from the "no pain" endpoint to the respondent's mark. Electronic administration of the VAS has been found to have good psychometric validity and reliability than pen and paper administration.[46–48] However, depending on the electronic administration modality, anchoring bias must be considered when evaluating responses. Selection of the anchor (where the mark initially appears on the scale, e.g. at zero or five) may unintentionally bias pain reporting toward that anchor.

The McGill pain questionnaire (MPQ)[49] is a lengthier measure designed to assess the quality and affective component of the pain experience, not simply pain intensity. Respondents choose pain descriptors from a list of 78 potential descriptors that fall into 20 pain categories. These descriptors assess four pain domains: sensory, affective, evaluative, and miscellaneous. Within each category, the individual descriptors reflect varying degrees of intensity and are assigned corresponding numeric values that reflect this difference. Respondents also highlight the location of their pain on a figure drawing and provide information about the factors that alleviate and aggravate their pain intensity. The MPQ generates three scores: 1) the pain rating index, which is the sum of all words chosen in the available categories (the sum of the value of each subclass can also be obtained; 2) number of words chosen, a score that reflects the number of words chosen from each of the four categories; and 3) the present pain intensity, a rating of current pain on a scale from zero (no pain) to five (excruciating).[23] The MPQ has been widely used in a variety of pain focused research and has been validated in several other languages.[50–54] A 15 item short version of the MPQ (SF-MPQ) is also available.[55] The MPQ has demonstrated validity across various criteria, including pain intensity, perceived quality of life, ability to discriminate among pain conditions, pain medication use, and sensitivity to the effects of pain treatment.[56,57] The SF-MPQ demonstrated high correlations with the pain rating indices of the MPQ and was sensitive to change produced by pain medications in patients with pain.[58,59] Furthermore, the SF-MPQ2 includes an NRS, which allows for evaluating both the quality and intensity of the pain experience.[60,61]

Pain Interference

Pain intensity is an insufficient measure of pain, and there has been a strong trend toward focusing on the constructs of pain related functioning and the ability to attain personally valued and meaningful behavioral goals as treatment foci.[42] In line with this, providers are encouraged to assess patients for high impact chronic pain (HICP)—pain at least most days for ≥3 months with ≥1 activity limitation/participation restriction.[42] Patients with HICP experience more severe effects of pain across multiple domains, and experience more psychiatric diagnoses, cognitive impairment, difficulty with self-care, increased healthcare utilization, and worse overall health than patients reporting chronic pain without limitations. Subsequently, this diagnosis provides clinicians with a useful indication of pain severity and expected morbidity. Patients can be assessed for HICP with the question, "over the past six months, how often did pain limit your life or work activities? Would you say never, some days, most days, or every day?"[62,63] Patients reporting pain-related limitations most days or every day meet criteria for HICP.

Additional measures of pain interference include the brief pain inventory (BPI), the pain, enjoyment of life, and general activity scale (PEG), graded chronic pain scale–revised (GCPS-R), West Haven-Yale multidimensional pain inventory (WHYMPI), pain disability index (PDI), patient-reported outcomes measurement information system pain interference and behaviors (PROMIS pain interference and pain behaviors), and sickness impact profile (SIP).

The brief pain inventory (BPI)[64] was initially developed to measure pain intensity and interference in patients with cancer pain, but it has been widely used to assess non-cancer pain. A short form of the BPI containing 15 items is also available. The short form of the BPI has been found to have high internal consistency scores ranging from 0.82 to 0.95 for the Severity and Interference scales in a sample of patients with arthritis and lower back pain.[65] Demonstrations of its reliability and validity and its availability in multiple languages have contributed to it being recommended by IMMPACT to measure physical functioning in pain clinical trials.[6] The PEG is an ultra-brief version of the BPI consisting of three items: (P) pain intensity, (E) enjoyment of life, and (G) general activity. Development studies demonstrated reliability and validity for the PEG comparable to that of the longer BPI.[66]

The graded chronic pain scale-revised (GCPS-R) can also be used to distinguish between high impact chronic pain (grade three), bothersome chronic pain (grade two), and mild chronic pain (grade one).[67] The six item scale assesses for chronic pain, HICP, and inability to work because of pain and includes the PEG (pain, enjoyment, and general activity) scale. The measure is short and easily interpretable for both patients and clinicians. Unlike other measures of pain related interference, the GCPS-R provides a clinically meaningful gradation of patients with chronic pain, with analysis finding statistically significant differences in adverse health statuses (i.e. pain coping beliefs, affective disorders, activity limitation, and the likelihood of receiving long-term opioid therapy) between the different groups.[67]

The West Haven-Yale multidimensional pain inventory (WHYMPI)[68] is designed to measure psychosocial and behavioral aspects of chronic pain and is useful across various pain complaints. It is a 52 item multidimensional self-report instrument that employs seven point Likert scales. The instrument consists of three sections. Section one includes six scales measuring pain related interference across several domains, including work and leisure activities as well as interpersonal relationships, perceived support from a spouse or significant other, pain severity and suffering, perceived life control, and negative mood. Section two assesses the patient perception of significant others' responses to overt expressions of pain, classifying responses as solicitous, distracting, or negative. Section three measures the frequency with which the patient engages in four clusters of everyday activities, including household chores, social activities, outdoor work, and

activities away from home. The WHYMPI takes approximately 10 to 15 min to complete and is written at a fifth grade reading level. Test-retest reliability over two weeks ranges from 0.62 to 0.91, and internal reliability coefficients range from 0.70 to 0.90.[68] Several investigative teams have generally replicated the factor structure and psychometric properties of the WHYMPI.[69] Turk and colleagues have proposed an empirically derived taxonomy of the WHYMPI that includes three reliable profiles of patients with persistent pain labeled as dysfunctional, interpersonally distressed, and adaptive copers,[70] and these investigators and several other groups have replicated these findings in numerous samples of patients with various pain conditions.[71] The measure has been used in numerous empirical studies, including clinical trials of psychological and pharmacologic interventions, studies of the psychosocial impact of pain, and studies examining the role of psychosocial factors as contributors to the development and maintenance of persistent pain. The IMMPACT group recommended using the interference scale of the WHYMPI for use as an outcome measure in pain clinical trials.[6] The second section of the measure that focuses on significant other responses has been particularly valuable in evaluating the role of such responses as predictors of severity of pain and pain related disability and distress.[72]

Three additions to the original version of the scale have enhanced its overall reliability, validity, and clinical utility. Rudy[73] added two items to the life control and interference scales, Okifuji and her colleagues[74] proposed alternative instructions for the significant other response section to reduce missing observations, and Bruehl and colleagues[75] developed a scale to detect random responding and malingering. A version using significant others as the reporters has also been published.[29]

The pain disability index (PDI)[1] is a brief measure of pain related interference with role functioning. The PDI includes seven items assessing perceived disability in each of seven areas of functioning: family/home responsibilities, recreation, social activity, occupation, sexual behavior, self-care, and life-support activity. Each item is rated on a ten point Likert scale (zero = no disability to ten = worst disability). The PDI has demonstrated internal consistency values of 0.85 to 0.86 and excellent test-retest reliability.[76] Validity has been demonstrated through its association with the Oswestry disability questionnaire (focused specifically on chronic lower back pain),[77] physical functioning tests,[78] and measures of pain intensity.[77]

The National Institutes of Health (NIH) PROMIS is a standardized item bank developed by a cooperative group for the purpose of developing psychometrically sound standardized measures to assess patient-reported outcomes. These measures provide information in the domains of physical, mental, and social health across a variety of medical illnesses. Measures for pain currently available in the PROMIS assessment center (www.healthmeasures.net) include the general measures of pain interference and pain behaviors and more specific measures of neuropathic pain quality.[79] The pain interference item bank includes 41 items, with four short forms consisting of four to eight items.[80] The pain behaviors item bank includes 39 items with a single short form consisting of seven items.[81] Both measures demonstrated reliability and validity in psychometric evaluation, were related to other measures of pain related outcomes, and discriminated among groups of patients with differing self-reported health, numbers of chronic conditions, and numbers of disabling conditions. Further studies have demonstrated that the pain related measures and global scores of quality of life are higher in clinical pain samples than samples from the general population.[82] Extant research has found the PROMIS pain interference and pain behaviors scales to provide comprehensive, sophisticated, and psychometrically sound measures for pain related patient-reported outcomes: the measures have been translated into other languages and have been found to be reliable and valid.[83–85] Recently, measures of pain interference and behavior have also been developed specifically for use with pediatric patients,[86–88] and their parents,[87] but there is a small body of existing literature on the reliability and validity of these measures.

The sickness impact profile (SIP)[89] measures the degree of disability across 12 domains of functioning. One hundred and 36 items are used to derive measures of sleep and rest, eating, work, home management, recreation and pastimes, ambulation, mobility, body care and movement, social interaction, alertness behavior, emotional behavior, and communication. These domain scores are combined to produce physical, psychosocial, and total disability scores. The SIP can be self-administered or administered by an interviewer in about 20 to 30 min.

An extensive period of development and testing and reports on these efforts support the reliability and validity of the measure. It has been found to be responsive to change during treatment for chronic pain.[90] A brief version, called the Roland Morris disability questionnaire, consisting of 24 items, has been developed specifically for use with patients with chronic low back pain.[91] This measure has also been shown to have strong evidence of reliability, validity, and responsiveness to change as a function of psychological interventions and is recommended by IMMPACT[6] as the preferred measure of physical functioning for evaluating persons with back pain.

Personality

The Minnesota multiphasic personality inventory (MMPI)[92] is the most commonly employed evaluative measure for the psychological functioning of patients with pain. The MMPI-2-RF is comprised of 338 true-false items used to derive scores on three higher-order scales, and nine restructured clinical scales, eight validity scales, 14 somatic/cognitive and internalizing scales, 11 externalizing, interpersonal, and interest scales, and the personality psychopathology five scales.[92] The MMPI-2-RF was normed on a representative sample of the United States population, and the restructured clinical scales have demonstrated validity in predicting psychopathology. Earlier versions of the MMPI (MMPI or MMPI-2) were considered inappropriate for assessing patients with chronic pain, owing to psychometric limitations that caused clinical scales to reflect disease status rather than psychological functioning.[93,94] The MMPI-2-RF's restructured clinical (RC) scales were developed to address psychometric and theoretical limitations of the earlier MMPIs, and the RC scales have demonstrably improved discriminant validity in patients with chronic pain.[95,96]

The Millon behavioral health inventory (MBHI)[97] was developed to assess the psychological functioning of patients with medical conditions. This 150 item measure contains eight scales designed to assess the respondent's interaction style (e.g. cooperation), six scales that assess the respondent's response to illness (e.g. pain treatment responsivity), and six scales that assess the presence of psychosocial stressors (e.g. social alienation). Questions are posed in a true/false format. Respondent's answers are scored by comparison with the base rate in the normative sample, which consisted of patients with various medical illnesses.

The MBHI has been demonstrated to have substantial reliability and validity indices. It may have advantages relative to

the MMPI-2-RF for use in the assessment of patients with pain conditions as a function of its relative brevity and the fact that it was developed and normed on medical, as opposed to psychiatric, populations. However, to date, studies have failed to demonstrate the predictive validity of the MBHI in studies of psychological interventions,[98] surgical interventions,[99] or multi-disciplinary treatment of patients with chronic pain.[100]

Emotional Functioning

Assessment of the emotional functioning of patients experiencing chronic pain should be conducted in the context of any pain-relevant intervention. The high prevalence of emotional distress among patients with chronic pain conditions, the negative effects of emotional distress on pain and pain related disability, the inflated healthcare costs associated with emotional distress among patients with chronic pain, and the influence of emotional distress on pain treatment participation provides the rationale for this recommendation.[6] The following brief review considers just a few of the many standardized measures of depressive symptom severity, anxiety, and anger, the three most commonly cited and studied emotional concomitants of the experience of persistent pain.

The Beck depression inventory (BDI) was developed to measure the behavioral manifestations of depression in adolescents and adults and standardize the assessment of depressive symptom severity to monitor change over time.[101] In its original form, the BDI consisted of 21 groups of four to five statements describing symptoms in each cluster from low to high. Respondents were instructed to endorse the single item in each group that best describes how they were feeling "right now." The original version was designed to be used in an interview format, but subsequent versions have more commonly been used in a self-report questionnaire format. In 1978 the full scale was revised to eliminate redundancy among some of the items, and the time frame for assessment was altered to "during the last week, including today." Only four possible responses for each symptom cluster are now included so that scores on the measure range from 0 to 63. In 1996, the BDI-II was published and included revisions to some items and the time frame for assessment to be consistent with the Diagnostic and Statistical Manual of Mental Disorders-IV (DSM-IV). Although the BDI-II has advantages in terms of the content of the items and consistency with current diagnostic nomenclature, concerns have been raised about its sensitivity to change during brief periods.[102] The 21 item version of the BDI takes about 5 to 10 min to complete.

The reliability and several dimensions of validity of the measure have been extensively reported. In a review of 25 years of research with the BDI, Beck and colleagues reported on 25 studies that reported on the internal consistency of the measure.[103] Across psychiatric, healthy, and medically ill samples, indices of internal consistency (alphas) ranged from 0.73 to 0.95. Stability estimates (i.e. test-retest correlations) have consistently been high as well, typically varying in the 0.80 to 0.90 range depending on the assessment interval and sample. Validity estimates for psychiatric patients have been assessed by examining the correlation between BDI scores and clinical ratings of depression (e.g. using the Hamilton rating scale for depression) average of about 0.72. For nonpsychiatric patients, the average validity estimate is 0.60. In a review of eight studies of sensitivity to change, Moran and Lambert[104] found that the BDI was sensitive to change as a function of psychotherapy and pharmacotherapy outcome studies. Some evidence suggests a reporting bias for certain populations, including women, adolescents, and elderly persons, although the robustness of these observations is not clear.

The BDI has been used extensively in studies designed to evaluate the efficacy of pharmacologic and nonpharmacologic treatments for chronic pain,[105–109] and there is ample evidence of its sensitivity to change. Results of most studies provide compelling support for the use of the BDI in assessing improvements in depressive symptom severity as a function of pain treatment, and it has been recommended as one of the core outcome measures for assessment in pain clinical trials.[6]

The Center for Epidemiologic Studies depression scale (CES-D) was developed to screen for the presence of depressive illness and to measure levels of symptoms of depression in community samples.[110] The scale's 20 items were selected from existing scales (e.g. BDI, MMPI depression scale, Zung self-rating depression scale) to represent the major components of depression based on clinical and empirical studies. Respondents are asked to rate the frequency of a given symptom on a zero (rarely or none of the time) to three (most or all of the time) scale with reference to the past week. Four items are worded in the positive direction to partially control for response bias. The CES-D takes about 5 min to complete.

Indices of internal consistency (Cronbach's alpha) have been reported to be 0.85 for community samples and 0.90 for psychiatric samples. Split-half reliabilities are also high, ranging from 0.77 to 0.92. Test-retest correlations over a six to eight week period range from 0.51 to 0.67.[110] Roberts[111] reported that studies of African American and Mexican-American respondents revealed similar reliability estimates. The reliability and validity of the measure have also been examined in numerous ethnic populations, and it has been translated into several languages.[110] Overall, high levels of internal consistency have been reported across numerous samples from the general population and patient samples, irrespective of age, gender, race, and geographic location. In a sample of chronic pain patients, the level of internal consistency was found to be 0.90.[112] Indices of criterion-related validity have generally been reported to be moderate to high. For example, correlations between the CES-D and the depression scale of the SCL-90 for samples of psychiatric patients have been reported to range from 0.73 to 0.90. Correlations with the Hamilton rating scale for depression for similar samples have ranged from 0.49 to 0.85. Studies of elderly samples have revealed somewhat lower validity estimates.

Investigators have challenged the diagnostic sensitivity of the CES-D.[113,114] Investigators in the pain field have called for modifications of the measure in terms of item content[115] or scale cutoffs for the diagnosis of depression.[114,115] Ultimately, it is fair to say that the measure lacks the sensitivity and specificity for supporting its use in clinical diagnosis without concurrent use of a psychiatric interview. The CES-D has increasingly been used for the assessment of outcome following pain interventions, and in numerous cases, the measure has been demonstrated to be sensitive to change.[116,117]

The geriatric depression scale (GDS)[118] was specifically developed to assess depressive symptom severity among older patients and was encouraged by observations that all of the other self-report measures of the construct were developed and validated with medically healthy younger adults. These measures suffer from the criticism that they include numerous somatic symptoms common among non-depressed older adult patients and that their format for responding may be difficult for some older patients.

The GDS consists of 30 "yes" versus "no" questions; 10 are negatively keyed, and 20 are positively keyed. Questions are ordered

with more "acceptable" items presented first. A 15 item short form is also available.[119]

In the original publication, indices of internal consistency (0.94) and split-half reliability (0.94) were extremely high.[118] The GDS demonstrated high correlations with other measures of depression and was successful in discriminating mild from severely depressed groups in this same study and depressed older patients with arthritis from non-depressed patients with arthritis. Brink and colleagues[120] reported a high degree of sensitivity and specificity in discriminating depressed from non-depressed patients in a separate sample.

This measure seems to have substantial advantages for the assessment of depressive symptom severity among older adult patients. However, additional research with chronic pain samples will be necessary before its use in pain treatment outcome research can be supported.

The patient health questionnaire depression module (PHQ-9) is a self-administered diagnostic questionnaire that assesses for the presence of Major Depressive Disorder (MDD), based on the criteria set forth by the diagnostic and statistical manual (DSM-IV).[121] The PHQ-9 lists the nine DSM-IV depressive symptoms and asks how often the person has experienced the symptoms over the past two weeks: response options range from zero (not at all) to three (nearly every day). At the end of the screener, a separate question assesses the extent to which these symptoms have interfered with day-to-day life. Severity scores on the PHQ-9 can range from 0-27; higher scores indicate increased depression severity and are associated with measures of health-related quality of life.[121,122] The PHQ-9's reliability and validity have been examined across multiple care contexts, clinical populations, and racial and ethnic groups, and it has been translated into several languages.[123,124] Overall, the PHQ-9 has been found to have good internal reliability in primary care samples (Cronbach's alpha = 0.89), obstetrics and gynecology patients (Cronbach's alpha = −0.86), and patients with migraine (Cronbach's alpha = 0.89). In initial validation, test-retest correlation over a 48 h period was 0.84.[121,125]

Before making a final diagnosis, the provider should assess for and rule out physical causes of depression, current bereavement, and/or a history of a manic episode. A diagnosis of MDD is appropriate if the patient endorses experiencing five or more symptoms more than half of the days, with one of the symptoms being either depressed mood or anhedonia. If the patient endorses depressed mood or anhedonia more than half the days and one other depressive symptom, then the patient meets the criteria for "other depression."[121] For diagnostic purposes, endorsement of suicidal ideation (item nine) of any frequency (> zero) counts as a symptom and clinically indicates the need for further suicide risk assessment and safety planning with the patient.

The GAD-7 is a self-administered seven item screening measure for generalized anxiety disorder (GAD). The items assess the frequency of physiologic and cognitive anxiety symptoms in the past two weeks, and response options range in frequency from zero (not at all) to three (nearly every day). A final question assesses if these problems have interfered with daily activities.[126] The GAD-7 was initially validated on primary care patients and was found to have excellent internal consistency (Cronbach's alpha = 0.92), test-retest reliability (intraclass correlation = 0.83), and validity with established anxiety screening measures (intraclass correlation = 0.83).[126] The GAD-7 has also been found to be valid and reliable in the general population,[127] and patients with pain.[128]

The Beck anxiety inventory (BAI) is a 21 item self-report questionnaire that assesses the severity of anxiety symptoms, with items asking how much the symptoms bothered the respondent in the last two weeks from zero (not at all) to three (severely - it bothered me a lot). The measure focuses on the somatic symptoms of anxiety and was developed to discriminate anxiety disorders from depressive disorders, although it should not be used as a solo differential diagnostic tool.[129] The summed score of response options can be interpreted using the following ranges: 0 to 7 minimal anxiety, 8 to 15 mild anxiety, 16 to 25 moderate anxiety, and 26 to 63 severe anxiety, with a score greater or equal to 16 indicating clinically significant anxiety.[130,131]

The BAI was initially validated on psychiatric patients with anxiety and depressive disorders and was found to have high internal consistency (Cronbach's alpha = 0.92) and good test-retest reliability over one week (r = 0.75). The BAI's reliability and validity have been examined across multiple care contexts, clinical populations, and racial and ethnic groups, and it has been translated into several languages.[130,132–136]

The pain anxiety symptom scale (PASS)[137] was designed to assess the cognitive, physiologic, and behavioral domains of pain related fear. It includes 53 items distributed across four subscales measuring fear of pain, cognitive anxiety, somatic anxiety, and escape and avoidance. Respondents use zero (never) to six (always) scales to endorse the frequency of each of the symptoms. The PASS has been demonstrated to have adequate internal consistency,[137] with indices of internal consistency ranging from 0.81 to 0.89 for each of the four scales and 0.94 for the total scale. Good predictive validity,[138] and acceptable criterion validity have also been demonstrated.[139] The PASS has been criticized for its poor prediction of disability relative to other pain related fear measures,[139] and its factor structure has also been challenged.[140]

The Spielberger state-trait anxiety inventory (STAI)[141] was designed to identify and quantify both situational anxiety (state) and dispositional anxiety (trait). The STAI consists of two 20 item self-report inventories of each of these constructs. Respondents rate the degree of agreement to brief statements (e.g. "I feel calm") on four point scales ranging from "not at all" to "very much so" in terms of both their present state (state version) and their frequency over time (trait version). There is a high concordance between pain and anxiety as measured by the STAI,[142] and it has been widely used in the pain literature. It has acceptable psychometric properties,[139,141] and it is sensitive to change in anxiety as a function of pain treatment.[143]

The medical outcomes study short form health survey (SF-36)[144] was developed as a general measure of perceived health status and is typically self-administered. The measure contains 36 items combined to form eight scales: physical functioning, physical role functioning, bodily pain, general health, vitality, social functioning, emotional role functioning, and mental health. Respondents use "yes-no" or five or six point scales to endorse the presence or degree of specific symptoms, problems, and concerns. Scores on the scales range from 0 to 100, with higher scores indicating better health status and functioning. The measure takes about 10 to 15 min to complete. The SF-36 has been extensively validated with large samples from the general population and across several demographic subgroups, including samples of healthy persons over 65.[145]

Estimates of internal consistency (alphas) for most samples range from 0.62 to 0.94 for the subscales, with most estimates ranging over 0.80. Test-retest coefficients ranged from 0.43 to 0.81 for six months and from 0.60 to 0.81 for two weeks.[146] The SF-36 has been shown to correlate reasonably well with other criterion measures, measures of ability to work, utilization of healthcare

resources, and other clinically meaningful criteria such as "burden of care."[145–148] Factor analytic studies have supported the presence of two distinct factors labeled physical health and mental health functioning that account for 82% of the measure's variance.[148–150]

In one multi-site trial of cognitive-behavior therapy, exercise, and their combination, for patients with Gulf War Illness that included chronic, diffuse musculoskeletal pain as a primary feature, each of these treatments was found to be associated with improvements in the mental health functioning component score.[151] On a more negative note, Rogers and his colleagues reported that the SF-36 lacked reliability for the assessment of outcomes following multi-disciplinary pain treatment, and they questioned aspects of the measure's validity in discriminating dimensions of functional limitations.[152] Similar concerns about the sensitivity of the SF-36 to change have also been raised.[153] Continued examination of the sensitivity of the SF-36 Mental Health Functioning component to change as a function of pain interventions is indicated.

Pain Beliefs and Coping

The survey of pain attitudes (SOPA)[154] was developed to measure beliefs about chronic pain. It included five domains: perceived ability to control pain (control), perceived level of pain related disability (disability), belief in medical cures for pain (medical cures), belief that others should be solicitous toward them when they are in pain (solicitude), and the importance of medication as a treatment for pain (medication). The measure was later expanded to include two new dimensions: belief in the influence of emotions on pain (emotions) and belief that pain indicates underlying physical damage that necessitates the limiting of physical activity (harm).[155, 156] The final version of the SOPA has 57 items and employs a zero (this is very untrue for me) to four (this is very true for me) response scale. The SOPA is grounded in cognitive behavioral theory, which specifies that patients' beliefs about their pain influence important pain related outcomes, including emotional and physical functioning. A 30 item brief form of the SOPA (the SOPA-B)[157] and a 35 item short version (SOPA-R)[158] are also available.

Internal consistency alphas for the 57 item SOPA scales are good, ranging from 0.71 (control) to 0.81 (disability), and test-retest stability ranged from 0.63 to 0.68.[156] The shorter version of the SOPA, the SOPA-B, has demonstrated a seven-factor structure consistent with the original measure, adequate internal consistency (ranging from 0.56 ([medication] to 0.83 [solicitude]), and strong correlations with the corresponding SOPA scales (0.79–0.97).[157] The original factor structure of the SOPA-R has largely been confirmed by other investigators, and the measure has demonstrated good internal consistency (0.65–0.84) except for the medication scale (0.49).[159]

The main strength of the various versions of the SOPA is their correlation with clinical treatment outcomes. The disability scale of the SOPA (the belief that one is disabled) has demonstrated significant correlations with physical and emotional functioning.[156,159,160] The harm scale showed significant association with reported physical disability, and the medication scale was associated with treatment utilization.[156]

The most frequently used measure of the construct of "pain readiness to change" is the pain stages of change questionnaire (PSOCQ).[161] The PSOCQ measures beliefs about the degree of patient personal responsibility for pain control and interest in making behavioral changes to cope with pain. The PSOCQ is a 30 item self-report measure composed of four distinct scales. The precontemplation scale measures the degree to which a patient endorses little personal responsibility for pain control and no interest in making behavioral changes. Contemplation represents an increasing recognition of personal responsibility for pain control and interest in behavioral changes that support pain management. The action scale measures the extent to which patients believe that they are actively learning pain management skills. The maintenance scale quantifies patients' degree of commitment to using self-management strategies in their daily life and a high degree of personal responsibility for pain management.

A review of the empiric literature documents the reliability, and criterion, and concurrent validity of the measure.[162] Internal consistencies of the four scales range from 0.77 to 0.86, and stability indices range from 0.74 to 0.88. However, the utility of the PSOCQ hinges on its ability to predict important treatment process variables. Thus far, research has been encouraging. For example, PSOCQ subscales (i.e. precontemplation, contemplation, action, and maintenance) predict completion of self-management treatment programs,[163] and improvements in pain coping during treatment.[164] Furthermore, changes in PSOCQ during treatment consistent with increased readiness to change or "forward stage movement" are associated with improvements in pain and physical and emotional functioning.[163–166] However, the readiness to change model has not been without critics. For example, Strong and colleagues[167] challenged the external validity of the PSOCQ and demonstrated that a measure of self-efficacy had greater predictive validity than the PSOCQ.

The chronic pain coping inventory (CPCI)[168] is a 64 item questionnaire designed to assess patients' use of pain coping strategies. The questions contained in the scale fall into three broad categories and include eight subscales: wellness-focused or positive coping strategies (exercise, relaxation, task persistence, coping self-statements), illness-focused or negative coping strategies (guarding, asking for assistance, resting), and neutral coping strategies (seeking social support). Respondents report the number of days in the last week that they used each strategy.

The CPCI subscales demonstrated good internal consistency (0.74–0.91) and test-retest reliability (0.65–0.90).[168] Spouse report of patient disability and coping skill use was strongly associated with CPCI scales.[168] Other studies have largely confirmed the initially specified eight-subscale factor structure.[169,170]

Studies have found various associations between CPCI subscales and patient adjustment and outcomes. However, overall, illness-focused coping strategies were found to be significantly associated with poorer patient adjustment and outcomes, and wellness-focused strategies were significantly associated with better patient adjustment and outcomes.[169,171] An exception is relaxation, with some studies showing a counterintuitive association between relaxation and higher affective distress and lower pain control,[169,171] and another showing no associations between relaxation and any patient adjustment or outcome variable examined.[170] Importantly, even after controlling for pain severity and demographic factors, CPCI subscales were significant predictors of patient-reported physical functioning, mood, disability, and activity level.[170] A six month longitudinal study of patients with low back pain following a work accident demonstrated that higher guarding scores were predictive of prolonged leave from work.[171]

The pain catastrophizing scale (PCS) is a 13 item scale designed to measure the extent to which patients engage in catastrophic thinking regarding their pain.[172] Catastrophic thinking is characterized by thoughts that the pain is horrible, unbearable, and that the worst possible outcome of the patient's pain will manifest.

Patients record the frequency with which they experience thoughts and feelings described by items on a five point Likert-type scale ranging from zero (not at all) to four (all the time).

Initial scale development occurred in an undergraduate sample.[172] However, the PCS has demonstrated reliability and validity in both non-clinical and clinical samples. Factor analyses tend to identify three subscales: magnification, rumination, and helplessness.[172–175] These factors have demonstrated gender invariance.[174] However, evidence from a single study suggests that, particularly for African Americans, two subscales of rumination and magnification/helplessness might be more appropriate.[176] Internal consistency coefficients range from 0.60 to 0.91 for subscales and from 0.87 to 0.95 for the full scale.[172–175] The PCS has demonstrated validity through its association with catastrophic thought patterns identified through clinical interview,[172] pain severity,[173,175,176] pain interference,[173] pain related disability,[176] and mood and anxiety symptoms.[173] Further, the PCS has demonstrated discriminant validity from affect,[175] and psychological disturbance.[173]

The PCS has demonstrated responsiveness to cognitive behavioral and physical activity pain treatments and is considered an important mechanism of changes in these treatments.[177–181] The PCS has also been translated into several languages.[182–187]

The chronic pain acceptance questionnaire (CPAQ) is a 20 item scale designed to measure chronic pain acceptance or the extent to which patients accept the inevitability of chronic pain and engages in activities despite experiencing pain.[188] The recent interest in acceptance and commitment therapy as an effective psychological intervention for chronic pain has precipitated widespread use of the CPAQ.[189] Patients respond to statements of acceptance-related pain beliefs using a seven item Likert scale ranging from one (never true) to six (always true).

The CPAQ has two subscales: engagement in activities and willingness to experience pain.[188] Additional factor analyses have confirmed these two subscales with the scale as published,[190] or with minor revision.[191] Internal consistency coefficients of the total scale range from 0.72 to 0.91.[188,190,192] Regarding validity, the CPAQ has been associated with lower pain severity and pain related disability, less healthcare utilization and medication use, lower self-reported depressive symptoms, pain related anxiety and pain catastrophizing, higher self-efficacy, and lower dysfunctional pain coping and social support interaction styles.[192] The CPAQ has also demonstrated responsiveness to acceptance-based and cognitive behavioral pain treatment,[190,193] as well as a yoga-based pain treatment.[194]

The CPAQ is available in an adolescent version[195] and multiple languages.[196,197] An eight item version of the CPAQ has demonstrated reasonable reliability (internal consistency coefficients = 0.77–0.89) and validity, as evidenced by relationships with pain severity and interference, pain treatment-seeking, and depressive and anxious symptoms.[191]

Quality of Care

The quality of pain care offered to patients can differ substantially by institution, clinician, and individual patient experience. High quality pain care is thought to improve outcomes of pain treatment through a high quality patient-provider relationship and faithful administration of validated treatments.[198] Any effort to improve the quality of pain care across a system must first begin with measurement. For this reason, the American Pain Society produced its first patient outcome questionnaire (APS-POQ) to assess multiple domains of quality of patient care.[199] The most recent version of the measure, the APS-POQ-R,[200] is a 12 item scale that assesses pain severity, the impact of pain on affect, sleep, and activity, side effects, satisfaction with information provided about pain treatment, shared decision making, and use of non-pharmacologic strategies. Patients circles or checks the statement that best applies to their pain management care (e.g. "were you allowed to participate in decisions about your pain treatment as much as you wanted to?" with responses ranging from zero "not at all" to ten "very much so"). In the initial development study, inpatients who had been in the hospital less than 72 h were administered the APS-POQ-R orally, evaluating the first 24 h of their hospital stay.[200] Overall internal consistency was $\alpha = 0.86$. Factor analysis identified five subscales that corresponded with the domains described above, with αs = 0.63-0.83. As with previous versions of the APS-POQ-R,[199] higher pain severity was associated with higher interference with activities, adverse effects from pain treatments, and affective distress, and with lower satisfaction with pain care, providing preliminary evidence for validity.[200] However, cross-cultural validity studies have found poor reliability and inconsistent factor structure in countries other than the United States.[201,202] Findings suggested the APS-POQ-R may be most relevant to patients receiving care within the healthcare system in which it was developed (United States).

In response to concerns about cross-cultural validity, the APS-POQ-R measure was adapted into the international pain outcomes questionnaire (IPO) by PAIN OUT, a multinational European project on postoperative pain management.[203] The measure was developed in two phases, both with large samples (N = 5,134 & N = 4,590) for phases one and two, respectively. Factor analysis found that the final measure loaded on three factors: pain intensity and interference, adverse effects, and perceptions of care. While the IPO questionnaire provides a culturally sensitive alternative to the APS-POQ-R, further validation of the questionnaire across different languages is necessary, as the psychometric validity of the translated versions has not yet been reported.

The pediatric American Pain Society patient outcomes questionnaire (pediatric APS-POQ) was recently developed to assess the six domains—pain intensity, functional interference, emotional response, side effects, perceptions of care, and usual pain—of pain management care in hospitalized pediatric patients.[204] The pediatric APS-POQ was adapted from the APS-POQ-R: wording on items was adjusted for pediatrics, and some items were changed based on updates to the literature. Patient-report and parental-report versions of the pediatric APS-POQ were developed and found to be highly correlated. The measure requires additional testing in more varied populations to establish psychometric validity, as it was developed on a predominately Caucasian, American sample (N = 232) of pediatric patients three years old or older without developmental delays and has not yet been validated in other populations. Additionally, during development, the measure was administered in interview format, and other methods of administration have not yet been validated.[204]

Special Patient Populations

We will briefly review considerations for the psychological and behavioral assessment of pain in the pediatric and older adult populations. Pain is often poorly assessed and managed in these populations, and both require specific considerations and pain assessment measures.[205–208] Further, a substantial proportion of children and older adults cannot self-report their pain, which poses significant limitations to pain assessment.[207]

Recent clinical practice recommendations for pain assessment in patients unable to self-report recommend following a hierarchy of pain assessment techniques: 1) be aware of potential causes of pain; 2) attempt self-report; 3) observe patient behaviors; 4) solicit proxy reporting of pain and behavior/activity changes; 5) attempt analgesic trial.[207] Specific considerations within this hierarchy for pediatric and older adult patients unable to self-report are provided below. As this chapter focuses on the psychological and behavioral assessment of pain, particular attention will be given to these two steps of the hierarchy.

Pain in pediatric patients presenting for health care is extremely common but is generally poorly assessed and treated.[208,209] Clinical practice recommendations suggest considering pediatric patients by cognitive development status. Neonates and infants are unable to self-report as they are nonverbal. However, around the second year of life, children begin to be able to verbalize the presence of pain, and by age three can provide basic descriptions of their pain quality and quantity. Children ages three to six often conflate their affective pain experience with sensory pain symptoms and other aversive physical symptoms and demonstrate reporting bias, making interpretation of self-reported pain scores challenging.[207] The "poker chip tool" (children are asked to pick the number of red poker chips from zero to four that best describe their pain intensity) is recommended for pain assessment in children three to four years old, the faces pain scale-revised is appropriate for children four to 12 years, and the VAS can be used in children eight years and older.[207]

Behavioral pain assessment in pediatric patients can also help identify pain. However, it is important to remember that pain behaviors, and scoring on pain behavior scales, do not necessarily directly correlate with experienced pain intensity. Pain behaviors observed in children differ between acute and chronic pain. In acute pain, facial expressions, physical activity, and crying and other verbalizations are often used as the basis for behavioral pain assessment. In contrast, children experiencing chronic pain tend to limit energy expenditure and display functional limitations. Multiple behavioral pain assessment tools exist for different pediatric populations, including the CHEOPS: Children's Hospital of Eastern Ontario pain scale, CHIPPS: children's and infants' postoperative pain scale, and FLACC: faces, legs, activity, cry, consolability, observational tool (see Herr et al. for further detail).[207] The adolescent pediatric pain tool, based on the MPQ, can provide a useful evaluation of the affective and sensory qualities of pain in children eight years and older. Additionally, the PedsQL provides measures of physical, emotional, social, and academic functioning in children and has both parent and child report versions available. Measures of pediatric pain are discussed further in Chapters 28 and 43.

An estimated 25% to 50% of older adults experience chronic pain. However, multiple barriers to effective pain assessment and management in older adults have been noted, including myths that pain is a normative part of the aging process, stoicism and tendency toward underreporting, fears of opioid addiction, and the increased prevalence of cognitive impairment.[205] Prior to the clinical interview, sensory deficits should be assessed for, and sensory assistive devices should be used as indicated. As with all patients experiencing pain, older adults should receive measures of psychosocial and affective functioning in addition to pain specific self-report assessment measures (see Hadjistavropoulos et al. for a detailed consensus statement on pain assessment in older adults).[205]

Patients with mild to moderate cognitive impairment from dementia can often still self-report their pain, but as dementia progresses, patients' ability to accurately self-report pain decreases.[205] In these cases, observation of patient behaviors—facial expressions, verbalizations/utterances, activity changes, motor movements, and mental status changes—becomes the next best method of pain assessment. The presence of pain indicators should be assessed while patients are in motion, as pain is often less severe at rest.[205] Behavioral pain assessment tools appropriate for older adults with dementia include the CNCPI: checklist of nonverbal pain indicators and the CPAT: certified nursing assistant pain assessment tool.[205] Measures for the assessment of pain in older adults are discussed further in Chapters 44 and 84.

Conclusion

This chapter provides an overview of the role of psychological and behavioral assessment in the context of the provision of comprehensive and integrative care to patients with painful medical conditions. Discussion of more general principles that can be used to guide decisions regarding psychological assessment of pain in the clinical setting was followed by a more detailed consideration of some of the most commonly employed standardized psychological assessment strategies. This review serves as a general guide to clinicians who are compelled by the value of more thorough consideration of psychosocial factors in the assessment of patients with pain that may be used to guide and evaluate pain care. Having acknowledged the potential value of such an approach, several relevant issues that may serve as cautionary notes and targets for future research and clinical investigation may be highlighted.

Of particular note are the overall limitations of this field with regard to consideration of the influence of cultural, racial, ethnic, and other aspects of diverse society on the reliability and validity of existing psychological and behavioral assessment methods. Given a growing awareness and empirical evidence of reliable differences in the experience of pain among patients of differing racial/ethnic backgrounds, gender, and age, among other relevant variables,[210] caution is encouraged when employing most of the reviewed assessment strategies, and specific consideration of culturally specific norms for the measures is important.

Already emphasized throughout this chapter is that several measures frequently used in this field were not originally developed for use with patients with painful conditions, and as a result, the validity of these methods is still subject to concern. The continued development and evaluation of psychological and assessment methods designed specifically for patients with painful conditions and the further evaluation of the psychometric properties of these measures are indicated. With increasing appreciation of differences in the experience of pain and its impact among patients with different conditions, specific examination of the psychometric properties among patients with similar disorders is encouraged. Consistent with this observation, the IMMPACT group, for example, although providing recommendations for the use of specific measures in the assessment of pain treatment effects, has encouraged the selection of measures that were developed and normed for a specific population (e.g. osteoarthritis patients) when such instruments are available.

Another area for continued work is the importance of developing patient-oriented outcome measures. For example, one group

uses a qualitative approach to collect information to develop measures of pain coping in older adults living in the community.[211] Several other investigator groups are currently working on the development and validation of more comprehensive measures for assessing patient-oriented outcomes, and the future availability of these methods promises to provide alternatives to existing methods that may have increased sensitivity to important and meaningful changes in pain and its impact, at least from a patient's perspectives.

Clinicians must consider pragmatic issues related to the use of existing methods and measures for the psychological and behavioral assessment of patients with pain in the clinical setting. Response burden is an important factor to consider when selecting measures for use in the clinical setting. Clinicians are encouraged to consider specific objectives of the assessment and the importance of reaching a balance between the desire for a more thorough assessment and patient burden. Clinicians should also consider measurement precision, brevity, and costs of the assessment process in making decisions about the use of psychological assessment strategies. As already emphasized, the clinical interview and examination remain the core method for clinical assessment and should not be displaced by the use of questionnaires, diaries, and other methods. Finally, managed care reimbursement methodologies are, of course, critical to consider in most clinical settings.

The potential value of incorporating assessment methods that permit a more comprehensive evaluation of the psychological and behavioral aspects of the experience of pain has been emphasized. As in most similar contexts, the "devil is in the details," and clinicians and investigators alike are encouraged to consider a range of important issues when designing an assessment approach consistent with their goals and objectives.

Key Points

- Chronic pain is challenging to assess because pain complaints are inherently subjective, and pain has a wide-ranging influence on patient functioning.
- Psychological and behavioral assessment of pain serves several clinical goals: 1) providing information about a patient's pain experiences, treatment histories, current, and past emotional and physical functioning, and beliefs about pain, 2) identifying the patient's strengths and weaknesses, 3) identifying factors that contribute to the development and maintenance of problems in physical, social, and emotional functioning, 4) identifying comorbid psychiatric or behavioral conditions that may interfere with pain treatment, 5) determining if the patient is psychologically appropriate and likely to benefit from surgery or invasive procedure, and 6) providing a benchmark of the patient's pain and functioning against which the efficacy of treatments can be measured.
- Because of the wide range of clinical goals for psychological and behavioral assessment of pain, when making a request for psychological and behavioral assessment, it is necessary to explicitly state the reasons for the request or pose a question to be answered about the patient or their treatment.
- A useful guide for the assessment of the multidimensional nature of pain is the IMMPACT group consensus statement on the core outcome domains that should be assessed when evaluating the efficacy of a pain treatment and recommended instruments for measuring those domains. The group has encouraged the selection of measures that were developed and normed for a specific population (e.g. low back pain patients) when such instruments are available.
- The consistency, validity, and reliability of the numerous measurement tools have been noted in the following domains: pain intensity, personality, psychosocial impact, physical and social role functioning, emotional functioning, pain beliefs and coping, and quality of care (see Table 22.2). Several of these tools were not originally developed for use with patients with painful conditions, and their validity has not been tested in specific pain populations.
- Technological advances, including smartphone apps and wearable technologies, allow for information about pain, sleep, physical and emotional functioning to be recorded prospectively and frequently in the patients' natural environment. These devices provide objective measures of modifiable health behaviors and are useful tools for clinicians and patients.
- Pain intensity should not be used as a primary, unitary pain outcome measure as it does not directly correlate with pain related disability, and its measurement does not improve the quality of patient pain management.
- Patients with HICP, pain at least most days for ≥3 months with ≥1 activity limitation/participation restriction, experience worse outcomes. Subsequently, providers are encouraged to assess patients for HICP with the question, "Over the past six months, how often did pain limit your life or work activities? Would you say never, some days, most days, or every day?" Patients reporting pain related limitations most days or every day meet the criteria for HICP.
- Pain is often poorly assessed and managed in pediatric and older adult populations, and both require specific considerations and pain assessment measures, particularly for patients unable to self-report pain.
- In patients unable to self-report pain, it is recommended that providers follow a hierarchy of pain assessment techniques: 1) be aware of potential causes of pain; 2) attempt self-report; 3) observe patient behaviors; 4) solicit proxy reporting of pain and behavior/activity changes; 5) attempt analgesic trial.
- Areas for continued research include developing patient-oriented outcome measures, evaluating standard measures in specific populations, and evaluating measures across diverse cultural populations, particularly those with limited communication capability.

Disability Assessment

MOHAMMED I. RANAVAYA, MOHAMMED I. RANAVAYA II, JAMILA I. RANAVAYA

Introduction

The transition from acute to chronic pain and disability because of multiple factors has been well documented in the literature.[1] According to a morbidity and mortality weekly report from the Centers for Disease Control and Prevention (CDC), one in four United States adults, 61 million Americans, have a disability that impacts major life activities.[2] These numbers are likely to increase in the next few decades with our aging generation of baby boomers currently living with potentially disabling conditions.[3] Continued advancements in medical and surgical technologies enable increased survival after catastrophic injuries and illnesses and may help mitigate the disabling consequences, as well as allow for an increased prevalence of disability within our society. Persons with disabilities face greater barriers to health care than do those without disabilities.[4] Impairment and disability resulting from claims of functional losses secondary to chronic pain continue to challenge pain medicine specialists and independent medical examiners because of the problem's polemic nature. The decade long opioid epidemic has led some in the medical community to question the very existence of disability from chronic pain and the very basis of it as a specific disease entity. Everything about disabling chronic nonmalignant pain engenders controversy except for the suffering associated with the diagnosis and the isolation, frustration, and marginalization experienced by these patients.

Physicians dealing with the evaluation and treatment of patients with chronic nonmalignant pain and disabling conditions can expect to be called upon occasionally to formally evaluate the impairment and disability of these patients for legal purposes, mainly for receiving benefits under many disability compensation systems. This skill is not taught in any medical education or residency training.[5] The treating pain medicine specialist must become familiar with and adapt their practice to better address patient needs associated with these assessment requests by gaining greater knowledge and understanding of the concepts and terminology of disablement and the practices of impairment rating and disability evaluation.

The scientific approach to impairment and disability differs from the legal.[6] To deal with this disparity between law and medicine, a pain medicine specialist must understand the fundamentals of the disability and compensation system, the nuances of legal procedure, and their duties and rights within the legal system. This chapter intends to educate and provide critical information, principles, and practical knowledge unique to the emerging field of disability medicine essential for pain medicine professionals looking to enhance their skills and empower themselves with knowledge, skills, and abilities to further care for their patients. The intention is to not only provide a brief historical and conceptual overview of models of disablement and United States disability systems but also to familiarize the processes and tools available for impairment rating and disability determination and to examine the medical-legal pitfalls and ramifications of these clinical activities. At the conclusion of this chapter, there are also suggestions and recommendations for further reading and available training in disability evaluation.

United States Disability and Personal injuries Compensation Systems

Historical Perspective

It is written in the Bible that "if any would not work, neither should he eat."[7] Hence there has been a long-standing expectation among individuals within society that members must contribute individually to benefit and share collectively. It appears equally valid that individual members who cannot contribute because of disability may be exempt from such expectation and yet still enjoy benefits to which other group members are entitled. It is also possible for an individual to exploit society through unfair and exaggerated claims of disability, which becomes an issue of social justice. Although social justice systems compensate in some way for bodily illness or injury, they must also afford protection against benefits being paid to those who choose not to be productive and fake or exaggerate their disability. Various legal disability and compensation systems provide rules defining disability and entitlement as well as procedures for determining who qualifies as disabled. These rules are intended to provide fair and equitable distribution of limited system resources to those whose needs are greatest and whose disabilities are most compelling.[8]

Within the United States, various disability and compensation systems have arisen to ensure that members of society with a medically determinable impairment that may lead to disability have recourse to compensation from various avenues. This includes state tort laws to provide compensation for personal injuries from intentional or negligent acts of others and state and federal workers' compensation laws for work related injuries and illnesses, social security disability benefits, veterans' benefits, and social

welfare programs where appropriate. These systems have diverse historical origins and statutory requirements. Consequently, there remains considerable variability between them concerning definitions of disability, entitlement, benefits, claims application procedures, adjudication, and the role and relative weight given to medical versus administrative deliberations.

Contemporary Perspective

The United States legal system is complex because of its large territory (50 state jurisdictions plus two commonwealth territories). However, as it relates to disability and compensation of individuals, it is essentially based on two basic types of law: federal and state statutory (legislative) laws and common law (judicial precedent). Both federal and state statutory laws are then mainly adjudicated through administrative law, which has a modified evidentiary and procedural process for ease of judicial administration.[9] The administrative law decisions are then subject to review by various state and federal courts upon appeal by parties. The common law claims of personal injuries, for example, from motor vehicle accidents to slip and fall claims seeking compensation are mainly based on state tort laws.

Tort Law

All states in the United States, under their common law, recognize physical or psychological injury as a personal injury for which monetary damages can be awarded under the law of torts. Common law is a system of law in the United States inherited from the British colonial period based on previous legal judgments (precedent setting cases), which is a defining characteristic of common law sometimes referred to as "judge made law." This is contrasted with statutory law, which is adopted through the legislative process, and regulations enacted by the executive branch. A majority of the United States contract, property, and tort law are based on common law.

Under tort law, a claim is usually made against the defendant for personal injury arising out of negligence and, in some instances, an intentional act. Common examples include those claims arising out of motor vehicle accidents, slip and fall claims against property owners (both private and business), defective products, medical negligence, hospital and nursing home negligence, assault claims, and work related injuries outside of the aegis of workers' compensation. Plaintiffs are entitled to monetary awards for both actual and general damages (e.g. pain and suffering, nonpecuniary damages). The severity of the injury and its outcome in the form of physical or mental impairment and or disability is the main driver for the compensation. Physicians who have not participated in the medical care of the patients are retained by both sides as independent medical examiners (as expert witnesses) to evaluate the plaintiff's claims of personal injury by performing an independent medical examination (IME). The physician is typically required to evaluate the causation, the nature and the severity of the injury, the exacerbation or aggravation of the preexisting pathologic condition, if any, and apportionment. Sometimes, the physician may also be called on to comment on the necessity of the treatment previously provided or future treatment proposed for the condition under question. In addition to the tort claims that may arise from a personal injury caused by motor vehicle accidents, slip and fall, medical malpractice, or defective products are adjudicated in the individual state court system. The following are other contemporary disability compensation systems in the United States.

State Workers' Compensation Systems

The workers' compensation system is statutory law administered by a governing board or agency in each state, commonly referred to as an industrial commission, Bureau of Workers' compensation or commission, which oversees various public/private combinations of workers' compensation systems in that state. In nearly all states, workers' compensation insurance is available through private insurance companies that underwrite the risk of occupational injury/ disease in a particular occupation or industry in return for payment of a premium paid by the employer. A few states have a state-owned monopoly insurance fund that employers must pay into unless they qualify as a self-insurer. Large employers with sufficient financial strength can also self-insure and are responsible for paying the claims through a third party administrator who administers these self-insured workers' compensation programs.[10]

An injured worker is entitled to three types of benefits: medical and rehabilitation expenses, wage loss benefits, and survivor benefits. In the event of death, the surviving spouse and/or children are entitled to survivor benefits. Coverage for medical and rehabilitative expenses is 100% for authorized services. Wage loss benefits are paid according to four separate levels of work disability. Temporary disability occurs for the duration of the treatment period and may be total (employee is incapable of any work) or partial (employee may resume "modified duty" with restrictions).

General damages for pain and suffering and punitive damages for employer negligence are not available in workers' compensation schemes, and negligence is generally not an issue in these cases unless the employer had wanton, reckless disregard to workplace safety, or intentionally caused injury. Thus a workers' compensation system is desirable for employers because the cost of workers' compensation insurance is predictable and can be passed on to the consumer within the cost of goods. In contrast, the employer avoids the potential risk of expensive and time-consuming common law litigation as well as financial insolvency that could result from a substantial jury award.

The workers' compensation statutes in various states may have some subtle differences from each other. However, fundamental features are common to all of these statutory schemes:

- A no-fault system for injuries arising out of and in the course of employment.
- Compulsory insurance is required for employers with very few exceptions.
- Exclusive legal remedy for employees for work related injuries/ illnesses with few exceptions.
- The injured worker retains the right to sue any third party liable for injury.
- Dispute resolution through administrative law adjudication with less rigorous rules of procedure and evidence than the civil court system.
- Expedited benefits for medical and rehabilitation treatment with wage replacement during the temporary disability phase.
- Final compensation for permanent partial and permanent total disability.

Under the workers' compensation system, upon completion of the treatment phase under a claim, a physician must determine the point of maximum medical improvement (MMI) so case closure can occur. The employee may receive monetary compensation for permanent total or partial disability. Generally, this is a lump sum payout calculated according to a predetermined formula specific to each jurisdiction. It considers the value of the "whole person impairment" as several weeks' pay multiplied by the average

weekly wage up to a cap, and then multiplies by the impairment percentage of the "whole person" based almost always on a certain edition of *American Medical Association (AMA) Guides to the Evaluation of Permanent Impairment* as prescribed by the relevant law or regulation.

Medical determination of physical or psychological impairment is almost always performed at MMI by a physician skilled in the use of the *AMA Guides,* as impairment is only determinable by medical means. In contrast, disability requires consideration of numerous other non-medical factors. However, in some cases, the physician is empowered to render an opinion regarding the nature and extent of medically determined impairment resulting in disability.

Federal Workers' Compensation Systems

In the United States, federal workers' compensation laws provide no fault based compulsory broad coverage of injuries and illnesses arising out of and in the course of employment for over 2.9 million federal employees. The United States Department of Labor (USDOL) maintains exclusive jurisdiction over these programs subject to judicial review.

The major federal workers' compensation programs are administered by the Office of Workers' Compensation Programs (OWCP), an agency within the USDOL. One of the major federal programs, the Federal Employee's Compensation Act (FECA), covers federal employees in more than 70 different agencies along with several other worker groups adopted by Congress in various acts of expansion of the federal authority.[11] Additionally, the Longshore and Harbor Workers' Compensation Act, Energy Employees Occupational Illness Compensation Act, and Federal Black Lung Program (coal mine workers' compensation) are other federally mandated compensation acts administered by the OWCP. These four major federal workers' compensation programs provide wage replacement benefits, medical treatment, vocational rehabilitation, and other benefits to injured workers that experience work related injury or occupational disease or their dependents.[12] USDOL also oversees the Defense Based Act (DBA) that provides workers' compensation protection to civilian employees working outside the United States on military bases or under a contract with the United States government for public works or national defense. Similar programs that cover a specialized group of workers, such as the Non-Appropriated Fund Instrumentalities Act (NAFIA) and Outer Continental Shelf Lands Act (OCSLA), exist but are beyond the scope of this discussion.

Other federally mandated workers' compensation programs include the Federal Employers Liability Act (FELA), commonly known as the Railroad Worker Act, and the Jones Act (Merchant Marine Act). FELA provides disability benefits to employees of the interstate railroad industry for job-related injuries. It is the only remedy for injured railroad workers employed by a common carrier railroad. It is a fault-based system, and the injured railroad worker must sue the railroad in civil court (similar to negligent tort action) to prove that the injury was caused in whole or in part by the negligence of an agent, employee, or contractor of the railroad or from faulty equipment. The civil action can be brought in either a state or federal court, and the case is tried in front of a judge and jury. The monetary damages awarded against the negligent railroad are generally much higher than those of other no fault based state or workers' compensation systems.[13]

The Merchant Marine Act of 1920, also known as the Jones Act, allows civilian sailors, while in the service of a ship in the United States navigable waters and between United States ports, to claim compensation for injuries resulting from the unseaworthiness of the vessel on which they served or negligence of a ship's owner, agents, and employees. It operates similar to FELA, and the claimant must bring suit in civil court against the master or owner of the ship to collect monetary compensation.

Social Security Disability Benefits Program

The Social Security Administration (SSA) manages the largest federally mandated disability insurance program in the United States, providing benefits to approximately half of all persons who qualify as disabled under its two titles. Social Security Disability Income (SSDI; Title 2) covers individuals who are disabled (unable to engage in substantial gainful activity) because of a medically determinable physical or mental impairment that has lasted or is likely to last for more than 12 months or is likely to result in death.[14] It is currently funded by a payroll tax contributed to by both the employer and, while gainfully employed, the employee. Self-employed workers are also required to contribute to the system. Benefits are available to those individuals who have worked in a qualified job for a requisite period, paid into the social security system, and subsequently become disabled before age 65 years. SSDI benefits are provided to those considered totally incapacitated and extend to their surviving spouse and children. Benefits are paid as a monthly stipend, and beneficiaries may receive payments until age 65 years, after which they are eligible for social security retirement benefits.

Supplemental Security Income (SSI; Title 16) is a second disability benefits program within the SSA, which operates as a federal-state partnership providing SSI benefits to disabled individuals whose income and assets meet minimum criteria according to a means test. It is funded through general revenue (i.e. income tax revenues) and does not require work history for eligibility. Most SSI recipients are below the federal poverty income threshold and must remain below that threshold to continue receiving SSI, but this is not the case with SSDI.[15] The SSI provides income for medically indigent persons who are blind, disabled, or older (>65 years of age). SSI also provides assistance to children if they have "medically determinable impairments of comparable severity" to an adult's and if the impairment "limits the child's ability to function independently, appropriately, and effectively in an age-appropriate manner."[16] SSI operates as a federal-state partnership and, in addition to the means test, also requires that a "medically determinable impairment" be established.

When an applicant submits an SSI application, and non-medical eligibility has been established, the application is forwarded to their state Disability Determination Service (DDS) for further medical review. The SSI has its own set of medical criteria, the "listing of impairments," which, if met or equaled, will cause an automatic award of benefits. There are separate listings for adults and children arranged by body system. Each listing typically contains a diagnosis and some clinical markers of severity. If listing criteria are not met, the applicant can appeal based on "residual functional capacity."

Physicians, including the patient's treating physician, who assist applicants when filing for SSDI or SSI disability, should be familiar with the "five-step" appeals process and the listings themselves.[17] They may be asked to provide the DDS evaluating team with a statement about the patient's ability to do work related activities and backed by objective evidence. They may also be asked to comment on an applicant's physical and psychological capacities and limitations. If the condition in question does not

meet or equal the listings, to assist the DDS evaluating team in estimating the claimant's "residual functional capacities."

Disability Benefits Under the Veterans Benefits Laws

The Veterans Benefits Administration (VBA) within the Veterans Health Administration (VHA) oversees the Department of Veterans Affairs' (VA) compensation and pension program (C&P) providing service to United States veterans.[18] Eligibility for VA disability benefits is based on discharge from active military service (full-time service to the army, navy, air force, marines, or coast guard, or as a commissioned officer of the Public Health Service, the Environmental Services Administration, or the National Oceanic and Atmospheric Administration). Only honorable and general discharges (as opposed to dishonorable or bad-conduct discharges) qualify. Entitlement to compensation is determined by the Adjudication Division of the C&P Service within the VBA. It is classified as service connected if the disability relates directly to injury or disease incurred while on active duty or as a direct result of VA care or as nonservice connected if determined to have not been incurred while on active duty. Presumptive service connection applies to various conditions, such as chronic diseases (e.g. hypertension, diabetes mellitus) or tropical diseases (e.g. malaria), and qualifies for compensation if such conditions manifest themselves within one year of discharge from active duty.

Disability compensation is paid as a monthly stipend to veterans who are disabled because of service connected injury or disease. The amount of compensation received depends on the amount of impairment caused by the injury or disease where the rating percentages themselves are expressed according to "the average impairment in earning capacity resulting from such disease and injuries and their residual conditions in civil occupations." Disability compensation is not subject to federal or state income tax, it varies according to the number of dependents, and it is regularly adjusted to reflect changes in the cost of living. Benefits may also include disability pensions for veterans of low income according to a means test, who are permanently and totally disabled, and who have experienced 90 days or more of active duty, at least one day of which was during wartime. Other benefits include insurance benefits, specially adapted housing, motor vehicle modifications, and durable medical equipment.

The benefit amount is based on the VA Schedule of Rating Disabilities (VASRD), a graduated scale from 10% to 100% (in increments of 10%) depending on the degree of the veteran's disability based on medical evidence. The multiple percentages are combined using a combined rating chart similar to the combined values chart in the *AMA Guides to Evaluation of Permanent Impairment.*[19]

VA C&P examinations may be performed by physicians, nurse practitioners, physician assistants, psychologists, optometrists, audiologists, and "other qualified" clinical personnel. The VHA oversees and ensures that C&P examiners are adequately qualified, and all C&P examination reports must be assigned by a physician or psychologist. The physician examiner is asked to render an opinion as to the diagnosis of the ratable condition, to address permanency of the condition, and to opine as to whether the individual with the condition is considered totally disabled (fails to meet minimal employability criteria), which is defined as physical inability to be employable at a sedentary level, or psychiatric or psychological inability to be employed in a loosely supervised situation with minimal exposure to the public.

Physician disability evaluations are generally performed at VHA facilities with the automated medical information exchange data processing system and associated disability examination worksheets disability based questionnaires (DBQ) and the VA's schedule of rating disabilities.[20]

The adjudication division of the C&P programs, through its rating officers (rater), determines the nature and amount of entitlement benefits, which include monthly disability payments to the veteran or the veteran's spouse, child, or parent in the event of a service connected death. Additional benefits include hospitalization and medical care, orthotic and prosthetic devices, durable medical equipment, and allowances for adaptive modifications to the veteran's home and/or motor vehicle where necessary. Title 38 of the Code of Federal Regulations contains both the VA's schedule for rating disabilities in Part 4 and other VA regulations about compensation and pension in Part 3. The schedule is organized according to 16 body parts and systems.

Private Disability Benefit Systems

According to some estimates,[21] about 40 million Americans are covered by private short and long term disability insurance that pays replacement income in the event of a temporary or permanent disability that prevents the insured from working. Private disability insurance generally available through the workplace is a contract between the insurer and insured. Specific contractual language governs the criteria for eligibility, entitlement, and benefits. The injured party must complete a certain waiting period (usually three months), after which the long term disability policy takes effect. Such policies may be group policies (more affordable) with coverage to individuals who cannot perform their usual and customary job during a finite period (typically two to three years). Subsequently, disability benefits may continue only if the individual can be determined unable to perform any occupation according to the definitions and provisions of their policy. Private disability generally pays up to 60% of the individual's wages (to a cap) and may have a built-in cost of living allowance to adjust for inflation.

Working Terminology and Definitions

Physicians performing impairment and disability evaluations must be familiar with precise meanings and definitions of the terms impairment and disability, as well as the fundamental requirements, nuances, and jurisdictional variations of the particular disability system within which they are working. See Table 23.1 for a comparison between various disability compensation systems in the United States and a section on working terminology and definitions.

To effectively communicate medical and other scientific information to claims examiners, claims managers, lawyers, and adjudicators, doctors must become familiar with the important definitions and terminology that are commonly used in disability assessment and medicolegal practice, as some are "terms of art" having specific meanings within the field of disability medicine that differ from their traditional meanings.[22] This section defines common medicolegal terms that physicians dealing with disability evaluation should be familiar with and includes annotations for better understanding.

TABLE 23.1 Comparison of Major Disability Compensation Systems in United States

Compensation System	Eligible Individuals	Adjudicating Body	Rating Schedule	Employability Status	Benefits	Maximum Monthly Benefit
State tort laws	Personal injuries resulting from negligence or intentional acts of others	State court system by civil actions (lawsuits)	Jury award for both compensatory and general damages, i.e. pain and suffering	Based on state tort law	Damages for various pecuniary and non-pecuniary losses	Lump sum award
State workers' compensation	Workers injured out of and in the course of employment in a particular state. Excludes federal employees	Individual state worker's comp statutes	AMA *Guides* in most states; particular edition of *Guides* prescribed by law. Few states have their own rating guide	Return to work in one's own occupation, or in modified duty, if available	Medical and rehabilitation benefits, wage loss benefits. Survivor's benefits. Permanent partial or total disability benefits	Determined by statute
Social security	Workers <65 years or survivors who are or have contributed to the SS Trust Fund (SSDI); needy disabled children, aged, disabled and blind adult (SSI) without means for support	Social security administration	*Disability evaluation under social security schedule. (listing of impairments)*	Unable to engage in the substantial gainful activity by a physical or mental impairment for >12 months	Monthly stipend	There is an annually adjusted cap on benefits
Federal employees' compensation act (FECA)	Federal employees, including the United States postal service, peace corps	United States department of labor (USDOL)–office of workers' compensation prog. (OWCP)	AMA *Guides sixth edition*	Loss of earnings (no schedule loss) because of disability resulting from personal injury sustained while in the performance of duty	66.6%–75% of wages, reasonable medical care. Lump sums not available	75% of wages if worker married or has dependents
Longshore and harbor workers' compensation program	Maritime employees such as seamen, longshoremen, harbor workers, ship workers (not seamen)	Office of workers' compensation programs in the United States department of labor	AMA *Guides* 6th *edition*	Wage loss and schedule loss benefits for injuries arising out of and in the course of employment	Full medical care, death benefits, lump sum awards, 66.6% of weekly wages	200% of the current national average weekly wage
FELA-railroad workers' act and Jones Act for seamen	Railroad workers and seamen	Federal or state court system by civil actions (lawsuits)	Jury award for both compensatory and general damages, i.e. pain and suffering	Based on FELA or Jones Act as the case may be	Damages for various pecuniary and non-pecuniary losses	Lump sum award

Continued

TABLE 23.1 Comparison of Major Disability Compensation Systems in United States—cont'd

Compensation System	Eligible Individuals	Adjudicating Body	Rating Schedule	Employability Status	Benefits	Maximum Monthly Benefit
Veterans disability programs	Honorable or general discharge from the armed forces or a survivor of a veteran	Adjudication division of the compensation and pension service of the veterans benefits administration	*VA schedule for rating disabilities (VASRD)(Ref)*	Wage loss and schedule loss for the average person unable to follow a substantially gainful occupation	Disability pension, death benefits, hospitalization, medical care, orthotics, prosthetics, durable medical goods, adaptive modifications	Variable based on rating and other criteria
Private disability insurance	Individual covered under a long term disability insurance plan after a wait period of short term disability defined by the policy	Long term private disability insurance company	Based on the contractual language of the disability insurance policy	Inability to engage in own occupation up to 3 years, or in any occupation, after that, depending on the individual policy	Wage loss compensation	Generally, 60% of previous income

Key Terminology and Definition

Abnormal illness behavior: Conscious or unconscious, intentional or unintentional exaggeration or fabrication of symptoms and/or physical findings because of psychological, social, financial, or other reasons.

Accommodation: In the context of the Americans with Disabilities Act, any modification of the workplace or a specific job that allows a person with a disability to perform essential functions of a job and/or able to be gainfully employed.

Activities of Daily Living (ADLs): Basic self-care activities performed in one's personal sphere (e.g. feeding, bathing, hygiene, dressing). Instrumental ADLs (IADLs) are complex self-care activities that may be delegated to others (e.g. financial management, medications, meal preparation). ADLs do not include highly individualized work duties.

Adjudicate: To make a formal judgment on a disputed matter through judicial authority.

Administrative hearing: An oral proceeding similar to a trial with the presentation of testimony and evidence before an administrative hearing officer or a law judge. Unlike a trial, an administrative hearing is usually less formal and shorter in duration with abbreviated procedural rules.

Administrative law: The body of law that governs all the activities of administrative agencies of government, including rule making, adjudication, or the enforcement of specific regulatory mandates given by the legislative bodies.

Affidavit: A written statement under oath for use as evidence in a legal proceeding subject to the penalty of perjury for falsehood as if giving false evidence in court.

Aggravation: Permanent worsening of a preexisting condition.

Allegation: A claim or assertion of a fact by a party in a legal proceeding made without proof.

Apportion/Apportionment: To divide something proportionally, such as allocating contributions among various causes of disease or impairment. The first step in causation apportionment is scientifically-based causation analysis.[23] Second, one must allocate responsibility among the probable causes and select apportionment percentages consistent with the medical literature and facts of the case in question. Arbitrary, unscientific apportionment estimates, which are nothing more than speculations, must be avoided.

Case law: Accumulated decisions and holdings by appellate courts interpreting and applying legal principles, common law, statutes, or provisions of a constitution in previous cases. The aggregate of reported cases sets the precedents (authority) that must be followed as the law (binding) by the lower courts within the same jurisdiction when deciding subsequent cases with similar issues or facts in similar cases. The legal principle *stare decisis* (Latin for "to stand by the things decided") requires that similar cases be treated alike to create stability and predictability in common law.

Cause/Causation: In general, anything that produces an effect. In medicine, cause refers to an identifiable factor (e.g. trauma, toxic, or infectious exposure) that results in injury or illness. The cause or causes must be scientifically probable following causation analysis.

Cause of action: Legal grounds for which a plaintiff can sue in court for the legal wrong the defendant is alleged to have caused. A specific legal theory upon which a plaintiff can legally sue and seek legal remedy. Some examples are medical malpractice, intentional infliction of emotional distress, battery, false imprisonment, or breach of contract.

Civil action: A legal proceeding (lawsuit) by a party to enforce, redress or protect private rights and mostly seek relief in the form of the monetary damage award. These suits most often

are between private parties, although governments and corporations may be parties to a civil lawsuit.

Claim adjuster: Usually an insurance company employee or an independent agent who investigates insurance claims to determine the extent of the insuring company's liability, assesses the amount of compensation to be paid and negotiates and settles claims against the insured.

Combined Values Chart: A method used in the *AMA's Guides to the Evaluation of Permanent Impairment (AMA Guides)* to combine two or more impairment percentages, derived from the formula A + B (1 – A) = Combined Values of A and B. Combining, as opposed to adding, ensures that the total value will not exceed 100% whole person impairment and considers the impact of impairment from one body part on impairment of another body part.

Compensable injury: Workers' Compensation statutes define this as an injury or illness arising out of and in the course of employment.

Contingency fee: A charge or fee, the collection of which is based upon the client winning or settling the case.

Contract: A legally binding and enforceable agreement made between parties.

Cross examination: The interrogation under oath to test the truthfulness of witness testimony in a legal proceeding (deposition or trial) by challenging or probing the testimony given during the *direct examination* that precedes the cross examination.

Damages: In law, damages are monetary sums awarded by a court in a civil action as compensation to someone who has been injured or suffered loss because of the wrongful conduct of another party. In a tort action, damages are meant to restore an injured party to the position before being harmed, which in addition to being compensatory (reimbursement for actual losses such as lost income and medical expenses), also include general damages that are non-economic (non-pecuniary) losses, such as pain and suffering, mental anguish, loss of life's enjoyment, loss of consortium, and so on.

Deposition: A process of taking testimony under oath of a witness (deponent) by oral interrogations outside the trial by an attorney for the parties involved in civil litigation. Usually, depositions for a physician witness are done as pre-trial fact findings in which the retaining counsel asks questions (direct examination), and the other side then tests the truth of the witness statements by cross examination. The questions are asked by attorneys in the same manner as if the witness was testifying in a live trial. The proceeding is recorded by a court reporter, and a transcript of the testimony is produced that may be submitted as evidence or used to impeach the witness at trial by confronting the witness with inconsistencies in statements.

Direct examination: The primary or initial questioning (also known as examination in chief) of a witness by the party that has called that witness to give evidence that supports their case.

Disability: An umbrella term for activity limitations and/or participation restrictions in an individual with a health condition, disorder, or disease. The definition may differ and be more specific in certain compensation systems. For example, the United States SSA defines disability as the inability to engage in substantial gainful activity because of a medically determinable physical or mental impairment that has lasted for 12 months or likely to result in death.

Exacerbation: Temporary worsening of a preexisting condition. Following a transient increase in symptoms, signs, disability, and/or impairment, the person recovers to her baseline status, or what it would have been had the exacerbation never occurred.

Expert witness: A person tendered as a witness in a legal proceeding stipulated as having special knowledge, education, training, experience, or skill in a field for which she may give testimony if it assists the trier of fact (jury or the judge) in determining the truth of a matter.

Impairment: A significant deviation, loss, or loss of use of any body structure or function in an individual with a health condition, disorder, or disease.

Impairment evaluation: The acquisition, recording, assessment, and reporting of medical evidence, performed by a licensed physician, using a standard method such as described in the *AMA's Guides to the Evaluation of Permanent Impairment (AMA Guides)*, to determine permanent impairment associated with a physical or mental condition.

Malingering: According to the *Diagnostic and Statistical Manual of Mental Disorders, fifth edition (DSM-5)*, malingering is not a psychiatric condition but rather a conscious and intentional production of false or grossly exaggerated physical or psychological problems motivated by external incentives such as avoiding military duty or work, obtaining financial compensation, evading criminal prosecution, or obtaining drugs.

MMI: Also known as the maximum degree of medical improvement, it is the point at which a condition has stabilized and is unlikely to change (improve or worsen) substantially in the next year, with or without treatment. While symptoms and signs of the condition may wax and wane over time, further overall recovery or deterioration is not anticipated. Simply put, the person is now as good as they are going to get, signifying that the injured person can exit the temporary disablement stage of recovery, facilitating claim settlement and case closure.

MMI does not preclude the deterioration of a condition that is expected to occur over time, i.e. beyond 12 months; neither does it preclude allowances for ongoing follow-up or maintenance medical care, should such care be indicated based on current evidence-based practice generally accepted by the scientific community.

However, both the name given to and exact definition of this status vary depending on the jurisdiction. Among the numerous synonyms for MMI are (in alphabetical order): ascertainable loss, end of healing, fixed and stable, maximum cure, the maximum degree of medical improvement, maximum medical healing, maximum medical recovery, maximum medical rehabilitation, maximum medical stability, medical end result, medical stability, medical stabilization, medically stable, medically stationary, permanent and stationary, and stable and ratable.

Negligence: Failing to exercise the degree of care that a reasonably prudent person would exercise under the same or similar circumstances. It can also be thought of as a breach of legal duty that causes an injury resulting in liability to the injured party.

Pecuniary: Pertaining to money as in pecuniary damages awarded for actual monetary losses.

Permanent impairment: The impairment present at the point of MMI.

Reasonable degree of medical certainty/probability: Two phrases commonly used in medicolegal reports and expert testimony to express the idea that their opinions are based on at least a 51% probability conveying that the opinions are "more probable than not" correct or true.

Rules of civil procedure: A body of law that provides the rules that courts must follow when adjudicating civil lawsuits.

Stare decisis: Latin for "to stand by the things decided" or also "let the decision stand." A legal principle requiring courts to apply the same approach and rationale of the legal principles

as decided in similar prior cases setting precedent. See also *case law*.

Statute: A written law enacted by a legislative body (state or federal) that declares, forbids, or commands something specific to achieve a specified legislative objective.

Subjective: In health care, refers to that which is perceived, reported, and/or demonstrated by a patient but cannot be verified by an examiner on physical examination or via diagnostic tests. The adjective is most commonly used in the context of symptoms such as pain, but many physical findings are also subjective, including tenderness, range of motion, and strength.

Subpoena: An official written command issued in judicial process directing the person to appear at a certain time and place to give testimony under oath or provide documents in her possession or control (*subpoena duces tecum*) that may help resolve an issue in a pending litigation.

Whole person impairment: A concept described in *AMA Guides* that relates the impact of the impairments from various body parts on the individual's overall ability to perform ADLs, excluding work.

Models and Classification of Disablement

Models of Disability

The "medical model" of disability was the paradigm for understanding disablement throughout much of the 19th and 20th centuries, during which causation of disability was directly viewed in terms of the underlying pathology (impairment) arising through illness or disease. Management of disability was closely linked to the diagnosis and treatment of the underlying pathology, long considered the purview of the physician examiner, who then became empowered to rate and diagnose and treat the disabling condition (impairment). Anatomic and physiologic objectivity is the conceptual lynchpin of the medical model of disability described above.[24] This model worked well for conditions whereby the diagnosis was unambiguous, and the pathology was well understood, and where treatment strategies and end points were often well established and clearly understood.[25] Today, the medical model still serves as the basis for social security disability determinations as described in some of the compensation systems in section III above.

The "social model" of disability grew out of the disability advocacy movement of the 1970s and 1980s and was founded on the notion that society imposes disability upon individuals with impairments by failing to address their special needs in terms of priority awareness, environmental access, and infrastructural accommodation for major life activities. The resulting disability was viewed in terms of restrictions imposed upon the impaired individual ranging from individual and institutional prejudicial thinking and discrimination, architectural and other physical barriers to access and transportation, educational segregation, and the lack of accommodation in the workplace.[26]

An understanding of the social model has helped foster strategies to better neutralize social barriers to individuals with impairments, enabling them and minimizing their disability.

The "biopsychosocial model" of disability[27] is now widely accepted as the preferred conceptual model of disablement. It simultaneously recognizes the contributions of medical, social, personal, and psychological determinants of disability. The *biologic* component refers to the physical and/or mental aspects of an individual's health condition. The *psychological* component recognizes personal and psychological factors that are impacting that individual's functioning. The *social* component recognizes contextual and environmental factors that may also affect functioning in each case.[28]

Classifications of Disablement

The most commonly used, contemporary, internationally-accepted definitions, terminologies, and classification of disablement have been created by the World Health Organization, the origins of which can be traced to the work of Bertillon's *Classification of Causes of Death* (1893), which later was expanded into the *International Statistical Classification of Diseases, Injuries and Causes of Death*.[29] In 1948 the World Health Organization took over this effort, which ultimately led to creating the *International Classification of Impairments, Disabilities and Handicaps* (ICIDH) in 1980.[30] This system applied a model of disablement with four ordinal domains linked in a linear relationship as follows (Fig. 23.1).

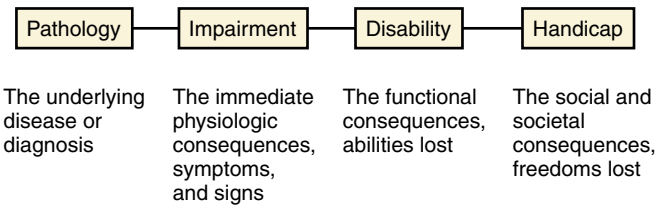
Pathology - "a disease or trauma acting at a tissue anatomical or physiological level to potentially alter the structure and/or function of an organ."

Impairment - "any loss or abnormality of psychological, physiological or anatomical structure or function and resulting from a pathology." Impairment occurs at an organ system level.

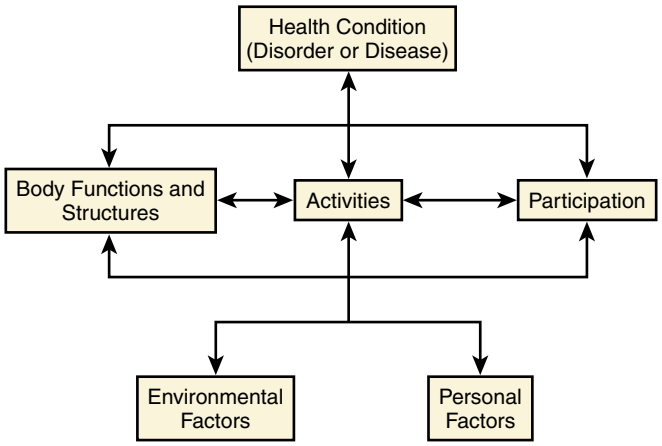
Disability - "any restriction or lack (resulting from impairment) of ability to perform an activity in the manner or within the range considered normal for a human being." Disability is commonly conceptualized in terms of limitations on activities within one's sphere, including mobility (transfers and ambulation) and self-care (activities of daily living or ADLs).

Handicap - "a disadvantage for an individual that limits or prevents the fulfillment of a role that is normal (depending upon age, sex, social and cultural factors) for that individual."

There were several shortcomings of the ICIDH system. It was rooted in the medical model of disease whose limitations are described above. The linearity of the system implies a unidirectional and causal relationship among its elements which may not always be the case. It inadequately accounted for various modifiers (e.g. personal, environmental), which could influence the magnitude of disability.[31] For example, other work showed that environmental factors played a key role in determining outcomes of disability that could be studied independently.[32] Subsequent work by the Institute of Medicine (IOM)[33] and the National Center for Medical Rehabilitation Research,[34] expanded upon the view that resulting disability was the product of the individual with an impairment interacting with their environment in each specific case. Additional attention was given to the role of personal modifiers (e.g. lifestyle choices, belief systems, entitlement, and coping abilities) affecting outcomes of disability for individual cases.[35]



• **Figure 23.1** World Health Organization's international classification of illness. (Reproduced with permission from World Health Organization. *International Classification of Impairments, Disabilities and Handicaps*: *A Manual of Classification Relating to the Consequences of Disease*. Geneva, Switzerland: World Health Organization; 1980. Figure 2*.)



• **Figure 23.2** Components and interactions of the World Health Organization's international classificaion of funtioning. (Reproduced with permission from World Health Organization. *International Classification of Functioning, Disabilities and Health: ICF.* Geneva, Switzerland: World Health Organization; 2001.)

The International Classification of Functioning, Disabilities, and Health (ICF)[36] is depicted in Fig. 23.2.

The ICF has replaced the ICIDH and portrays an interactive (as opposed to linear) association between an individual with a health condition, the functional consequences of their impairment, and contextual factors of a personal and environmental nature. The ICF classification system embraces the biopsychosocial model of disease described earlier, considering environmental and personal modifiers of functional outcomes in any given case.

The components of disablement according to the ICF classification system include:

Body functions and body structures: physiologic functions and body parts, respectively.

Activity: the execution of a task or action by an individual (typically within their personal sphere).

Participation: involvement in a life situation (typically within a social sphere).

Impairments: problems in body function or structure such as a significant deviation or loss.

Activity limitations: difficulties an individual may have in executing activities.

Participation restrictions: problems an individual may experience in involvement in life situations.

Within this conceptual framework, the disabling consequences of impairment may be amplified or mitigated by factors unique to the individual with a health condition, interacting with their environment and according to personal choice. To illustrate the importance of environmental factors, consider Fig. 23.3.

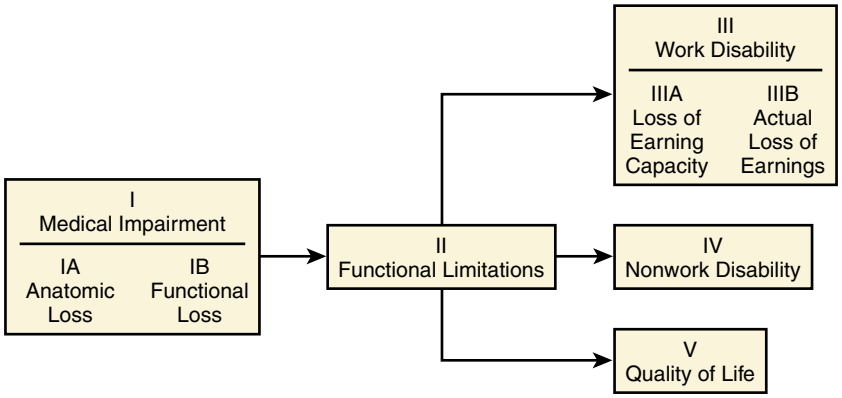
Despite its superiority as a classification system, shortcomings of the ICF can be noted. The distinctions between activities and participations are often blurred, and inadequate attention has thus far been given to quality of life (QOL) measures (e.g. life satisfaction, burden of care) in the model itself.

Measuring Disability for Compensation Purposes

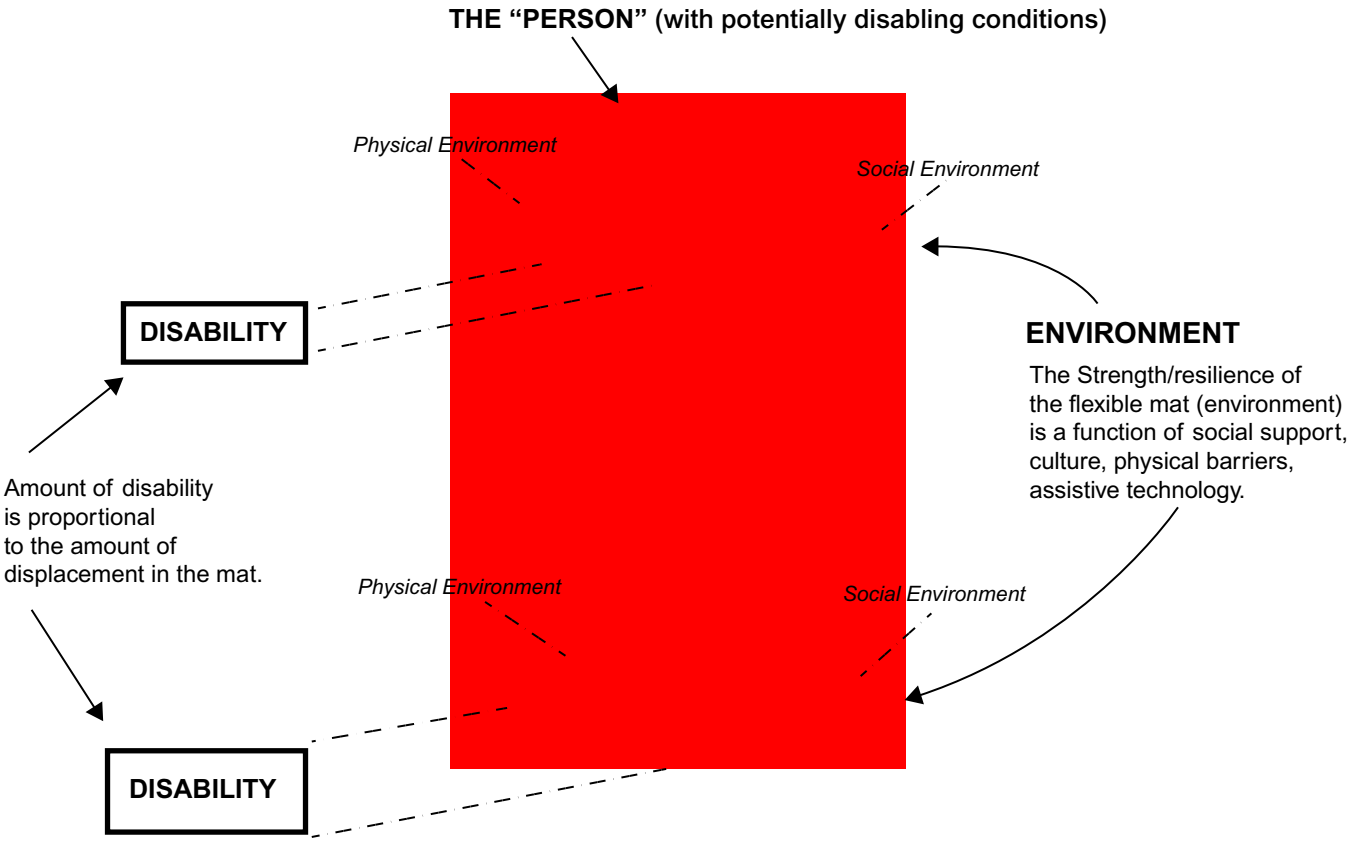
Social justice requires that individual group members contribute productively to the common good of the whole. However, provisions must be made to exempt this requirement and support those incapable of such productivity by virtue of age, illness, or disability. A related expectation is that individuals who incur loss or disablement because of illness or injury are thereby entitled to some compensation for their losses.

Within our social system, there are many different disability compensation systems (see section III above) designed to compensate individuals for such losses. They share a common conceptual and operational platform in which the initial estimate of physical and/or psychological loss can be translated into an estimate of functional and economic losses expressed in monetary terms.

By convention, the severity of the physical and psychological loss is operationally defined and measured in terms of a *medical impairment rating* at an organ system level. That is typically expressed as a percentage of regional loss of the affected body part(s) and can be further extrapolated to the body as a whole. The severity of functional and, hence, economic loss associated with this impairment percentage is further estimated in terms of a *disability rating* expressed as a percentage of the economic worth of the "whole person." The disability rating is operationally derived from the impairment percentage and is at once intended to reflect direct economic losses, non-economic losses, and negative impact on QOL in terms of a monetary sum. The whole person value and magnitude of awards vary according to the disability system in question, and disability payments may be awarded as lump sum payments or on an annuity basis.



• **Figure 23.3** Disabling consequences of an injury or disease. (Reproduced with permission from McGeary M, Ford M, McCutchen SR, et al. (eds). *IOM Committee on Medical Evaluation of Veterans for Disability Compensation. A 21st Century System for Evaluating Veterans for Disability Benefits. The Rating Schedule*. Washington, DC: The National Academies Press; 2007, pp. 117.)



• **Figure 23.4** Reproduced with permission from the Institute of Medicine. *Enabling America: Assessing the Role of Rehabilitation Science and Engineering*. Washington, DC: The National Academies Press, 1997. doi:10.17226/5799.

The IOM[37] has recently developed a generalized model to demonstrate the essential features common to all disability systems. Individuals seeking compensation and meeting criteria of entitlement must demonstrate losses according to five domains of interest (see Fig. 23.4).

The first of these, *Medical Impairment*, traditionally carries the most weight for several reasons. It is largely anatomically and physiologically based and, hence, can readily be measured in objective terms. Objectivity enables codification of the disability and fosters standardization, reliability, and reproducibility of measurement according to some uniform scale. Impairment can be measured and expressed in terms of anatomic or functional losses.

The second domain of interest, *functional limitations*, can be expressed and measured in terms of basic ADLs and/or instrumental (advanced) activities of daily living (IADLs). ADLs include basic self-care activities such as feeding, toileting, grooming, bathing, hygiene, and dressing—activities that generally occupy our personal sphere. IADLs require greater cognitive and physical capacity and include such activities as meal preparation, driving, managing finances, medications, and one's daily routine.

The third domain, *Work Disability*, can be understood in terms of loss of earning capacity (an actuarial determination of negative impact on employability and earnings brought about by work restrictions because of the impairment, and other considerations such as age, baseline employment, and earnings history, availability of accommodation and alternative job opportunities, and other local factors). It can also be understood in terms of actual loss of earnings directly attributable to the impairment.

A fourth domain, *non-work disability*, includes losses in terms of inability to visit friends and relatives, engage in communal activities, hobbies, or other recreational pursuits because of barriers of access or performance attributable to the impairment.

A fifth domain, *QOL*, includes losses attributable to diminished life satisfaction, self-esteem, and increased burden of care in terms of treatment compliance and caregiver support.

The metrics whereby each of these constructs is defined and measured vary and remain incompletely understood. This is partly because of persisting confusion of terminology, definitions, and criteria of impairment and disability across the various systems and the continuing emphasis upon objective, medically determined impairment as the prime determinant of disablement.

Unfortunately, there is also a lack of agreement upon the metrics whereby the impairment ratings themselves are determined between and even within the various disability systems of interest. For example, United States workers' compensation jurisdictions show considerable variability in terms of their acceptance or rejection of standard and uniform impairment rating guides and those that mandate or recommend the use of the same variable in the choice of reference. Even in the case of the *American Medical Association Guides to the Evaluation of Permanent Impairment (AMA Guides)*, the actual edition chosen for reference varies from state to state.[38] The same is true for the international use of the *AMA Guides* where in many countries (e.g. Australia, Netherlands, South Africa), the various editions are used in motor vehicle accidents and other personal injury claims to determine the injury severity (a threshold) before access to benefits for general damages (non-pecuniary, non-economic losses) is granted.[39]

The importance of the impairment rating to cash awards also varies within and between the various disability systems, as a closer examination of the United States workers' compensation (WC) system illustrates. Operationally, the WC system awards cash benefits according to three basic approaches: The first of these, the *impairment approach*, awards benefits in direct relationship to the percentage of impairment rating. The second, the *loss of earning capacity approach,* requires that the injured worker have an impairment rating but then bases the actual amount of cash benefits on the estimate of associated loss of earning capacity. The third approach, the *actual wage loss approach*, requires the worker to have both an impairment and loss of earning capacity and then base the amount of cash benefits on demonstrating the actual loss of workers' earnings.[40]

The mechanism of WC cash benefits are awarded is further complicated by distinguishing between various types of injuries as scheduled vs. unscheduled. *Scheduled* injuries typically affect the upper or lower extremities and are listed as percentage of extremity; unscheduled injuries affect the spine, nervous system, or other organ systems and are awarded as a percentage of the "whole person."[41]

Although the impairment rating is the common factor in disability determinations as cash benefits, it is not the sole factor. However, in practice, many jurisdictions implement procedural shortcuts whereby the impairment rating percentage becomes a direct surrogate for the disability rating according to a predetermined formula that multiplies the impairment percentage times several weeks wages (up to a cap) times a percentage (generally two-thirds to three-fourths) of the average weekly wage (up to a cap) and resulting in a lump sum pay out. The adequacy of applying the impairment rating as an operational surrogate measure of disability continues to be a subject of debate.

Implications for pain sufferers can be noted: The metrics for medical impairment rating clearly favor and emphasize objective over subjective criteria. As such, painful entities such as headache, fibromyalgia, or low back pain often occur in the absence of objective, verifiable pathology or may present in a setting where objective clinical findings are most consistent with normal anatomic variation and the aging process and may be of little or no clinical significance to the individual's actual complaints. Impairment ratings in such cases are ineffective since minimal or no rating percentage is currently allowed in relation to any apparent (and often profound) negative impact that these conditions may be having upon ADLs. The disablement, and ensuing losses in such cases, potentially become more evident if viewed in terms of QOL. There are well respected psychometric instruments now available to measure the QOL. Notable examples include the quality of wellbeing (QWB) scale, the WHOQOL-100, and the QOL index (QLI).[42] Unfortunately, such metrics are not familiar tools to the typical rating physician and are not routinely taken into account by the rating systems per se. Consequently, losses in terms of QOL remain largely unaccounted for by the rating practice summarized above.

American Medical Association Guides

The process whereby disability determinations are made requires that an initial impairment rating be made according to standard and specific medical criteria. Since the physician is empowered and charged to render such ratings, the AMA has produced a rating manual to assist physicians in this regard. The *American Medical Association Guides to the Evaluation of Permanent Impairment (AMA Guides)* is a standardized, objective reference for this purpose, initially published in 1971 as a compilation of a series of impairment rating articles for different organ systems that were published in the *Journal of the American Medical Association* from 1958–1970. It has periodically been updated and revised to the most current *AMA Guides, sixth edition* published in 2008.[43]

The *AMA Guides* is recognized nationally and globally as the preferred reference for medical impairment ratings. Various editions are required or recommended by statute in the majority of United States WC jurisdictions. To date, the *AMA Guides, sixth edition* has recently been adopted by 19 jurisdictions in the United States and is the reference mandated by the USDOL in the various disability systems outlined above. It is also adopted and used internationally in WC and personal injury claims, including nine of ten Canadian provinces and all three Canadian territories, the Netherlands, South Africa, Australia, New Zealand, Malaysia, Korea, Hong Kong, and the Middle east. The United Nations peacekeeping operations also use the *AMA Guides, sixth edition* to adjudicate personal injury claims arising from peacekeeping mission assignments.

The *AMA Guides, sixth edition* builds upon the precedent of the previous edition of the *Guides* in placing increasing emphasis upon a diagnosis-based approach, with particular emphasis on musculoskeletal impairment ratings of the spine and extremities. Diagnosis-based impairment (DBI) grids are provided for each anatomic region (cervical spine, thoracic spine, lumbar spine and pelvis for the spine; digits/hand, wrist, elbow, and shoulder for the upper extremity; and foot & ankle, knee, and hip for the lower extremity). Each grid has five potential impairment classes (Class 0–4) consistent with the ICF classification system, and each covers a broad and precise array of diagnoses ranging from soft tissue conditions (non-specific, chronic, or recurrent) to muscle-tendon and/or motion-segment injuries (sprains, strains, tendinopathy), and to ligament, bone, and joint injuries (fractures, dislocations, arthrodesis). The impairment rating is a two-step process whereby an initial assignment to an impairment class requires the rating examiner to identify the most appropriate diagnosis. Each diagnostic-based impairment class has an available range of impairment values with an initial "default" mid-range value. The rating is then adjusted within-range as a second step, using three separate criteria to validate the diagnosis and severity (functional history, examination findings, and clinical test results) of the condition and by using a simple triangulation method enables a final numerical adjustment upward for less-favorable outcomes or downward for more optimal outcomes according to the specific result in each case.[44]

Medicolegal Constructs and Constraints

In general, the pain practitioner has unique legal liabilities that include administrative, civil, and criminal liability exposure both at the state and federal level, the discussion of which is beyond the scope of this chapter. Alternatively, a brief overview of the interaction between impairment and disability assessor and the law is indicated. The pain practitioner participating in such evaluation is encouraged to become familiar with the emerging field of disability medicine described as a sub-specialty of clinical medical practice that encompasses identifying, predicting, preventing, assessing, evaluating, and managing impairment and disability in both human individuals and populations.[45]

The IME

IME: A (usually) one-time evaluation performed by a physician examiner who is not treating the patient or claimant to answer specific questions posed by the referring party, including MMI

determination, impairment rating, and return to work restrictions, if applicable.[46]

IMEs are examinations performed by a physician who is not involved in the person's care to clarify medical and job issues. IMEs are performed to provide information to case management and for evidence in hearings and other legal proceedings. IMEs are a component of most WC statutes, although the specifics vary by state and country. They are performed at several stages during the cycle of injury/illness, treatment, rehabilitation, and return to work. The key issues associated with an IME differ from clinical consultations in role and focus. In the WC arena, IMEs may be performed any time there is a dispute, concern, or question regarding the medical treatment or condition of the injured worker. These issues include such topics as:

1. Diagnosis, proximate causation, and work-relatedness of an illness or injury.
2. Current and proposed medical treatment or diagnostic efforts.
3. Appropriate work and general activity level during treatment.
4. Stability of the medical condition and status regarding maximal medical improvement.
5. Identification of other non-medical factors that can have a significant impact on the outcome of the medical condition or treatment.
6. Impairment rating and related disability issues under certain circumstances.
7. Ability to return to work (fitness for duty) and reasonable accommodation.

IMEs can help to untangle the complex relationship between *pathology* (a medical condition or diagnosis), *impairment* (an anatomic or functional abnormality or loss), *activity limitations* (a reduction in ADLs that can be assessed by functional metrics), and *participation restrictions* (a reduction in the ability to perform socially-defined activities or roles). The opinions outlined in the IME report are expected to be expressed in terms of medical probability vs. medical possibility in all cases, where the following definitions apply:

Medical Possibility: Something could occur because of a particular cause (probability less than or equal to 50%).

Medical Probability: Something is more likely to occur than not (probability exceeds 50%).[47]

Physician Testimony and Liabilities

The IME is a form of expert witness testimony that embraces the important task of assessing a claimant's health in accordance with their legal rights, entitlement, and potential for monetary gain. The independent medical examiner, acting as an agent to the consulting party rather than as a patient advocate, also bears the risk of becoming a target for allegations of wrongdoing leveled by the disgruntled claimant.

From a legal perspective, an independent medical examiner or a disability evaluator is essentially an expert witness. As such, and until recently, the expert had enjoyed essentially the same type of immunity as to any other witness in the judicial process. This immunity from civil liability ran quite deep and included protection from claims of defamation and negligence. The witness immunity can be traced back to the 16th century English common law.[48] The idea behind witness immunity was to ensure that the witness would speak freely when giving testimony.[49] Subsequently, the American courts considered the issue of witness immunity to be so important that it was maintained even when there might be negligence.[50] Traditionally, the argument for such immunity has been that expert witnesses are an important part of the legal system, and in the interest of justice, expert witnesses need to be protected from liability. Several state courts have affirmed the concept of witness immunity for reasons of public policy because, without immunity, there would be a loss of objectivity, and the fear of infinite vexation would have a chilling effect on the witness and the reluctance to testify.[51]

The United States Supreme Court, in the 1980s, confirmed the importance of witness immunity in two cases. In *Briscoe*,[52] the court noted that a witness who knows that he might be forced to defend a subsequent lawsuit and perhaps to pay damages might be inclined to shade his testimony in favor of the potential plaintiff, to magnify uncertainties and thus to deprive the finder of the fact (judge or jury) of candid, objective, and undistorted evidence.

In *Mitchell*,[53] the United States Supreme Court reasoned that witness immunity is important because the judicial process is an arena of open conflict, and in virtually every case there is, if not always a winner, at least one loser. The court noted that it is inevitable that many of those who lose will pin the blame on witnesses and would bring suit against them in an effort to re-litigate the underlying conflict.

The continuous theme that ran through these cases emphasized that the object of immunity is not to protect those whose conduct is open to criticism but those who would be subject to unjustified and vexatious claims by disgruntled litigants. However, recent development in the law of liability of expert witnesses in the past two decades has caused many cracks in the expert witness armor.

The legal liabilities of the independent medical examiner as an expert witness are mainly grounded in legal theories (referred to in legal parlance as causes of action) of tort law and to some extent in contract law by which the injured party as a plaintiff may bring a lawsuit against a healthcare provider. It should be noted that a liability claim against a practitioner can be and is usually brought simultaneously under several legal theories. The plaintiff hopes to win under any or all of these claims leading to the recovery of a monetary award from the defendant practitioner.

Insert Table 23.2 here:

The underlying principle of the common law (both law of tort and contracts) is to provide a venue for a person who has suffered damages because of an action or inaction by others to seek redress for his or her grievance in the courtroom. The tort law has been described as a great equalizer as it gives the individual an ability to bring a potentially mightier wrongdoer (referred to in legal parlance as tortfeasor) before the bar on a more equal footing for the wrongs that may have been done to her and secure compensation for her loss. Obviously, the law cannot make the tortfeasor undo the injury or harm but makes them pay monetary compensation for both intentional wrongs (for example, defamation, assault, and battery) and unintentional (e.g. negligence). The law of tort shifts the burden of the cost of the injury or damages to the responsible party and serves to prevent similar harm to other members of society through enforced accountability. The idea is to make the offensive, and undesirable behavior costly to the tortfeasor and, in principle, serves to deter others from engaging in behaviors such as the defendant in the future.[54]

Traditionally, the healthcare provider's liability to their patients arises out of medical malpractice claims. The term *malpractice* refers to any professional misconduct that encompasses an unreasonable lack of skill or unfaithfulness in carrying out professional or fiduciary duties.[55] Under the theory of negligence, the law of

TABLE 23.2 Legal Theories of Causes of Action Against IME Doctors/Expert Witnesses

A. Intentional Tortes
1. Assault
2. Battery
3. Intentional infliction of emotional distress
4. False imprisonment
5. Defamation
6. Invasion of privacy
7. Fraud and misrepresentation
8. Conspiracy
9. Bad faith
10. Deceptive trade practices

B. Unintentional Tortes
1. Ordinary negligence
2. Professional malpractice
3. Failure to warn
4. Wrongful death
5. Loss of chance of recovery or survival
6. Vicarious liability for the acts of others
7. Negligent referral
8. Failure to diagnosis
9. Failure to inform

C. Actions Under Law of Contract
1. Breach of contract
2. Breach of warranty
3. Abandonment

D. Miscellaneous Causes of Action
1. Deceptive trade practices
2. Violation of a statute or regulation

torts is the most common basis for a medical malpractice action against a healthcare provider. However, under this action, the plaintiff must prove that the practitioner had a duty to the patient and breached that duty because of which (causation) harm or damage occurred.

Until recently, the medical malpractice actions against the IME doctors and expert witnesses failed because of a lack of doctor/patient relationship with the examinee/plaintiff.[56] The continuous theme that ran through the cases across various jurisdictions in the United States was that as long as the IME doctor neither offered to nor intended to treat the individual examinee, there was a lack of doctor/patient relationship, which prevented the medical malpractice cause of action.[57] Many potential cases were either not filed because of prevailing notions among the legal community based on the previous case law, or cases when filed were dismissed upon pre-trial motions from the defendants.[58,46–48] However, this has changed significantly in the past two decades with increasing case law from various jurisdictions holding independent medical examiners and expert witnesses accountable for the alleged harm suffered by the plaintiff/examinee. This was initially done under the cause of action of simple negligence and outside of the law of torts for medical malpractice.[49]

More recently, at least two state Supreme Courts have allowed the civil action against the IME doctors to proceed under the traditional medical malpractice theory. The legal commentators have observed that this increasing erosion of immunity from civil action for the independent medical examiner as an expert witness is because of the proliferation and growth of the litigation/expert witness industry, as well as the courts' perception of lack of protection of injured party from unscrupulous witnesses and the inadequacy of the traditional safeguards against expert witness malfeasance from potential prosecution for perjury and inadequate cross examination.

The beginning of this trend of judicial hostility toward expert witness immunity can be traced back to the mid-1990s when the state courts in the United States started holding independent medical examiners and expert witnesses without any doctor/patient relationship accountable to their examinee in ordinary negligence. This trend began in Colorado with the *Greenberg*[59] case. Several other jurisdictions have since followed. The Virginia Supreme Court in *Harris*[60] held as a matter of the first impression (making new precedent) that a doctor could be sued for malpractice for the negligent performance of a doctor's mental and physical examination of a party during an IME.

Similarly, the Court of Appeals in Arizona in the *Stanley*[61] case found that a formal doctor/patient relationship is not the only source of a doctor's duty toward a patient and that the doctor owed a duty of care to the patient despite the absence of a formal doctor/patient relationship. The Arizona Supreme Court took it a notch further in *Ritchie*[62] and allowed for medical malpractice to go forward despite no doctor/patient relationship, essentially stating that the court can envision no public benefit in not holding a doctor accountable to a duty to conform to the legal standard of reasonable care.

As can be seen from above, under case law of various jurisdictions in the United States, the expert witnesses' (as well as IME doctors') immunity, traditionally enjoyed up until recently against various legal causes of action, is now rapidly eroding. The news from the other side of the Atlantic is even worse. In a recent decision by the United Kingdom Supreme Court in *Jones*,[63] the United Kingdom Supreme Court practically stripped the expert witness from all immunities that are available to the fact witnesses, generally. After a lengthy discussion, the majority of the Jones court concluded that they see no public policy reason to justify immunity for the expert witness. While this recent decision in the United Kingdom has no authority in the United States jurisprudence, it is nonetheless regarded by some as a persuasive argument.

In summary, the pain practitioner should be aware of the legal liabilities in the overall practice of their subspecialty and the additional liabilities entailed with exposure to independent medical examinations and expert witness work. Even though the recent case law in some jurisdictions has significantly removed the traditional immunity from medical malpractice claims against providers with no doctor/patient relationship with their examinees. In American jurisprudence, there remains a great need for expert medical witness service. Practitioners attracted to disability assessment and inclined to serve as independent medical examiners are encouraged to attend several of the high-quality training programs offered in the United States to independent medical examiners and expert witnesses to empower them with the knowledge, skills, and abilities necessary to practice as an independent medical examiner and/or expert witness in the field of disability medicine.

Implications for Disability Assessment of Chronic Pain

An important point of this chapter can best be made by drawing into focus the distinction between impairment ratings and disability ratings as they pertain to the issue of pain. The construct of impairment is conceptually and operationally grounded in

the medical model of disease discussed earlier. Impairment is codified and systematically defined according to a predetermined set of objective and measurable criteria for each organ system. Conditions that affect one or more organ systems and manifest themselves in terms of objective, measurable organ system pathology are infinitely ratable according to these organ systems. The painful experience that often accompanies specific pathology can and should be accounted for in some systematic manner and included in such ratings. However, pain can occur in the absence of observed pathology specific to the organ system, and chronic painful conditions transcend the organ system boundaries of the individual and can perhaps be best described and understood in terms of the biopsychosocial model described above.[54,64]

Global pain or other chronic painful conditions not attributable to any specific organ system pathology according to the impairment rating method alluded to above can perhaps be more adequately accounted for by adopting and applying QOL measures.[65] Such metrics have the necessary empirical foundation from which to develop standards for losses in terms of non-vocational function, life satisfaction, and burden of care and medical compliance needed to maintain optimal function in the presence of chronic pain and other disabling conditions. Such metrics, when properly applied, can and should enable modification of any disability payment as a percentage add-on or standalone cash award according to specifications of each disability system. Perhaps the disabling consequences of chronic painful conditions can be more favorably captured in overall disability determinations at the point of final integration of the impairment rating, functional outcomes, and other relevant disability criteria as evidenced through such QOL assessments.

QOL measures are important factors in determining impairment and ultimately disability, as pain is a subjective experience and thus hard to quantify outside of the patient's description. Pain affects all aspects of life, which in the long term increases depression and anxiety. This is underscored by the fact that many of the patients with chronic pain do not seek out a physician's help because their pain cannot be relieved. Therefore it is important to make the experience of pain easier to bear, and QOL measures allow a validated approach to reach that goal and assess a patient's function in the context of their illness.[66]

When choosing a QOL measurement tool, it is important to determine the objective of the tool. Some tools are very narrow in their measurement and only examine certain aspects of a patient's life, such as those that measure health-related QOL, which the CDC defines as "an individual's or group's perceived physical and mental health over time." Others are disease specific such as the gastrointestinal QOL index (GIQLI), the asthma quality of life questionnaire, and the stroke specific QOL scale.[67] It is important to note that these questionnaires examine the patients' QOL in the context of the disease rather than examining the patients' overall QOL, which can be a limitation in assessing the true QOL of the patient.

Some QOL measurement tools are very broad, and rather than looking at the QOL from the standpoint of disease, examine the patients' QOL holistically. The downside to such a QOL measurement is that it can be difficult to administer because of the potential for large question numbers and length of completion. To counteract that and still measure a patient's general QOL, several QOL tools have been developed using data from the larger tool items to create smaller, easier to use ones. One such example is the medical outcome study short-form 36 (MOS SF-36). This tool measures eight aspects of the patient's life over 36 questions.[68]

Because of QOL being influenced by cultural and societal values, some measurement tools also account for those. An example of such a tool would be the World Health Organization's QOL instrument developed by the World Health Organization. This tool seeks to create a QOL evaluation that spans different cultures and languages. It covers six total domains: physical capacity, psychological, level of independence, social relationships, environment, and spirituality/religion/personal beliefs. To allow the cross cultural application, it allows additional questions that apply to the culture to which the patient belongs. This helped to produce a 100 questions test called the WHOQOL-100.[69] A shorter version was also developed called the WHOQOL-26 BREF, which is shorter and maybe more practical to administer. It should be noted that there are other QOL measures that are used in clinical trials. These are discussed in Chapter 84.

The use of a suitable QOL as a tool for disability assessment of pain must recognize that a valid disability assessment of pain may require a skill set and applied metrics beyond those typically embodied by the physician disability examiner. Until this ideal can be more closely achieved, the role of pain as a contributor to disability can be most properly accounted for in two ways:

Pain directly affecting impairment can be viewed in terms of functional outcomes accompanying specific impairment, as it is now possible, using the DBI approach outlined above for impairment rating as put forward in the *AMA Guides, sixth edition*, to modify the "expected" impairment rating upwards using a functionally-based "grade modifier" sensitive to pain and other limiters of function, to award additional impairment for pain-associated loss of function.

Alternatively, in cases where a specific diagnosis is lacking, and pain appears to be the primary problem, the *AMA Guides, sixth edition* currently offers a "stand alone" assessment of pain that awards up to 3% loss to the whole person where pain is not effectively rated elsewhere. Additional work is needed to perfect our current disability infrastructure to further enhance the relevance, validity, and reliability of medical impairment ratings and provide alternative metrics to expand and modify disability determinations to properly account for functional losses because of chronic pain.

Resources Available to the Physician Disability Examiner

Several educational venues and reference resources are available to enable interested physicians to gain the additional necessary knowledge, expertise, and credentials to perform impairment ratings, disability evaluations, and IMEs competently and authoritatively. These include training programs, credentialing, and certification by examination, as well as several reference texts as listed below:

1. American Board of Independent Medical Examiners: www.abime.org
2. American College of Independent Medical Examiners: www.acime.org
3. American College of Occupational and Environmental Medicine: www.acoem.org
4. American Medical Association: www.ama-assn.org

Key Points

- A pain specialist must understand the impairment and disability system they will be working with to be successful.
- Historically, there have been systems in place to provide for those unable to work because of disability. These date back to biblical times and continue into the present with various laws at state and federal levels, including social security and WC and compensation for personal injuries arising out of the negligence of others.
- State WC has three kinds of benefits: medical and rehabilitation expenses, wage loss benefits, and survivor benefits.
- State tort law allows for monetary awards for both mental and physical damage, given that it can be proven that another was at fault.
- Federal worker's compensation systems are governed by the USDOL with administration done by the OWCP (a subagency of the USDOL) and include FECA, Longshore and Harbor WC Act, Energy Employees Occupational Illness Compensation Act, Federal Black Lung Program, DBA, NAFIA, OCSLA. The other federal laws not under USDOL providing compensation include FELA (Railroad Worker Act and the Jones/Merchant Marine Act).
- SSDI covers those who are disabled because of a medically determined physical or mental impairment that lasted or likely to last greater than 12 months or end in death.
- SSI provides income for those below the poverty line who are blind, disabled, children, or older than 65 years.
- Eligibility for veterans' benefits is based on how the veteran was discharged and whether the disability was service connected, nonservice connected, or presumptive service connected.
- Private disability insurance are usually group policies and available through the workplace. They are split into short term (three months) and long term (two to three years) before reevaluation for lifetime benefits.
- The "medical model" of disability defined disability as being because of underlying pathology from illness or disease and relied on diagnosis and treatment of pathology. The "social model" of disability defines disability as the failure of society to address the disabled individual's special needs regarding priority awareness, environmental access, and infrastructural accommodation for major life activities.
- The ICIDH considered a disability to be four linear linked domains: pathology, impairment, disability, and handicap. The ICF, which replaced it, focused on an interactive association between an individual and their disability, including the functional consequences of their impairment and the context of personal versus environmental nature. ICF focused on activity, participation, impairments, activity limitations, and participation restrictions.
- Pain medicine practitioners should focus more on QOL measures, and the tools available are helpful when evaluating chronic pain and resulting impairment and Disability.
- The *AMA Guides* are essential to describing an impairment in many legal jurisdictions.
- One key difference between independent examiners and everyday patient interactions is that there is no patient-physician relationship between an independent medical examiner and the examinee.
- There are multiple ways to become proficient in medicolegal and disability ratings, particularly training courses.

Chronic Post-surgical Pain Syndromes: Prediction and Preventive Analgesia

NANTTHASORN ZINBOONYAHGOON, YUN-YUN K. CHEN, KRISTIN L. SCHREIBER

Introduction

Chronic post-surgical pain (CPSP) is a growing area of study in pain medicine.[1] An increasing number of patients undergoing surgery each year,[2] multiplied by a variable reported incidence (5%–85%),[3] produces an increased number of patients with new chronic pain. In recognition of CPSP as an important global health problem, the International Association for the Study of Pain (IASP) named 2017 the Global Year Against Pain After Surgery.[4] In the upcoming International Classification of Disease (ICD-11), which is expected to be implemented in January 2022 by the World Health Organization, CPSP is recognized as one of the seven major types of chronic pain (MG 30.XX) under distinct codes for "chronic postsurgical pain" (MG 30.21), "chronic postsurgical or posttraumatic pain, unspecified" (MG30.2Z), and "other specified chronic postsurgical or posttraumatic pain" (MG30.2Y).[5,6] CPSP is a distinct subset of chronic posttraumatic pain, the definition of which is "pain developing or increasing in intensity after a tissue injury (involving any trauma including."[6] The code for chronic posttraumatic pain also includes persistent pain after trauma, spinal cord injury, nerve injuries, and burn injury.[6]

Publications regarding CPSP have grown exponentially over the last decade, from 178 publications by 2009 to 938 publications by 2019,[7] providing a strong but heterogeneous and complex body of evidence. This chapter will cover the definition, incidence, and proposed pathophysiology of CPSP, summarize what is known about potential risk factors that may aid prediction, and outline strategies for preventive efforts.

Definition of CPSP

The concept of CPSP is pain that lasts longer than the physiologic healing process after surgery. Simple diagnostic criteria for CPSP were proposed by Macrae[8] in 2001 as pain developing after a surgical procedure of at least two months duration, with other causes for the pain having been excluded (e.g. continuing malignancy or chronic infection), including the possibility that the pain continues from a preexisting problem. However, there have been additions and modifications to this simple definition, including:[9]

1) Many patients already experience pre-surgical pain. To define CPSP for patients who already had pre-surgical pain, post-surgical pain should have increased severity and/or be accompanied by a change in location or character.
2) The duration of two months may be too short to be considered as chronic pain in some cases, and thus the required duration of pain should be extended to at least three–six months.
3) Rather than simply categorizing pain as absence/presence, pain severity and impact should be considered, with CPSP defined as pain that the patient feels has at least a minimal impact on quality of life.
4) CPSP commonly develops immediately after surgery but may also develop after a pain-free period, possibly because of the delayed onset of neuropathic pain after nerve injuries (inguinal hernia repair, breast surgery with axillary dissection).
5) The CPSP may involve locations outside the surgical site. For example, patients suffering from persistent pain after breast cancer surgery report pain not only at the breast or axilla, both in the upper medial arm,[10] likely because of intercostobrachial neuralgia from axillary node dissection.[11]

IASP updated the definition of CPSP in 2017:[12] "Chronic post-surgical pain is chronic pain developing or increasing in intensity after a surgical procedure and persisting beyond the healing process, i.e. at least three months after surgery." The pain is either localized to the surgical field, projected to the innervation territory of a nerve situated in this area, or referred to a dermatome (after surgery/injury to deep somatic or visceral tissues). Other causes of pain, such as infection and malignancy, need to be excluded, and pain continuing from a preexisting pain problem. Depending on the type of surgery, CPSP often includes elements of neuropathic pain (Table 24.1). These newly proposed criteria provide a more comprehensive picture of CPSP and may be used as diagnostic criteria in the ICD-11 coding system.

Incidence of CPSP

Having a well-developed definition and standard diagnostic criteria has assisted the visibility and recognition of CPSP, which had previously been underestimated.[13] However, the diagnostic criteria for CPSP do not specify a clinically meaningful pain severity to define CPSP. Even with these more closely defined diagnostic criteria, variation in cut points for the severity constituting clinically significant pain and at timepoints chosen to study CPSP likely contributes to the wide range of reported incidence of CPSP in the literature. Studies have used different definitions to denote clinically meaningful CPSP, ranging from anything >0/10 on the pain scale to only considering pain >3 or >4/10 as significant.[10] Frequency may be variable (constant vs. intermittent), and the

TABLE 24.1 Evolution of the Definition and Diagnostic Criteria of Chronic Post-surgical Pain

Macrae 2001[8]	Werner and Kongsgaard 2014[9]	IASP 2019[6]
(1) The pain should have developed after a surgical procedure. (2) The pain should be of at least two months duration. (3) Other causes for the pain should be excluded, e.g. continuing malignancy (after surgery for cancer) or chronic infection. (4) The possibility that the pain is continuing from a preexisting problem should be explored, and exclusion attempted. (There is an obvious grey area here in that surgery may exacerbate a preexisting condition but attributing escalating pain to the surgery is clearly not possible as natural deterioration cannot be ruled out.)	(1) The pain develops after a surgical procedure or increases in intensity after the surgical procedure. (2) The pain should be of at least three to six months' duration and significantly affect the HR-QOL. (3) The pain is either a continuation of acute post-surgery pain or develops after an asymptomatic period. (4) The pain is either localized to the surgical field, projected to the innervation territory of a nerve in the surgical field, or referred to a dermatome (after surgery in deep somatic or visceral tissues). (5) Other causes of the pain should be excluded, e.g. infection or continuing malignancy in cancer surgery.	The pain that develops or increases in intensity after a surgical procedure or a tissue injury and persists beyond the healing process, i.e. at least three months after the initiating event. The pain has to be localized to the surgical field or area of injury, projected to the innervation territory of a nerve situated in this area, or referred to a dermatome or Head's zone (after surgery/injury to deep somatic and visceral tissues). Other causes of pain, such as preexisting pain conditions or infections, or malignancy, have to be excluded in all cases of chronic posttraumatic and post-surgical pain.

quality of the pain may depend on its location and the exact mixture of its mechanistic basis. From mild to debilitating pain, this range of severity correspondingly results in varying degrees of negative impact on quality of life.[14]

Thus the estimates for the incidence of CPSP vary substantially even among studies using the same procedure (Table 24.2),[15,16] according to the methodologic differences in defining CPSP by pain intensity (Table 24.2),[6] and by time (Fig. 24.1), and across study samples.[16] The procedures with the highest reported incidence of CPSP include thoracotomy (5%–65%), mastectomy (11%–57%), and amputation (30%–85%). These procedures also have a higher prevalence of moderate to severe pain (5%–10%) than herniotomy (2%–4%)[12] and seem to have more neuropathic characteristics (66%–68% for thoracotomy and mastectomy) than hip or knee arthroplasty (6%).[15]

TABLE 24.2 Incidence of Chronic Post-surgical Pain by Operation and Pain Intensity and Proportion of Neuropathic Pain

Type of Surgery	Incidence of All CPSP	Incidence of Severe CPSP (>5/10 of 10/10)	Proportion of Neuropathic Pain in CPSP
Amputation	30%–85%	5%–10%	80%
Cesarean delivery	6%–55%	5%–10%	50%
Cholecystectomy	3%–50%	Not reported	Not reported
Coronary bypass	30%–50%	5%–10%	Not reported
Craniotomy	7%–30%	25%	Not reported
Dental surgery	5%–13%	Not reported	Not reported
Hip arthroplasty	27%	6%	Not reported
Inguinal herniotomy	5%–63%	2%–4%	80%
Knee arthroplasty	13%–44%	15%	6%
Melanoma resection	9%	Not reported	Not reported
Mastectomy	11%–57%	5%–10%	65%
Sternotomy	7%–17%	Not reported	Not reported
Thoracotomy	5%–65%	10%	45%
Vasectomy	0%–37%	Not reported	Not reported

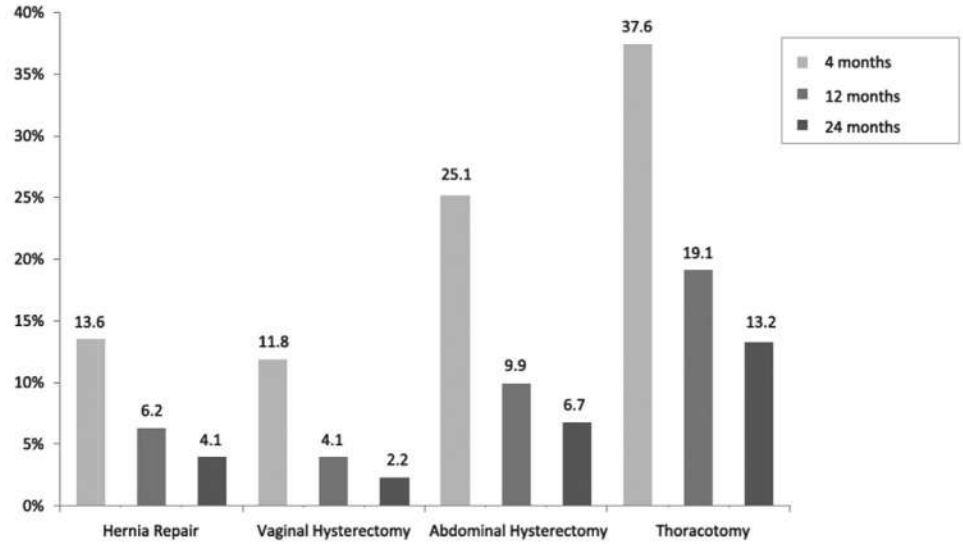
With permission from Schug et al.[12]

Although cross-sectional studies are the most common, some longitudinal studies have tracked the incidence of CPSP at later time points and generally show a decrease over time. For example, the incidence of CPSP after thoracotomy in the study by Montes et al. showed 38% at four months, 19% at 12 months, and 13% at 24 months.[16] A similar mean trajectory of CPSP has been reported after hysterectomy and hernia repair (Fig. 24.1).[16] In contrast, other studies have suggested a relatively low but stable incidence beyond three months, as in the case of mastectomy, where both cross-sectional studies querying patients at six months to six years,[17] and longitudinal studies out to 12 months,[18] suggest a similar incidence of about 30% reporting pain of ≥3/10 or more. A more in-depth analysis, taking interpatient variability into account, suggests that there may be multiple pain trajectories within the first year after surgery, depending on severity, experienced by different subgroups of patients.[19]

A large international study averaging across multiple surgical types showed an overall incidence of CPSP of 41% (95% CI 38–43) at six months and 35% (95% CI 32–39) at one year. However, patients with severe pain (NRS ≥6/10), who also reported greater pain interference with activities and mood than patients with more moderate pain, represented only 2% of patients in the same study (95% CI 1–3).[14]

Proposed Mechanisms of CPSP

Surgical injury leads to acute postoperative pain that may be nociceptive, inflammatory, and/or neuropathic when viewed according to classic pain categorizations. However, the exact mechanism(s) involved in the pathophysiology leading to the maintenance or chronification of post-surgical pain is not well established and may vary according to *nature* of the injury and tissues involved. Three important mechanistic concepts that may be important for understanding the chronification of pain after



• **Figure 24.1** Incidence of chronic post-surgical pain after hernia repair, hysterectomy, and thoracotomy at different time points after surgery. With permission from Montes et al.[16]

surgery include neuroplasticity, nerve injury, and opioid-induced hyperalgesia.

Neuroplasticity

Neuroplasticity is a term that describes the adaptability within the structure and function of the nervous system, a quality that fundamentally underlies several crucial tasks of the nervous system, such as learning and memory, and also includes self-preservation from noxious stimuli.[20] The intense nociceptive and inflammatory stimuli from tissue injury that occurs during surgery is a message that the nervous system cannot evolutionarily afford to ignore. The nervous system response to tissue injury can be regarded as functional neuroplasticity. Increased pain immediately after surgery can drive adaptive behaviors that facilitate healing. However, these processes, when sustained or solidified into CPSP, represent a maladaptive change.

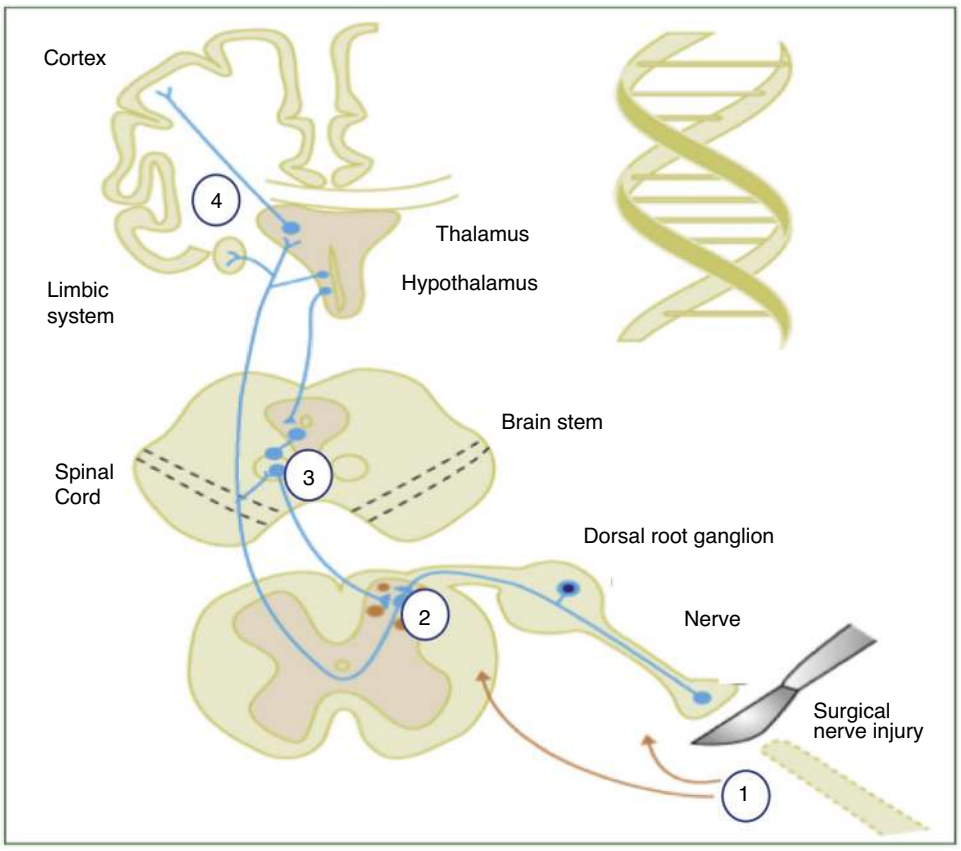
Surgical injury of tissues leads to a local release of inflammatory and other mediators and creates an acidic and often locally ischemic environment. These mediators activate peripheral nociceptors both directly through binding of mediators and by decreasing the threshold to activation by other stimuli, making normally painful stimuli more painful (hyperalgesia) and painful nonpainful stimuli (allodynia) at the site of injury (primary hyperalgesia and allodynia, limited to injury site).[3] intense and maintained nociceptive input from the periphery also activates central nociceptive pathways, starting at the level of the dorsal horn,[21] and modulating descending facilitation and inhibition from supraspinal centers,[22] and cortex.[23] This multi-level activation contributes to increased sensitivity at the primary site and sites distal to the injury (secondary hyperalgesia), otherwise known as central sensitization (Fig. 24.2).

Changes in receptor and gene expression in the dorsal root ganglion contribute to this prolonged excitability of primary nociceptors (peripheral sensitization) and thus enhanced transmission of the nociceptive signal.[3] Correspondingly, the continued transmission of this nociceptive input can cause transcriptional changes at the level of the spinal cord that underlie central sensitization.[3] The *N*-methyl-D-aspartate (NMDA) receptor plays a pivotal role in the amplification of pain and central sensitization at the level of the spinal cord, as evidenced in pre-clinical and human models.[24] The application of NMDA receptor antagonists to prevent hyperalgesia in experimental models[25] provided hope for a similar outcome in humans. Some studies showed that NMDA receptor antagonism with agents such as ketamine might modify the incidence or intensity of CPSP in clinical application.[26] Additionally, the response from surrounding immune, stromal, and glial cells in the periphery and spinal cord causally contributes to and sustains peripheral and central sensitization, influencing the extent and duration of pain and its transition to a more chronic state.[3] In keeping with the idea of noxious nociceptive input from the periphery driving central sensitization, efforts to interrupt the intense nociceptive signal have long been viewed as a way to prevent pain amplification and nervous system plasticity (preventive analgesia, sometimes called preemptive analgesia).

The concept of preemptive analgesia was described in 1983 as an early analgesic intervention initiated before a nociceptive stimulus, which may "preempt" the development of persistent pain.[27] However, clinical studies comparing analgesics given before vs. immediately following an injury failed to strongly confirm the idea of preemption.[28] The subsequent concept of preventive analgesia recognized the need to extend the time window of intervention to cover not only the initial intense nociceptive stimulation (during injury or hours after injury) but also the ongoing inflammation and aberrant firing of injured nerves at later time points (days after injury), when ongoing nociception has not yet abated.[29,30] The impact of regional anesthesia (nerve blocks),[31] and pharmacologic agents such as ketamine,[26] and lidocaine,[32] have been often studied, with mixed but promising results in preventing CPSP. The definitions of these concepts are summarized in Table 24.3.

Opioid-Induced Hyperalgesia

Opioids have long been commonly used as potent analgesics. However, when used chronically and at high doses, analgesic efficacy may diminish, disappear, or even lead to increased pain. This paradoxical phenomenon, where opioids lead to a hyperalgesic state, is called opioid-induced hyperalgesia.[36]



• **Figure 24.2** Sites and possible mechanisms responsible for chronic post-surgical pain: (1) Tissue and nerve injuries signal intense pain stimuli and peripheral sensitization; (2) changes in the sensitivity in the dorsal root ganglion producing central sensitization; (3) brainstem descending controls modulate pain transmission in spinal cord; (4) limbic system, hypothalamus, and cortex contribute to altered mood and behavior. Modified with permission from Kehlet et al.[3]

TABLE 24.3 Terms and Definitions

Term	Definition
Preemptive analgesia	An intervention initiated before a nociceptive stimulus, aimed at significantly decreasing or eliminating the nociceptive stimulus to the point that it does not lead to central sensitization and prolonged pain.[30,33]
Preventive analgesia	An intervention that is initiated before a nociceptive stimulus and continues until the majority of nociceptive stimuli have abated.[30,34]
Peripheral sensitization	Changes in the peripheral nociceptor and its milieu that lower the pain threshold and lead to a greater response for any given stimulus.[30,35]
Central sensitization	Changes in the central nervous system at the level of the spinal cord or higher that result in pain hypersensitivity.[3,30]

Opioid-induced hyperalgesia (OIH) can be conceptualized as secondary hyperalgesia. The mechanism underlying OIH likely involves transcriptional changes leading to an imbalance between pro and antinociceptive pathways,[37] including μ-opioid signaling, pronociceptive ion channel modulation, and microglial activation.[38] Chronic exposure to opioids has been shown to result in μ-opioid receptor phosphorylation by G-protein coupled receptor kinases, which leads to β-arresting-2 recruitment, μ-opioid receptor endocytosis, and receptor unavailability.[38,39]

A systematic review of clinical studies suggests that high intraoperative doses of remifentanil are associated with small but significant increases in acute pain after surgery. [40] Even lower dose and briefer exposures to remifentanil (0.1 mcg/kg/min for 30 min) have been associated with OIH.[41] In pre-clinical studies, the hyperalgesic effect of a single dose of fentanyl can last for three weeks.[36] OIH may potentially augment hyperalgesia from tissue injuries itself, making opioid-sparing strategies such as multimodal analgesia especially important in treating both acute postoperative pain and CPSP. Ketamine, an NMDA receptor antagonist, has been shown to decrease β-arresting-2 transcription in mice[42] and to clinically decrease punctate hyperalgesia in humans who received remifentanil.[41] Within a clinical context, it may be challenging to distinguish OIH from opioid tolerance, inadequate analgesia, and changes in underlying disease pathology. However, it may be suggested by altered sensory processing such as allodynia and hyperalgesia and worsening pain with further doses of opioids.[38] Assessing specifically for signs of OIH early after surgery may allow a better determination of the extent to which OIH contributes to CPSP.

Nerve Injury

Peripheral nerves are among the tissues that can be injured by surgery. Peripheral nerve injury is often considered a central contributor to the mechanistic basis of CPSP. As outlined in the

neuroplasticity section above, peripheral nerves contribute fundamentally to carrying an augmented message of pain after any tissue injury, whether the nerves themselves have sustained structural damage. However, pre-clinical studies have shown that a variety of damage to peripheral nerves may cause increased and spontaneous firing of action potentials, changes in gene expression including up and downregulation of neurotransmitters, and immune system activation after injury. These changes occur at the dorsal root ganglion level but reverberate to the dorsal horn and higher centers.[3]

Neuropathic pain in the context of CPSP can be defined in various ways, although typically utilizing questionnaires such as the DN4, S-LANSS, and painDETECT, or by including similar questions in a surgery specific questionnaire.[43] The presence of pain features of a certain quality (e.g. burning, tingling, stabbing) are indicators of nerve injury. Based on these definitions, the prevalence of neuropathic pain in CPSP varies from 6% to 68% among various surgeries,[15] although the highest reported ranges appear after thoracic and breast surgery and lowest after hip or knee replacement.[15] While more extensive nerve damage is associated with a higher incidence of CPSP,[3] higher pain severity,[44] and functional impairment,[14] nerves are rarely injured in isolation, and causation cannot be inferred from this correlation.

Risk Factors and Prediction of CPSP

Many putative factors have been linked to the incidence of CPSP and its severity, impact, and related complications, such as persistent opioid use. These factors may allow further insight into the mechanism underlying CPSP and have been put to practical use to estimate the risk of CPSP in many predictive models.

Risk Factors for Developing CPSP

Although surgical injury, by definition, is the inciting event for CPSP, the surgical extent is not always the best predictor of greater incidence and severity of CPSP. Chronic pain is a complex interaction between nociception and an individual's life. Many factors beyond the degree of tissue injury are formative to the individual experience of pain after surgery, including genetic, psychological, and social factors. The biopsychosocial model of pain, which includes biophysical differences between individuals (genetic variation, baseline nociceptive sensitivity, opioid dependence), and differences in psychosocial factors known to be involved in the processing of pain (anxiety, depression, coping strategies, social support), provides a comprehensive picture of the risk and predictive model for CPSP (Fig. 24.3).

Surgical Factors

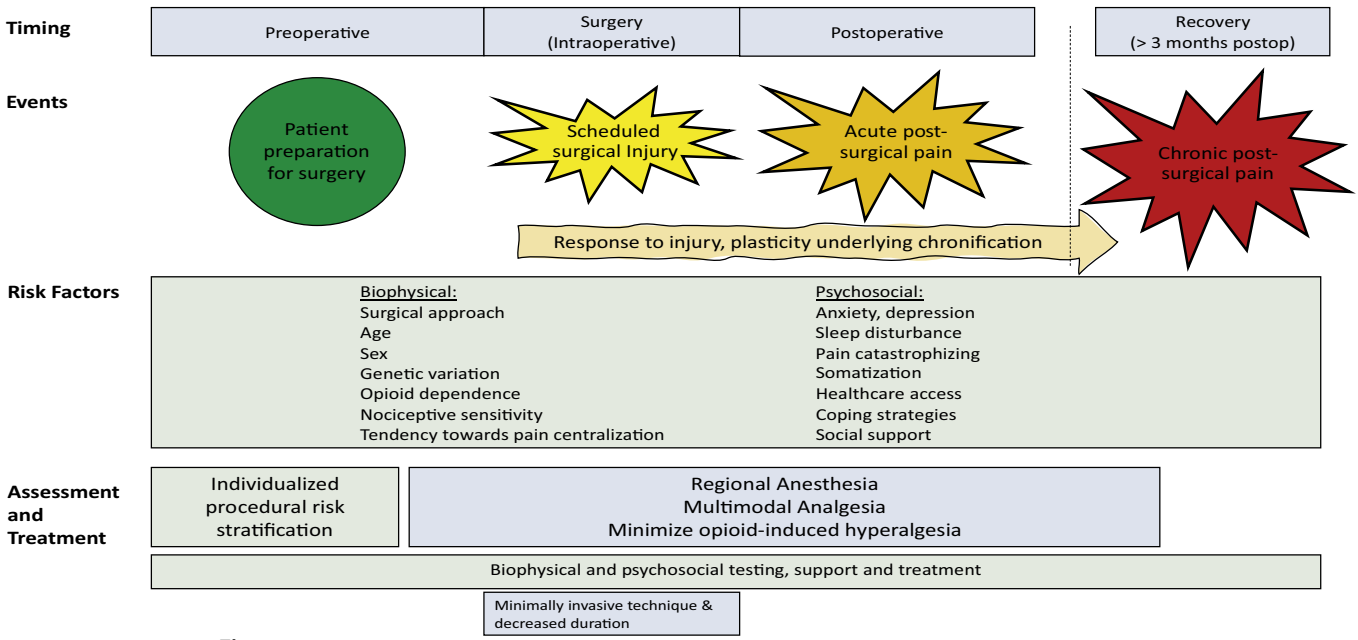
Tissue and nerve injury in each procedure must also be considered as part of the biologic variation that occurs between individuals undergoing surgery. Certain procedures are associated with different ranges of CPSP incidence,[12,16] typically with procedures of greater extent associated with higher rates. Surgical factors associated with CPSP include longer duration of surgery, low (vs. high) volume of surgical center, open (vs. laparoscopic) approach for some operations such as inguinal hernia repair,[46–48] and intraoperative nerve damage.[21]

Tissue injury is not necessarily limited to the initial surgical injury. For example, patients who underwent repeated inguinal hernia repair were more likely to develop moderate or severe pain.[49] Similarly, and patients who received radiotherapy after breast cancer surgery had a higher likelihood of CPSP in a meta-analysis (odds ratio [OR] = 1.35[1.16–1.57]),[50] possibly because of the increased incidence of tissue fibrosis, neural entrapment, and impaired glenohumeral motion.[51]

Patients Characteristics

Age and Sex

Younger age and female sex are associated with an increased risk of CPSP.[12,21] A multivariable analysis by Montes et al. found that, compared to older patients (>64 years), younger patients had a greater incidence of CPSP (OR 3.1 [2.4–4.0] for 18–50-year-olds, and OR 1.6 [1.2–2.1] for 51–64 patients).[16] Similarly, in a meta-analysis of 30 studies involving 19,813 patients undergoing breast cancer surgery, the absolute risk of CPSP increased 7% [5%, 9%] for every ten years decreased from age 70.[50]



• **Figure 24.3** The comprehensive risk factors in the biopsychosocial model for developing chronic post-surgical pain. Chen Y-YK, Boden KA, Schreiber KL. The role of regional anaesthesia and multimodal analgesia in the prevention of chronic post-surgical pain: a narrative review. *Anaesthesia*. 2021;76(1):8–17.[45]

Preoperative Pain

Preexisting pain at the surgical site represents sensitization of nociceptors in the area,[21] and further nociceptive input from surgical injury likely further augments this sensitization in an additive or supra-additive fashion.[49] Chronic pain in nonsurgical areas is also an important risk factor, indicating a tendency toward amplification of the pain signal over endogenous pain inhibition,[16,52] or central sensitization.[53] Other studies have associated longer duration and higher intensity of preoperative pain with the development and persistence of CPSP.[21,54] One study reported a slightly higher risk of CPSP for preoperative pain at the surgical site than preoperative pain at a remote site. However, both surgical site and generalized pain appear to be robust predictors of CPSP.[52] A multivariable analysis from a large observational multinational study showed the presence of chronic preoperative pain at any site is the strongest predictor of CPSP at 12 months after surgery (OR 1.89 [1.12–3.18]).[14] Preoperative pain, either at the surgical site or chronic pain at another site, are consistently included among the key predictors in most prediction models for CPSP.[14,16,18,54–56]

Preoperative Opioid Use

Long term opioid use for the treatment of chronic pain may increase the risk of CPSP, either as a marker of preoperative chronic pain severity or OIH, or both.[57] However, whether opioid use serves as a causal contributor to CPSP or is simply a common coincidental finding because of chronic pain is still unknown. In one cohort study, preoperative opioids were associated with CPSP on a simple univariable analysis (relative risk [RR] 2.0 [1.2–3.3]). However, when other factors, including preoperative pain status, were included in the multivariate analysis, preoperative opioid use was no longer a significant predictor (RR 1.3 [0.8–1.9]).[58]

Psychological and Social Factors

The experience of pain involves a complex interaction between nociception and psychology. The impact of psychological factors on acute postoperative pain, CPSP, and other types of chronic pain is well documented. An earlier meta-analysis indicated an important association of psychological factors including depression, psychological vulnerability, and stress with CPSP after various surgeries, including thoracotomy, mastectomy, hernia repair, and orthopedic surgery.[59] Then an even broader investigation of psychological factors including both state and trait anxiety or depression, pain catastrophizing, sleep disturbance, somatization, positive and negative affect, coping strategies, and expectations found an association of higher psychological distress with greater incidence and severity of CPSP.[10,17,60–63] In particular, pain catastrophizing, defined as a tendency to magnify, ruminate, or feel helpless in the face of painful sensations,[62] has proven an interesting and consistent correlate of CPSP,[17,61] and chronic pain generally.[64] A meta-analysis showed a strong association between pain catastrophizing and CPSP (pooled OR of the minimum effect of 2.13 [1.26, 3.59]).[61] Psychological factors can be assessed perioperatively with validated questionnaires such as the National Institutes of Health Patient-Reported Outcomes Measurement Information System (PROMIS) short forms for depressive symptoms, anxiety, and sleep disturbance,[65] the Brief Symptom Index (BSI)-Somatization Scale for somatization,[66] or questionnaires such as the Pain Catastrophizing Scale.[67]

Social and sociodemographic factors may also influence pain experiences, including resources and access to care. Socioeconomic factors and disability status have been variably implicated as risk factors in systematic reviews and meta-analyses.[12] Lower educational and employment status have been associated with vulnerability to developing chronic pain.[68–71] The contribution of social factors to CPSP risk has been understudied compared to biologic and psychological constructs.[72] However, social interactions appear to also play an important role in modulating pain and the ability to cope with chronic pain,[73] although the interaction of social and psychological factors, both complex and difficult to study, may also be important. Several studies suggest that a more insecure attachment style is associated with greater distress, lower self-efficacy to decrease pain, greater pain catastrophizing, more disability because of pain, and greater pain sensitivity.[74]

Acute Postoperative Pain

Greater nociceptor activation leads, on the one hand, to more severe acute pain, but also to a greater likelihood of central sensitization, which may contribute to the development of CPSP.[14,16] Thus greater acute postoperative pain is cited as a risk factor in many studies and is often included in models of CPSP prediction.[14,50,56] In one meta-analysis, acute postoperative pain severity was associated with an OR of 1.16 [1.03,1.30] and an absolute risk increase of 3% [1%, 6%] for every 1-cm increment on a 10-cm visual analog scale.[50] Besides acute pain severity per se, the percentage of time in severe pain on day one after surgery has also been shown to be strongly associated with moderate to severe pain from CPSP (NRS ≥3/10) at 6 and 12 months after surgery (Fig. 24.4).[14]

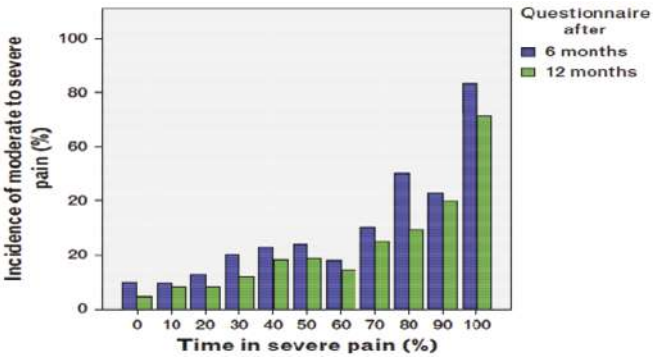
However, the severity and daily duration of acute postoperative pain may also be viewed as reflecting patient susceptibility to pain amplification, which also underlies the propensity toward central sensitization and the development of CPSP.[14] Acute pain is less of a *predictor* than a *temporal correlate* of the same process involved in the development of CPSP.

It is yet unclear whether adequate or inadequate perioperative analgesia could meaningfully affect CPSP development,[3] and in light of the goals of providing analgesia in the perioperative period, this principle may be difficult or unethical to prove. Provision of excellent acute postoperative pain control leads to a better experience for the patient, both in terms of satisfaction and perioperative recovery,[75] independent of whether it may prevent CPSP.

Other Factors

Genetic Variations

Clinical and pre-clinical studies have linked genetic factors to chronic pain. Many single nucleotide polymorphisms (SNPs), including catechol-O-methyltransferase (COMT), GTP cyclohydrolase 1 (GCH1), and DA receptor 2 (DRD2), have been linked with the risk of CPSP,[76]



• **Figure 24.4** The incidence of moderate to severe chronic post-surgical pain (≥3/10) at 6 and 12 months and the percentage of time in severe pain at postoperative day one. With permission from Fletcher et al.[14]

but a definitive genetic profile of elevated CPSP is still the object of much ongoing research. One analysis of a larger set of 90 SNPs, including those aforementioned, selected based on functional genetic variants associated with pain sensitivity and chronic pain conditions, failed to show significant differences in allele frequencies between patients with and without CPSP.[16] However, this is likely to be an area of continued interest, particularly as larger collaborative studies emerge.

Quantitative Sensory Testing

Quantitative sensory testing (QST) of an individual's response to standardized pain stimuli may help to characterize overall pain susceptibility.[77] Many studies have shown the predictive value of QST for CPSP after thoracotomy,[52] shoulder surgery,[78] and mastectomy.[10] Nevertheless, the application of QST in the clinical setting is still limited, and a relatively small pool of studies have investigated the predictive potential of these modalities, with somewhat variable QST protocols employed. Given that the application of QSTs is somewhat time consuming and requires access to standardized equipment and specially trained personnel,[79] future development of practical bedside tests is needed to offer a more practical application of QST to CPSP prediction,[80] and to determine whether these tests add predictive power independent of other measured risk factors.

Risk Factors for Other CPSP-Related Outcomes

Risk Factors for Pain Interference From CPSP

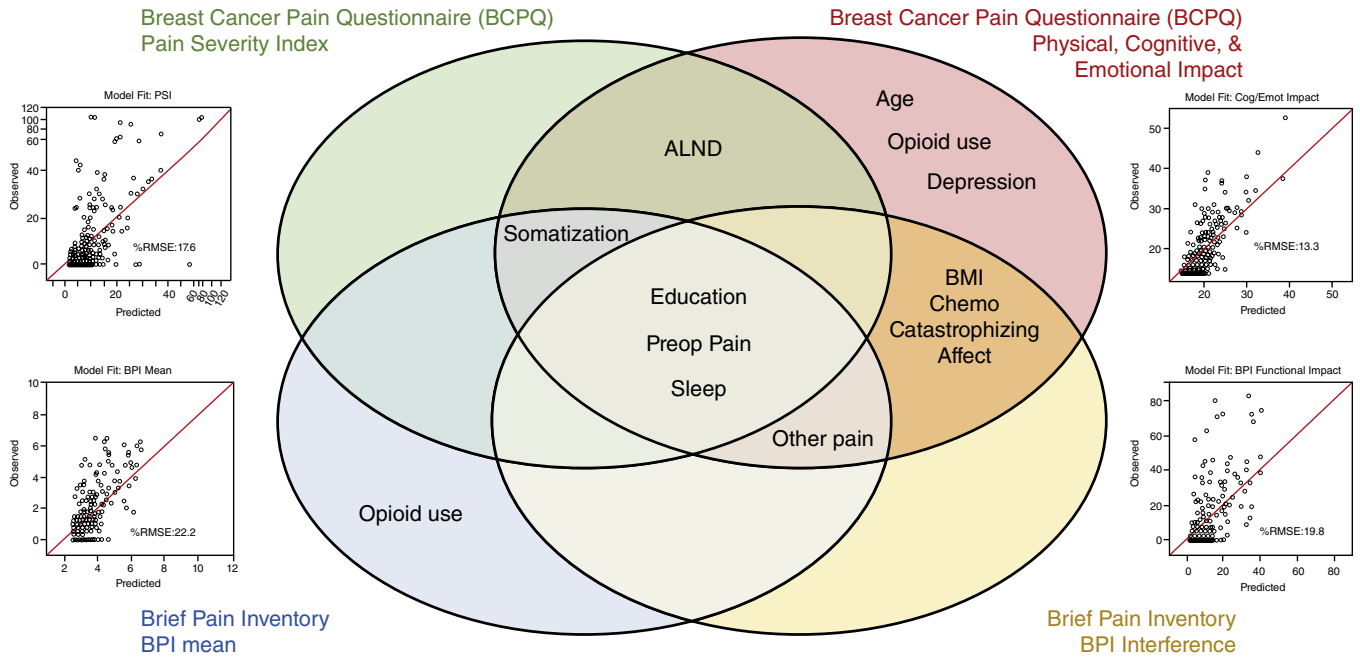
As pain is a multidimensional experience, measures of pain severity alone are insufficient to estimate the impact of pain,[81] especially when pain persists. Greater pain interference after surgery (a subscale of the Brief Pain Inventory) is closely associated with greater reported CPSP severity and the presence of neuropathic characteristics at 6 and 12 months.[14] Preoperatively assessed characteristics including state anxiety, preoperative pain status, and moderate to severe acute postoperative pain predicted greater CPSP interference.[54] A prospective longitudinal examination of a comprehensive set of preoperative variables (demographic, biomedical, and psychosocial factors) allowed an assessment of these variables' independent predictive potential for CPSP, including both pain measures of severity and impact on physical, cognitive, and emotional functioning impact.[18] Interestingly, predictors of severity and predictors of impact were only partially overlapping and depended on whether a surgery-specific questionnaire or a more general pain questionnaire was used (Fig. 24.5). Consistent independent predictors across pain outcomes included preoperative surgical area pain, less formal education, and greater baseline sleep disturbance, while pain catastrophizing, affect, younger age, higher body mass index, and chemotherapy were more consistently predictive of pain impact, but not severity.

Risk Factors for Persistent Postoperative Opioid Use

Rates of new persistent opioid use, defined as use for over 90 days after surgery in opioid-naïve patients, were 5.9% for minor surgeries and 6.5% for major surgeries (non-operative control arm 0.4%) according to a large study of 36,177 patients undergoing various procedures in the United States.[82,83] As the prevalence was similar between minor and major surgeries (OR 1.04 [0.93,1.18]), these findings suggest that prolonged opioid use after surgery cannot be simply explained by the extent of surgical injury. The multivariable analysis revealed that significant risk factors for persistent opioid use included tobacco use, alcohol and substance abuse disorders, mood disorder, anxiety, and preoperative chronic pain, thus including many of the same risk factors associated with CPSP.

Risk Factors for Neuropathic Features Involved in CPSP

Neuropathic features, such as burning, pins and needles, and stabbing, are often coincident with CPSP, with a reported range from 6% to 80%.[12,15] These features are also often associated with a



• **Figure 24.5** Assessment of comprehensive set of biopsychosocial risk factors for independent association with different post-surgical pain outcomes at one year. Schreiber KL, Zinboonyahgoon N, Flowers KM. Prediction of Persistent Pain Severity and Impact 12 months after Breast Surgery using Comprehensive Preoperative Assessment of Biopsychosocial Pain Modulators. *Ann Surg Oncol* 28, 5015–5038 (2021). https://doi.org/10.1245/s10434-020-09479-2[18]

more pronounced functional impairment.[14] Similar to the close relationship between acute and chronic pain severity, early neuropathic features (on postoperative day two) are strongly associated with persistent post-surgical neuropathic features at later time points (two months), OR 4.22 [2.19–8.12].[84]

Prediction Models

Previous research has uncovered many candidate risk factors through cross-sectional and prospective longitudinal studies of CPSP. Recognizing the interrelatedness of many of these candidate risk factors, several groups have worked to identify independent predictors using multivariable regression models. Such multivariable prediction modeling aims to achieve the most accurate prediction while reducing the number of predictors to a manageable set. These models may gain a better understanding of the mechanisms underlying CPSP and enrich preventive interventional CPSP trials.

A risk index for CPSP was developed by Althaus et al. in 2012,[56] which included several previous and acute pain-related variables (preoperative pain in the operative area, other preoperative pain, acute post-surgical pain) and two variables related to physical and psychological stress (answering yes to a question about capacity overload/overstrain, and answering yes to having one of the following: sleeping disorder, exhaustibility/exhaustion, frightening thoughts, dizziness, tachycardia, feeling of being misunderstood, trembling hands, or intake of sleeping/sedation pills). This risk index was used to classify patients into low risk (zero to one risk factor), moderate risk (two risk factors), and high risk of developing CPSP (three–five risk factors presented) (Fig. 24.6). In this model, when including acute pain and other preoperative pain variables in the model, other predictors such as sex and type of surgery, minimally invasive versus open, did not emerge as independent predictors from the multivariable analysis process.

In 2015, Montes et al.[16] developed a predictive model from a large prospective multicenter cohort study that enrolled 2,929 patients scheduled for various surgical procedures (vaginal hysterectomy, abdominal hysterectomy, hernia repair, and thoracotomy). The resultant multivariable model included six predictors: preoperative pain at the surgical site, preoperative pain at another body site, more extensive surgery (higher risk for thoracotomy), younger age, and overall physical and mental condition (SF-12 physical and mental score subscales) (Table 24.4). Taken together, these factors predicted the risk of developing CPSP at four months after surgery with reasonable accuracy (approximately 70%), even when the procedure type was excluded. One advantage of a model that includes only factors known before the procedure is that it may allow the clinician to develop preventive plans for high-risk individuals in the preoperative period. This model was applied for validation at additional hospital centers and reported a similar accuracy of prediction, demonstrating reasonable geographic and temporal generalizability across populations of comparable patients.[85]

Prevention of CPSP

Considering the putative mechanisms and modulators of CPSP, many therapies aimed at modulating or preventing CPSP involve aspects of this proposed pathophysiology, targeting events in peripheral tissues, including nerves at the site of injury, as well as events at the spinal cord or above (Table 24.5). The strategies include early and aggressive pain control by analgesic and regional anesthesia, modification of the surgical approach, and psychological-behavioral adaptation.

TABLE 24.4 Comparison of Two Models to Predict the Development of Chronic Post-surgical Pain (CPSP)

Model	Althaus et al. 2011[56]	Montes et al. 2015[16]
Study design	150 patients undergoing various types of surgery	Prospective multicenter cohort, 2929 patients undergoing vaginal hysterectomy, abdominal hysterectomy, hernia repair, or thoracotomy
Factors	1. Capacity overload (+)* 2. Preoperative pain, surgical site (+) 3. Other chronic preoperative pain (+) 4. Postoperative acute pain (+) 5. Comorbid stress symptoms (+)	1. Surgical procedure (+,–) 2. Age (–) 3. SF-12 physical (–) 4. SF-12 mental (–) 5. Preoperative pain, surgical site (+) 6. Preoperative pain, other sites (+)
Risk calculation	Summation of the five risk factors and classify them into low, moderate, and high risk of developing CPSP six months after surgery.	Complex equation from six factors calculating the risk of developing CPSP four months after surgery in 73% of the patients.

(+) increased risk, (–) decreased risk, *capacity overload = answering yes to having one of the following: sleeping disorder, exhaustibility/exhaustion, frightening thoughts, dizziness, tachycardia, feeling of being misunderstood, trembling hands, or intake of sleeping/sedation pills.

TABLE 24.5 Targets to Prevent Chronic Post-surgical Pain (CPSP): Various Interventions Can Act at Several Targets Along the Pain Pathway Initiated by Surgical Injury to Prevent CPSP

Targets and Risk Factors	Intervention
Peripheral tissues, including nerves	Modification of surgical approach
Peripheral nerve activation	Regional anesthesia
Local inflammatory response and neurogenic inflammation	Regional anesthesia Anti-inflammatory (COX-2, NSAIDs, acetaminophen)
Peripheral nerve sensitization and continued ectopic firing	Regional anesthesia Ca_v α2-δ ligands (gabapentin, pregabalin)
Changes in gene expression at dorsal root ganglion	Regional anesthesia Corticosteroids (dexamethasone) Anti-inflammatory (COX-2, NSAIDs)
Central sensitization	Regional anesthesia NMDA antagonists (ketamine, magnesium, dextromethorphan, amantadine) Corticosteroids α-2 adrenergic agonists (clonidine, dexmedetomidine) Opioid receptor agonists
Descending facilitation from the brainstem	Anti-inflammatory (COX-2, NSAIDs, acetaminophen) Anti-depressant
Limbic system and hypothalamus	Psychological-behavioral interventions Anti-depressants Anxiolytics
Cortical pain processing	Assessment and pre-screening Psychological-behavioral interventions Setting appropriate expectations
Genomic DNA leading to a predisposition to chronic pain	Assessment and pre-screening

COX-2, Cyclooxygenase-2; NMDA, *N*-methyl-D-aspartate; *NSAIDs*, nonsteroidal anti-inflammatory drugs.

Chen Y-YK, Boden KA, Schreiber KL. The role of regional anaesthesia and multimodal analgesia in the prevention of chronic post-surgical pain: a narrative review. *Anaesthesia*. 2021;76(1):8–17.

Analgesics and Regional Anesthesia

As the severity of acute pain after surgery is strongly associated with CPSP, excellent perioperative pain control is a logical goal. Early and proactive perioperative pain management using a combination of different analgesic agents and techniques (multimodal analgesia) has been applied to this goal, with varying effects and conclusiveness.

Analgesics

Systemic Lidocaine

Lidocaine is classically known to block voltage-gated sodium channels when administered in direct proximity to nerves. However, additional mechanisms of action may include modulation of hyperpolarization-activated cyclic nucleotide-gated channels, transient receptor potential ion channels, and certain G-protein-coupled receptors (GPCRs),[86,87] when administered systemically via the intravenous route. Administration of intravenous lidocaine is associated with analgesia beyond the duration of its pharmacokinetics, possibly by its impact on immune and neural targets and by reduction of central sensitization.[86]

A recent meta-analysis including six high-quality post-surgical studies using 1.5–2 intravenous lidocaine bolus over 10–15 min, then 1.5–2 mg/kg/h infusion until the end or 1–2 h after the operation,[32] found that perioperative lidocaine administration reduced the incidence of CPSP at three and six months after surgery (OR 0.29 [0.18 to 0.48]).[32] Intravenous lidocaine was also associated with a trend toward lower pain scores (Fig. 24.7). There were no reported adverse events of systemic lidocaine in these studies, although only one study reported lidocaine plasma levels.[88] The subgroup analysis for lidocaine infusion in a meta-analysis by Weinstein[31] also showed a preventive effect for CPSP after breast cancer surgery (Table 24.6).

Ketamine

As NMDA receptors play a pivotal role in central sensitization,[89,90] the NMDA receptor antagonist ketamine has been frequently studied for its utility in the prevention of CPSP.[26,91,92] A meta-analysis by Chapparo showed that perioperative infusion of ketamine decreased the incidence of CPSP (any value greater than 0/10) at six months, compared to a placebo (OR 0.50, [0.33, 0.76]), and the number needed to treat to prevent one patient from moderate to severe CPSP was 10.83 [5.7–109].[26]

The analysis did not show a preventive effect of ketamine at three months and was underpowered to determine a preventive effect at 12 months because of heterogeneity. Subsequent meta-analyses by McNicol et al.[92] and Klatt et al.[91] were not supportive of a long-term preventive effect for ketamine, again possibly because of heterogeneity in study design and definition of CPSP (Table 24.6), as most of the trials included were small, the populations heterogenous, and ketamine used in varying protocols (intravenous bolus 0.2–1 mg/kg or infusion 0.05–0.25 mg/kg/h).[92] An important consideration for studying the prevention of clinically meaningful CPSP (pain of at least 3/10 or higher) is that the majority of subjects entering the study do not develop the

TABLE 24.6 Meta-analyses of Pharmacologic Agents to Prevent Chronic Post-surgical Pain

Medication	Surgery	Odds Ratio (95% Confidence Interval)	Heterogeneity	N	Pain Score and Follow-up (Months)	References
Lidocaine	Breast	0.24 [0.08–0.69]	I2 = 0%	97	Any pain, three to six months	Weinstein 2018[31]
	Breast, thyroid, kidney	0.29 [0.18–0.48]	I2 = 0%	420	Three to six months	Bailey 2018[32]
Ketamine	Amputation, breast, thoracic, orthopedics, abdomen/pelvis	0.50 [0.33–0.76]	I2 = 0%	516	Any pain, six months	Chapparo 2013[26]
	Amputation, breast, thoracic, orthopedics, hemorrhoid, mixed	0.84 [0.70–1.01]	I2 = 15%	771	Any pain, three to six months	McNicol 2014[92]
Gabapentin	breast, thyroid, cardiac, cesarean section, gyn, orthopedics, abdomen	0.52 [0.07–0.98]	I2 = 30.5%	356	Three to six months	Clarke 2012[94]
	Amputation, breast, thoracic, cardiac, cesarean section	0.97 [0.59–1.59]	I2 = 0%	280	Any pain, three months	Chapparo 2013[26]
Pregabalin	Cardiac, orthopedics	0.09 [0.02–0.79]	I2 = 0%	285	Three to six months	Clarke 2012[94]
	Orthopedics, cardiac, spine, thyroid	0.60 [0.39–0.93]	I2 = 28.5%	439	Any pain, three months	Chapparo 2013[26]
	Orthopedics, cardiac, spine, thyroid, thoracic, abdomen	0.87 [0.66–1.14]	I2 = 43%	1,884	Any pain, three months	Martinez 2017[95]

outcome (if only 35% develop CPSP); thus many studies are underpowered. Studies employing screening to enrich preventive trials with patients at higher risk of CPSP are needed to confirm the efficacy of ketamine in preventing CPSP. Meanwhile, ketamine is also increasingly being used to treat already established chronic pain,[89] including CPSP, although little is known about the efficacy and duration of the effect of such treatments.

Other NMDA receptor antagonists, including dextromethorphan, magnesium, memantine, and nitrous oxide, have shown some benefit in acute postoperative pain, but their role in CPSP is largely unknown.[26,79] A small randomized controlled trial showed that women treated with memantine had a modest reduction in pain (p = 0.017) and reduced referral for postoperative neuropathic pain treatment (p = 0.040) three months after mastectomy.[93]

Gabapentinoids

Gabapentinoids, including gabapentin and pregabalin, reduce pain by inhibiting the α2δ subunit of presynaptic voltage-gated calcium channels, which are upregulated after injury, forming a rational target for prevention.[79] However, the clinical evidence for their potential to prevent CPSP is still mixed.[26,94–96]

Gabapentin

Most clinical trials failed to demonstrate a reduction in the incidence of CPSP with gabapentin at three and six months. Although a meta-analysis by Clarke et al.[94] (pooled data from eight studies) showed marginal benefit over placebo (OR 0.52 [0.27–0.98]), subsequent meta-analyses by Chaparro et al.[26] (ten trials) and Verret et al.[96] (27 trials for gabapentinoids, risk ratio, 0.89 [0.74–1.07])

did not support its preventive effect. Some studies with relatively high doses of gabapentin (1,200–1,800 mg/day) have suggested an analgesic effect, but these doses are associated with significant side effects such as sedation, dizziness, and visual trouble.[79]

Pregabalin

The evidence for the preventive effect of pregabalin was also mixed. The early meta-analysis by Chapparo (five trials) and Clarke (three trials) appeared promising,[26,94] with OR 0.60 [0.39–0.93] and OR 0.09 [0.02–0.79], respectively. However, several negative unpublished trials were not included, and subsequent additional negative studies contributed further evidence against a preventive effect.[95,96] This included a meta-analysis of 18 trials in which pregabalin failed to demonstrate effectiveness in preventing CPSP (Table 24.6).[95] Similar to gabapentin, pregabalin was also associated with significant sedation and decreased satisfaction.[79]

Other Pharmacologic Agents

Peripheral and central sensitization involves the activation of inflammatory mediators and changes in the plasticity of multiple receptors along the pain pathway, with many corresponding potential pharmacologic targets aimed at preventing CPSP.

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

The inflammatory state from surgery leads to upregulation of several mediators, including cyclooxygenase-2 (COX-2) and prostaglandins, which can drive both peripheral and central sensitization.[97] COX inhibitors and classical NSAIDs help reduce the intensity of acute pain but still lack high quality clinical evidence showing as preventive for CPSP.[79,98]

α-2 Adrenergic Agonists

The activation of α-2 adrenoceptors spinally results in analgesia and may show important synergism with spinal opioids. However, antagonism of these receptors outside of the spinal cord results in side effects, including sedation and reduction of sympathetic tone.[99] The most commonly studied α-2 adrenoceptor agonists are clonidine and dexmedetomidine. One study showed that dexmedetomidine infusions during breast surgery reduced chronic pain intensity three months postoperatively.[100] A few studies investigating systemic or neuraxial clonidine reported efficacy in preventing CPSP. However, these studies were small, preliminary, uncontrolled, and did not have CPSP as a primary outcome.[79] Despite the potential of α-2 agonists for acute postoperative pain,[101] evidence is currently too limited to draw a conclusion regarding the preventive effect of CPSP.

Based on available data, there is very limited evidence on the preventive effects of CPSP available for other drugs, including mexiletine, acetaminophen, corticosteroids, and opioids.[79,98] High-quality, well-controlled, enriched, and stratified studies are needed to confirm or refute the efficacy of these agents.

Regional Anesthesia

Regional anesthesia (RA), including both peripheral nerve or neuraxial blocks, aims to inhibit nociceptive impulse transmission. Because RA reduces pain signals transmitted to the spinal cord and supraspinal and cortical nociceptive centers, it may also indirectly prevent glial cell activation and minimize the synaptic plasticity of neurons, thus decreasing central nervous system sensitization. Reduction of central sensitization with RA has been demonstrated in several animal models in the acute phase.[13] Local anesthetics may also have anti-inflammatory properties, which could also decrease sensitization. Animal models and in vitro studies have suggested that local anesthetics may reduce ectopic firing of neurons, expression of cytokines and other inflammatory mediators, and decrease neutrophil priming.[13,30] When used in combination with other multimodal analgesics, RA serves as a potent tool that affects many targets along the pain pathway, as shown in Table 24.5.

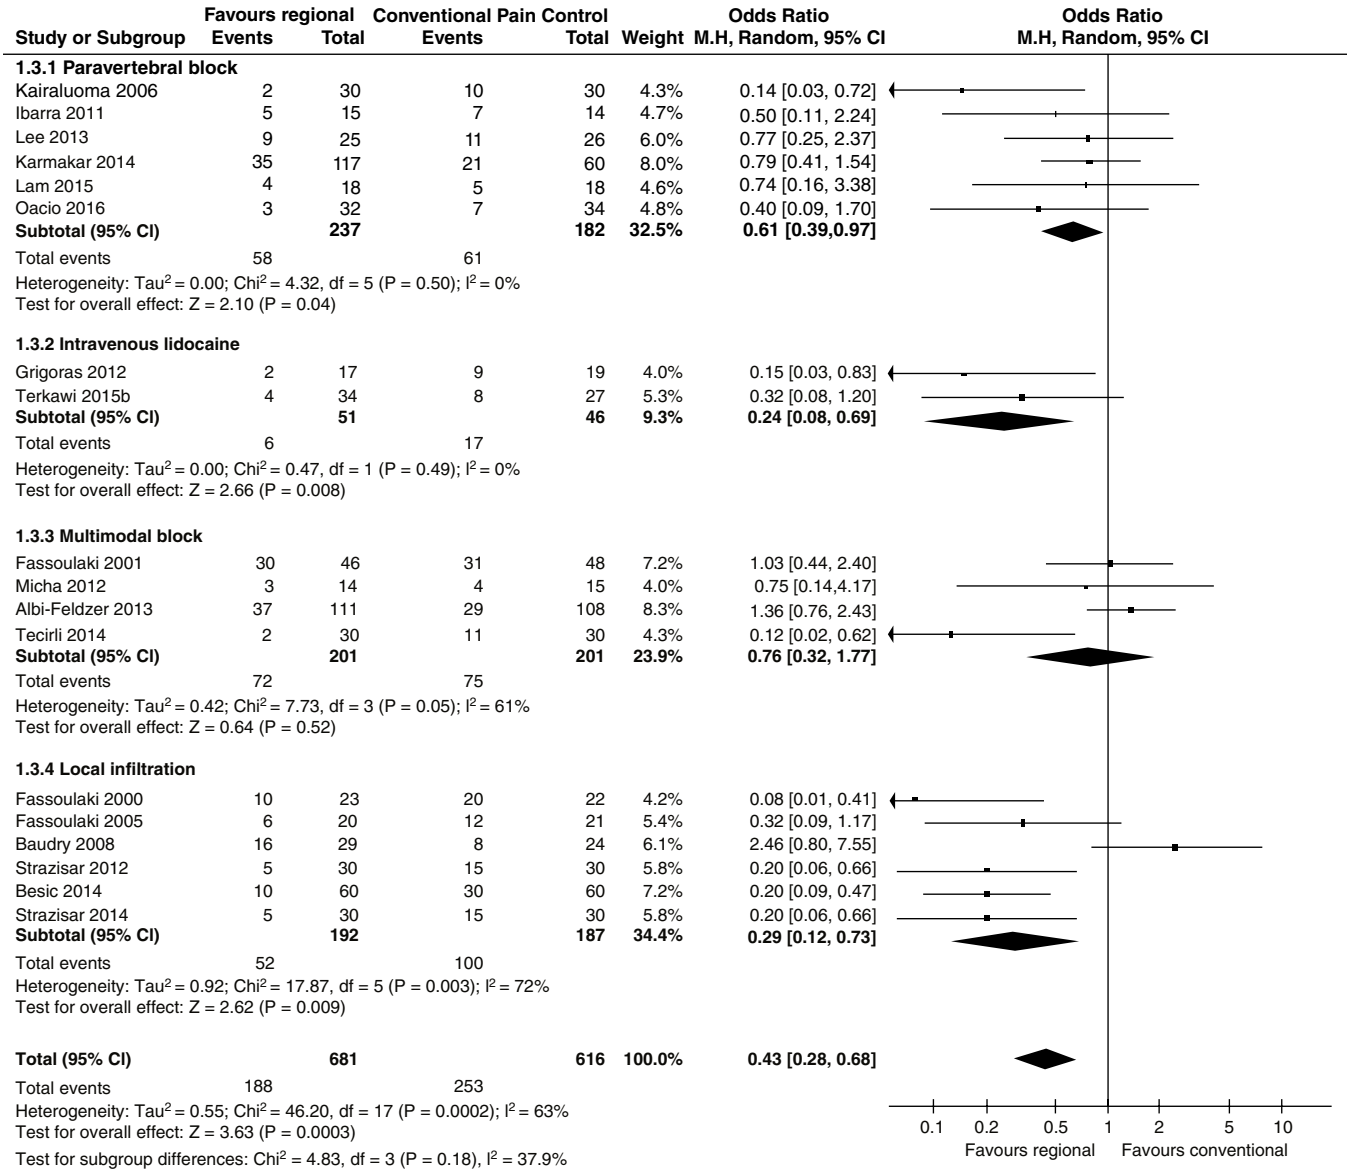
Beyond the theoretical and pre-clinical benefits, growing clinical evidence of the potential preventive impact of RA on CPSP is especially clear for breast and thoracic surgery. A meta-analysis by Weinstein et al.[31] showed that a variety of regional anesthetic techniques, including epidural block, peripheral nerve block, and local infiltration, are associated with a lower risk of CPSP (Fig. 24.8). Subgroup analysis also showed independent preventive effects for breast surgery, thoracic surgery, and cesarean delivery (Table 24.7).

Breast surgery has been the most widely studied surgical intervention for the impact of RA on CPSP. A meta-analysis[31] showed an overall benefit for CPSP from local anesthetics in multiple modes of administration, including intravenous lidocaine, local infiltration, paravertebral block, and multimodal block (intercostal block, intercostobrachial nerve block) despite the high degree of heterogeneity (OR 0.43[0.28–0.68], p = 0.0003) (Table 24.7). Subgroup analyses also showed a preventive effect for paravertebral blocks and some promise of less common alternative approaches, including intercostal and pectoral nerve-2 (PECS 2) blocks.[102,103]

A preventive effect of RA for post-thoracotomy persistent pain has been shown in a meta-analysis that favor regional anesthesia (epidural analgesia, five studies; intercostal nerve block and wound irrigation, one study each) with an OR of 0.52 [0.32–0.84] (p = 0.008).[31] Epidural block showed the greatest preventive effect for CPSP, while other modalities, including continuous wound irrigation and intercostal nerve blocks, were less effective (Table 24.7).[104,105] Nevertheless, this analysis did not include paravertebral blocks. Paravertebral blocks have been shown to provide efficacy equivalent to epidural blocks for the management of thoracic surgical pain, and paravertebral blocks may also reduce the incidence and/or intensity of CPSP.[105–107]

Overall, a reduction in CPSP after cesarean delivery is associated with RA use (transverse abdominis plane [TAP] blocks, intraperitoneal installation, or local infiltration) (OR 0.46 [0.28–0.78], p = 0.004) (Table 24.7).[31] However, the number needed to treat to prevent one case of CPSP is much higher than mastectomy or thoracotomy (19 versus 7 and 7, respectively), mainly because of the lower incidence of CPSP after cesarean delivery. The role of RA in other surgical procedures, including limb amputation, cardiac surgery, laparotomy, hernia repair, prostatectomy, and hysterectomy, is informed by a smaller pool of randomized controlled studies available for review, supporting CPSP prevention by RA for these operations is less clear.

A growing body of evidence regarding pharmacologic and interventional measures, such as RA, to prevent CPSP is welcome. However, while evidence is needed to inform clinical practice, the heterogeneity of design, definition, and methods makes the cogent interpretation of this evidence challenging. As the definition of CPSP is not universal (pain intensity and time after surgery), the estimated incidence in each study can vary considerably, from to 70%–80% in some studies, with more conservative estimates in the 20%–30% range. Although the performance of meta-analyses may abrogate this problem to some extent, the heterogeneity of studies in the pool often makes the results inconclusive.



• **Figure 24.8** Forest plot and subgroup analysis of the effect of local anesthetics and regional anesthesia on postmastectomy pain at three to 12 months. With permission from Weinstein et al.[31]

TABLE 24.7 The Effect of Regional Anesthesia on Prevention of Chronic Post-surgical Pain in Mastectomy, Thoracotomy, and Cesarean Delivery

Surgery	Regional Anesthetic Technique	Odds Ratio (95% Confidence Interval)	NNT (95% Confidence Interval)	Heterogeneity	*N*	Follow-Up (Month)
Mastectomy	Paravertebral, nerve block, local infiltrate, intravenous lidocaine	0.43 (0.28–0.68)	7 (6–13)	I2 = 72%	1297	Three to 12 months
	Paravertebral	0.61 (0.39–0.97)	NA	I2 = 0%	419	Three to 12 months
Thoracotomy	Epidural analgesia, intercostal block, wound irrigation	0.52 (0.32–0.84)	7 (4–23)	I2 = 14%	499	Three to 18 months
Cesarean section	TAP block*, intraperitoneal installation or local infiltration	0.46 (0.28–0.78)	19 (14–49)	I2 = 0%	551	Three to eight months

TAP block, Transversus abdominis plane block.

As surgical techniques and instrumentation have improved over time, the degree of surgical extent may be quite different between studies over time (e.g. reduction in the performance of radical or even radical mastectomy in the case of breast cancer, although all surgeries were grouped together as breast surgery).

Surgical Technique Modification

Surgical factors, including a greater degree of tissue or nerve injury, have been variably associated with increased incidence and severity of CPSP. Some evidence suggests that more minimally invasive surgical approaches may result in lower CPSP incidence, such as vaginal vs. abdominal hysterectomy, which is associated with a lower incidence of CPSP at all time points (Fig. 24.1).[16] Laparoscopic inguinal hernia repair is associated with less acute and chronic post-surgical pain than open inguinal hernia repair.[46–48] In breast cancer surgery, axillary lymph node dissection (ALND) is a consistent risk factor for CPSP across many studies and meta-analyses (compared to sentinel node biopsy or no axillary procedure).[18,108] Injury of the intercostobrachial nerve (ICBN) has been cited as a likely mechanism of CPSP after ALND because the ICBN traverses the axillary lymph node bed. Studies showing preservation of the ICBN during ALND are associated with a reduced incidence[109] and severity[110] of CPSP, and less sensory deficit, without a significant increase in total surgery time.[111]

In other cases, the surgical extent appears to play a less important role. Patients who undergo breast-conserving surgery (lumpectomy) do not have lower rates of CPSP than patients undergoing total mastectomy, especially when measured at later time points (> one year).[10] Less invasive surgery has also not consistently resulted in a lower incidence of CPSP in the case of thoracic surgery, especially at later time points. Compared to open thoracotomy, video-assisted thoracoscopic surgery is variably associated with a lower incidence of CPSP at six months,[112,113] but similar incidence at one year.[113] Laparoscopic cholecystectomy also tends toward reduced rates of moderate to severe CPSP, but overall laparoscopic and minimally invasive procedures versus open for cholecystectomy are associated with similar incidences of CPSP, with a similar result for colectomy.[14] These modest effects of surgical modification underline the importance of considering other risk factors in the biopsychosocial model to understand and prevent CPSP.

Psychological Intervention

Many psychological factors such as anxiety, depression, and pain catastrophizing are associated with a higher risk of CPSP. Psychological treatments such as cognitive-behavior therapy or acceptance and commitment therapy are associated with improved pain related outcomes in patients with chronic pain.[34,114–117] Increasingly, these strategies are employed as a possible preventive measure in the perioperative period, with some studies indicating that preoperative psychological interventions, such as brief acceptance-based psychological intervention,[118] along with the routine pre-surgical protocol or pain education,[119] can improve pain related outcomes, analgesic demand, anxiety,[118] and pain intensity,[119] in the acute postoperative period. However, the effect of these behavioral interventions on the prevention of CPSP remains largely unknown.

Understanding an individual patient's psychological profile may facilitate the rational application of behaviorally based preventive strategies. One study that stratified the results of a regional anesthetic based on whether patients scored higher or lower on a measure of pain catastrophizing suggested that RA (paravertebral block) provided analgesic benefit for mastectomy patients was more pronounced among patients with higher baseline catastrophizing scores.[120] More research on the differential effect of traditional or non-traditional preventive interventions for CPSP among patients with different risk factors is needed to tailor treatment according to individual risk.

Future Directions

CPSP is an active area of study, with much left to be understood, from understanding the underlying mechanisms to identifying the best preventive strategies. Having a consistent taxonomy, definition, and diagnostic criteria for CPSP is an important first step to better delineate its true incidence, temporal characteristics, and impact. Although evidence consistently shows a strong association between acute post-surgical pain and CPSP, and this risk factor dominates many of the prediction models developed up to this point, it is unclear whether acute pain should be considered a temporal correlate of chronic pain or a truly modifiable risk factor. Providing excellent control of acute postoperative pain is unquestionably an important goal in its own right, and thus proving causality may be challenging. Viewing CPSP through the lens of the biopsychosocial model, it seems clear that CPSP, like many types of chronic pain, is a complex reaction to the physical injury of surgery, which is influenced by biologic, psychological, social, and psychosocial factors. Comprehensive assessment of a wide range of putative factors from this biopsychosocial model, including pain sensitivity and psychological and genetic factors, may allow greater fidelity of risk assessment and specific preventive, personalized preventive strategies based on an individual's profile.[121] Long-term pain outcomes other than severity, including functional impairment and impact, and long term opioid use, should also be included in efficacy studies. Testing novel preventive measures, including psychological interventions, new pharmacologic agents, or combinations of multimodal analgesia, will continue to advance the capacity to prevent CPSP. Preoperative evaluation and consultation will continue to be essential to the design of preventive trials and clinical care planning.[122]

Summary

CPSP has a high impact on a patient's quality of life and is a common untoward consequence after surgery. CPSP is defined as pain developing or increasing in intensity after a surgical procedure and persisting beyond three months. Proposed mechanisms include nerve injury, peripheral and central neuroplasticity, and possibly OIH. As the type of operation and degree of tissue injury cannot solely explain the risk of CPSP, additional risk factors from the biopsychosocial model, including preexisting pain and pain sensitivity, as well as contributing psychosocial factors, may allow for a more comprehensive explanation and prediction of CPSP. Clinical evidence regarding the efficacy of preventive measures has been mixed, but mainly positive for systemic lidocaine, ketamine, RA, and surgical technique modification for certain procedures. Although our understanding of CPSP has grown tremendously over the years, more studies are needed to understand this complex phenomenon.

Key Points

- CPSP is a relatively common consequence of surgery and may negatively impact patients' quality of life. Effective prevention of CPSP is an important clinical goal, as informed by a growing body of studies.
- CPSP is defined as chronic pain that develops or increases in severity after a surgical procedure, which persists beyond the healing process, typically at least three months or longer. CPSP is most commonly localized to the surgical field, but may also include pain within the innervation territory of a nerve affected by the surgery. Other causes must be excluded from the diagnosis of CPSP to be made.
- The mechanism by which CPSP develops is not completely understood, but it likely includes nerve injury and neuroplasticity and may involve OIH. Preventive analgesia, opioid-sparing strategies, and modification of surgical techniques may modify the transmission of the nociceptive signal and subsequent maladaptive plasticity in the peripheral and central nervous systems.
- Risk factors for CPSP may be categorized using the biopsychosocial model, ranging from biologic factors such as surgical extent, genetics, age, sex, preexisting pain, and pain modulation, to psychological and social factors such as anxiety, depression, catastrophizing, coping strategies, and community support and resources. Recognizing and measuring these baseline factors may inform the assessment of CPSP risk. Some general and procedure-specific predictive models using some of these risk factors have been proposed to help stratify risk and tailor preventive measures.
- Preventive measures may include minimally invasive surgery, aggressive acute postoperative pain control, and preventive analgesia. Several perioperative pharmacologic interventions such as ketamine, lidocaine infusion, and RA appear promising for the prevention of CPSP, although the evidence remains somewhat mixed.
- Successful preventive treatment for CPSP likely depends on identifying the type of pain, recognizing the type of individual, and employing a multimodal, multi-disciplinary, and personalized approach to tailor treatments according to individual risk factors.

Evaluation and Pharmacologic Treatment of Postoperative Pain

LAUREN K. DUNN, PRIYANKA SINGLA

Pain after a surgical procedure is inevitable. However, as stated by Haruki Murakami, "Suffering is optional."

Management of postoperative pain has come a full circle. The Joint Commission recognized the underassessment and undertreatment of pain in 2000 and introduced the concept of pain as the fifth vital sign.[1] However, the emphasis of The Joint Commission on the use of opioids for pain control has been criticized as a contributing factor in the prescription opioid epidemic that the modern world is facing.[2] Enhanced recovery pathways involving multimodal analgesia with emphasis on limiting opioids have become the cornerstone of managing pain in the postoperative setting.

A majority of patients who undergo surgery report inadequate pain control.[3] Causes of ineffective pain control include lack of accurate assessment and patient factors such as fear of adverse effects or addiction from medications.[4] Poorly controlled pain increases the incidence of postoperative complications such as pneumonia, delirium, delayed wound healing, and evolution of acute pain into chronic pain,[5,6] while optimal pain control improves patient satisfaction and enhances the quality of recovery.[4,7]

Pain management is an important ethical responsibility of every clinician. Adequate pain control requires finesse to find the delicate balance between minimizing immediate adverse effects and preventing long term dependence on opioids. Many institutions have developed standardized guidelines for perioperative analgesia in the form of enhanced recovery after surgery (ERAS) protocols. The acute pain service is an integral part of most anesthesiology departments, with a focus on providing optimal pain management in the postoperative period. Assessment and management of pain in opioid dependent patients and pain in children are beyond the scope of this chapter and are discussed in Chapters 27 and 28, respectively.

Management of postoperative pain starts with an accurate assessment. Guidelines from the American Pain Society recommend that "*clinicians use a validated pain assessment tool to track responses to postoperative pain treatments and adjust treatment plans accordingly*."[3] Effective pain management takes into account the surgical procedure performed and individual patient factors such as comorbidities and the use of preoperative narcotics.[3] The goal of pain assessment is to determine the analgesic requirements of the patient and if there is a need to change the treatment plan.[3]

Evaluation of pain can be extremely challenging as pain is largely subjective.[4,8] There are multiple evaluation tools available for postoperative pain assessment. However, most require patient participation, which can be difficult in the immediate postoperative period when the patient is still emerging out of anesthesia.

Comprehensive postoperative pain assessment includes several components. Although severity is the most easily quantifiable measure, attention should be paid to other characteristics of pain, including location, quality, onset, progression, radiation, aggravating and relieving factors, and effects of therapy.[3] Pain symptoms that are at an inappropriate site or of unexpected severity based on the surgical procedure performed should be investigated for causes other than the surgery itself.[3,4] Unexpectedly high pain can be because of opioid tolerance, anxiety, a new medical problem unrelated to surgery, or a potential complication from the surgery itself.[3]

Evaluation of Pain Using Pain Scales

Numerous self-reported pain scales have been developed to quantify the severity of pain (Table 25.1). Among the most frequently used scales are:

Visual Analog Scale (VAS)
Numeric Rating Scale (NRS)
Verbal Rating Scale (VRS)

Visual Analog Scale

VAS is measured by drawing a 10 cm or 100 mm straight line. This line is anchored at each end by a perpendicular line that represents two extremes of pain—no pain on the left end and most intense pain imaginable on the right end. The patient is asked to make a mark at a point on the line, which represents the patient's level of perceived pain intensity, and the scale is scored by measuring the distance from the end with no pain to the patient's mark.[9–12] The line may be depicted with a horizontal or vertical orientation, though a horizontal line is generally preferred.[10] The VAS has often been recommended as the measure of choice for assessment of pain intensity.[10]

It has been suggested that a single VAS score is probably not the most accurate measure of a patient's pain but is probably within the range of +/–20 mm.[13] A change of 10 mm out of 100 mm pain VAS is considered the minimal clinically important difference, i.e. the minimal change in a pain VAS score that would indicate a significant change in a patient's pain intensity, and the VAS of 33 or less signifies acceptable pain control after surgery.[14,15] VAS is sensitive to treatment effects[10] and shows ratio level scoring properties.[10,16] The reliability of VAS depends on the patient's

TABLE 25.1 Commonly Used Scales for Postoperative Assessment of Pain

Pain Scale	Range	Advantage	Disadvantage
Visual Analog Scale	0–10 (cm) 0–100 (mm)	Sensitive to treatment effect Shows ratio level scoring property	Requires visual motor coordination from the patient
Numeric Rating Scale	0–5(6) 0–10(11) 0–20(21) 0–100(101)	Verbally scored Easy to administer High compliance Sensitive to treatment effect	Lacks ratio level scoring property
Verbal Rating Scale	No pain to most intense pain	Easy to understand Better compliance in elderly	Requires patient familiarity with adjectives Interval between adjectives not equal

ability to place a mark at the intended spot and requires visual and motor coordination.[11] VAS may be challenging to obtain in patients with cognitive impairment,[10] and freedom of choice provided by VAS could be confusing for some patients.[12]

VAS shows a good correlation with NRS in patients with arthritis.[12] However, its usefulness may be limited in the immediate postoperative period, especially in phase 1 of recovery when the patient may have residual effects of anesthesia, blurred vision, or nausea.[13] Nonetheless, it is a simple, useful, and valid tool to assess and reassess a patient's pain and response to therapy if the problems intrinsic to the score itself are considered.[13]

Numerical Rating Scale

NRS consists of a numeric scale ranging from 0 to 10, 0 to 20, or 0 to 100.[3,9,10,17,18] Zero represents no pain, whereas the higher end (10, 20, or 100) represents the most intense pain. NRS can be administered verbally or in a written format.[10,17] When presented graphically, the numbers are often enclosed in boxes, and the scale is referred to as an 11 or 21-point box scale depending on the number of levels of discrimination offered to the patient.[17] Its advantages include that it is simple, easily understood by the patient, and is easily administered and scored by the caregiver.[10] It is a valid tool with a high compliance rate and good consistency over time, which correlates positively with other measures of pain and shows sensitivity to treatments.[8,10] The principal limitation of NRS is that it does not have ratio qualities, implying that the difference between two and four and the difference between four and six may not represent equivalent intervals in terms of scaling of the intensity of pain.[10] Its major advantage over VAS is that it can be used in patients with visual impairment by recording verbal responses.[17] One author has described the successful use of a six-point NRS (0-5) during the postoperative period in patients with dementia.[17] The six-point NRS is a simplified version of NRS 11.[17] It was reported to be reliable, valid, and much easier to administer in patients with dementia.[17]

The 100 mm VAS and NRS 11 are the most commonly used scales for postoperative pain assessment.[14] A limitation of both scores is that the definition of worst imaginable pain differs among individuals.[10] This can be taken care of by providing the patient with some context of the worst imaginable pain.

Verbal Rating Scale

The VRS comprises a list of adjectives that describe increasing levels of pain.[9,18] The most common words used are no pain, mild pain, moderate pain, and severe or intense pain.[18] To simplify the documentation, each adjective is assigned a number. The least intensity (no pain) is assigned the number 0, with subsequent intensity assigned one number higher.[9,18] The strengths of VRS include its simplicity, ease of administration, and scoring.[10] It is straightforward for patients to comprehend, which is important in the very early postoperative period and is most easily understood by patients with cognitive impairment.[19,20] VRS has much superior compliance rates in the elderly than other scales.[10] One of the pitfalls of this scale is that the interval between each adjective is not equal.[18] Also, the patient must be familiar with words used to describe the pain and should be able to choose the one that describes his/her pain accurately.[10]

Clinical Evaluation of Pain

Along with self-reporting of pain, patients should be observed for clinical signs of distress that include:[8]

- facial expression of pain, such as grimacing;
- audible expression of pain, such as moaning or crying;
- ambulation in the form of limping or posture, e.g. lying in a fetal position; and
- avoidance of activities or specific movements.

Assessment tools such as the behavioral pain scale (BPS) and critical-care pain observation tool (CPOT) can help clinicians assess pain control in patients with cognitive impairment or sedation.[3,21] The CPOT has four components[22,23]—facial expression, body movements, resistance to passive flexion, and compliance to the ventilator in intubated patients or vocalization in extubated patients. The scale is scored from zero to eight, with zero being no pain and eight being maximum possible pain (Table 25.2).[23] The BPS has three components—facial expression, upper limb movements, and compliance with mechanical ventilation, scored on a scale of one to four.[23–25] BPS scores range from three (no pain) to 12 (maximum pain) (Table 25.3).[23]

Both scales are used routinely in the intensive care unit to assess pain in intubated and sedated patients. Increases in heart rate and blood pressure have been suggested as sympathetic responses to noxious stimuli. However, caution must be used when interpreting changes in these vital signs that may also be influenced by other factors, such as postoperative use of vasopressors and inotropes. Behavioral and physiologic indicators are especially important indices for the assessment of pain in patients who are unable to self-report.[22]

Functional Assessment of Pain

Another objective way to access pain is to ascertain the extent to which pain interferes with functional ability after surgery.[4] It may vary with the type of surgery performed. Some examples include taking a deep breath and performing incentive spirometry after abdominal surgery, participating in physical therapy after musculoskeletal or spine surgery, or swallowing after tonsillectomy.[3,4] NRS 11 can be used to assess the impact of pain on functional ability with similar anchors as pain (0= does not interfere, 10= completely interfere).[8] However, objective measures should not be used as the sole criterion for assessing pain in patients who can participate in assessment as there is marked interindividual variability in pain behaviors at a similar level of pain.[3]

TABLE 25.2 Critical-Care Pain Observation Tool (CPOT)[23]

Component	Description	Score
Facial expression	No muscular tension observed	Relaxed 0
	Presence of frowning, brow lowering, orbit tightening, and levator contraction	Tense 1
	All of the above facial movements plus eyelid tightly closed	Grimacing 2
Body movements	Does not move at all	Absence of movements 0
	Slow, cautious movements; touching or rubbing the pain site; seeking attention through movements	Protection 1
	Pulling tube, attempting to sit up, moving limbs/thrashing, not following commands, striking at staff, trying to climb out of bed	Restlessness 2
Muscle tension evaluation by passive flexion and extension of upper extremities	No resistance to passive movements	Relaxed 0
	Resistance to passive movements	Tense, rigid 1
	Strong resistance to passive movements, inability to complete them	Very tense, rigid 2
Compliance with ventilator	Alarms not activated, easy ventilation	Tolerating ventilator or movement 0
	Tolerating ventilator or movement	Coughing but tolerating 1
	Asynchrony: blocking ventilation, alarms frequently activated	Fighting ventilator 2

Total zero to eight, with zero being no pain and eight being maximum possible pain.

Pain measurement in mechanically ventilated patients after cardiac surgery: comparison of the behavioral pain scale (BPS) and the critical-care pain observation tool (CPOT). *J Cardiothorac Vasc Anesth.* 2017;31(4):1227–1234.

Assessment of pain requires frequent reassessment, guided by response to therapy and the type of surgical procedure.[3] It has been suggested that the progress of pain relief of an individual patient can be evaluated better by trending pain scores on a graph instead of looking at individual numbers.[19] The effectiveness and adverse effects of analgesic medications should be evaluated at frequent intervals, and appropriate adjustments should be made to the regimen for each patient.[3] Pharmacokinetic principles such as route of administration and time to achieve peak analgesic effect should be kept in mind when evaluating the response to medications. Most oral analgesics require 1 to 2 h to reach peak effect, whereas for analgesics administered parenterally, it is 15 to 30 min.[3] An important part of the evaluation is a documented follow-up assessment to note the efficacy of the therapy and the patient's satisfaction with it.[3,4] Pain should be assessed at rest and with activity. The goal should be optimum pain control with activity, which is often more difficult to achieve.[3,19,26,27]

Pharmacologic Treatment of Pain

Pharmacologic treatment of postoperative pain has traditionally favored the use of opioids as the primary analgesic treatment. However, with the growing realization of the adverse effects of opioids, including nausea, vomiting, constipation, urinary retention, respiratory depression, sedation,[28] and risk for opioid dependence,[3] the practice is slowly changing to optimize the use of non-opioid medications first.

The ideal treatment of postoperative pain involves the use of multimodal analgesia regimens. Multimodal analgesia is defined as using multiple analgesic agents and techniques that act in a synergistic or additive manner.[3] The multimodal approach aims to target multiple different pain receptors within both the central and peripheral nervous systems to provide maximal pain relief and minimize adverse effects.[3] Multimodal analgesia is discussed in depth in Chapter 26. Many enhanced recovery (ERAS) protocols

TABLE 25.4 Systemic Opioid and Nonopioid Analgesic Options

Agent	Delivery	Analgesic Ceiling	Side Effects	Comments
Opioids	PO, IV PCA, IM	No	Induced hyperalgesia, nausea, vomiting, sedation, respiratory depression, pruritus, constipation, urinary retention	Side effects limit full their analgesic potential
Acetaminophen	PO, IV	Yes	Hepatotoxicity	Coadministration with opioids appears to provide opioid-sparing analgesia but may not reduce opioid-related side effects
NSAIDs	PO, IV, IM	Yes	Renal, GI, platelet inhibition, inhibition of bone healing, inhibition of osteogenesis, cardiovascular	Coadministration with opioids appears to provide opioid-sparing analgesia but may not reduce opioid-related side effects
COX-2 inhibitors	PO	Yes	Renal, cardiovascular, inhibition of bone healing, inhibition of osteogenesis	Coadministration with opioids appears to provide opioid-sparing analgesia but may not reduce opioid-related side effects
Ketamine (low dose)	IV	Yes	No cognitive impairments or psychotomimetic effects are seen with dosing of 0.25 mg/kg	May attenuate both postoperative pain and chronic pain; may attenuate opioid-induced hyperalgesia
Gabapentin and pregabalin	PO	Unknown	Dizziness, somnolence, ataxia, memory impairment, weight gain, edema, altered vision	May be useful for acute analgesia and chronic antihyperalgesia, pending further study

COX, Cyclooxygenase; *IM*, intramuscular; *IV*, intravenous; *NSAID*, nonsteroidal anti-inflammatory drug; *PCA*, patient-controlled analgesia; *PO*, per oral.

incorporated multimodal analgesia to minimize opioid use and facilitate pain control and recovery. Recently, the American Pain Society published updated guidelines for the management of postoperative pain.[3] These guidelines provide the reference for clinicians treating postoperative pain to devise a plan, individualized based on patient's expectations, comorbidities, and the surgical procedure.

Pharmacotherapy for pain can be broadly divided into opioid and non-opioid medications (Table 25.4). Non-opioid pain medications should be the first line of treatment for postoperative pain. It is a heterogeneous group of medications with a diverse mechanism of actions and includes:

- Non-steroidal anti-inflammatory drugs (NSAIDs) and acetaminophen
- Local anesthetic agents: lidocaine
- Ketamine
- Gabapentin, pregabalin
- Alpha two agonists

Acetaminophen and Non-steroidal Anti-inflammatory Drugs

Acetaminophen (Paracetamol) is an integral part of any multimodal analgesia regimen. It is the most commonly prescribed analgesic for the treatment of acute pain.[29]

Its mechanism of action is not precisely understood. It has been found to cross the blood-brain barrier.[30] There are several possible explanations for its mechanism, including inhibition of central prostaglandin synthesis,[29–33] inhibition of central nitric oxide generation via inhibition of *N*-methyl-D-aspartat (NMDA) e or substance P,[29,34] activation of descending serotonergic pathways, and inhibiting the uptake of endocannabinoids from the extracellular space.[29,31,35,36]

It can be administered orally, rectally, or intravenously (IV). The peak acetaminophen plasma concentration occurs 3 to 4 h after a rectal dose, 45 to 60 min after an oral dose, and 15 min after IV infusion.[37–39] IV paracetamol may be more than suitable in patients in whom faster onset is desirable and oral route is not available.[29] However, the cost of the IV formulation may be a limiting factor as well as its availability. The dosage for oral and IV acetaminophen in adults is 1 gram every 4 to 6 h, not to exceed 4 grams in a 24 h period. Once the patient can tolerate oral drugs, oral acetaminophen can be scheduled every 4–6 h to ensure therapeutic plasma levels. Acetaminophen can be administered rectally as an alternative to the oral route. However, its main disadvantage is unpredictable bioavailability.[40,41]

Acetaminophen is metabolized in the liver and excreted by the kidney. The dose interval should be at least 6 h in patients with renal insufficiency (creatinine clearance <=30 mL/min).[29,42] Hepatotoxicity is rare and occurs when supra-therapeutic doses are administered or in patients with preexisting hepatic disease.[29]

In a Cochrane meta-analysis of 75 studies, IV acetaminophen was found to be a useful adjunct to opioids as it reduces opioid consumption.[29] Acetaminophen lacks the adverse effect profile of NSAIDs, such as interference with platelet function, and is safe in patients with peptic ulcers, gastrointestinal bleeds, and asthma.[29,43]

NSAIDs are a diverse group of medications that have anti-inflammatory, antipyretic, and analgesic effects.[28] Surgical stimulus leads to the release of inflammatory mediators such as prostaglandins, leading to stimulation of nociceptors and perception of pain.[44] NSAIDs exhibit these effects by inhibiting the cyclooxygenase enzymes (COX) and, therefore, inhibit the synthesis of prostaglandins that are mediators of acute inflammatory response. Prostaglandins are important mediators of peripheral and central nervous system hyperalgesia as well.[45] COX has two

major isoforms with different functions: COX-1 and COX-2. NSAIDs are classified into two major groups based on their mechanism of action on each of these enzymes. The non-selective reversible competitive inhibitors block both COX-1 and COX-2 enzymes, whereas the selective ones only block the COX-2 isoform. The COX-1 enzyme mediates platelet aggregation, hemostasis, and gastric mucosal protection. Non-selective NSAIDs may cause adverse effects via inhibition of COX-1, including gastrointestinal bleeding, impaired renal function, inhibition of platelet aggregation, and inhibition of bone healing and osteogenesis. The pharmacokinetic profile of the drug should guide selection in the perioperative period. When given at higher doses, NSAIDs have faster onset with a longer duration.[44] Therefore in the initial postoperative period, patients should be started on a high dose, followed by titrating the dose down to limit adverse effects (Table 25.5).[44]

The development of selective COX-2 inhibitors was based on the premise that selective inhibition of COX-2 would provide analgesia without the side effects associated with COX-1 inhibition. Although selective COX-2 inhibitors are associated with a lower incidence of gastrointestinal complications,[46] and exhibit minimal platelet inhibition even when administered in supratherapeutic doses,[47] recent data indicate that COX-2 inhibitors may be associated with a higher incidence of cardiovascular events such as myocardial infarction.[48] Because COX-2 inhibitors inhibit PGI2, these agents may contribute to coronary thrombosis via the unopposed action of thromboxane A2.[49] A meta-analysis of rofecoxib trials indicated that administration of rofecoxib is associated with a 2.3-fold greater risk for cardiovascular events,[48] leading to the withdrawal of rofecoxib. Some data suggest that celecoxib is also associated with a higher incidence of cardiovascular events.[50–52] Therefore it should be avoided in patients with coronary artery disease.

Multiple studies have shown the opioid-sparing effects of NSAIDs by decreasing the opioid requirements, reducing adverse effects, and improving patient satisfaction. NSAIDs have been shown to be effective in almost all types of surgeries.[44] Several meta-analyses suggest that the use of NSAIDs, COX-2 inhibitors, or acetaminophen in combination with IV patient-controlled analgesia (PCA) results in an opioid-sparing effect. However, only non-selective NSAIDs have been shown to decrease the relative risk for some opioid-related side effects (e.g. PONV, sedation), which leads to early discharge as patients can tolerate oral fluids early.[28,53–57]

NSAIDs and acetaminophen have different mechanisms of action,[3] and it has been proven that a combination of both is superior to either drug alone.[58] The American Pain Society, in the most recent guidelines for the management of perioperative pain, recommends that all the patients should receive acetaminophen and/or NSAIDs as part of multimodal analgesia unless contraindicated.[3]

TABLE 25.5 Commonly Used NSAIDs for Postoperative Pain

Drug	Oral dose	Frequency	Maximum Dose in 24 h
Aspirin	600 mg	QID	
Naproxen	250–500 mg	BID	
Naproxen sodium	275–550 mg	BID	
Ibuprofen	200–800 mg	QID	3200 mg
Ketoprofen	50 mg–75 mg	BID-QID	300 mg
Ketorolac Limit to <five days	Oral 10 mg IV 15 mg	QID QID	40 mg 60 mg
Diclofenac	50–75 mg	BID-QID	200 mg
Etodolac	200–300 mg	BID-TID	1000 mg
Nabumetone	500–750 mg	BID	1500 mg
Meloxicam	7.5 mg	BID	15 mg
Celecoxib	100–200 mg	qD-BID	200 mg

Local Anesthetic Agents—Intravenous Lidocaine

Local anesthetics are used for peripheral nerve blocks, neuraxial analgesia and anesthesia, local infiltration, topical use, and intravenous administration.

Lidocaine has been used as an adjunct to general anesthesia to reduce inhalational anesthetic requirements,[59] and reduce airway reactivity with extubation in patients who smoke.[60] It is commonly used at the time of induction of general anesthesia to blunt the sympathetic response with laryngoscopy. Intravenous lidocaine (IVL) has been found to be beneficial in several surgical procedures, especially abdominal surgeries. However, the effectiveness varies with the type of surgical procedure.

Intravenous lidocaine has analgesic and antihyperalgesic properties and is known to attenuate the proinflammatory effects of surgery itself.[59–61] The precise mechanism by which IVL exerts these effects remains unclear. Possible explanations include a blockade of sodium channels, which is common to all local anesthetics, along with inhibition of G protein-coupled receptors, which leads to blockade of priming of polymorphonuclear neutrophils, attenuating inflammation.[59,60,62,63] Antihyperalgesic effect of lidocaine is modulated by a decrease in the activity of neurons and NMDA receptor-mediated postsynaptic depolarization in the spinal cord.[59,64–67]

The benefits of perioperative lidocaine infusion include reductions in pain, nausea, ileus duration, opioid requirement, and length of hospital stay, promoting early rehabilitation.[60,68] Multiple studies have confirmed these effects in open and laparoscopic abdominal surgeries,[69–71] including colectomy, cholecystectomy, and appendectomy.[59,60] Typical dose includes a bolus of 1.5 mg/kg followed by infusion of 1.5-3 mg/kg/h. The clinically effective serum concentration of lidocaine for pain relief has been estimated at 2 to 10 μg/mL.[69] IVL infusion can be continued postoperatively at a dose of 0.5-1 mg/min. Maximum benefit has been observed within 24 h of surgery, with no additional benefit beyond that duration.[60,72]

In open prostatectomy, thoracic, and major spine procedures, IVL has been shown to decrease postoperative pain and opioid consumption and improve functional outcomes.[60] In breast surgery, it may help to prevent the development of chronic postsurgical pain.[60,73] However, it has shown no benefit in patients undergoing total abdominal hysterectomy, total hip arthroplasty, or renal surgery.[60] Opioid-sparing effects of IVL are particularly helpful in obese patients undergoing bariatric procedures to help mitigate the respiratory depressant effects of opioids.[60,74]

It is rare for patients to develop toxic symptoms. However, healthcare providers need to know the presenting symptoms of

toxicity, including tinnitus, perioral numbness, and cardiac dysrhythmia.[60] Monitoring plasma lidocaine levels may be considered in patients at increased risk for lidocaine toxicity, such as those with abnormal liver or kidney function or those who cannot be queried about symptoms of lidocaine toxicity.[60]

To summarize, intravenous lidocaine is inexpensive, easy to administer, relatively safe, and effective as an analgesic to reduce opioid requirements and facilitate earlier recovery in appropriately selected surgical procedures.[59]

Ketamine

Ketamine is a commonly used anesthetic agent. Recently, there has been renewed interest in the use of ketamine as an analgesic agent in subanesthetic doses.[75] Ketamine is a noncompetitive antagonist of NMDA glutamate receptors in nociceptive neurons.[76] It is most commonly used clinically as a racemic mixture, although the S (+) enantiomer is more potent than the R(-) enantiomer.[75,77,78] Ketamine is used most commonly intravenously and can be used intramuscularly. The safety of the neuraxial route has not been established and is therefore not recommended.

Typically low doses are used intraoperatively, including 0.25–0.5 mg/kg slow bolus injection intravenously before incision, dose depending on the expected pain intensity after the procedure.[75] Maintenance doses can be repeated injections of 0.125–0.25 mg/kg ketamine at 30-min time intervals or a continuous infusion of 250–500 μg/kg/h.[75] It has been recommended to decrease the dose when planned to continue postoperatively or stop the infusion at least 60 min before the end of surgery to prevent prolonged recovery for surgeries lasting more than 2 h.[75] The optimum dose in the postoperative period is uncertain.

Ketamine reduces postoperative pain, both at rest and with movement, and postoperative opioid requirements make it a suitable adjunct for analgesia, regardless of the anesthetic technique used. In a recent systematic review, perioperative intravenous ketamine reduced postoperative opioid consumption by 8 mg morphine equivalents over 24 h (95% confidence interval [CI] 6–9; 19%) and by 13 mg (95% CI 10–15; 19% from 67 mg) over 48 h when compared with a placebo in a variety of surgical procedures.[79] In a meta-analysis of 36 randomized control trials, Wang et al. found that adding ketamine to morphine/hydromorphone PCA provides a small improvement in postoperative analgesia while reducing opioid requirements.[80]

Ketamine has been shown to attenuate central sensitization and chronic postsurgical pain, reduce opioid-induced hyperalgesia (OIH) and opioid tolerance in opioid dependent patients.[79,81] OIH is a paradoxical increase in pain because of opioid administration, which does not respond to escalating opioid doses. In contrast, opioid tolerance responds to increasing the dose of opioids.[78,79] One of the proposed mechanisms in the development of OIH involves activation of NMDA receptors. Treatment of OIH involves tapering off the opioids and administration of NMDA modulators such as ketamine.[78,79] Ketamine does not cause respiratory and cardiovascular depression, which could be beneficial in patients with tenuous respiratory and cardiovascular status.[28]

The adverse effects of ketamine are dose-dependent and include hypersalivation, nausea and vomiting, and central nervous system (CNS) psychotomimetic effects, including hallucinations, nightmares, and delirium.[79] However, the adverse effects of ketamine are minimal when used at lower doses for analgesia. The CNS adverse effects can be further reduced by premedicating with benzodiazepines, especially midazolam.[82]

Gabapentin, Pregabalin

Gabapentin and pregabalin are commonly used for the treatment of neuropathic pain. Gabapentin is an inhibitor of calcium influx at voltage-dependent calcium channels, which decreases excitatory transmitter release and spinal sensitization.[83]

Gabapentin and pregabalin are available only for enteral use. Gabapentin absorption is dose-dependent.[84] Gabapentin is absorbed in the upper small intestine, whereas pregabalin is absorbed throughout the small intestine and colon. Therefore pregabalin may be preferred in patients with small bowel pathologies.

Recommendations from the American Pain Society suggest that gabapentin or pregabalin be administered preoperatively for major surgeries with a severe anticipated intensity of pain.[3] Although the optimum dose has not been described, typical doses evaluated in trials include 600 or 1200 mg of gabapentin or 150 or 300 mg of pregabalin, administered 1–2 h preoperatively.[3] There is limited evidence to show postoperative administration to be effective (typically gabapentin 600 mg as a single or in multiple doses and pregabalin 150 or 300 mg after 12 h).[3] Doses of both drugs need to be reduced in patients with altered renal function. The effect of perioperative gabapentin and pregabalin has not been consistent across studies. A recent meta-analysis found the risk of adverse events with gabapentin and pregabalin to outweigh the modest benefit of the opioid-sparing effect.[85,86] In contrast, some studies support the theory that perioperative gabapentin may reduce the incidence and intensity of postoperative pain up to six months after otolaryngology, orthopedic, mastectomy, and abdominal/pelvic operations.[83,87]

In a randomized controlled trial including 422 patients to evaluate the efficacy of perioperative gabapentin, 1200 mg was administered preoperatively plus 600 mg every 8 h continued for 72 h after surgery. The study was terminated prematurely as gabapentin did not affect the time to pain cessation, the rate of pain resolution, or the proportion of patients with chronic pain at six months or one year following surgery.[83] However, perioperative gabapentin was found to have a modest effect in promoting postoperative opioid cessation and, therefore, may have a role in preventing the development of chronic opioid use after surgery. Pregabalin has a great opioid-sparing effect in the first 24 h and significantly reduces opioid-related side effects.[88] Similar results were reported in a study of patients undergoing total knee arthroplasty.[89] The side effects of gabapentin and pregabalin are respiratory depression, sedation, and dizziness, particularly at high doses. Their role in the intra and postoperative pain relief is limited by the potential for serious respiratory depression. The Food and Drug Administration (FDA) recently issued a warning for both gabapentin and pregabalin to be used cautiously in conjunction with opioids and other CNS depressants and in elderly patients and those with chronic obstructive pulmonary disease. Their use is further limited because both these drugs can only be administered orally, which can be challenging in the immediate postoperative period.

α-2 Agonists

The α-2 adrenergic receptor agonists such as dexmedetomidine and clonidine have been used via several routes perioperatively. We will discuss the use of dexmedetomidine relevant to adult patients in this chapter as dexmedetomidine is more selective than clonidine for alpha two receptors. The use of dexmedetomidine in pediatric patients as a preoperative medication is beyond the scope of this chapter.

α-2 Agonists have sedative, analgesic, and anti-sympathetic effects.[90] Dexmedetomidine has been shown to attenuate OIH.[91]

Most commonly used regimen includes a loading dose of 0.5–1 mcg/kg over 10 min followed by an infusion of 0.3–0.7 mcg/kg/h.[91,92] In patients undergoing thoracic surgery, intraoperative dexmedetomidine improved pain scores and had an opioid-sparing effect.[92] Opioid-sparing effect was also observed in patients undergoing bariatric surgery.[93] This is specifically useful as dexmedetomidine does not cause respiratory depression. However, in patients undergoing spine deformity correction surgery, dexmedetomidine did not show any benefit of reducing postoperative opioid use.[94] The adverse effects of dexmedetomidine depend on the speed of the injection of the bolus dose. A bolus dose is often accompanied by initial hypertension, which is followed by hypotension and bradycardia. This can be attenuated by giving the bolus over 10–15 min.

Opioids

Opioids are the most effective drugs for the treatment of acute postoperative pain.[79] (Table 25.4) Opioids exert their analgesic effect through μ-opioid receptors. These receptors are located mainly in the CNS, although some are also present in the peripheral nervous system.[95] Pharmacology of opioids is further discussed in Chapter 47.

Opioids are known to cause several undesirable adverse effects such as nausea, vomiting, pruritus, ileus, OIH, tolerance, and respiratory depression, which limit the universal appeal of this most potent analgesic medication.

Opioids are one of the most versatile analgesics in terms of available routes of administration. They can be given enterally and parenterally, including IV, intramuscular (IM), intranasal, transdermal, sublingual, buccal, and neuraxial. The American Pain Society, in its recently updated guidelines, provides several recommendations in terms of routes of administration of opioids. These include preference of oral over parenteral route when possible, avoidance of IM injections, and use of IV PCA without a basal infusion when the parenteral route is necessary for opioid naïve patients.[3]

In a meta-analysis of forty-nine studies, PCA led to improved patient satisfaction and lower VAS pain intensity scores by nine points over the first 24 h (95% CI –13 to –5) and by 10 points over the first 48 h (95% CI –12 to –7) versus non-PCA. However, the amount of opioids consumed was higher in the PCA group, along with the incidence of pruritus. There was no difference in the length of hospital stay.[96]

TABLE 25.6 Intravenous Patient-Controlled Analgesia Regimens in Adults

Drug Concentration	Bolus Size* (Adult)	Lockout Interval (min)
Morphine (1 mg/mL)	0.5–2.5 mg	5–10
Fentanyl (0.01 mg/mL)	10–20 μg	4–10
Hydromorphone (0.2 mg/mL)	0.05–0.25 mg	5–10
Methadone (1 mg/mL)	0.5–2.5 mg	8–20
Meperidine (10 mg/mL)	5–25 mg	5–10
Alfentanil (0.1 mg/mL)	0.1–0.2 mg	5–10
Sufentanil (2 mcg/mL)	2–5 μg	4–10
Nalbuphine (1 mg/mL)	1–5 mg	5–15
Buprenorphine (0.03 mg/mL)	0.03–0.1 mg	8–20
Pentazocine (10 mg/mL)	5–30 mg	5–15

*Bolus doses should be titrated and based on clinical evaluation of the patient.

IV PCA allows the clinician to compensate for variability in analgesic requirements as the patients can themselves control how much medication they receive. The lockout period, and the negative feedback loop, enhance the safety of PCA. However, excessive sedation or respiratory depression may occur when the negative feedback loop is violated.[97,98] Optimal settings for IV PCA administration of opioids for the management of postoperative pain are not known. Table 25.6 enumerates the common doses used for PCA. PCA should be weaned off, and oral medication started as soon as possible after the surgery. In summary, opioids are potent analgesics with potential dangerous adverse effects, and there has an impetus to limit the use of opioids postoperatively by supplementing several adjuncts.

Other pharmacologic agents, such as anti-depressants that include tricyclic anti-depressants (TCA) and selective serotonin reuptake inhibitors, and skeletal muscle relaxants such as baclofen, are primarily used for neuropathic pain and myofascial pain, respectively, and have been discussed elsewhere.

Summary

Multimodal analgesia is recommended for use in all surgical patients for postoperative pain relief. Opioids have long been the mainstay for pain relief. However, in recent years, there has been an emphasis on limiting narcotics to minimize the short and long term adverse effects. Several pharmacologic agents have shown great promise for postoperative analgesia in appropriate patient populations. NSAIDs in combination with acetaminophen have shown opioid-sparing properties and should be used in all patients without contraindications. IV lidocaine is a useful adjunct in patients undergoing abdominal procedures. Several other agents such as ketamine, gabapentinoids, and dexmedetomidine help in postoperative pain relief therapy with the ultimate goal of early recovery. The treating physician must effectively treat the patient's pain while limiting the pharmacologic side effects. Effective postoperative analgesia should be based on the patient's preference, expectation, comorbidities, and the surgery performed.

Key Points

- Postoperative pain assessment is a dynamic process.
- Pain should be assessed at regular intervals to guide therapy and assess for adverse effects.
- Commonly used pain scales such as VAS, NRS, and VRS can be used postoperatively, but their limitations should be kept in mind.
- Clinical evaluation of pain and functional assessment play an important role along with the pain scales to guide therapy.
- Multimodal regimens should be a part of the postoperative pharmacotherapy.

- A combination of NSAIDs and acetaminophen should be used in all patients without contraindications.
- IV lidocaine and ketamine are adjuncts that have shown benefit in appropriately selected patients.
- Opioids should be used as the last options, with the oral route being preferred over IV.
- IV PCA is the modality of choice for systemic administration of opioids.

Acknowledgments

The authors would like to thank Dr. Marie N. Hanna and colleagues who authored the previous chapter: "Postoperative Pain and Other Acute Pain Syndromes," authored by Dr. Marie N. Hanna and Colleagues in Practical Management of Pain, 5th edition, from which portions of this chapter have been transcribed and modified.

Regional and Multimodal Treatments of Perioperative Pain

RYAN S. D'SOUZA, REBECCA L. JOHNSON

Introduction

According to the American Society of Anesthesiologists (ASA) practice guidelines, acute pain in the perioperative setting is defined as the presence of pain in a surgical patient after a procedure.[1] The United States Institute of Medicine reported that despite advancements in perioperative pain control, 80% of patients who have surgery report postoperative pain, and 88% of these patients grade their severity as moderate, severe, or extreme.[2] Uncontrolled postoperative pain may be associated with slower recovery times, prolonged hospital length of stay, increased readmission rates, increased time before ambulation, increased hospital costs, and decreased patient satisfaction.[3,4] Suboptimal analgesia may also have organ-specific complications, including poor respiratory effort from splinting and atelectasis, increased incidence of myocardial ischemia, impaired wound healing, delayed gastrointestinal motility with prolonged ileus, psychological distress with anxiety, and lack of sleep.[5–7]

The concept of multimodal analgesia was introduced in 1993 to improve analgesia while concomitantly limiting opioid consumption and reducing the risk of opioid-related adverse effects.[8] This involves the combined use of regional anesthesia or local anesthetic infiltration, opioid medications, as well as various classes of non-opioid analgesics, including nonsteroidal anti-inflammatory drugs (NSAIDs), selective-cyclooxygenase-2 (COX2) inhibitors, N-methyl-D-aspartate (NMDA)-receptor antagonists, and antiepileptic drugs. Multimodal regimens may also be associated with the attenuation of the transition from an acute to a chronic postoperative pain state.[9,10]

Regional anesthesia techniques include both the central neuraxial blockade and peripheral nerve blockade, both of which are frequently used either intraoperatively as the primary anesthetic or perioperatively as adjunctive therapy to manage acute postoperative pain, reduce opioid consumption, improve satisfaction and quality of life, decrease hospital expenditures, and improve other postsurgical outcomes.[11] More recently, the use of ultrasonography in the fascial plane and neurolocalization has expanded the utilization of peripheral nerve blockade. Ultrasound guided regional anesthesia (UGRA) has been associated with improvements in performance time, reduction in doses of local anesthesia, and reductions in some complications (e.g. pneumothorax).[12]

This chapter discusses the use of regional anesthesia techniques to control postoperative pain in various surgical types. The authors support a multimodal approach to the management of postoperative pain control, and more details on pharmacologic treatment in a multimodal approach can be found in Chapter 25 and adjuvant medications are addressed in Chapter 54.

Pathophysiology of Acute Postoperative Pain

Surgical trauma activates peripheral nociceptors, including both high threshold neurons sensitive to mechanical, thermal, and chemical stimuli, which then relay afferent signals to the cerebral cortex via the spinal-thalamic tract.[13] However, these afferent signals may be amplified at various points along the pathway. The presence of inflammation at the site of surgical trauma leads to local release of neurochemical factors, which increase sensitivity to endogenous ligands and decrease the threshold of afferent nociceptive neurons (peripheral sensitization).[13] Inflamed neurons may also alter the expression of sodium channels, which may show an increased proportion of tetrodotoxin-resistant channels, which have greater spontaneous ectopic activity.[13] Surgical insults may also lead to increased neuronal excitability within the spinal cord because of a persistent signal from peripheral afferent nociceptive neurons (central sensitization).[14,15] The nociceptive afferent neurons synapse in laminae I and II of the dorsal horn, and signals at this location may be modified as wide dynamic range neurons decrease their threshold for activation and widen their receptive field, and NMDA receptor activation is increased.[13] This mechanism leads to a decrease in pain threshold at the surgical site (primary hyperalgesia) as well as surrounding uninjured tissue (secondary hyperalgesia). Thus even a tactile stimulus that is not painful may elicit a painful response (allodynia) in postsurgical patients because of sensitization.

Biochemically, surgical insult leads to the release and upregulation of a pro-inflammatory cytokine profile, particularly an increase in interleukin-1b (IL-1b) and peripheral COX-2. Furthermore, IL-1b induces COX-2 in the central nervous system because of the presence of peripheral inflammation.[16] There are also humoral signals released from the inflamed surgical tissue that cross the blood-brain barrier directly and induce central COX-2. Thus while peripheral-acting COX-2 inhibitors and local anesthetic blockade may work peripherally to block COX-2 expression and provide analgesia, only central-acting COX-2 inhibitors block the expression of central COX2.[17,18]

Preoperative Assessment and Informed Consent

A thorough patient evaluation, including history, medication review, and physical examination, is vital prior to perioperative anesthesia and analgesia. Preoperative pain levels, certain age groups, anxiety, and depression may be associated with heightened postsurgical pain.[19] In contrast, in high-risk groups such as those with chronic pain (please refer to Chapter 36), regional anesthesia as an adjunct to analgesia may be beneficial. In some patients, regional anesthetic techniques may be inappropriate. For instance, in patients with a history of severe respiratory disease undergoing shoulder surgery, interscalene blockade may be disadvantageous because it will lead to phrenic nerve blockade and potential for subsequent respiratory decompensation.[20] History should also be elicited on preexisting nerve injury, whether it is localized to the site of the surgical procedure, its chronicity, and its temporal change (e.g. recent improvement or worsening nerve function). Preexisting nerve damage or deficit is considered a relative contraindication to regional anesthesia. In some instances, if the patient's preexisting neuropathy is stable, regional anesthesia may be pursued after a thorough discussion of the risks. The clinician should convey to a patient that a preexisting nerve injury may serve as a priming event ("first hit") and that any sequential insults ("second hit") can culminate in an increased risk of further nerve damage compared to the general population (please refer to Chapter 35).[21]

As part of a multimodal approach to pain management, preventive analgesia should also be considered. Preventive analgesia is defined as analgesia administration prior to the occurrence of painful stimuli, which may prevent or reduce subsequent intraoperative and postoperative pain and analgesic requirements.[22] Preventive analgesic techniques involve the use of pharmacologic agents that reduce the activation of nociceptors by blocking or decreasing receptor activation. Multiple studies have demonstrated that patients receiving preventive analgesia experience a decrease in total analgesic consumption (please refer to Chapter 24).[23,24]

After ensuring that the patient is a good candidate for regional anesthesia, the clinician performing the regional anesthetic procedure should provide thorough informed consent. This is not only important from a medicolegal standpoint but also improves ethical practice that respects the patient's autonomy and supports the patient-physician relationship. Studies in the regional anesthesia and perioperative setting demonstrate that patients desire to know the risks, benefits, and alternatives for the anesthetic modality that they will receive.[25,26]

The utilization of regional anesthesia checklists is also an important part of the pre-procedural period. Checklists typically comprise of patient identification, review of allergies and anticoagulation, confirmation of informed consent and marked site, obtaining the necessary equipment and labeled drugs, application of standard ASA monitors, establishment of intravenous access, administration of sedation and oxygenation if indicated, preparation of site using sterile technique and use of gloves and mask, and performing a verbal "time out."[27] By implementing a regional anesthesia-specific pre-procedural checklist, studies have demonstrated a lower incidence of procedures being performed on the wrong side.[28]

After administration of an analgesic, the clinician must follow up with the patient's response, which is typically performed routinely after surgery using an 11 point (0–10) pain assessment scale or other pain measurement tools. Clinicians should assess patient satisfaction and tolerance of the current level of pain and whether more analgesia would be desirable. This patient-centered approach with reliable follow up of analgesic response and good communication is crucial for successful perioperative pain management.

Multimodal Analgesia

Multimodal analgesia involves the use of multiple medications to treat pain, each with different mechanisms of action that may have synergistic or additive effects when combined.[29] The combination of different types of analgesics captures analgesic efficacy at optimal doses while minimizing side effects from any one analgesic, particularly undesirable effects of opioids such as nausea, vomiting, and respiratory depression. It is important to note that the use of local anesthetic alone to block the neuronal pathways is not always sufficient and does not decrease the humoral biochemical responses that occur following surgery; systemic pharmacologic agents may be required to attenuate the humoral biochemical and inflammatory postsurgical response.[17] In addition to opioids and regional anesthetic techniques, examples of medications commonly utilized during the perioperative period with different mechanisms of action include NSAIDs, acetaminophen, ketamine, α-2-agonists, glucocorticoids, gabapentinoids, and duloxetine (Table 26.1).[29] A sample multimodal analgesic plan is provided for perioperative management in Table 26.2.

Enhanced Recovery After Surgery (ERAS) Protocols

Enhanced recovery after surgery (ERAS) perioperative care pathways, previously known as "fast-track" programs, are designed to achieve early recovery after surgery by maintaining preoperative organ function and decreasing the stress response associated with surgery.[30] Studies demonstrate that implementation of ERAS pathways lead to a reduction in complications, decreased hospital stay, improved cardiopulmonary function, improved bowel function, and earlier resumption of physical and regular activities.[31] The main elements of ERAS comprise providing preoperative counseling, optimizing nutrition, avoiding perioperative fasting, implementing multimodal analgesic pathways (regional and non-opioid analgesia), and early mobilization.[30] A sample ERAS protocol pathway is provided in Table 26.3.

Drug Toxicity

A life-threatening event from local anesthetic medication is local anesthetic systemic toxicity (LAST), which currently has an estimated incidence of 0.03% or 0.27 events per 1,000 peripheral blocks.[32] While accidental injection of a local anesthetic directly into a vessel is a well-known cause of LAST, other predisposing factors may include increasing use of continuous catheter techniques, high volume fascial plane blocks, multiple peripheral nerve blocks in the same patient, and utilization of tumescent anesthesia. It is recommended that the proceduralist adhere to guidelines on the maximum recommended local anesthetic dose.[33]

There has also been a growing use of non-local anesthetic adjuvants in regional nerve blocks, including epinephrine, α-2-agonists, neostigmine, and steroids (e.g. dexamethasone).[34] Data on the additional analgesic benefit are mostly lacking, and caution is advised when using certain adjuvants. The addition of α-2-agonists (e.g. clonidine) may be associated with bradycardia and hypotension.[34] Gastrointestinal side effects may be frequent with neostigmine.[34]

TABLE 26.1 Systemic Opioid and Non-opioid Analgesic Medications

Medication Class	Example of Drugs	Mode of Delivery	Analgesic Ceiling	Side Effects	Comments
Acetaminophen		PO, IV	Yes	Hepatotoxicity, pruritus, rash	
Non-selective NSAIDs	Ibuprofen, naproxen, meloxicam	PO, IV, IM	Yes	Platelet inhibition, GI bleeding risk, renal and hepatotoxicity, inhibition of bone healing and osteogenesis, cardiovascular risk (MI, stroke)	Provides opioid-sparing analgesia. Consider concurrent PPI use
COX-2 inhibitor	Celecoxib	PO	Yes	Renal and hepatotoxicity, cardiovascular risk (MI, stroke)	Provides opioid-sparing analgesia. Caution is advised in those with cardiovascular risk factors
Opioid	Fentanyl, morphine, hydromorphone	PO, IV, IM, SQ, NA, PNB, TD, TM, IN	No	Nausea/vomiting, respiratory depression, sedation, pruritus, constipation, urinary retention, dizziness	Choice of the agent should depend on potency and the expected duration of action. Use shorter-acting agents (e.g. fentanyl) for shorter hospital LOS or same-day discharge, and reserve longer-acting opioids (e.g. hydromorphone) for inpatients or opioid tolerant patients
Tramadol and tapentadol		PO, IV	Yes	Nausea/vomiting, dizziness, sedation, headache	Low affinity for opioid receptors; inhibits serotonin reuptake and may precipitate serotonin syndrome; contraindicated in patients taking MAOi; may lower the seizure threshold and caution is advised in those with a history of seizures; adjuvant in neuropathic pain
Anti-convulsant/ Gabapentinoid	Gabapentin, pregabalin	PO	Unknown	Dizziness, sedation, fatigue, tremor, ataxia, impairment in memory, edema, weight gain, vision abnormalities	Provides opioid-sparing analgesia, useful in both acute postoperative pain and chronic antihyperalgesia; adjuvant in neuropathic pain
NMDA Antagonist	Ketamine, methadone (opioid with NMDA receptor antagonism)	IV, IM, PO	Yes	Confusion, disorientation, dissociation, nausea/ vomiting, sedation, ataxia, double-vision	Provides opioid-sparing analgesia; may attenuate chronic pain after surgery; implicated in preventing opioid-induced hyperalgesia; more effective in use in opioid tolerant patients but benefits seen in those opioid naïve
α-2-agonist	Dexmedetomidine, clonidine	PO, IV, IM, IN	Yes	Changes in blood pressure and heart rate (usually hypotension, bradycardia), nausea/ vomiting	Suppression of opioid-withdrawal symptoms, preserves minute ventilation
Corticosteroid	Dexamethasone	IV, PO	Unknown	Edema, hypertension, elevated blood glucose, confusion, and delirium	Place in pain therapy is unclear, but evidence suggests analgesic effect as an adjuvant for opioid tolerance

COX, Cyclooxygenase; *IM*, intramuscular; *IV*, intravenous; *PO*, per oral; *SQ*, subcutaneous; *TD*, transdermal; *PNB*, peripheral nerve block; *NA*, neuraxial; *TM*, transmucosal; *IN*, intranasal; *NSAID*, nonsteroidal anti-inflammatory drug; *MI*, myocardial infarction; *GI*, gastrointestinal; *LOS*, length of stay; *MAOi*, monoamine oxidase inhibitor; *PPI*, proton pump inhibitor.

TABLE 26.2 Multimodal Analgesia Pathway for Cardiac Surgery

Preoperative
Acetaminophen (paracetamol) 1000 mg PO
Caffeine 200 mg PO if the patient reports regular caffeine intake[a]
Celecoxib 400 mg PO (administered if aged 18–64 years and glomerular filtration rate >50 mL/min)[b]
Consider oxycodone immediate release 5 or 10 mg PO (administered if aged 18–64 years) in patients with preoperative opioid dependence
Intraoperative
Utilization of regional anesthetic techniques (may consider surgeon-administered wound infiltration and various PNB techniques including interscalene, anterior suprascapular, or supraclavicular block with supplementation of cervical plexus)
Consider dexamethasone up to 0.2 mg/kg IV
Consider dexmedetomidine 0.5 mcg/kg/min IV
Postoperative
Re-dose acetaminophen (paracetamol) 1000 IV every 6 hours until the patient starts taking oral medications
Ketorolac 7.5–15 mg IV every 6 hours up (up to five doses maximum; adjusted for age, creatinine clearance, and weight); avoid if age > 70 or creatinine clearance < 30 mL/min)[b]
Fentanyl 25 mcg IV prn or hydromorphone 0.2 mg IV prn for pain score> four
Oxycodone 5–10 mg PO every 4 hours prn and/or hydromorphone 1–2 mg PO every 4 hours prn when taking oral medications
Ketamine 10 mg IV every 5 minutes for severe pain (7–10) and consideration of initiating ketamine infusion 0.1–0.3 mg/kg/h for persistent severe postoperative pain

[a]There is currently weak evidence for preoperative caffeine. Source: Hampl et al. Perioperative administration of caffeine tablets for the prevention of postoperative headaches. *Can J Anaesth*. 1995;42(9):789–792.

[b]Careful patient selection for NSAID therapy is warranted; in certain patient populations undergoing colorectal surgery (e.g. Crohn's disease and ulcerative colitis), NSAIDs may be contraindicated.

Regional Anesthesia Techniques

The aforementioned ERAS pathways and the regional anesthetic techniques described below should be tailored to the individual patient while keeping in mind the surgical type, side effects of the individual medications, and the patient's comorbidities.[35] The regional anesthetic blocks described below include neuraxial regional techniques as well as peripheral/perineural nerve blocks commonly performed in the perioperative setting and may serve as rescue blocks for postoperative pain management in the wards and beyond. The goal of this section is not to provide a comprehensive list but instead provide examples of common regional anesthetic blocks and to appraise the evidence in the literature for their analgesic efficacy in the perioperative setting.

Neuraxial Analgesia

Generally, neuraxial techniques provide better analgesia than systemic opioids and have the advantage of decreasing adverse perioperative pathophysiology (e.g. stress response) while improving patient outcomes. For instance, continuous epidural infusion has been shown to be associated with decreased pulmonary,[36] cardiovascular,[37–39] and gastrointestinal[40] complications in high-risk patients after high-risk procedures. Below, we describe the spinal (intrathecal), epidural, and caudal anesthesia techniques.

Spinal Analgesia

While intrathecal local anesthetic administration is often used as the primary anesthetic for many surgeries (e.g. cesarean deliveries, certain abdominal procedures) instead of general anesthesia, the focus of this section will be on intrathecal medications for postoperative analgesia only. Intrathecal opioids are potent, centrally acting analgesic drugs and are commonly administered to provide intraoperative and postoperative analgesia.

When administering neuraxial opioids, it is important to consider the lipophilic properties of opioids. Studies have demonstrated that the liposolubility of intrathecal opioids is inversely proportional to spinal selectivity and spinal-mediated analgesia, which is higher for hydrophilic opioids than for other more lipophilic opioids.[41] While all opioids administered intrathecally produce some degree of spinal-mediated analgesia, hydrophilic opioids provide primarily spinal-mediated analgesia, while lipophilic opioids tend to provide analgesia via either a spinal or systemic mechanism.[42] Hydrophilic opioids, including morphine and hydromorphone, remain in the cerebrospinal fluid (CSF) for a long duration and can produce a delayed but longer duration of analgesia. Because of this property, hydrophilic opioids may have a higher incidence of delayed respiratory depression because of greater CSF spread.[43] Intrathecal morphine may lead to severe respiratory depression lasting up to 24 hours.[43] The respiratory

TABLE 26.3 Enhanced Recovery Pathway for Colorectal Surgery

Preoperative
Fluid and carbohydrate loading,[a] and avoidance of prolonged fasting
Caffeine 200 mg PO if the patient reports regular caffeine intake
Antibiotic prophylaxis
Thromboprophylaxis
Acetaminophen (paracetamol) 1000 mg PO
Celecoxib 200–400 mg PO (adjusted for age, creatinine clearance, and weight)
Consider granisetron 1 mg IV or scopolamine patch if the patient reports a history of severe PONV
Intraoperative
Administration of short-acting anesthetic agents (e.g. fentanyl IV or remifentanil IV)
Utilization of regional anesthetic techniques (may consider neuraxial analgesia, liposomal bupivacaine wound infiltration, and various truncal blocks such as TAP blocks and rectus abdominis sheath block)
Avoidance of excessive fluid administration
Maintenance of normothermia
Re-dose Acetaminophen (paracetamol) 1000 IV if 6 hours since preoperative dose
Ketorolac 7.5–15 mg IV (adjusted for age, creatinine clearance, and weight) at skin closure; avoid if age > 70 or creatinine clearance < 30 mL/min)
Avoidance of surgical drain placement
PONV prophylaxis: dexamethasone 4–8 mg IV at induction, ondansetron 4 mg IV at the end of the case (if the patient has two or more PONV risk factors,[b] consider the addition of droperidol 0.625 mg IV or promethazine 12.5 mg IV or haloperidol 1–2 mg IV at the end of the case)
Postoperative
Maintenance of continuous regional anesthetic technique (e.g. epidural catheter)
Early removal of urinary catheter
Early oral nutrition
Bowel regimen and agents to promote stimulation of gut mobility
Early mobilization
Use of non-opioid analgesics: Re-dose acetaminophen (paracetamol) 1000 IV every 6 hours until the patient starts taking oral medications Re-dose ketorolac 7.5–15 mg IV every 6 hours up (up to five doses maximum; adjusted for age, creatinine clearance, and weight) at skin closure; avoid if age > 70 or creatinine clearance < 30 mL/min)
Oxycodone 5–10 mg PO every 4 hours prn when taking oral medications

[a]Source describing evidence on preoperative carbohydrate loading. Bilku et al. Role of preoperative carbohydrate loading: a systematic review. *Ann R Coll Surg Engl.* 2014;96(1):15–22.

[b]PONV risk factors include female sex, young to middle age, history of PONV or motion sickness, and non-smoking status.

PO, Mouth; *IV*, intravenous; *PCA*, patient-controlled analgesia; *prn*, as needed; *PONV*, postoperative nausea, and vomiting; *TAP*, transversus abdominis plane.

depression after intrathecal morphine administration usually follows a biphasic pattern with an initial onset in the first 1–3 hours and a late-onset at 6–12 hours because of their hydrophilic nature and cephalad spread.[43] On the other hand, lipophilic opioids, such as fentanyl and sufentanil, have a faster onset of action but a shorter duration of analgesia because of more rapid diffusion from CSF.[41] Common side effects of all intrathecal opioids include pruritus in up to 60% of patients,[44,45] nausea and vomiting in over 50% of patients,[46] and urinary retention in up to 80% of patients.[47]

There is limited evidence on the use of other intrathecal medications for postoperative pain control, including α-2-agonists,[48] steroids,[49] and neostigmine.[50] A randomized clinical study by Sarma and colleagues showed that a low dose of intrathecal dexmedetomidine or clonidine with bupivacaine produced a shorter onset and longer duration of motor and sensory blockade than bupivacaine alone in lower limb surgeries.[48] Another prospective, double-blind study[51] showed that intrathecal dexmedetomidine with bupivacaine provided earlier onset of sensory and motor block, longer duration of analgesia, and preserved hemodynamic stability compared to bupivacaine alone in infraumbilical surgeries. Of all adjuvants for neuraxial analgesia, only clonidine is approved by the FDA.[52] Future well-designed randomized controlled trials (RCTs) assessing postoperative analgesia with intrathecal adjuvant medications are warranted.

In summary, intrathecal administration of lipophilic opioids produces short-term analgesia for approximately 1–4 hours and may be helpful for immediate postoperative pain. Although hydrophilic intrathecal opioids provide longer duration analgesia (for up to 24 hours) useful for more invasive and painful surgeries, we recommend that it be limited to patients expected to remain hospitalized in an appropriately monitored setting for at least one postoperative day.

Epidural Analgesia

Continuous epidural analgesia offers postoperative pain management for a longer duration than a single injection spinal injection and analgesia superior to systemic opioids.[53] In terms of pharmacokinetics, medications placed in the epidural space must cross the dura prior to reaching the spinal cord.[54] In addition, because of the high vascularity of the epidural space, there may be a significant redistribution of epidural medications into the systemic circulation.[54] Furthermore, the presence of epidural fat may serve as a repository for lipophilic drugs.[54]

Notably, compared to the intrathecal space, significantly larger amounts of medication need to be delivered via the epidural route to obtain equivalent analgesic efficacy because diffusion of drugs across the dura is concentration and time dependent.[54] This pharmacokinetic concept is complex and involves inherent drug properties, primarily lipophilicity. For instance, lipophilic opioids (fentanyl and sufentanil) readily cross the dura to reach spinal cord receptors, whereas hydrophilic opioids (morphine) would cross the dura more slowly; thus when calculating the epidural dose for a medication that is equianalgesic to the intrathecal route, a higher epidural dose would be required for hydrophilic medications than for lipophilic medications. As a general rule of thumb, 10 mg of epidural morphine (hydrophilic opioid) would be equianalgesic to 0.1 mg of intrathecal morphine (10:1 ratio), whereas 33 mcg of epidural fentanyl would be equianalgesic to 6–10 mcg of intrathecal fentanyl (5:1 to 3:1 ratio).[55] However, further well-designed dosing studies are warranted to validate these findings.

Typically, epidural local anesthesia with or without opioids offers better physiologic benefits after most surgeries than opioids alone and may decrease opioid-related side effects. The choice of local anesthetic may vary based on provider preference, but a local anesthetic with a longer duration of action with preferential sensory blockade and limited motor blockade is preferable for postoperative analgesia.[56] However, in certain circumstances, such as persistent hypotension, epidural opioids alone may be more advantageous because of sympathectomy often associated with epidural local anesthetic.

When initiating epidural analgesia, small epidural bolus doses (5–10 mL) are usually administered first over a short period of 5–10 minutes to achieve an adequate depth of analgesia prior to initiating a continuous epidural infusion rate that can be titrated to effect. Furthermore, different delivery modes of epidural analgesia may be instituted, including fixed continuous infusion or patient-controlled epidural analgesia (PCEA). Similar to intravenous patient-controlled analgesia (PCA), PCEA allows analgesic requirements to be individualized to the needs of the patient and improves patient satisfaction.[57,58] Various combination settings may be employed, including continuous epidural infusion rate with PCEA together or a programmed intermittent epidural bolus technique with PCEA.

Similar to the intrathecal route, there is limited evidence of certain epidurally delivered adjuvant medications. Clonidine may provide analgesia via the epidural route by activating the descending noradrenergic pathway but may be limited by hypotension, bradycardia, and sedation.[59] Epinephrine may increase the intensity of sensory blockade when administered with a local anesthetic.[60]

In summary, continuous epidural analgesia provides superior analgesia and better patient outcomes than intravenous opioids and can provide postoperative pain control with epidural local anesthetic alone or a combination of epidural local anesthetic and opioids. Continuous infusion and other delivery modes can provide prolonged postoperative analgesia and may be titrated to an analgesic effect.

Caudal Analgesia

Caudal analgesia involves injection through the sacrococcygeal ligament with entrance into the epidural space.[61] There is limited utility of caudal analgesia for acute postoperative pain control in adult patients because it is more technically challenging to perform caudal injection compared to lumbar or thoracic epidural blocks. Caudal analgesia is useful in the pediatric population and provides excellent postoperative analgesia for inguinal hernia repair, urologic interventions (e.g. circumcision, hypospadias correction, orchidopexy), anal atresia repair, and lower extremity surgeries.[62,63] Additional details on pediatric analgesia may be found in Chapter 28.

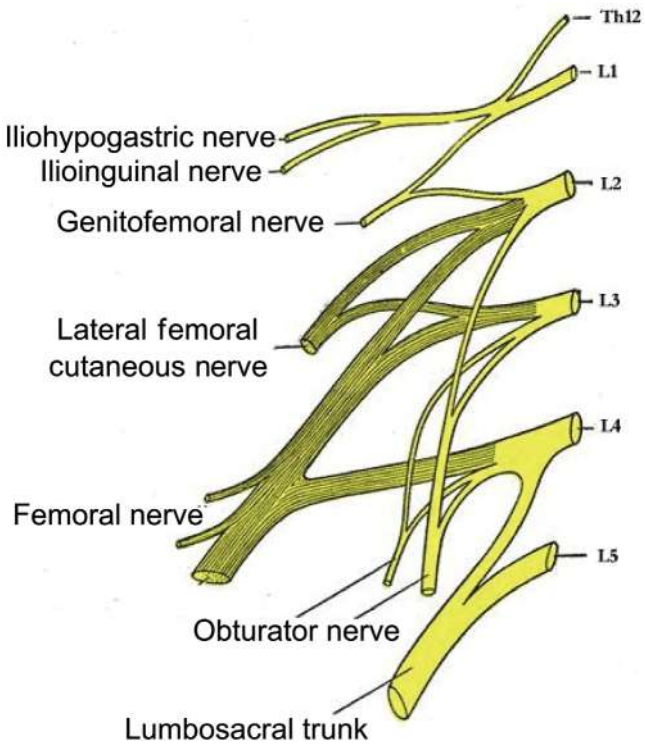
Complications With Neuraxial Techniques

The most common risks from neuraxial analgesia include hypotension, nausea and vomiting, and back pain.[64] Transient neurological syndrome (TNS) is severe lower back pain localized in the buttocks and lower extremities after recovery from spinal anesthesia with no evidence of localized nerve damage.[65] Risk factors for TNS include intrathecal lidocaine administration, lithotomy position, and ambulatory surgery.[65–67] Postdural puncture headache (PDPH) is because of lumbar puncture with subsequent CSF leak through the puncture site causing symptoms related to traction of pain-sensitive central nervous system structures.[68] To decrease the risk of PDPH, it is recommended to use a non-cutting needle.[68] When utilizing a pencil-point spinal needle, a meta-analysis by Zorrilla-Vaca et al. demonstrated no difference in PDPH rates between 22-gauge and 25-gauge needles. Thus this study concluded that providers might consider using larger-caliber pencil-point spinal needles in all but the youngest patients to maximize technical proficiency instead of risking a failed spinal anesthetic by using a smaller sized spinal needle.[68] Epidural catheters may be misplaced or may migrate after placement,[69] leading to ineffective or inadequate analgesic coverage. Epidural placement closer to one side may result in a one-sided blockade with inadequate coverage of the contralateral side. Inadvertent placement of an epidural catheter in the subdural space may lead to unpredictable block characteristics, including an inappropriately high block because of extensive spread, delayed onset, segmental distribution, and potential for motor blockade.[70] The feared complication is total spinal anesthesia, which occurs if excess local anesthetic is administered intrathecally, leading to coma, paralysis, hypotension, bradycardia, and apnea.[71] Other rare adverse events include infection, hematoma, and nerve injury.[69]

Peripheral Nerve Blockade

Utilization of peripheral nerve blockade in the perioperative setting is associated with adequate pain control, reductions in hospital length of stay, decreased hospital costs, better rehabilitation, and other improved postsurgical outcomes.[72,73] Peripheral nerve blockade can be established with a single injection of local anesthetic or with a continuous infusion through a perineural catheter. A perineural catheter with continuous infusion may provide equivalent analgesia to an epidural for certain surgeries while carrying fewer side effects than epidural analgesia.[74] Patients may be discharged home with continuous local analgesic medications delivered via a perineural catheter and may remove the perineural catheter themselves without requiring a hospital visit.[75,76]

Techniques for peripheral nerve blockade localization include paresthesia, peripheral nerve stimulator, and UGRA, although there has been a recent preference for UGRA. UGRA may be associated with a greater block success rate, faster onset of sensory block, fewer needle passes, and less discomfort during the block.[77,78] Lidocaine and mepivacaine are commonly used to provide short to intermediate duration peripheral nerve blockade.[79] In contrast, bupivacaine, levobupivacaine, and ropivacaine are preferred for longer duration peripheral nerve blockade.[80,81] Other adjuvant medications are not currently approved but are commonly added to local anesthetics, including epinephrine[82] (detects inadvertent intravascular uptake, denser and prolonged blockade related to vascular constriction) and clonidine (prolongs the duration of analgesia with added risks for hypotension and cardiac arrhythmias).[83,84] Below, we discuss various peripheral nerve blocks of the upper extremity, lower extremity, and trunk.



• **Figure 26.1** Lumbar Plexus. (Adapted from 20th United States edition of Gray's Anatomy of the Human Body [No copyright needed as the image is available in the public domain].)

Lower Extremity Peripheral Nerve Blocks

The ventral rami from the lumbar plexus (L1–4) and the sacral plexus (L4–5, S1–3) provide innervation to the lower extremity.[85] The specific nerves derived from the lumbar plexus (Fig. 26.1) include the lateral femoral cutaneous nerve (L2–3), obturator nerve (L2–4), femoral nerve (L2–4); the lumbar plexus also gives rise to the iliohypogastric, ilioinguinal, and genitofemoral nerves, which innervate the inguinal and genital areas.[85] The sciatic nerve (L4–5, S1–3) is derived from the sacral plexus.

Lumbar Plexus Block

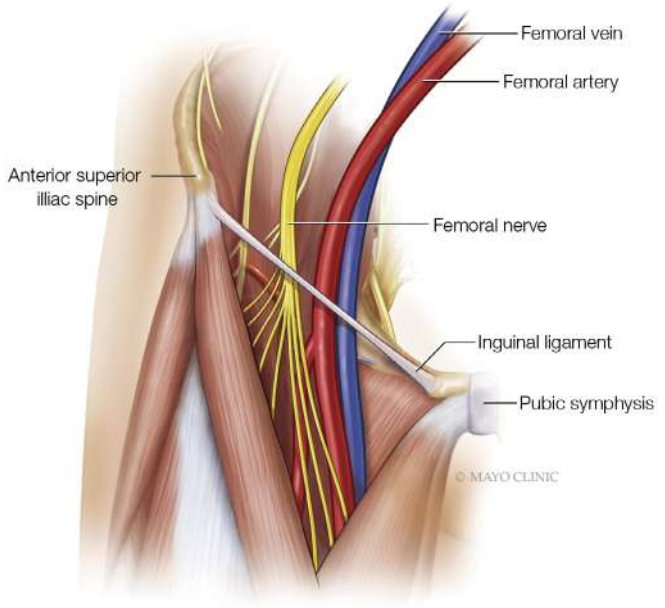
The lumbar plexus is triangular-shaped, with the femoral nerve situated in the middle, the lateral cutaneous femoral nerve situated laterally, and the obturator nerve situated medially in the plexus.[86] When the local anesthetic is injected within the psoas muscle, there is cephalad spread of the local anesthetic to the lumbar nerve roots. Hence, the term "psoas compartment" block is often used interchangeably with "lumbar plexus block."[86,87] Since lumbar plexus blockade covers both the femoral and obturator nerves, it provides surgical anesthesia and postoperative analgesia for surgeries of the hip joint (e.g. total hip arthroplasty, hip arthroscopy) and knee joint (total knee arthroplasty, multi-ligament reconstruction, and ligament repair surgeries) in conjunction with a sacral plexus block.[88,89] In certain invasive knee surgeries where coverage from the obturator nerve is not required, it may be technically easier to perform a femoral nerve block instead of a lumbar plexus block.[90]

Compared to hip surgery patients who did not receive any nerve blockade, those who received lumbar plexus blockade experienced decreased intraoperative blood loss, decreased postoperative opioid consumption, improved patient satisfaction, earlier postoperative ambulation, and improved participation in physical therapy and rehabilitation.[89,91,92] Compared to epidural analgesia, continuous lumbar plexus blockade may be associated with less motor blockade, faster time to ambulation, and fewer overall complications.[93] Thus the lumbar plexus block may play a pivotal role in ERAS protocols for hip surgery.

By itself, the lumbar plexus block is unlikely to provide complete anesthesia for hip surgeries because the sacral plexus provides innervation to the posteromedial capsule of the hip.[94] Compared with general anesthesia, a combination of lumbar plexus and parasacral blocks for hip surgeries in elderly patients may be utilized as the primary anesthetic and is associated with less hypotension, shorter hospital length of stay, fewer intensive care unit admissions, and improved patient satisfaction.[95,96]

Femoral Nerve Block

The femoral nerve is the largest nerve from the lumbar plexus.[97,98] It travels in the groove between the psoas muscle and iliacus muscle, passes under the inguinal ligament, and presents at the femoral triangle where it runs laterally to the femoral vessels (Fig. 26.2).[97,98] The femoral nerve then divides into anterior and posterior terminal branches, with anterior branches providing mainly cutaneous innervation and posterior branches providing primarily motor innervation.[99] The femoral nerve provides motor and sensory innervation to the skin and muscles of the anterior compartment of the thigh (e.g. quadriceps muscle), while its terminal branch (saphenous nerve) provides sensory innervation only to the medial portion of the leg from below the knee to the



• **Figure 26.2** Femoral Nerve. (Courtesy of Mayo Clinic.)

big toe.[99] Given the proximity of the femoral nerve to the artery, which is located in a separate sheath about 1 cm apart, accidental intravascular injection and hematoma formation are potential complications during blockade.[100]

Femoral nerve blockade provides excellent postoperative analgesia for mid-femur and knee surgeries, such as total knee arthroplasty (TKA), and may also be a satisfactory analgesic alternative to posterior lumbar plexus blockade for hip arthroplasty.[101] Because blockade occurs distally to the lumbar plexus, there is preservation of the hip flexion and hip adduction function, but patients cannot perform knee extension (function of quadriceps muscle).[102] While femoral nerve blockade may be utilized as the sole regional analgesic modality for knee surgeries, it is commonly supplemented with sciatic nerve blockade to provide coverage of the posterior aspect of the knee (e.g. TKA surgery, anterior cruciate ligament [ACL] surgery with hamstring autograft) or for below the knee procedures.[103,104] Similarly, if more proximal coverage of the medial compartment of the knee is required, supplementation with an obturator nerve block may be desirable.[105]

Compared to systemic pharmacologic therapy alone in patients undergoing TKA, studies and systematic reviews demonstrate that both single injection and continuous femoral nerve blockade are associated with superior analgesia.[73,106,107] Patients receiving femoral nerve blockade may also experience faster time to ambulation, improved knee flexion, reduced intraoperative and postoperative bleeding, quicker recovery, and decreased hospital length of stay.[73,106–108] Compared with surgeon-performed periarticular injection after TKA, continuous femoral nerve blockade may be associated with lower opioid consumption and improved recovery after six weeks.[109] Studies have also compared epidural analgesia versus continuous femoral nerve blockade after TKA, demonstrating that femoral nerve blockade provides equivalent postoperative analgesia, rehabilitation indices, and hospital duration of stay, but with fewer side effects (e.g. pruritus, postoperative nausea and vomiting, and dizziness).[110–112]

Saphenous Nerve Block

The saphenous nerve is a distal sensory branch of the femoral nerve that innervates the medial portion of the leg, medial calf, medial malleolus, and anteromedial foot.[113,114] Depending on the nature of the surgery and the location where analgesia is desired, the saphenous nerve may be blocked in several different locations, including perifemoral, subsartorial, transarterial, block at the medial femoral condyle, below the knee, paravenous approach, and at the medial malleolus.[115] Below, we focus on the subsartorial approach and discuss the saphenous nerve block at the medial malleolus in the "ankle block" section.

The subsartorial approach to the saphenous nerve block (proximal, mid-thigh approach in the middle third of the thigh) may be performed in patients who have undergone knee arthroplasty. This technique is often called the "adductor canal block." The adductor canal is a triangular-shaped canal with borders formed by the vastus medialis laterally, adductor longus or magnus medially, and roofed medially by the sartorius muscle, and can be visualized as a round hyperechoic structure anterior to the femoral artery using ultrasonographic guidance.[116,117] Given that femoral nerve blockade leads to quadriceps muscle weakness and impairment of early mobilization, the acute pain interventionalist now more often substitutes the adductor canal block for postoperative analgesia for TKA because it provides sensory blockade while sparing quadriceps strength and facilitating rehabilitation.[118] Similarly, a meta-analysis on patients undergoing ACL repair also demonstrated that adductor canal blockade is associated with similar analgesic requirements and short-term preservation of quadriceps muscle strength (24–48 hours) compared to femoral nerve blockade.[119] However, reports of significant quadriceps muscle weakness from local anesthetic spread in an adductor canal block have been described.[120] Risk factors, including advanced age, elimination-related activities (e.g. while in the bathroom, going to and from the bathroom, while using bedside commode), and intermediate phase of recovery (late postoperative day one to postoperative day three), also make patients vulnerable to fall after orthopedic surgery, and fall prevention strategies should be an institutional priority.[121]

Fascia Iliaca Block

The fascia iliaca is derived from fascicular aponeurotic sheets of the psoas and iliacus muscles. It is hypothesized that since there are multiple peripheral nerves enclosed within the fascia iliaca compartment in close proximity, including the femoral, lateral femoral cutaneous, genitofemoral, and obturator nerves, a high volume injection of local anesthetic may block all these peripheral nerves with one injection along this fascial plane.[122,123] Studies have demonstrated that the fascia iliaca block may provide adequate analgesia after hip, knee, and femoral shaft surgery.[124,125] A loss-of-resistance technique may be used to block the fascia iliaca compartment. However, studies have demonstrated that ultrasound guidance increases block success rates and the percentage of patients experiencing blockade of the femoral, obturator, and lateral femoral cutaneous nerves.[126] Compared to systemic opioid therapy alone, fascia iliaca block may provide superior pain relief postoperatively after hip surgery[127–130] and femoral fracture surgery.[131]

Sciatic Nerve Block

The sciatic nerve is the largest of the peripheral nerves supplying the lower extremity and provides innervation to the posterior thigh, leg below the knee, except for its medial portion (supplied

by the saphenous nerve), and the foot. It is commonly blocked either via the subgluteal or popliteal approach (discussed below). Sciatic nerve blockade provides excellent coverage for all foot and ankle surgeries[132,133] and is often performed in conjunction with femoral or lumbar plexus blocks for postoperative analgesia after hip or knee surgeries.[104] However, sciatic nerve blockade is often accompanied by hamstring muscle weakness, limiting its utility in many distal foot and ankle surgeries where postoperative weakness is undesirable.[134] Phantom limb pain following below-knee or above-knee amputation may significantly improve with continuous sciatic nerve blockade.[135]

Compared to femoral nerve blockade alone, both a femoral nerve block and sciatic nerve block provide superior postoperative analgesia and reduce postoperative opioid consumption.[136,137] Furthermore, a meta-analysis revealed that patients undergoing TKA who received sciatic nerve blockade as an adjunct to femoral nerve block reported lower postoperative pain scores and consumed fewer opioids up to 24 hours postoperatively compared to those who received femoral nerve blockade with local infiltration analgesia.[138]

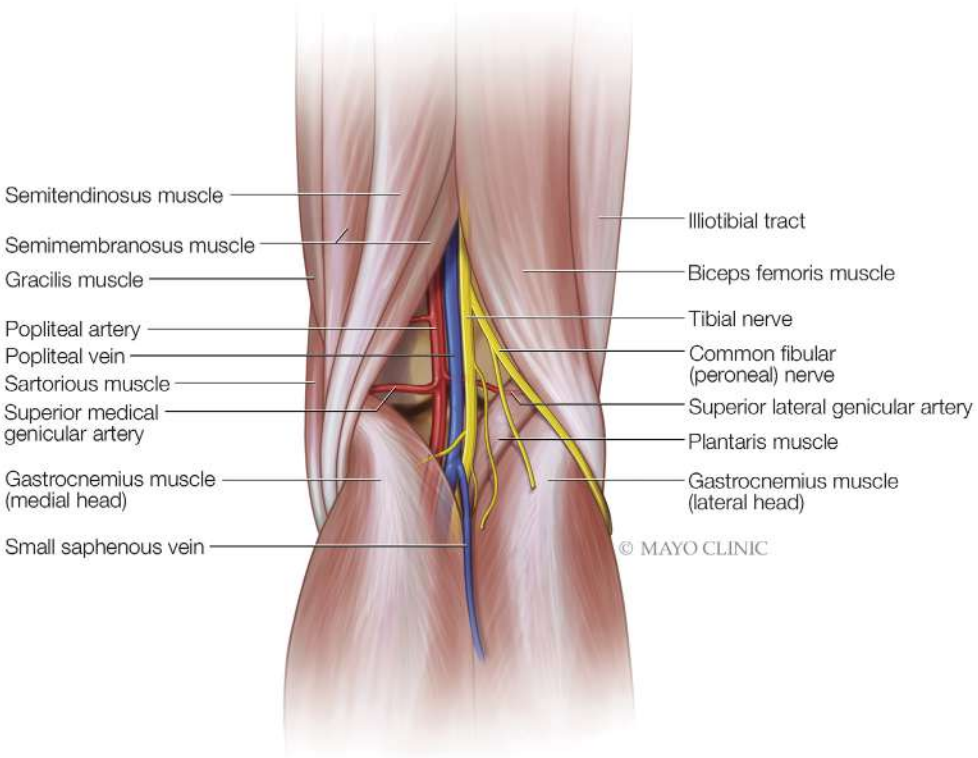
Popliteal Sciatic Nerve Block

The popliteal fossa is bordered superomedially by the semimembranosus and semitendinosus muscles, superolaterally by the biceps femoris, and inferiorly by the two heads of the gastrocnemius muscle. Within the popliteal fossa, the sciatic nerve is located posterolateral to the popliteal vessels (Fig. 26.3). Compared to the subgluteal approach to sciatic nerve blockade, the more distal location of popliteal sciatic nerve blockade preserves hamstring muscle strength and may facilitate earlier ambulation.[134] Pertaining to the technique of performing popliteal block, studies have demonstrated higher sensory block success, reduced time to perform the block, reduced risk of vascular puncture, and requirement for less local anesthetic with ultrasonographic guidance versus peripheral nerve stimulation techniques.[139,140] When popliteal sciatic blockade is performed using ultrasonographic guidance, performing the block separately for the tibial and common peroneal nerves at the bifurcation may be associated with faster block onset and denser motor block compared to a prebifurcation popliteal sciatic blockade.[141,142]

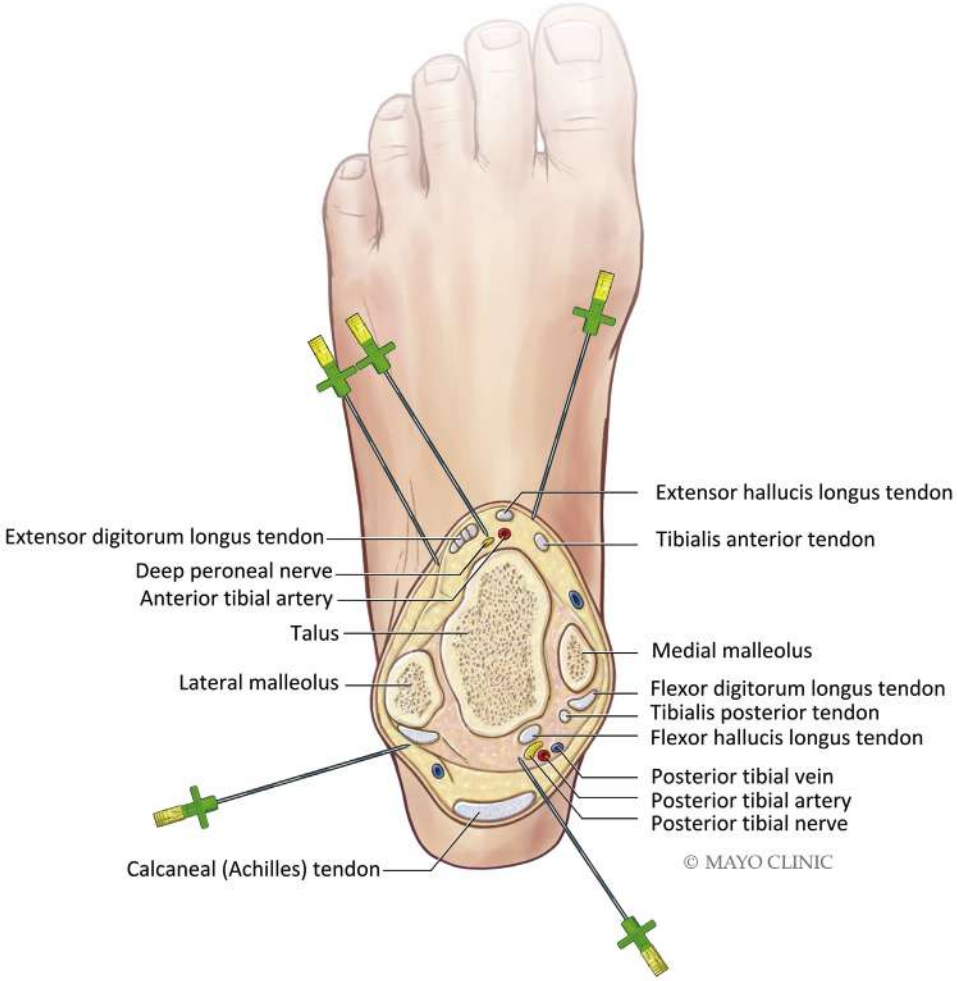
Popliteal sciatic nerve blockade provides excellent analgesia and surgical anesthesia for surgeries below the knee joint, notably foot and ankle surgery.[143,144] While an ankle block may be pursued for foot surgeries, a popliteal block is preferable when the surgery involves the use of a calf tourniquet. Supplementation with a saphenous nerve block is required for coverage of the medial aspect of the leg. Compared to single injection popliteal sciatic nerve blockade for foot and ankle surgery, continuous infusion of local anesthetic is associated with lower postoperative pain scores at 24 and 48 hours.[144] Although popliteal sciatic nerve blockade is primarily utilized for below the knee procedures, the combination of a popliteal sciatic nerve block and an adductor canal block may provide sufficient analgesia after TKA.[145] Furthermore, a combination of continuous popliteal sciatic and continuous femoral nerve block may improve postoperative pain control during movement following ankle surgery.[146]

Ankle Block

The ankle block involves injection at multiple sites around the ankle and foot to block several peripheral nerve targets (Fig. 26.4). These include derivatives from the sciatic nerve (deep fibular/



• **Figure 26.3** Popliteal Nerve. (Courtesy of Mayo Clinic.)



• **Figure 26.4** Ankle Block. (Henry Gray, Anatomy of the Human Body, 20e, Lea & Febiger, 1918.)

peroneal, superficial fibular/peroneal, sural, and posterior tibial nerves) and one derivative from the femoral nerve (saphenous nerve), which innervates the medial side of the ankle and foot.[147] This provides excellent surgical anesthesia and postoperative analgesia for surgeries of the foot, particularly surgeries not requiring calf tourniquet application. Since motor blockade is often unnecessary, high volumes of lower concentrations of local anesthetics may be administered to provide adequate sensory blockade; hence, the term "volume-block" is often used to describe the ankle block. Epinephrine is not recommended for use in ankle blocks, particularly if a circumferential infiltration technique around the ankle is used. The ankle block is ideal for ambulatory surgeries as patients may still ambulate with assistance, facilitating earlier discharge with adequate pain control.[148]

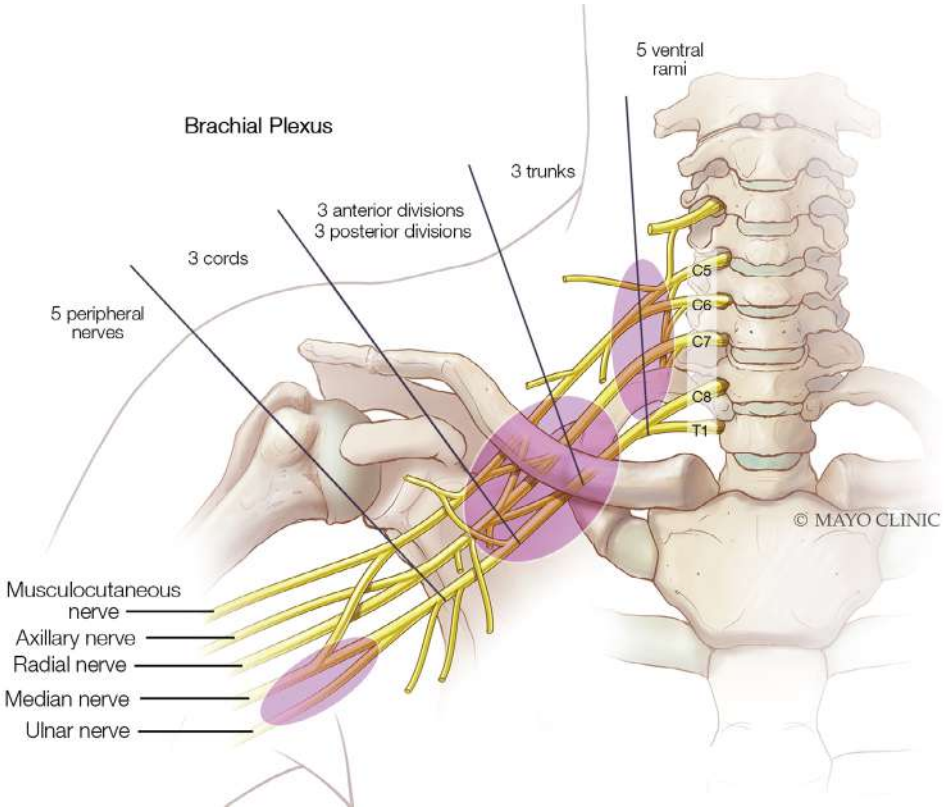
The ankle block may be performed using either a landmark-based approach or an ultrasound guided approach. Compared to the landmark approach, the use of an ultrasound for ankle block may be associated with a higher block success rate, although the lower local anesthetic volume in ultrasound guided injections may compromise postoperative analgesia in the first 24 hours.[148,149] In a study comparing spinal anesthesia and ankle block, ankle block was associated with lower pain scores and longer time to first need for analgesics but was associated with a longer time to sensory block.[150]

Upper Extremity Peripheral Nerve Blocks

The brachial plexus is formed by the anterior rami of the cervical nerves from C5–C8 and the first thoracic spinal nerve (T1) and provides motor and sensory innervation to the upper extremity. The brachial plexus consists of five roots, three trunks, six divisions, three cords, and five terminal branches (Fig. 26.5). The terminal branches include the radial, median, ulnar, musculocutaneous, and axillary nerves.[151] Depending on the nature and location of the upper extremity surgery, blockade of the brachial plexus can be targeted at any of these levels to provide surgical anesthesia and postoperative analgesia. Ultrasound allows reliable visualization of the brachial plexus. It may be associated with an increase in overall block success rate, quicker block performance time, use of less local anesthetic, faster onset of motor and sensory block, and minimal side effects when compared to traditional landmark-based and nerve stimulation techniques.[152–155]

Interscalene Block

An interscalene block is performed at the distal roots/proximal trunk level of the brachial plexus and provides excellent analgesia for shoulder and upper arm surgeries.[151] It is effective in providing a complete block of the superior and middle trunks, but coverage



• **Figure 26.5** Brachial Plexus. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.

of the inferior trunk is frequently missed, thus making the interscalene block an unsuitable option for forearm and hand procedures that require ulnar nerve coverage.[156] If an interscalene block is performed for elbow procedures, additional supplemental nerve blocks may be required, including the intercostobrachial nerve block to cover the medial aspect of the arm, as well as the medial antebrachial cutaneous and ulnar nerve blocks to cover the medial aspect of the forearm. The spread of local anesthetic injectate in an interscalene block consistently spreads to cover the supraclavicular nerve (C3–4), which provides innervation to the cape of the shoulder.[157] If paresthesia or nerve stimulation technique is utilized, the desired response is preferably a paresthesia or motor twitch of the upper arm or hand. However, the stimulus of the deltoid/anterior shoulder may be acceptable.[158] If the contraction of the diaphragm is sometimes visualized as hiccups, this indicates phrenic nerve stimulation from a needle that is placed too anterior. If the needle is placed too posteriorly, stimulation of the dorsal scapular nerve may elicit rhomboid muscle movement.[159]

The interscalene block should be avoided in patients with impaired pulmonary function because the phrenic nerve is usually blocked using this technique.[160] The interscalene nerve block should not be performed in a patient under general anesthesia or deep sedation because of the risk of syrinx and other major neurological complications, including intrathecal and epidural injection.[161] Other potential complications from interscalene block include intravascular injection, particularly into the vertebral artery, pneumothorax, and Horner's syndrome.[160] Nerve injury may potentially occur in the dorsal scapular nerve, leading to a dull ache in the medial scapula and weakness of the rhomboid and levator scapulae muscles.[162] Nerve injury is also possible to the long thoracic nerve, resulting in chronic shoulder pain and serratus muscle weakness.[162–164]

A meta-analysis revealed that patients undergoing arthroscopic shoulder surgery who received an interscalene block with general anesthesia experienced lower pain scores up to one day postoperatively, lower intraoperative systolic blood pressure, shorter extubation time, and a lower rate of adverse events compared to general anesthesia alone.[165] Compared to systemic opioids, interscalene block is associated with superior analgesia, less postoperative opioid consumption, and less incidence of opioid-related side effects.[166] Patients may maintain the continuous perineural local anesthetic infusion via an interscalene catheter while at home with a portable infusion pump, allowing better pain control and improvement in rehabilitation indices with greater shoulder range of motion.[167,168] If there is concern for respiratory insufficiency in a patient undergoing shoulder surgery, an anterior suprascapular nerve block or a supraclavicular block approach may be pursued instead of an interscalene approach. However, even the more distal supraclavicular approach is associated with phrenic nerve blockade.[169] A meta-analysis of patients undergoing shoulder surgery revealed that patients receiving a supraclavicular block reported similar postoperative pain scores and postoperative opioid consumption but with lower rates of hemidiaphragmatic paresis and Horner's syndrome compared to those receiving an interscalene block.[170]

Supraclavicular Block

A supraclavicular block is commonly known as the "spinal of the arm" because the brachial plexus in this approach is tightly packed and can achieve quick, reliable, and dense blockade with little to

no sparing after local anesthetic infiltration.[171] The supraclavicular block is performed at the distal trunks/proximal cords level of the brachial plexus[172] and provides surgical anesthesia and postoperative analgesia for surgeries of the hand, forearm, and arm. While studies have shown that supraclavicular block may provide analgesia similar to that of an interscalene block,[170] other studies recommend supplementing the supraclavicular block with a separate superficial cervical plexus block of the supraclavicular nerve (C3–C4) to provide coverage of the shoulder cape.[151,173] In addition, supplementation with an intercostobrachial nerve block to provide coverage of the medial arm may be required for elbow surgeries or tourniquet application.

A feared complication from a supraclavicular block is pneumothorax, which may occur if the needle angle is aimed at the apex of the lung. The supraclavicular approach carries the highest risk for pneumothorax among all brachial plexus block techniques.[174,175] Phrenic nerve blockade occurs commonly, although not as common as in the interscalene approach, and thus may be avoided in those with impaired pulmonary function.[176] Hematoma may occur in the supraclavicular approach, commonly because of puncture of the subclavian artery.[177] Higher local anesthetic volumes should be avoided because ischemic compression within the tightly packed supraclavicular space is possible and may lead to indirect nerve injuries. Direct injury to the suprascapular nerve may also occur and manifests with shoulder pain and weakness of the supraspinatus and infraspinatus muscles.[178]

Although the supraclavicular block is considered to be the approach that provides the fastest and most reliable onset of dense blockade, RCTs have demonstrated that ultrasound guided brachial plexus blocks via the supraclavicular, infraclavicular, and axillary approaches all led to similar success rates, pain scores, and total anesthesia-related times.[179,180] Studies have also investigated the addition of dexmedetomidine adjuvant to supplement local anesthetic in supraclavicular blocks, demonstrating that it leads to improved analgesia with shorter onset time and longer duration compared to local anesthetic (ropivacaine) alone.[181] Furthermore, there was no difference in the rates of bradycardia or hypotension.[181] In terms of technique, UGRA and nerve stimulation techniques are considered superior to the blind technique because of a higher success rate and decreased rate of complications.[182]

Infraclavicular Block

The infraclavicular block is performed at the level of the brachial plexus cords, and either a single injection or continuous catheter infusion provides surgical anesthesia and postoperative analgesia for arm, elbow, forearm, and hand procedures.[151,183] The three cords (lateral, posterior, and medial) are named in relation to the axillary artery, but substantial variation in the true location of the cords in relation to the axillary artery may be present at the coracoid level.[184] Of all the brachial plexus block techniques, the infraclavicular approach likely allows for a more secure insertion site for catheters.[151] While there are three main approaches to the infraclavicular block described (coracoid, lateral sagittal, and vertical approach), the coracoid approach may be preferable to some because of the clear anatomic landmarks and the lateral entry point reducing the probability for pneumothorax and hemidiaphragmatic paresis.[185] However, the evidence on a preferred technique is limited, which is an area for future investigation.

Complications may include hematoma and vascular puncture, particularly of the axillary artery or vein, LAST potential, especially because of the need for a high volume of local anesthetic injectate, and sparing of the radial nerve distribution in the single injection technique.[186] Compared to the supraclavicular and interscalene approach, there is a lower incidence of pneumothorax or inadvertent neuraxial injection with the infraclavicular approach because it is more distant from the lung and neuraxis.[187] The infraclavicular block is also suitable for patients with pulmonary insufficiency, as phrenic nerve blockade is markedly reduced compared to supraclavicular and interscalene techniques.[188]

As aforementioned, an infraclavicular approach for arm surgeries provides equivalent regional anesthesia and analgesia compared to other brachial plexus blocks.[179,180] However, when comparing an infraclavicular continuous catheter infusion to a supraclavicular continuous catheter infusion, the former is associated with superior analgesia.[189] Compared to general anesthesia with volatile anesthetic for ambulatory hand and wrist surgery, infraclavicular nerve block as the primary anesthetic was associated with lower postoperative pain scores, decreased time to ambulation, and lower post-anesthesia care unit admissions.[190] Placement of an infraclavicular catheter with continuous local anesthetic infusion may result in less dynamic postoperative pain, reduced postoperative opioid requirements, and less sleep disturbance compared to placebo infusion.[191] Studies have also investigated the addition of dexmedetomidine adjuvant to supplement local anesthetic in infraclavicular blocks, demonstrating that it leads to increased duration of analgesia and enhancement of sensory and motor blockade, lower postoperative pain scores, and reduction in postoperative opioid requirements compared to local anesthetic (bupivacaine) alone.[192]

Axillary Block

The axillary block is performed at the level of the terminal nerves surrounding the axillary artery, consisting of the radial, ulnar, and median nerves. However, with ultrasound guidance, a more proximal cord/terminal nerve block is possible. The relationship of the musculocutaneous nerve deserves special attention with the axillary approach because it courses away from the axillary artery and is located in the belly of the coracobrachialis muscle.[193,194] Thus a separate injection into the coracobrachialis muscle or ultrasound guided perineural injection of the musculocutaneous nerve is warranted during an axillary block.[193,194] The axillary block provides surgical anesthesia and postoperative analgesia for hand and arm surgery and can be blocked through various techniques, including paresthesia, nerve stimulation, perivascular, trans-arterial, and ultrasound guided.[151,195,196] If an axillary block is utilized for primary surgical anesthesia, supplementation of the musculocutaneous, intercostobrachial, medial brachial cutaneous, and medial antebrachial cutaneous nerves are warranted to prevent tourniquet pain.

A review by Chin et al. demonstrated that the multiple injection technique for axillary block improved the block success rate, although the block time was longer than that with single- and double-injection techniques.[197] Compared to general anesthesia alone for ambulatory hand surgery, an axillary block for surgical anesthesia provides superior postoperative pain control, decreases postoperative opioid requirement, and increases the time to first analgesic medication request.[198,199] Potential complications include LAST, postoperative neuropathy, hematoma, and vascular puncture, particularly the axillary artery. Pulmonary complications are rare, and this block is preferable in patients with pulmonary insufficiency undergoing distal arm, forearm, and hand surgery.

Bier Block

Intravenous regional anesthesia, also known as the Bier block, provides surgical anesthesia and a bloodless surgical field for shorter duration distal extremity surgeries.[200] The Bier block may also be utilized to treat certain chronic pain conditions, including complex regional pain syndrome.[201] The mechanism of action involves the diffusion of local anesthetic from the veins to the nerves.[202] The local anesthetic of choice commonly used in Bier blocks is lidocaine. Long-acting local anesthetic agents, including bupivacaine, are not appropriate for Bier blocks.[203,204] It is recommended that the tourniquet remain inflated at least twice the systolic blood pressure for 30 minutes prior to deflation.[200,205] However, seizures have been reported even with a tourniquet time as long as 60 minutes with the use of the lowest effective dose of lidocaine.[206] In the event of Bier block failure, surgeon-administered infiltration of local anesthetic at the surgical site or conversion to general anesthesia may be performed.

The Bier block is relatively contraindicated in localized or systemic infections, peripheral vascular disease, sickle cell anemia, presence of arteriovenous fistulas, and lack of IV access. Side effects include phlebitis and LAST, which may be because of improper technique or tourniquet failure, nerve injury, compartment syndrome, and tourniquet pain. In addition to local anesthetic infusion, other studies have also evaluated other adjuvants to the Bier block, including opioids, steroids (e.g. dexamethasone, methylprednisolone), α-2-agonists (dexmedetomidine, clonidine), ketamine, and NSAIDs, notably ketorolac.[202,207,208] Of all opioids, some studies have described the efficacy of only meperidine,[209] while the remaining opioids are considered non-effective adjuvants.[204] Dexmedetomidine at a dose of 1 mcg/kg and clonidine at a dose of 1 mcg/kg may be associated with improved tourniquet tolerance and reduced postoperative analgesic requirements.[210] Furthermore, 100 mcg/kg of ketamine has been shown to also reduce postoperative analgesic requirements and improve tourniquet pain.[211] Up to 24 hours of reduced postoperative analgesic requirements may also be observed with a combination of dexamethasone and lidocaine versus plain lidocaine alone.[212]

Fascial Plane/Truncal Nerve Blocks

With the widespread use of ultrasonography, fascial plane blockade has been applied to various surgical procedures and acute pain management strategies.[213] A combination of systemic analgesic medications with truncal blocks of the abdomen, chest wall, or paraneuraxial nerves may offer similar analgesic efficacy and a lower risk profile when compared to neuraxial techniques.[214] The most common truncal blocks performed in the perioperative setting include the transversus abdominis plane (TAP), rectus sheath, ilioinguinal/iliohypogastric, intercostal, and paravertebral blocks. While most truncal blocks were initially described in the literature through landmark-based techniques,[215,216] the advent of ultrasonography has renewed interest in truncal blocks. It has improved the placement of local anesthetic in the appropriate location while avoiding injury to surrounding structures.[217] Unlike other peripheral nerve blocks, truncal nerve blocks are usually performed along muscular or fascial planes that spread to traversing nerves; thus visualization of the individual nerve or nerve plexus is not a requirement.[218]

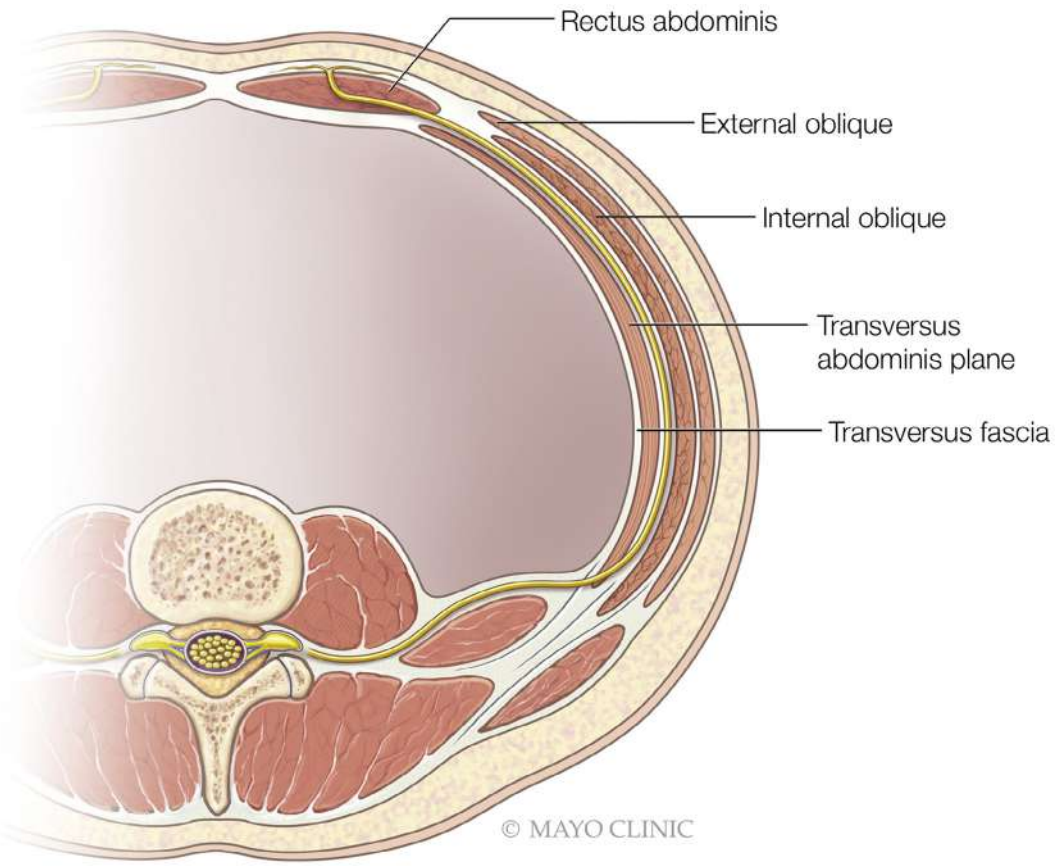
Transversus Abdominis Plane (TAP) Block

The (TAP) block has been used for postoperative analgesia after abdominal and gynecological surgeries, including hernia repairs, hysterectomies, appendectomy, and laparoscopic surgeries. The inclusion of TAP blocks in multimodal analgesia protocols is associated with a decrease in postoperative pain scores, opioid consumption, earlier ambulation, and shorter duration of hospital stay following laparoscopic cholecystectomy and appendectomy, as well as various laparotomy cases.[214,219–223] An RCT demonstrated that bilateral TAP blocks after abdominal hernia repair are associated with decreased time to ambulation and improved discharge readiness.[224] TAP blocks may obviate the need for neuraxial anesthesia and may be an option in the obese population, where neuraxial techniques may be challenging.[220] The TAP block covers nerves derived from the anterior rami of T7-L1 that provide sensation to the anterolateral abdominal wall skin, muscle, and parietal peritoneum (Fig. 26.6). Although statistically significant improvements in analgesia after TAP blocks for abdominal surgeries have been reported, these associations may only reflect a clinically modest benefit; thus this technique is not recommended for routine practice.[213] Furthermore, the TAP block may be limited in certain postsurgical settings, including coverage of midline incisional pain,[214] and presence of significant visceral pain,[225] and thus the implementation of a multimodal analgesia protocol is often necessary in these settings.

The TAP block should not be performed anteriorly in the abdominal wall because of concern for inadequate spread.[226] Furthermore, performing the block posterior to the midaxillary line has the advantage of targeting the lateral cutaneous branches prior to exiting the TAP.[227] Subcostal TAP blocks may provide analgesia for midline supraumbilical surgeries and upper abdominal incisions. The success of the block is dependent on the extensive spread of local anesthetic to traverse nerves across the abdominal wall; thus a high volume of dilute, long-acting local anesthetic (about 20 mL on each side) is preferred.[227,228] Adverse events may include damage to the viscera, retroperitoneal hematoma, nerve injury (e.g. femoral nerve palsy), and intravascular injection.[214] Caution is also advised when performing right-sided TAP blocks because of the proximity of the liver and the potential for liver injury in those with hepatomegaly.

Ilioinguinal and Iliohypogastric Nerve Block

The ilioinguinal and iliohypogastric nerve blocks provide postoperative analgesia following inguinal hernia repair, cesarean section, and other lower abdominal and inguinal surgeries. These nerves originate from the anterior ramus of the L1 nerve root and arise from the lateral border of the psoas muscle.[229] The iliohypogastric nerve travels superior to the ilioinguinal nerve and may give off lateral cutaneous branches that travel through the internal and external oblique muscles.[229] Thus these truncal nerves should be approached more proximally to avoid sparing of these lateral cutaneous branches.[229] The injectate is placed along the same plane as the TAP block (described above), although the optimal point of needle entry is 2.5 mm from the anterior superior iliac spine (ASIS) along a trajectory connecting the ASIS and the umbilicus.[214,230] Complications may include visceral damage, femoral nerve palsy, retroperitoneal hematoma, intravascular injection, and vascular injury, particularly of the inferior epigastric vessels that travel close to the ilioinguinal and iliohypogastric nerves.[214]



• **Figure 26.6** Abdominal Wall Innervation. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.

In an RCT comparing a landmark-based technique versus ultrasound guidance for ilioinguinal/iliohypogastric nerve blocks in children undergoing unilateral inguinal surgery, use of ultrasound was associated with lower sevoflurane requirement intraoperatively, lower pain scores, decreased requirement for analgesics in the post-anesthesia care unit and increased parent satisfaction despite using a lower dose of local anesthetic to perform the block.[231] A meta-analysis comparing ilioinguinal/iliohypogastric nerve block versus TAP blocks for inguinal herniorrhaphy revealed that both techniques were associated with similar postoperative opioid consumption and patient satisfaction. In contrast, the ilioinguinal/iliohypogastric cohort reported better analgesic efficacy at 6 and 8 hours postoperatively compared to the TAP block cohort.[232] In patients with cervical cancer undergoing surgery, the addition of ilioinguinal/iliohypogastric blocks with general anesthesia compared to general anesthesia alone was associated with decreased intraoperative propofol and sufentanil requirements, decreased postoperative pain scores, and longer time until the administration of first postoperative analgesic medication.[233]

Rectus Sheath Block

The rectus sheath block provides postoperative analgesia for midline abdominal and periumbilical surgeries. The location of local anesthetic deposition is beneath the rectus abdominis muscle, which traverses the anterior intercostal nerves from T9 to T11.[234,235] Specifically, the needle tip should be between the rectus abdominis muscle and the double layer that is created by the transversalis fascia and aponeurosis of the transversus abdominis muscle.[236] It is important to note that above the arcuate line, both the aponeurosis of the transversus abdominis muscle and the transversalis fascia separates the rectus abdominis from the abdominal cavity. However, caudal to the arcuate line, the rectus abdominis muscle is only separated from the abdominal cavity by the transversalis fascia.[237] Furthermore, rectus sheath blocks would only provide coverage for midline abdominal surgeries, and the presence of lateral incisions would need to be supplemented with a TAP block (discussed above). Similar to the TAP block, the rectus abdominis sheath block does not provide analgesia for visceral pain. The use of ultrasound is recommended as one study demonstrated that 21% of rectus sheath blocks performed using a landmark-based loss-of-resistance approach led to intraperitoneal needle entry.[238] Other risks include infection, post-procedural pain, LAST, visceral organ damage, and intravascular injection, particularly in superior or inferior epigastric vessels.[213,239]

Compared to patients undergoing abdominal surgeries who did not receive any block or received a sham block, those who received preoperative rectus sheath blocks generally had lower intraoperative anesthetic requirements, decreased postoperative analgesic requirement and opioid consumption, and decreased postoperative pain scores.[240,241] Furthermore, the combination of the TAP block and rectus sheath block may improve postoperative pain, reduce analgesic requirements, and accelerate postoperative recovery after major abdominal surgeries.[242] In certain high-risk patients with limited cardiovascular reserve, case reports of using

rectus sheath blocks as the primary surgical anesthetic for standard periumbilical surgery have been reported.[236]

Thoracic Paravertebral Block

The thoracic paravertebral block provides postoperative analgesia for cardiac and thoracic procedures, including thoracotomy, nephrectomy, rib fractures, chest tube insertion, and breast surgeries. Bilateral thoracic paravertebral continuous catheters are particularly useful when the placement of an epidural catheter is difficult or not pursued. A thoracic paravertebral block may also be performed in the chronic pain setting in cases of complex regional pain syndrome.[243] The proposed mechanism of the thoracic paravertebral block is the direct spread of local anesthetic into the spinal nerves, lateral tracking of local anesthetic toward intercostal nerves, and medial tracking of local anesthetic into the intervertebral foramina (Fig. 26.7).[244] Several factors may impact the efficacy of the paravertebral block. However, a successful block is usually correlated with inferior needle advancement to the transverse process, medially directed bevel, large-volume and higher speed of injection to overcome negative intrathoracic pressures, absence of surgical emphysema from subcutaneous air, absence of fracture or blood in the intercostal space, and absence of anatomical abnormalities such as foraminal stenosis, disc herniation, and facet joint hypertrophy.[244–246] Adverse effects may include procedural pain, LAST because of large volumes, nerve injury, pneumothorax, hypotension from neuraxial spread, potential for total spinal blockade, and potential for quadriceps muscle weakness if the block is inadvertently placed below L1 with resultant femoral nerve blockade.[244,247]

While the efficacy of analgesia from a paravertebral block may be similar to that of an epidural block, the paravertebral block may allow for a more targeted coverage (e.g. unilateral block), less sympathectomy, lower rates of failed block, and lower rates of side effects including urinary retention, nausea and vomiting, and hypotension.[244,248,249] Furthermore, continuous paravertebral anesthetic infusions are associated with superior postoperative analgesia, greater preservation of lung function, and fewer side effects than interpleural analgesia for thoracic surgery.[250,251]

Intercostal Nerve Block

The intercostal nerve block provides postoperative analgesia for upper abdominal and thoracic surgeries and surgical anesthesia for minor surgical chest or abdominal procedures (Fig. 26.8).[252,253] Intercostal nerve blocks may also provide analgesia for rib fractures, chest tube placements, and gastrostomy tube placements.[254] The mechanism of action is the direct local anesthetic effect on intercostal nerves. However, if a catheter is inserted medially at the angle of the rib and if the catheter lies medially to the border of the intercostalis intimus muscle, local anesthetic may spread to the paravertebral space.[255] Above the T7 level, an intercostal nerve block may be technically challenging to perform because of the scapula; thus if analgesia is desired above T7, alternative modalities such as a paravertebral block or epidural catheter should be pursued.

Because of the significant vascularity within the intercostal space, systemic concentrations of local anesthetic are high following intercostal nerve blocks, and caution must be exercised when performing multiple-level intercostal nerve blocks.[256] Furthermore, peak serum local anesthetic concentrations may not be reached until 15–20 minutes post-procedure, and thus the patient should be monitored for LAST during this interval.[256] Although rare, pneumothorax is a serious potential complication after intercostal block, with an overall incidence of 8.7% per patient and 1.4% per intercostal nerve block.[257]

• **Figure 26.8** Intercostal Nerve. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.

An RCT in patients undergoing video-assisted thoracoscopic surgery reported that the addition of an intercostal nerve block was associated with better postoperative analgesia and less morphine consumption in the early postoperative period (6 hours) compared to those who did not receive an intercostal nerve block.[258] This is consistent with another study reporting improved postoperative analgesia and quality of life after patients received intercostal nerve blockade for percutaneous nephrolithotomy.[253]

Erector Spinae Plane Block

The erector spinae plane block (ESPB) is a relatively novel interfascial plane block initially described in the setting of chronic thoracic neuropathic pain and video-assisted thoracoscopic surgery.[259] The deep needle approach to ESPB, which is the recommended approach, involves local anesthetic injection deep to the three erector spinae muscles (iliocostalis, longissimus, and spinalis) but superficial to the thoracic transverse processes.[259] The superficial approach involves local anesthetic injection between the erector spinae muscle and the rhomboid major muscle.[260] When utilizing the deep approach, studies have demonstrated injectate spread from C7 to T8 on the right side and T1 to T8 on the left side within the paraspinous gutter and lateral spread toward the transverse processes.[259,261] Owing to its relative distance from the pleura, major blood vessels, and spinal cord compared to the paravertebral block, the ESPB provides a favorable adverse risk profile. Furthermore, unlike neuraxial analgesia, ESPB may be performed in patients with thoracic vertebral fractures.[262]

ESPB has been described as an effective analgesic modality for rib fractures as well as a variety of surgeries, including thoracic surgery (e.g. video-assisted thoracoscopy, thoracotomy), cardiovascular surgery (e.g. aortic valve replacement), breast and thoracic mass surgery, open abdominal and laparoscopic surgery, and spinal surgery. Given the novelty of this fascial plane block, most of the evidence for its use in postoperative analgesia consists of case reports and small retrospective studies. A cohort study in patients with traumatic rib fractures who received ESPB showed significant improvement in incentive spirometry and reduction in pain scores with no hemodynamic instability. While there was a reduction in opioid intake, this did not reach statistical significance.[263]

Although complications specific to the ESPB are rare, there have been reported cases of pneumothorax,[264] bilateral lower extremity weakness,[265] and LAST with central nervous system effects.[266] It is recommended that those receiving an ESPB at the lower thoracic or lumbar levels be evaluated for motor weakness after completion of the block.[267] The potential for block failure or lack of analgesic efficacy has been reported in several studies, although risk factors have yet to be identified.[266,268] Future studies are warranted to characterize differences in the ESPB approach (superficial vs. deep technique), optimal volume and concentration of local anesthetic, timing of block, respiratory function, and efficacy of unilateral and bilateral ESPB for various surgical indications.

Modes of Local Anesthetic Delivery

There are many variations in the delivery of local anesthetic to the block target site. The most basic is the single injection of local anesthetic, which is commonly performed for intrathecal analgesia and various peripheral nerve blocks. Single injection blocks are performed for ambulatory and short-duration procedures and typically provide short-term surgical anesthesia and analgesia depending on the local anesthetic medication injected. For instance, a single injection of peripheral nerve block with bupivacaine provides longer postoperative analgesia than intermediate-acting agents such as lidocaine.

If a catheter is placed for continuous infusion of local anesthesia, different delivery settings, including continuous infusion, intermittent bolus dosing, or a combination of both, may be pursued. Intermittent bolus dosing may be categorized as either manually delivered intermittent bolus dosing or programmable intermittent bolus dosing. Studies have examined PCEA, which provides excellent analgesia for various surgeries and is

associated with few complications.[269] While many RCTs have compared intermittent bolus dosing and continuous infusion delivery modes, a recent systematic review demonstrated limited evidence and reported no differences between intermittent bolus dosing over continuous infusion modes in truncal and peripheral nerve blocks.[270] For certain ambulatory surgeries, the patient may be discharged home with a perineural catheter in place and an ongoing continuous local anesthetic infusion for prolonged postoperative analgesia.[75,271] If the patient is discharged with a continuous perineural local anesthetic infusion, it is important to educate the patient on potential risks, potential for LAST, signs of infection and bleeding, and vigilance for other concerns. Suppose the patient manifests any signs or symptoms of LAST or other adverse events from regional anesthesia. In that case, the patient should stop the local anesthetic infusion, contact the acute pain service (if available at their hospital), and consider transport to the emergency department for further evaluation.

Special Patient Populations

Obese Patients

Obesity may present unique challenges in terms of perioperative analgesia. A significant proportion of obese patients have obstructive sleep apnea (OSA) and, vice versa, up to 90% of OSA patients may have obesity.[272] Thus pain management plans for patients with severe obesity, morbid obesity, or OSA include a multimodal analgesia approach that avoids or limits sedating medications and systemic opioids and utilizes regional anesthesia modalities.[273,274] This is consistent with the guidelines from the ASA Task Force on perioperative management of OSA patients.[275] A study by Batistich and colleagues demonstrated that administration of regional anesthesia and systemic non-opioid analgesia to morbidly obese patients undergoing bariatric surgery decreased the requirement for systemic opioids.[276] If sedative medications and systemic opioids are administered, obese patients and patients with OSA should be monitored for respiratory depression during the first 24 hours postoperatively, and providers should consider instituting continuous and/or remote pulse oximetry.[275,277] Furthermore, regional anesthesia may be more technically challenging and associated with block failure in obese patients. Nielsen et al. demonstrated that obese patients were 1.62 times more likely than non-obese patients to experience block failure.[278] Finally, the regional anesthesiologist must consider the elevated risk for anticoagulation needs in the obese population postoperatively.[279] Refer to the section below regarding "Patients on Anticoagulation."

Patients with Pulmonary Disease

Patients with pulmonary disease and respiratory insufficiency may benefit from utilizing regional anesthesia and avoiding sedative medications and general anesthesia.[280] However, the adverse effect profile of certain regional techniques may be detrimental to a patient with existing pulmonary disease and merits discussion. Ipsilateral phrenic nerve palsy is a common complication in brachial plexus blocks and almost always occurs in interscalene blocks.[281,282] While healthy patients may compensate for the decrease in pulmonary function, patients with cardiopulmonary disorders and moderate to severe respiratory dysfunction (e.g. severe chronic obstructive pulmonary disease, preexisting contralateral phrenic nerve palsy) may not tolerate the reduction in pulmonary function from ipsilateral phrenic nerve blockade.[281,283] Although ultrasonography, low-volume local anesthetic infiltration, and digital pressure above the injection site have been implemented, these techniques have not been associated with reduced phrenic nerve palsy.[281,284] Alternative peripheral nerve blocks may be utilized, including direct local anesthetic infiltration at the surgical site, Bier block, infraclavicular block, and axillary block, all of which carry a much lower risk for phrenic nerve palsy.[281,285]

In terms of neuraxial blockade, the presence of a high spinal or epidural anesthesia may decrease expiratory reserve volume and vital capacity and reduce the ability to forcefully exhale, cough, or clear pulmonary secretions.[286] This is usually because of paralysis of the abdominal muscles.[286] A study in elderly patients with poor respiratory reserve who received spinal anesthesia with a level above T6 demonstrated significant decreases in forced expiratory volume in one second (FEV1), forced vital capacity, and forced expiratory flow 25%–75%.[287] Tidal volume is typically not impacted unless the phrenic nerve (C3–5) is affected by higher neuraxial blockade.[286]

Trauma and Critically Ill Patients

Trauma and critically ill patients experience an amplified inflammatory response, which may activate peripheral nociceptors and initiate neurogenic inflammation that increases the release of certain nociceptive neurotransmitters such as substance P and calcitonin gene-related peptide.[288] Undertreatment of pain in trauma and critically ill patients is a major concern. It may be attributed to the inability to perform a proper pain assessment, concern for unstable hemodynamics, fear of sedation and analgesia masking and interfering with the diagnosis of underlying injuries, the misconception that sleep implies lack of pain, concern for addiction, and the misconception that trauma patients do not recall painful episodes.[289–291] After establishing stable hemodynamics, cautious analgesic administration is indicated and may even make the patient more cooperative after adequate pain control is achieved, permitting further assessment and detection of unrecognized injuries. This may be especially critical in assessing cervical spine injuries because distracting injuries may interfere with accurate diagnosis.[292]

Peripheral nerve blockade and neuraxial techniques play an important role and may reduce the need for opioids and other sedative agents. Various regional anesthesia techniques may offer significant analgesia depending on the location of the injury. Brachial plexus blocks, lower extremity blocks, and neuraxial blocks may provide analgesia to the upper extremity, lower extremity, and thoracic/truncal injuries, respectively. With rib fractures, neuraxial analgesia, paravertebral blocks, ESPB, and intercostal blocks offer significant analgesia, decrease the need for opioids, and may be associated with improved respiratory indices by preventing splinting (improved oxygenation, tidal volume, and inspiratory force; decreased atelectasis and ventilation/perfusion mismatch).[293–295]

If neuraxial blockade is pursued, the proceduralist should ensure definitive spinal cord injury clearance. Furthermore, in patients with head trauma and the potential for elevated intracranial pressure, neuraxial techniques may not be an option because of the potential for herniation of the brain and cerebral structures as well as expansion of intracranial hematomas.[296] Additionally, coagulopathy is common in patients with polytrauma, which would be a contraindication to neuraxial analgesia. It is also recommended

that certain peripheral nerve blocks performed close to the neuraxis (e.g. lumbar plexus block, paravertebral blocks) and at non-compressible sites (e.g. infraclavicular nerve block) be avoided in polytrauma cases with coagulopathy. Finally, hemorrhagic shock and hemodynamic instability are commonly present in trauma patients, leading to ischemia and multiple-organ dysfunction.[297] Ketamine and various non-opioid analgesics have been shown to provide effective analgesia with limited effects on hemodynamics.[298] Furthermore, sympathectomy from neuraxial local anesthetics may be undesirable in trauma patients with hemodynamic instability; in such cases, opioid-only infusions may be utilized with a better hemodynamic profile.

Patients on Anticoagulation

The incidence of bleeding complications from neuraxial blocks is unknown, but some sources cite an incidence of one in 150,000 epidural blocks and one in 220,000 spinal blocks.[299] This risk is elevated in certain populations, such as those taking anticoagulants and those with coagulopathy disorders. Guidelines on performing regional anesthetic techniques are based on guidelines derived from a retrospective analysis of observational data and pharmacologic dosing studies.[299] There are no laboratory models available, and prospective randomized studies are not possible because of ethical reasons and the requirement for very large sample sizes. Finally, this issue is further compounded by medication-related factors (duration of therapy, degree of anticoagulation), procedure-related factors (location of regional block, need for catheter placement), patient-specific factors (obesity, advanced age, personal or family history of coagulopathy, trauma, pregnancy), surgery-related factors, and other pharmacologic factors (concomitant use of herbal medications that increase the risk of bleeding, polypharmacy, and drug-drug interactions), all of which may impact bleeding risk.[299]

As previously mentioned, certain regional techniques are less suitable for patients with potential coagulopathy and increased risk for bleeding, including neuraxial analgesia, nerve blocks performed close to the neuraxis (e.g. lumbar plexus block, paravertebral blocks), and peripheral nerve blocks performed at non-compressible sites (e.g. infraclavicular nerve block). The proceduralist should also refer to recommendations and guidelines published by reputable societies such as the American Society of Regional Anesthesia (ASRA) and the European Society of Regional Anesthesia (ESRA) regarding discontinuation of anticoagulation perioperatively and for high-risk regional anesthetic procedures.[300,301] Variations between the two practice recommendations have been narrowed as members of the ESRA anticoagulation Writing Committee helped formulate the latest edition of the ASRA guidelines.[300,301]

A thorough risk-benefit analysis of performing regional anesthesia in anti-coagulated patients is warranted and should be individualized. Further details on the implications of anticoagulation from common pain related procedures are included in Chapter 74.

Conclusion

With the increased implementation of ERAS and multimodal analgesia pathways in the perioperative setting, studies continue to show improvements in patient-reported pain scores, improvements in rehabilitation, and decreased hospital stays. Acute pain proceduralists should consider for each patient a unique and individualized treatment plan while taking into account the nature of the surgery, anatomic location, procedural factors, expected hospital duration, and side effect profile. Unless contraindicated, multimodal pathways should always include NSAIDs or acetaminophen and utilize regional anesthetic techniques.

Key Points

- While opioids remain the mainstay of postoperative analgesia for moderate to severe pain, multimodal analgesia is recommended and includes other non-opioid analgesics with different mechanisms of action.
- Neuraxial analgesia provides superior pain control over systemic opioids for various abdominal, thoracic, and lower extremity surgeries. This route of analgesia is not suitable in certain scenarios, including therapeutic anti-coagulation, bleeding disorders, certain neuroanatomic abnormalities, elevated intracranial pressure, and intracranial hematoma.
- Lumbar plexus blocks provide analgesia for hip and knee procedures, while the psoas compartment block is considered an advanced regional anesthetic block because of its proximity to the neuraxis as well as its non-compressible location.
- Sciatic nerve blockade may be performed through various approaches, including parasacral, subgluteal, and popliteal, as well as surgical anesthesia and postoperative analgesia for TKA and below the knee surgeries.
- The interscalene brachial plexus block provides analgesia for shoulder surgeries, supraclavicular block provides analgesia for upper arm and elbow surgeries, while both infraclavicular and axillary blocks provide analgesia for elbow, forearm, and hand surgeries.
- Depending on the approach to brachial plexus blockade, sparing of various nerves may occur, including the ulnar nerve (interscalene block), musculocutaneous nerve (axillary block), and intercostobrachial nerve (spared in all brachial plexus blocks).
- The transversus abdominus plane, rectus abdominus, and ilioinguinal/iliohypogastric nerve blocks provide somatic pain coverage of the abdominal wall but do not provide visceral pain coverage.
- Neuraxial analgesia, paravertebral blocks, and intercostal blocks may provide analgesia for breast, thoracic, cardiac, and upper abdominal surgeries, although more side effects are associated with neuraxial techniques.
- Administration of opioid analgesics and regional anesthesia warrants special consideration of the adverse effect profile in certain at-risk populations, including obese patients, patients with OSA, trauma and critically ill patients, patients with pulmonary disease, patients with bleeding disorders, or those taking anticoagulant medications.

Evaluation and Treatment of Postoperative Pain in Patients With Opioid Use Disorder

YI CAI, GREGORY A. ACAMPORA, T. ANTHONY ANDERSON

Background

Because of the dramatic increase in the number of opioid related deaths since 1999, the opioid epidemic was declared a "public health emergency" in the United States on October 26, 2017.[1] The opioid abuse epidemic arose in part from a lack of acknowledgment about the high addiction potential of opioids along with aggressive widespread pharmaceutical company marketing of prescription opioids for both acute and chronic pain treatment in the late 1990s.[2,3] This led to pervasive opioid diversion, opioid abuse, and a rapid rise in opioid overdoses, leading to over 47,000 people in the United States dying from an opioid overdose in 2017.[4] As seen in Fig. 27.1, from 2010–2015 the annual number of deaths from prescription opioids remained relatively stable. However, overdose deaths from illicit opioids (heroin followed by high-potency synthetic opioids such as fentanyl) nearly tripled. This large increase in illicit opioid use was driven in part by people prescribed opioids and who subsequently developed opioid use disorder (OUD).[5,6]

OUD is defined by the *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition, criteria as having at least two of the criteria illustrated in Table 27.1. As of 2015, two million Americans aged 12 years or older had an OUD involving prescription opioids, and nearly 600,000 had an OUD involving heroin. Opioid-attributable deaths increased 292% between 2001 and 2016.[7] In 2016, the approximate person-years of lives lost in the United States from opioid-attributable deaths was 1.68 million (5.2 per 1000 population),[7] and opioid overdose was linked to an average of two-thirds of the 175 daily deaths related to all drug overdoses in the United States.[8] The economic burden of prescription opioid abuse in 2013 was estimated to be almost $80 billion.[9] The global burden of disease from opioid related conditions approaches 11 million life-years lost from health problems, disabilities, and early death.[10]

Some patients are at a higher risk of developing OUD, and widely available scoring systems such as the opioid risk tool (ORT) were developed to screen for the likelihood of aberrant behavior. These criteria included a personal history or family history of illicit substance use, comorbid psychological disorder, age between 16 and 45 years, and history of preadolescent sexual abuse (Table 27.2).[11] One study found that patients who were younger, had comorbid depression, used psychotropic medications, and were impaired by pain had a significantly increased risk of developing OUD (odds ratio of eight).[6]

Comorbid chronic pain (CP) and substance use disorders (SUD) are very common. Chronic non-cancer pain (CNCP) is common among patients treated for SUD, and SUD is common among those treated for CNCP. The lifetime prevalence of CP in patients with SUD is over 50% and as high as 75% in those actively treated for SUD. The overall prevalence of current SUD among patients with CNCP is as high as 48%, and the lifetime prevalence of any SUD in those CNCP is as high as 74%.[12–14] SUD may result from substances used to cope with pain symptoms, and/or substance use-related injury may lead to CP conditions.[15,16] However, many experts now believe that a diathesis-stress model best explains these comorbidities. Patients have preexisting, semi-dormant characteristics of the individual before the onset of CP, which are then activated and exacerbated by the stress of this chronic condition, eventually resulting in diagnosable psychopathology.[17] Several studies have examined the chronologic relationship between CNCP and SUD with conflicting evidence.[18–21]

The management of pain in patients with SUD, specifically OUD, has not been investigated in detail. Studies published on the co-management of OUD and CNCP suggest the use of 1) multi-disciplinary care teams, 2) stepped care models, and 3) multimodal treatments with a combination of nonpharmacologic, non-opioid pharmacologic, and buprenorphine or methadone.[22–25] In 2012, the Center for Substance Abuse Treatment published a thorough set of recommendations for managing CP in patients with SUD based on expert recommendations.[26]

It is critical to understand that the risk of death in adults with SUD is significantly higher than in those without; even patients undergoing SUD treatment have a mortality rate approximately four times that of the general United States population,[27] while those with OUD also have a significantly elevated mortality rate.[28] Even those with OUD and treated with an opioid agonist have a significantly higher death rate from drug abuse and other causes than the general population.[29] Thus in those patients being actively treated for OUD, relapse may be lethal. Clinicians must be aware that pain management in patients with active addiction or in treatment, especially treatment involving opioids, is perilous.

This chapter will review the latest evidence for the management of acute postoperative pain in patients with comorbid OUD.

TABLE 27.1 DSM-V Criteria for Opioid Use Disorder

Opioids are often taken in larger amounts or over a longer period than was intended.
There is a persistent desire or unsuccessful efforts to cut down or control opioid use.
A great deal of time is spent in activities necessary to obtain the opioid, use the opioid, or recover from its effects.
Craving, or a strong desire or urge to use opioids.
Recurrent opioid use resulting in a failure to fulfill major role obligations at work, school, or home.
Continued opioid use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of opioids.
Important social, occupational, or recreational activities are given up or reduced because of opioid use.
Recurrent opioid use in situations in which it is physically hazardous.
Continued opioid use despite having a persistent or recurrent physical or psychological problem likely to have been caused or exacerbated by the substance.
Exhibits tolerance.*
Exhibits withdrawal.*

*This criterion is not considered for those taking opioids solely under appropriate medical supervision. At least two of the criteria should be observed within 12 months. If two or three Items cluster together in the same 12 months, the disorder is mild; if four or five items cluster, the disorder is moderate; and if six or more items cluster, the disorder is severe. These criteria are from the *Diagnostic and Statistical Manual of Mental Disorders,* fifth edition.[195]

Given the paucity of published evidence on this topic, recommendations from experts in the field and data from the management of perioperative pain alone are extrapolated to the care of patients with comorbid SUD.

Management of Opioid Use Disorder

The Substance Abuse and Mental Health Services Administration (SAMHSA) has determined that the combination of medication assisted treatment (MAT) and cognitive behavior therapy should be used to manage patients with OUD.[30] The three medications approved by the United States Food and Drug Administration for MAT are methadone, buprenorphine, or naltrexone.

The outcomes of MAT treatment in patients with OUD are dramatic; patients who use methadone have retention rates of 60%–84%,[31,32] and patients who use buprenorphine have similar results.[33,34] Importantly, mortality rates also decrease with the use of these medications. In a well-cited randomized placebo control trial comparing buprenorphine to a placebo, the

Total score		

Opioid risk tool may be used to screen patients and indicates the risk of opioid use. A ccore of zero to three indicates low risk, a score of four to seven indicates moderate risk, and a score higher than eight indicates high risk. Adapted from Webster and Webster 2015.[11]

placebo group dropout rate was 100% by the second month, with all subjects demonstrating urine samples positive for drug use and mortality rate of 20%.[32] Buprenorphine-treated patients demonstrated a 75% retention rate and a mortality of 0% at one year.[33] A meta-analysis assessing methadone versus buprenorphine treatment for patients with OUD found that subjects who received 8–12 mg/day buprenorphine had 1.26 times the relative risk of discontinuing treatment and 8.3% more positive urinalyses than subjects receiving 50–80 mg/day methadone.[34] However, different dropout rates have been observed with other doses of methadone. For example, patients who receive doses of less than 60 mg of methadone are significantly more likely to drop off treatment than those who received doses of 80 mg or more.[35]

Acute Pain Treatment Goals

The appropriate management of new-onset pain in patients with OUD depends on the origin of pain (i.e. new postoperative acute pain versus acute on chronic exacerbation). As recommended above, management should include a multispecialty approach and multimodal pharmacologic and nonpharmacologic treatments. The goals of treating acute pain in patients with OUD are to prevent withdrawal, provide adequate analgesia, and avoid triggering a relapse if a patient is in recovery (or worsening of the disorder if a patient has active addiction).

The most common causes of acute pain include surgery, fracture, dental work, cuts, and burns. Patients taking opioids to control CP, OUD, or illegitimately should not be intentionally weaned off opioids during an acute pain episode because of the risk of withdrawal and presumed hyperalgesia. A multimodal regimen, including nonpharmacologic therapies, regional anesthesia, and/or non-opioid medications, may reduce the need for additional opioid medications.[36] Continuous regional anesthesia provides superior perioperative analgesia compared to opioid-based management of acute pain and should be strongly considered when possible as part of the multimodal pain management plan for patients who undergo surgery.

Challenges of Postoperative Pain Management in Patients With Opioid Use Disorder

There are many challenges in treating acute pain in patients with OUD, including withdrawal, tolerance, hyperalgesia because of chronic opioid exposure, and comorbid psychological conditions, including the risk of relapse.

Withdrawal. Withdrawal during hospitalization can occur after underdosing inpatient opioids and/or sudden discontinuation of a misused drug if illicit drug use is not known, such as in an unconscious patient or one who voluntarily withholds details of their history. Withdrawal and severity may be diagnosed using the Clinical Opiate Withdrawal Scale (Fig. 27.2) using symptoms such as dysphoric mood, nausea or vomiting, muscle aches, lacrimation, rhinorrhea, pupillary dilation or piloerection or sweating, diarrhea, yawning, fever, or insomnia. The time to onset of withdrawal symptoms depends on the type of opioid used. Short acting opioids such as heroin have an onset of withdrawal at 8–24 h after last use and may last 4–10 days. Long-acting opioids such as methadone have an onset of withdrawal symptoms 12-48 h after last use and may last 10–20 days.

Hyperalgesia. Hyperalgesia is an increased sensitivity to painful stimuli. Patients with OUD report a pain sensitivity increase of 42%–72% compared with controls.[37,38] The mechanisms of hyperalgesia can be attributed to central activation of *N*-methyl-D-aspartate (NMDA) receptors and protein kinase C, upregulation of spinal dynorphin, and apoptosis of spinal dorsal horn neurons.[39–41] Patients with OUD maintained on methadone may be hyperalgesic and cross-tolerant to the anti-nociceptive effects of very high plasma morphine concentrations. Higher morphine doses may achieve pain relief, although there is a risk of respiratory compromise.[42]

Tolerance. Tolerance is thought to involve opioid receptor desensitization, internalization, and downregulation, whereas dependence and withdrawal are primarily because of opioid receptor counter adaptation.[43] Clinically, which is defined as an increasing requirement of a drug to gain the same effect. However, different opioids develop tolerance at different rates and different degrees; this is called differential tolerance.[44] For opioids, the development of tolerance is most profound for analgesia, followed by respiratory depression, and finally peripheral effects such as decreased gastrointestinal motility. Thus patients with OUD will be tolerant to the analgesic effects of opioids but may still have an increased risk of respiratory depression if the pain is treated with opioids.[44]

Psychological Comorbidities. There is a high association of substance use disorder with CP despite the absence of clear-cut directional causality.[45,46] Patients with CP often have SUD involving other substances such as benzodiazepines, alcohol, and cannabis.[47–49] CP patients also have a high incidence of psychological comorbidities, including major depressive disorder, anxiety spectrum disorders, post-traumatic stress disorder, and risk of suicide.[50] Data suggests that CP is a significant independent risk factor for suicidality.[51] Predictors of suicidality included frequent intermittent pain, sleep problems, and feeling negative about self-mental health. Interestingly, pain duration, intensity/severity, or type were unrelated to suicide risk.

Patient's Namef_____ Date and Time:___/____/___:_____

Reason for this assessment: _____

Resting Pulse Rate: _____beats/min.
Measured after patient is sitting or lying for 1 min.
0 pulse rate 80 or below
1 pulse rate 81-100
2 pulser rate, 101-120
4 pulse rate greater than 120

GI Upset: *over last 1/2 hour*
0 no GI symptoms
1 stomach cramps
2 nausea or loose stool
3 vomiting or diarrhea
5 multiple episodes of diarrhea or vomiting

Sweating: *over past 1/2 hour not accounted for by room temperature or patient activity.*
0 no report of chills or flushing
1 subjective report of chills or flushing
2 flushed or observable moistness on face
3 beads of sweat on brow or face
4 sweat streaming off face

Tremor *observation of outstretched hands*
0 no tremor
1 tremor can be felt, but not observed
2 slight tremor observable
4 gross tremor or muscle twitching

Restlessness *Observation during assessment*
0 able to sit still
1 reports difficulty sitting still, but is able to do so
3 frequent shifting or extraneous movements of legs/arms
5 unable to sit still for more than a few seconds

Yawning *Observation during assessment*
0 no yawning
1 yawning once or twice during assessment
2 yawning three or more times during assessment
4 yawning several times/minute

Pupil size
0 pupils pinned or normal size for room light
1 pupils possibly larger than normal for room light
3 pupils moderately dilated
5 pupils so dilated that only the rim of the iris is visible

Anxiety or Irritability
0 none
1 patient reports increasing irritability or anxiousness
2 patient obviously irritable or anxious
4 patient so irritable or anxious that participation in the assessment is difficult

Bone or Joint Aches *If patient was having pain previously, only the additional component attributed to opiates withdrawal is scored*
0 not present
1 mild diffuse discomfort
2 patient reports severe diffuse aching of joints/muscles
4 patient is rubbing joints or muscles and is unable to sit still because of discomfort

Gooseflesh Skin
0 skin is smooth
3 piloerection of skin can be felt or hairs standing up on arms
5 prominent piloerection

Runny Nose or Tearing *Not accounted for by cold symptoms or allergies*
0 not present
1 nasal stuffiness or unusually moist eyes
2 nose running or tearing
4 nose constantly running or tears streaming down cheeks

Total Score: _____
The total score is the sum of all 11 items

Initials of person completing assessment: _____

Score: 5–12 = mild; 13–24 = moderate; 25–36 = moderately severe; more than 36 = severe withdrawal

• **Figure 27.2** The Clinical Opiate Withdrawal Scale (COWS). COWS is an 11 item scale designed to monitor the symptoms and severity of opiate withdrawal over time. Score: 5–12, mild; 13–24, moderate; 25–36, moderately severe; >36, severe withdrawal. Revised from Wesson and Ling 2003.[194]

Evaluation of Patients With Opioid Use Disorder who Present for Surgery

Evaluation of both inpatients and outpatients with OUD is best accomplished using a multispecialty approach, including psychiatry, psychology, social work, physical therapy, and/or pain management specialists. Similar to the evaluation of patients with CP and SUD, patients should undergo a comprehensive assessment that includes their substance use history, whether they have active addiction or are in treatment, their comorbidities (including CP history and psychiatric history), a physical examination, and the patient's current mental status.[52] A thorough history and physical examination should include prescription-controlled medication use (which should be verified according to the state's prescription drug monitoring program), the dose of medications taken, use of recreational drugs, pain goals, withdrawal symptoms such as nausea, vomiting, diarrhea, anxiety, and shivering (Table 27.3), and even potentially a urine toxicology screen for controlled and

TABLE 27.3 Symptoms of Opioid Withdrawal, Grouped Into Categories Based on the Organ System Affected

Table 3. Opioid Withdrawal Symptoms	
Gastrointestinal distress	Abdominal cramps Diarrhea Nausea Vomiting
Flu-like symptoms	Lacrimation, rhinorrhea, diaphoresis, shivering, piloerection
Sympathetic arousal	Mydriasis Hypertension Tachycardia Tremor Myalgia/arthralgia
Psychological symptoms	Anxiety Irritability Dysphoria Insomnia Agitation
Other	Yawning, sneezing

illicit medications. If the patient had a history of CP, the baseline pain intensity at rest and during activity should also be assessed. In patients admitted for non-elective surgical procedures, perioperative (particularly post-surgical) withdrawal symptoms should be anticipated. For patients who will require postoperative pain management with opioids postoperatively, especially those who will be discharged with an opioid prescription, screening for opioid abuse risk may occur. While it is assumed that a history of OUD predicts increased risk, the degree of risk can be further anticipated with a simple screening tool. For example, the "ORT" scores patients based on their family history of substance use, personal history of substance use, age, history of preadolescent sexual abuse, and psychological disease.[11]

Patients With OUD in Remission who Present for Surgery

Patients with OUD in remission and without medication treatment may no longer have signs and symptoms of physical dependence, but will continue to be susceptible to triggers. Triggers for relapse include stress (i.e. surgery) and administration of the agents of abuse (i.e. opioids). Thus these patients are at a particularly high risk of relapse. Anxiety surrounding surgery, perioperative concerns (e.g. financial, social, and/or professional), and postoperative pain are stressors that can trigger drug cravings and relapse,[53] as may poor pain control, if it occurs perioperatively.[54,55] An acute pain consultation, even prior to surgery, can help with the development of a safe and effective perioperative pain plan, which may include regional anesthesia, multimodal pharmacologic therapy, and discharge planning.[56] Discharge planning may include storage and disposal of unused opioids and enlisting the help of a responsible friend or family member to assist in managing the patient's opioid use. Overdose prevention education and naloxone prescription should be considered.[57]

Management of postoperative pain in patients with OUD on MAT should start with the continuation of the home medication treatment regimen. Therapy should be based on the degree of expected pain, which depends on the type of surgery and includes, as appropriate, non-opioid adjuvant therapies, regional anesthesia, and nonpharmacologic therapies. Additional opioids can be added, but only when the benefits are deemed greater than the risk. If additional opioids are added, a postoperative tapering plan should be developed to discontinue them after the perioperative phase. Moreover, clear communication should be undertaken with the patient to set expectations and prevent opioid escalation. Multi-disciplinary discharge planning is critical.[58]

Postoperative Pain Management Techniques for Patients With Opioid Use Disorder

Non-opioid Pharmacologic Treatment

Patients on high-dose opioids have a high occupancy rate of opioid receptors, and thus non-opioid methods of pain control allow for the treatment of pain using medications that interact with different pain receptors. The type of medication should be tailored to the type of pain, inflammatory, nociceptive, or neuropathic pain. The use of non-opioid analgesics decreases the need for additional opioids. Most of the available evidence for the efficacy of non-opioid analgesics in reducing and improving perioperative pain is not available in patients with OUD. However, many pain experts recommend maximizing the perioperative use of non-opioid analgesics in patients with OUD when possible. Using a combination of analgesic medications with different mechanisms of action may decrease pain, improve functional outcomes, reduce opioid requirements, and decrease the duration of hospital stay. Although not well studied, even if individual medications only provide mild to moderate improvements in pain outcomes, a combination of agents may have an additive or synergistic effect on postoperative pain.

Intravenous Lidocaine

The pain-alleviating effects of systemic lidocaine in patients with CP conditions have been noted in patients with spinal cord injury,[59] diabetic neuropathy,[60] central pain syndrome,[61] chronic regional pain syndrome,[62] and postherpetic neuralgia.[63] One of the proposed pathophysiologic mechanisms of neuropathic pain is the upregulation of sodium channels in nociceptors. The change in channel density on nociceptor membranes creates an electrochemical environment that causes neurons to reach their depolarization threshold more rapidly, which leads to increased nociceptive signaling. Lidocaine acts as a sodium channel blocker and can modulate neuropathic pain by decreasing the function of these sodium channels, reversing the effects of sodium channel upregulation.[64] While the quality of the evidence is limited and results are variable, lidocaine has been demonstrated to improve postoperative pain scores, decrease opioid consumption, decrease nausea, decrease the duration of hospitalization, and decrease the length of ileus in patients undergoing open or laparoscopic surgery.[65] For instance, Koppert et al. reported a 35% reduction in morphine consumption between 0 to 72 h after surgery in 40 patients undergoing major abdominal surgery.[66] A continuous lidocaine infusion may take 4 to 8 h to achieve a steady state; the context sensitive half-life is 20–40 min after a three day infusion and does not accumulate in healthy individuals.[67] However, pain benefits can persist for many hours or even days after the termination of the infusion, partially because of the anti-inflammatory effects of lidocaine,

which block the activation of polymorphonuclear granulocytes, thus dampening the cascade of inflammatory responses.[65,68] A randomized clinical trial of 180 patients with OUD who underwent orthopedic surgery under general anesthesia were randomly allocated to receive an intravenous infusion of lidocaine, ketamine, or a placebo. Patients who received lidocaine had lower numeric pain scores and opioid consumption 24 h postoperatively than both the ketamine and placebo groups.[69] In addition, patients in the lidocaine group were less restless, calmer, and less drowsy than patients in the ketamine and control group. A 2018 Cochrane review assessed the efficacy of perioperative lidocaine and included 68 randomized controlled trials; the authors concluded that it was uncertain if systemic lidocaine had a clinical impact on pain scores or opioid consumption. The study found a reduction in ileus with a risk ratio 0.37 (95% confidence interval [CI] 0.15 to 0.87), a reduction of time to first bowel movement by a mean of −7.92 h (95% CI −12.71 to −3.13), and a reduction in postoperative nausea with a risk ratio of 0.78 (95% CI 0.67 to 0.91).[70]

N-methyl-D-aspartate (NMDA) Receptor Antagonists

Examples: ketamine, methadone, memantine, amantadine, dextromethorphan.

NMDA receptor antagonists modulate nociception in spinal pain fibers and the central nervous system. Ketamine is the most commonly used NMDA antagonist. At subanesthetic doses, ketamine has been used as an analgesic and to prevent central sensitization,[71] and the spreading of pain sensitivity beyond the original site of injury in the form of secondary hyperalgesia and allodynia. Ketamine can be administered intravenously to both inpatients and outpatients. It can also be used orally and intranasally but is commonly administered intravenously perioperatively. Inpatient delivery and monitoring (e.g. the level of care required, such as telemetry) will depend on institutional protocols. A meta-analysis assessing the efficacy of perioperative ketamine reported a decrease in morphine consumption at 24 h (15.7 mg) and a slight decrease in pain scores at 48 h postoperatively.[72] A meta-analysis assessing the utility of perioperative ketamine included 47 studies in subjects without OUD and found that its use decreased opioid consumption and the time to first analgesic need in the included studies, but with the greatest efficacy in thoracic, abdominal, and orthopedic surgeries. Despite using fewer opioids, 25 out of 32 treatment groups (78%) experienced less pain than the placebo group at some point postoperatively.[73] In patients without OUD taking opioids for CP, a ketamine infusion has been found to decrease average pain scores compared to a placebo, without a change in opioid consumption.[74]

Dextromethorphan is a common antitussive medication and an NMDA antagonist; its affinity with the NMDA receptor is lower than that of ketamine. A meta-analysis of randomized, double-blinded, placebo-controlled trials of subjects without OUD noted that perioperative dextromethorphan use reduced postoperative opioid consumption at 24 to 48 h and pain scores at 1, 4, 6, and 24 h.[75] In a meta-analysis of multimodal preemptive analgesic adjuncts in subjects without OUD benefit was found for preemptive nonsteroidal anti-inflammatory drugs, epidural analgesia, and local anesthetic infiltration, but the effects of ketamine and dextromethorphan were determined to be equivocal.[76]

α-2 Agonists

Examples: Dexmedetomidine, clonidine.

α-2 Agonists act on the a2 receptors of the peripheral and central nervous systems, resulting in sedation, hypnosis, anxiolysis, sympatholysis, and analgesia.[77,78] α2 Agonists appear to potentiate the analgesic effects of opioids.[79]

In a meta-analysis of 28 randomized controlled trials, patients without OUD treated with dexmedetomidine perioperatively reported lower pain intensity at 1 h postoperatively and reduced postoperative opioid consumption at 24 h postoperatively compared to a placebo. In addition, patients demonstrated a lower risk for nausea in the postanesthesia care unit (PACU).[77] In another meta-analysis of 30 trials analyzing both clonidine and dexmedetomidine, both were found to reduce morphine use after surgery. A decrease in morphine use was observed for dexmedetomidine from to 2–24 h postoperatively, with a cumulative decrease in morphine of 30%. The decrease in morphine use was observed for clonidine from 12–24 h postoperatively, with a cumulative morphine decrease of 25%.[78] The degree of morphine sparing was stronger than what has been reported with acetaminophen,[80,81] but weaker than with ketamine,[72] or nonsteroidal anti-inflammatory drugs.[81]

Gabapentinoids

Examples: gabapentin, pregabalin.

Anti-convulsants are typically prescribed for the management of neuropathic pain and have demonstrated efficacy in reducing perioperative pain.[82–86] Surgical tissue injury produces neuroplastic changes leading to spinal sensitization, hyperalgesia, and allodynia.[87,88] Anti-convulsant drugs may be important in the modulation of these postoperative neural changes by suppression of sodium channel and calcium channel activity and suppression of the glutamate action on the NMDA receptor in both the peripheral and central nervous systems.[89]

Gabapentin is an anti-convulsant that blocks the α-2-δ subunits of voltage-dependent calcium ion channels and has been found to reduce postoperative pain and opioid requirements when administered as a single 300–1200 mg dose in patients without OUD.[83,84,90,91] In meta-analyses of spine surgery patients without OUD, gabapentin was found to decrease pain, opioid use, and urinary retention.[91,92] However, in a meta-analysis assessing the effect of gabapentin after total knee arthroplasty, no difference in pain scores was found compared to a placebo.[93]

Pregabalin is similar in mechanism to gabapentin but is more potent with fewer side effects.[94] Pregabalin has been found to have similar benefits to gabapentin perioperatively.[85,95,96] In a systematic review, pregabalin improved postoperative analgesia and reduced morphine equivalent postoperatively than with a placebo.[85,97] Similarly, in a meta-analysis of knee arthroplasty, pain was reduced by approximately 0.5 on an 11 point numeric rating scale.[93] A meta-analysis of patients undergoing hysterectomy concluded that pregabalin decreased pain, morphine consumption, and postoperative nausea and vomiting (PONV).[98,99] When 100–300 mg is used, no difference in acute pain outcomes have been found when a single preoperative dose of pregabalin is given or multiple doses perioperatively.[85] In a meta-analysis of studies in which patients underwent bariatric surgery, a single preoperative dose of 75 mg pregabalin did not improve pain relief, quality of postoperative recovery, or reduction in opioid consumption.[100] However, this may have been because of the low dosage and large volume of distribution in the patient population. This is supported by a dose study in spine surgery patients in which 150 mg pregabalin administered before surgery and 12 h after surgery resulted in decreased opioid consumption. However, the lower dose of 75 mg before and after surgery produced no significant opioid-sparing effect.[101] Regrettably, both gabapentin and pregabalin have an

emerging potential for misuse, particularly in individuals with OUD,[102] and there may be an increase in the risk of respiratory depression when administered in combination with opioids.[103]

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

Examples: ketorolac, celecoxib, naproxen, ibuprofen.

In meta-analyses of trials with subjects without OUD, postoperative administration of nonsteroidal anti-inflammatory drugs (NSAIDs) has been shown to decrease pain across a wide range of surgeries, including lumbar spine surgery,[104] laparoscopic cholecystectomies,[105] and cesarean deliveries,[106] but not dental surgery.[107]

Ketorolac is a non-selective cyclooxygenase (COX)-1 inhibitor that has been found to decrease postoperative pain, and some studies have found a decrease in the need for opioids by 25%–45%.[108–111] Traditionally, 15–30 mg is administered intravenously to adults every 6–8 h. Even 10–15 mg ketorolac is effective in decreasing pain after spine surgery patients and in patients who present to the emergency department with pain.[112,113] Other medications such as celecoxib,[114,115] naproxen,[116,117] and ibuprofen[118,119] have also been shown to decrease postoperative pain. In a study assessing postoperative pain management and comparing ibuprofen 400 mg, oxycodone 5 mg, the combination of ibuprofen-oxycodone 400 mg–5 mg, and a placebo, the number needed to treat (NNT) for a 50% pain reduction was similar for ibuprofen and ibuprofen-oxycodone (NNT 2.3 [2.0–2.8]) than with oxycodone alone (NNT 2.9 [2.3–4]), and the combination of ibuprofen-oxycodone provided analgesia for longer than oxycodone alone.[120] In another study, the NNT for a 50% pain reduction was 2.9, for ketoprofen 50 mg, 2.5, ibuprofen 400 mg, and 2.7 for diclofenac 50 mg.[121]

Acetaminophen

Examples: N-acetyl-para-aminophenol (APAP), acetaminophen.

The mechanism of action of acetaminophen may involve inhibition of peroxidase reactions in the prostaglandin synthesis pathway.[122] A single dose of acetaminophen prior to surgery provides 4 h of effective analgesia for approximately half of patients with acute postoperative pain. The NNT with acetaminophen postoperative is five to prevent one rescue medication administration over 4–6 h.[123] Intravenous acetaminophen has been shown to reduce visual analog pain scores by 1.6 (95% CI, 1.0–2.2) and decrease morphine consumption by 30% in the first 4 h after surgery compared to a placebo.[124] In a separate study, acetaminophen led to a morphine sparing effect of 20% in the first 24 h postoperatively.[80] While acetaminophen has been found to be efficacious by itself, a Cochrane review found that ibuprofen combined with acetaminophen provided better analgesia than either drug alone at the same dose and with a smaller chance of an adverse event.[125] In a randomized controlled trial of intravenous ibuprofen versus acetaminophen in bariatric patients without OUD, both drugs reduced morphine consumption to similar degrees, but ibuprofen was superior in terms of pain relief.[118]

Muscle Relaxants

Examples: baclofen, diazepam, carisoprodol, tizanidine, methocarbamol.

While there is evidence that gamma-aminobutyric acid (GABA)–acting muscle relaxants hinder the release of substance P in animal models,[126,127] evidence for their efficacy in reducing postoperative pain is lacking.

Muscle relaxants should not be stopped perioperatively because of the risk of withdrawal. In 2020, an active clinical trial assessed the effect of a single oral dose of baclofen on postoperative pain and opioid consumption in non–opioid-naïve patients.[128] Intrathecal baclofen as an adjuvant in spinal anesthesia for total knee arthroplasty, decreased postoperative opioid usage, and decreased persistent post-surgical pain at three months after surgery.[129] Diazepam binds to $GABA_A$ receptors and potentiates GABAergic activity by increasing chloride conductance, resulting in presynaptic inhibition in the spinal cord. Diazepam is the only benzodiazepine that has been approved by the Food and Drug Administration for the treatment of spasticity and muscle spasms and is commonly prescribed for these symptoms. However, it is rarely recommended as a first line agent because of the risks of sedation and the potential for dependence or abuse.

No published studies have assessed the efficacy of methocarbamol for postoperative pain, but one study assessing its efficacy after a traumatic injury did not find improved pain control during the first three days of hospitalization.[130] Administration of 4 mg tizanidine prior to laparoscopic cholecystectomy was found in one study to reduce postoperative pain, opioid consumption, and the length of stay in the postoperative recovery unit.[131] In another study, the use of tizanidine after hernia repair decreased pain, increased time to first analgesic, and decreased total analgesic use postoperatively.[132]

Caffeine

Caffeine is a naturally occurring compound that acts on the central nervous system as a stimulant, and its anti-nociceptive actions have been linked to the antagonism of the adenosine receptors and blocking sites of prostaglandin synthesis.[133] A Cochrane review of caffeine as an analgesic adjuvant found caffeine combined with commonly used non-opioid analgesics (e.g. aspirin, NSAIDs, acetaminophen) to improve the duration and efficacy of analgesia without increasing side effects, and about 5%–10% more patients achieved a >50% pain relief with the addition of caffeine, leading to an NNT for caffeine alone to be 15.[134] Another Cochrane review assessing the efficacy of ibuprofen plus caffeine found the combination of 200 mg ibuprofen and 100 mg caffeine to have an NNT of 2.1 to achieve a >50% pain reduction.[135] In a 2019 Phase I trial, caffeine ingestion with aspirin or paracetamol was not found to alter the blood serum concentrations of those agents, suggesting caffeine enhances the analgesic efficacy of these drugs by pharmacodynamic rather than pharmacokinetic interactions.[136]

Esmolol

The analgesic effects of β-blockers have been reported in the treatment of allodynia in humans.[137] β-Blockers are also used to reduce the stress response and decrease the need for opioids following surgery.[138] A meta-analysis found that intraoperative esmolol use reduced intraoperative and PACU opioid consumption, with no change in PACU pain scores.[139] In bariatric surgery patients without OUD, patients who received intraoperative esmolol infusion had similar pain scores compared to those who received epidural analgesia; the two groups also exhibited similar rates of PONV.[140] In elective laparoscopic cholecystectomy, intraoperative esmolol infusion was not inferior to lidocaine infusion in terms of opioid requirement and pain severity in the first 24 h after surgery.[141]

Dexamethasone

Steroids are useful as adjuvant therapy for CP conditions, including metastatic bone pain, neuropathic pain, and visceral pain. Corticosteroids have been shown to reduce inflammation, edema, and spontaneous discharge in an injured nerve, which reduces

neuropathic pain.[142] Dexamethasone is the most commonly used corticosteroid because of its lack of mineralocorticoid effects, long half-life, and higher potency than other corticosteroids. Several meta-analyses assessing the efficacy of dexamethasone for perioperative pain management have concluded that it effectively reduces postoperative pain and opioid consumption.[143–145]

Lidocaine Patches

Transdermal lidocaine has been used to treat both acute and CP. Transdermal lidocaine has been found to be effective for the relief of pain in patients with postherpetic neuralgia and diabetic neuropathy.[146] In a study of patients who received a midline incision for gynecologic surgery, lidocaine patches applied to the incision resulted in reduced postoperative pain scores at rest. However, it did not result in reduced pain scores with activity, morphine consumption, or duration of hospital stay.[147] However, a meta-analysis that assessed its efficacy in the management of acute postoperative pain did not find a significant benefit for pain, opioid consumption, or hospital length of stay.[148]

Cannabinoids

In 2020, many clinical trials assessing the use of cannabinoids for acute and CP were conducted at clinicaltrials.gov. Cannabinoids may help manage some types of CP. A Cochrane review of cannabis-based medicines for neuropathic pain concluded that a higher proportion of patients experienced >50% pain relief compared with a placebo (21% versus 17%).[149] However, at this time, evidence for the efficacy of cannabinoids in managing postoperative pain suggests that they are not helpful.[150]

Regional Anesthesia: Neuraxial Blockade, Peripheral Nerve Blocks, and Local Infiltration

The use of regional anesthesia in patients with OUD who undergo surgery has not been extensively studied. However, there is significant evidence for the efficacy of regional anesthesia in improving postoperative pain compared to parenteral opioids.[151] Therefore most experts recommend the use of continuous regional anesthesia for patients with OUD who present for surgery when possible. Epidural analgesia, regardless of the location of catheter placement, time of pain assessment, or infusing agent, provides better postoperative analgesia than parenteral opioids and IV patient-controlled analgesia (PCA).[152,153] A Cochrane database review of nine randomized controlled trials showed that continuous epidural analgesia provided superior pain control 72 h after abdominal surgery compared with IV PCA alone.[154] A meta-analysis of elderly patients undergoing abdominal surgery found that the addition of epidural opioids to local anesthetics results in improved postoperative pain control.[155]

Peripheral nerve blocks for surgery of the extremities are also beneficial for managing postoperative pain. Specific regional anesthetic techniques have been discussed in detail elsewhere. For all surgeries, continuous peripheral nerve block, regardless of catheter location, provides superior postoperative analgesia, decreased opioid usage, and decreased opioid-related side effects than with opioid analgesia.[156] For abdominal surgery, transversus abdominus plane (TAP) blocks lead to a lower postoperative requirement for morphine at 24 and 48 h than with placebo.[157] If regional anesthesia is not used, infiltration of local anesthetics into the surgical area may provide some pain relief.[158,159] In a meta-analysis of total knee arthroplasty patients, periarticular local anesthetic infiltration was associated with lower pain scores, reduced opioid consumption, and a higher range of motion at 24 h compared to a placebo or no injection.[158] In lumbar spine surgery, a meta-analysis found that postoperative intramuscular local anesthetic infiltration resulted in a prolonged time to first analgesic and a significantly reduced postoperative opioid demand.[159]

Nonpharmacologic Analgesia Treatment

Overall, there is a paucity of studies assessing many different nonpharmacologic techniques for the treatment of postoperative pain. However, acupuncture and some mind-body therapies (MBTs) have been assessed for the treatment of pain. MBTs include hypnosis, meditation, cognitive behavior therapy, and guided imagery; these modalities have been shown to have a moderate effect on pain outcomes.[160] In a meta-analysis of 29 randomized controlled trials of patients without OUD, hypnosis was found to decrease postprocedural pain compared to standard care.[161] A Cochrane review suggested the efficacy of distraction, hypnosis, CBT, and breathing interventions for helping children with needle-related pain or distress. Unfortunately, the quality of evidence was low to very low.[162] Children who received acupuncture may have decreased postoperative pain and analgesic consumption with higher patient and parent satisfaction scores and no adverse outcomes.[163,164] A systematic review concluded that adults treated with acupuncture for the management of postoperative pain had lower opioid consumption, lower pain scores, and lower incidences of nausea, dizziness, sedation, pruritus, and urinary retention.[165]

Opioids

For patients who present for surgery who are prescribed opioids (non-MAT) chronically preoperatively, opioid medications should be continued perioperatively. If a patient cannot take oral medications post-procedurally, the oral morphine equivalent can be converted into a parenterally dosed opioid and administered on a scheduled basis. For patients with a history of OUD, a perioperative pain management plan that includes opioids should be developed by a multi-disciplinary care team. Opioids should be utilized after all other pain management strategies have been exhausted. The lowest effective dose of opioids should be used, and prescribed opioids should be scheduled rather than as needed.

For inpatient management, intravenous PCA is an effective method with high patient satisfaction in the emergency department (ED) and hospital.[166] For PCA to be most efficacious, patients should be counseled on the importance of delivering a self-bolus prior to painful stimulation, such as physical therapy or dressing changes. If the dose is not adequate to facilitate function, future doses can include a higher rescue bolus from the PCA machine or nursing staff prior to painful stimulation. For opioid tolerant patients, the starting dose recommendation is higher than that of opioid-naïve patients, although no firm consensus or guidelines are available. High opioid receptor affinity drugs, such as fentanyl, are preferred if patients are on MAT. The use of a PCA with basal infusion typically depends on provider preference and institution culture.

Once patients can tolerate oral intake postoperatively, the total dose of opioids required to provide adequate pain control should be calculated. Considering this, baseline home opioid medications should be restarted, plus additional opioids to manage acute pain. Given that patients with OUD have physiologic and psychological dependence, conversion to a non-injectable formulation is ideal. Providers must recognize that higher doses of opioids are

often needed in the setting of both hyperalgesia and opioid tolerance, and it is important to find a balance between the use of higher doses and respiratory depression. For all scenarios, a bowel regimen should be administered to aid gastrointestinal motility.

According to the Centers of Disease Control (CDC) recommendations in 2016, providers should consider offering outpatient naloxone when there are increased risk factors of overdose or concurrent benzodiazepine use.[167] For inpatient care, naloxone orders should be in place, so it is immediately available for use by staff. Most states have laws designed to protect healthcare professionals from civil and criminal liabilities for prescribing and dispensing naloxone.[168,169]

SAMPLE ACUTE PAIN REGIMEN FOR OPIOID TOLERANT PATIENTS

- Calculate home regimen OME; continue fentanyl patch or other long-acting meds for baseline control if patient able to tolerate PO intake
- Consider increasing home scheduled opioids by 30%
- Add short acting opioids to cover acute pain (10%–20% of 24 h baseline home dose), dosed PRN Q1-4 h
- If opt for PCA, may use hydromorphone, fentanyl, or morphine
- Avoid basal infusions unless a pain specialist agrees
- Reduce dose of new opioid by 30%–50% when switching from one opioid to another to account for tolerance

Postoperative Pain Management in Patients Taking Medication Assisted Treatment for Opioid Use Disorder

Patients on MAT for OUD, such as buprenorphine, methadone, or naloxone, require special consideration. As naloxone is an opioid receptor antagonist, it cannot be used to assist with acute pain management and should be discontinued perioperatively after consultation with an addiction specialist. Methadone and buprenorphine are dosed daily for addiction treatment, but their analgesic properties last 6–8 h; thus the continuation of outpatient dosing regimens for addiction is not sufficient for acute perioperative pain management. Patients on MAT require a pain management service consultation, and the physician prescribing the patient's MAT should be contacted.

Methadone

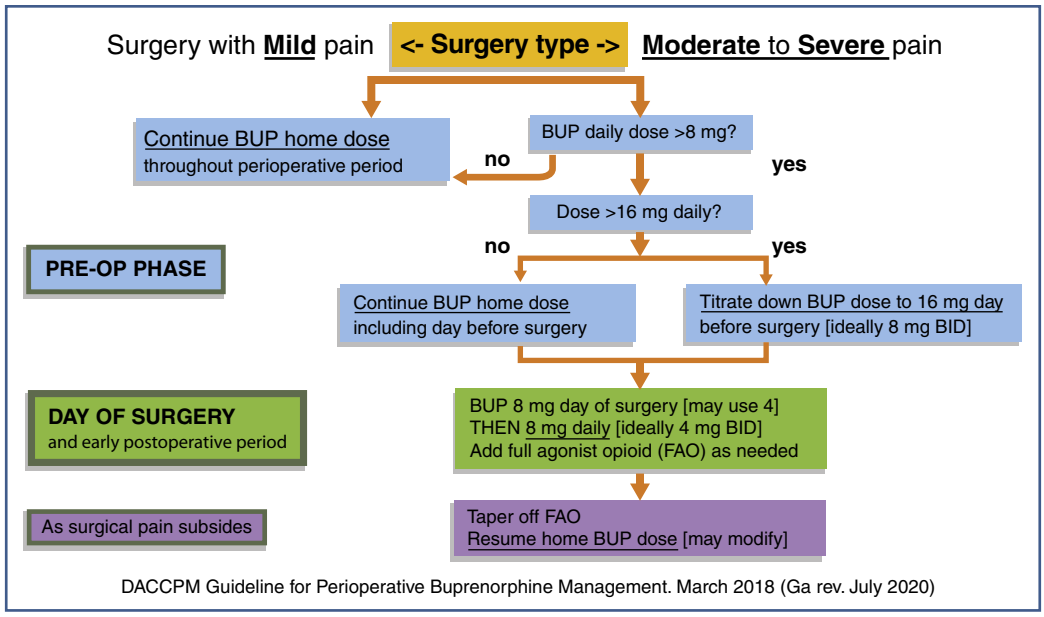
Methadone is a long-acting opioid receptor agonist that reduces opioid cravings by maintaining high levels of opioid tolerance and reducing the euphoric effects of subsequent shorter-acting opioids. As a controlled substance with a potential for abuse, it is only administered by certified SAMHSA opioid treatment programs (OTP). In patients admitted to the hospital, providers should contact the methadone treatment program to verify the dose of the patient and continue that dose in the inpatient setting, including the day of surgery.[170–172] If postoperative oral methadone is not feasible, oral methadone may be switched to the intravenous formulation; the conversion ratio will depend on the patient's baseline dose.[170,173,174] Consultation with a pain specialist is recommended. Non-opioid analgesics, including regional anesthesia, should be employed, and conventional opioid agonists may be used to supplement pain control.[171,172] The provider may also increase the daily methadone dose by 25%–30%, given in divided doses three to four times/day, allowing five to seven days between dose titration.[175] If doses are increased, intermittent electrocardiograms should occur as QT prolongation is a side effect of methadone, especially postoperatively when patients are more susceptible to electrolyte derangement.[176] In addition, monitoring for respiratory depression should occur.[176,177] Prior to discharge, patients should have a follow-up with their OTP for resumption of methadone. The final postoperative methadone daily dose used should also be communicated with the OTP. In opioid-naïve patients, methadone has been repeatedly proven to be a highly effective analgesic for controlling perioperative pain.[178,179] Thus if additional opioids are required for postoperative pain management in patients with OUD, strong consideration should be given to using methadone, both in patients taking methadone for MAT (as above, increased, divided doses) and those who are not.

Buprenorphine

Buprenorphine is a semi-synthetic partial μ opioid receptor (MOR) agonist and an antagonist of the κ-opioid receptor that can be prescribed in a clinician's office for medically supervised opioid maintenance. Although the half-life of buprenorphine is only 3 h, it has a very high affinity for, and a slow dissociation rate from, the opioid receptors to which it binds, leading to a long functional half-life.[180] Buprenorphine is used to treat CP and OUD. In 2007, the World Health Organization (WHO) recognized buprenorphine and buprenorphine-naloxone as a treatment for opioid dependence, including both drugs in the 15th WHO Model List of Essential Medicines. By 2017, at the height of the opioid abuse crisis, 14.6 million buprenorphine prescriptions were dispensed in the United States.[181] With such a high number of prescriptions, many institutions have developed their own protocol for dealing with patients on buprenorphine who present for surgery.[57] Buprenorphine's high affinity for the opioid receptor can be a challenge for treating acute pain, and there continues to be disagreement between practitioners about which has higher priority, acute pain management or continued OUD treatment.

In 2017, a well-cited article in *Anesthesiology* separated those on buprenorphine who were expected to have mild postoperative pain and moderate to severe pain postoperatively. The authors suggested that for patients with moderate-severe pain expected, tapering and cessation of buprenorphine should occur prior to elective surgery, and expectations should be for higher opioid use postoperatively.[182] The authors further suggested that multimodal analgesia should be maximized for all patients, including regional anesthesia, and follow up should be coordinated with the buprenorphine provider. In 2018, guidelines were established by *the pain physician.* Based on a review of 12 articles, providers were advised to discontinue buprenorphine three to five days preoperatively for patients with expected moderate-to-severe postoperative pain and to prescribe full opioid agonists until surgery.[183] However, discontinuation of buprenorphine in the highly stressful, emotionally charged perioperative period risks precipitation of OUD relapse.[184]

If postoperative pain is expected to be mild, most providers suggest continuing the baseline dose of buprenorphine and supplementing with multimodal analgesics.[182] If postoperative pain is expected to be mild-moderate, some clinicians suggest increasing the daily dose of buprenorphine (maximum 32 mg/day) and giving it in divided doses every 6–8 h.[183,185] Literature from 2019 and 2020 suggests that if moderate-to-severe postoperative pain is expected, buprenorphine should be continued, but decreased to 12–16 mg/day preoperatively (for those taking >16 mg/day).[182,186–188] Continuing buprenorphine



• **Figure 27.3** The protocol implemented at Massachusetts General Hospital (MGH) in March 2018. *BID,* "Bis en die" (twice/day); *BUP,* buprenorphine; *DACCPM,* department of anesthesia, critical care, and pain management at MGH; *mg, milligram; PRE-OP,* preoperative. Adapted with permission from Acampora et al. 2020.[186]

perioperatively, even at a lower than normal dose, should continue to provide OUD relapse risk mitigation. On the day of surgery and in the acute postoperative phase, if moderate-to-severe postoperative pain is expected and the daily dose is >16 mg, buprenorphine can be divided into two doses[186] (Fig. 27.3). A daily dose of buprenorphine 16 mg binds to approximately 70%–90% of μ-opioid receptors.[189]

For patients 1) who were administered monthly buprenorphine injections, 2) were scheduled for elective surgery, 3) whose daily dose of buprenorphine is >16 mg, and 4) are expected to have moderate-to-severe postoperative pain, it may be prudent to switch the patient to daily buprenorphine. For patients using the buprenorphine month implant, as the daily dose is about 8 mg/day once steady state is achieved after four weeks,[190] it should probably be continued. When pain subsided postoperatively, if additional opioid agonists were prescribed, they should be tapered and discontinued with a return to the patient's preoperative buprenorphine dose. A detailed plan should be developed preoperatively with the patient's prescription of buprenorphine.

Naltrexone

Naltrexone is an opioid antagonist that competitively binds to opioid μ receptors and can be taken as an oral formulation or a monthly intramuscular injection. Perioperative planning is ideal for discussing the risks and benefits of different options with the patient. Postoperative pain management is a clinical challenge for patients receiving naltrexone for the treatment of OUD and should include preoperative communication with the patient's naltrexone prescription.[191] For those who are on an oral formulation, naltrexone should be discontinued 72 h before surgery. For those prescribed subcutaneous injections, surgery should be scheduled for at least four weeks after the last injection. If emergency surgery is performed while the patient is on naltrexone, higher doses of opioids are required to overcome its MOR antagonist activity.[192] In contrast, when naltrexone does not occupy the receptors, opioid analgesics can elicit an exaggerated response because of opioid receptor upregulation, resulting in more exaggerated responses to opioid medications.[193]

Conclusions

Postoperative pain management in patients with OUD is complex and benefits from a cooperative multi-disciplinary treatment plan. The perioperative period is a vulnerable time for patients with OUD, as they may face adverse judgment and undertreatment of their pain because of the presence of opioid tolerance, hyperalgesia, withdrawal, and likely comorbid psychiatric disorders. A multimodal approach to pain management in patients who present for surgery with a history of OUD is highly recommended. This multimodal approach should include, as appropriate, non-pharmacologic therapies, regional anesthesia, and non-opioid analgesics. Opioid analgesics should be used only when necessary and after a risk-benefit analysis. For patients who undergo surgery with MAT for OUD, methadone should be continued perioperatively. However, to provide adequate analgesia, methadone should be administered in divided doses, not once a day. There is compelling evidence that methadone improves postoperative pain compared to other opioids in opioid-naïve patients who undergo surgery. Thus for patients with OUD, consideration should be given to increasing the patient's baseline dose of methadone postoperatively, when appropriate, to improve postoperative pain management. Many pain specialists now suggest that for patients with OUD managed with buprenorphine and who present for surgery, buprenorphine should be continued perioperatively to decrease the risk of OUD relapse and allow for adequate pain management. Patients with OUD who present for surgery must be closely monitored, and a perioperative strategy, including an opioid taper plan for those who require additional opioids, should be developed preoperatively.

Key Points

- Over 2.1 million Americans (0.7%) and 16 million people worldwide have OUD.
- Patients with OUD have a significantly increased mortality risk than those without OUD.
- Acute pain management for patients with OUD must occur within a risk minimization framework.
- Treatment for OUD should continue to occur during the perioperative period, especially MAT, as it has been shown to be the most efficacious in preventing relapse.
- Management of postoperative pain in patients with OUD necessitates an interdisciplinary care team.
- Perioperative challenges when managing pain in patients with OUD include hyperalgesia, opioid tolerance, the potential for withdrawal, and a high incidence of additional psychiatric comorbidities.
- Evaluation of patients presenting for surgery with OUD should include questions regarding whether the patient is in remission or not, past and current illicit substance use, and the amount and type of current substance use, including medication-assisted therapy.
- Postoperative pain management should maximize regional anesthesia, non-opioid pharmacologic, and nonpharmacologic therapies before opioid analgesics are employed.

Evaluation and Treatment of Acute Pain in Children

RAVI SHAH, SANTHANAM SURESH, NICHOLAS E. BURJEK

Recognition and treatment of acute pain is a vital component of pediatric medicine.[1,2] Adequate pain control is necessary to prevent adverse neurohormonal and developmental changes in response to painful stimuli.[3–5] Fortunately, advances in pharmacologic therapy and regional anesthesia techniques have helped expand the scope of pediatric acute pain management.[6] In addition, the establishment of pediatric acute pain services has played an important role in ensuring timely and consistent care of children.[7,8]

Developmental Neurobiology of Pain

The study of pain in neonates has been a significant focus in the field of neuroscience. Nociceptive pathways are well developed even at birth, resulting in hormonal, metabolic, cardiorespiratory, emotional, and behavioral changes in response to painful stimuli.[9] A study of brain perfusion in response to pain has demonstrated significant changes in perfusion with noxious stimuli versus non-noxious stimuli.[10] Newborn rats appear to have a significant proliferation of A and C fibers with a pattern of hyperalgesia developing at sites exposed to painful stimuli.[11] Analogously, human neonates exposed to repeated heel sticks develop cutaneous hyperalgesia, which can be reversed with topical local analgesia.[12] Therefore it is a misconception that pain control is less important in neonates and small children because they cannot form memories of painful experiences or communicate discomfort. Adequate analgesia can limit the immediate and long term effects of noxious stimuli, and treatment of pain in young patients should receive the same level of attention as in adults.

Assessment of Pediatric Acute Pain

Reliable assessment of pain level is essential for effective management.[13] Unfortunately, pediatric patients may be too young, developmentally immature, or unwilling to adequately communicate their pain level.[14] Assessment of acute pain in such patients often relies on observer reports, whereas older children may use self-report measures (see Table 28.1).[15–30] Observational pain assessment tools rely on the interpretation of pain related activity such as body movements, facial expression, and vocalizations; physiologic changes such as heart rate and oxygen saturation; and the child's behavioral state. These measures have been designed to assess procedural pain (e.g. premature infant pain profile [PIPP],[16] neonatal facial coding system [NFCS][17]) or postoperative pain (e.g. Children's Hospital of Eastern Ontario pain scale [CHEOPS],[31] toddler-preschooler postoperative pain scale [TPPPS]).[23] The FLACC scale (faces, legs, activity, cry, consolability) is a tool that can be used for all ages,[32,33] while the revised FLACC (rFLACC) scale incorporates additional observable behaviors to improve validity in children with cognitive impairment (see Table 28.2).[34] The rFLACCs ease of use and validation in patients with a wide range of ages and cognitive levels make it a practical choice for assessment of patients who cannot self-report. Observational assessment tools have limits in their specificity, particularly when including physiologic parameters that can vary because of conditions not associated with pain. Despite their intrinsic limits, these scales have been shown to have construct validity and internal and interrater reliability.[18–22,24–30]

Developmentally appropriate children five years and older can typically provide self-reports on one of several validated visual analog (e.g. colored analog scale [CAS][26]) or faces scales (e.g. faces pain scale-revised [FPS-R],[19,35] Oucher[21]) (Fig. 28.1). McGrath and Hillier[36] developed a separate facial affective scale designed to measure pain affect, as distinct from pain intensity. Interestingly, the faces scales anchored with a smiling face produce higher pain ratings than do those anchored with a neutral face.[37] Discordance between an observer's ratings of a child's pain and the child's self-report is well described.[38,39] Therefore the child's self-reported pain level should be considered the "gold standard" whenever it can reliably be obtained.[40]

The majority of pediatric pain assessment measures that have been developed focus on acute, procedure-related pain.[41,42] Alterations in the behavioral and sensory aspects of pain that can habituate when pain becomes chronic may not be captured by these measurement scales.[38] A systematic evaluation of chronic pain in children is beyond the scope of this chapter (see Chapter 42).

Nonmedical Management of Pediatric Acute Pain

Management of pain through nonmedical techniques (e.g. environmental and behavioral strategies) has proved effective in modulating pain, both independently and in conjunction with pharmacologic interventions in children.[43–47] Cognitive behavior therapy (e.g. relaxation, problem solving, cognitive coping skills) and distraction techniques such as deep breathing, cartoon videos, party blowers, and hypnosis have strong empirical support for their efficacy in easing procedure-related pain in children.[48–51]

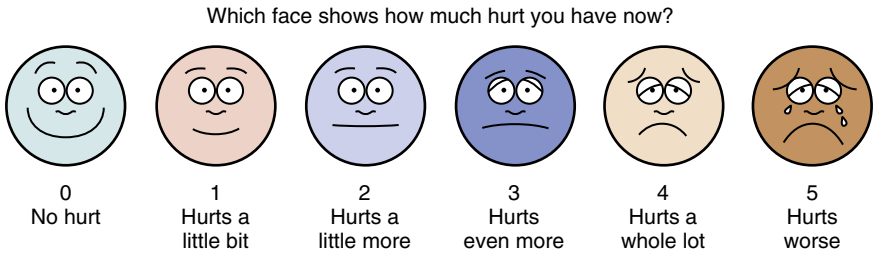
TABLE 28.1 Clinical Measurements of Pediatric Acute Pain

Age Group	Measure	Type of Measurement	Type of Pain
Neonates and infants	Premature infant pain profile (PIPP) (preterm and full-term neonates)[16]	Behavioral, physiologic, gestational age	Procedural
	Neonatal facial coding system (NFCS) (preterm and full-term neonates, infants ≤18 months)[17]	Behavioral	Procedural
	COMFORT scale (zero to three years)[18]	Behavioral, physiologic	Procedural, postoperative
	rFLACC scale (two months to seven years)[32–34]	Behavioral	Postoperative
Toddlers and preschoolers	Faces scales[19,20]	Self-report	Procedural, postoperative
	Oucher (≥ three years)[21]	Self-report	Procedural
	Poker chip tool (four to eight years)[22]	Self-report	Procedural
	Toddler-preschooler postoperative pain scale (TPPPS) (one to five years)[23]	Behavioral	Postoperative
	Children's Hospital of Eastern Ontario pain scale (CHEOPS) (one to seven years)[24]	Behavioral	Postoperative
	Children's and infants' postoperative pain scale (CHIPPS) (zero to four years)[25]	Behavioral, physiologic, alertness, calmness	Postoperative
	rFLACC scale (two months to seven years)[32–34]	Behavioral	Postoperative
School-age children and adolescents	Colored analog scale (CAS) (≥ five years)[26]	Self-report	Procedural, recurrent, chronic
	Visual analog scale (VAS) (≥ five years)[26,27]	Self-report	Procedural, recurrent, chronic
	Faces pain scale	Self-report	Procedural, recurrent, chronic
Non-communicating children, children with cognitive impairment	Non-communicating children's pain checklist-postoperative version (NCCPC-PV), non-communicating children's pain checklist-R (NCCPC-R)[28,29]	Behavioral	Procedural, postoperative injury, pain related to a chronic medical condition
	VAS[30]	Self-report	Procedural
	rFLACC scale [32,34]	Behavioral	Postoperative

TABLE 28.2 Revised FLACC Behavioral Pain Scale

Categories	Scoring 0	Scoring 1	Scoring 2
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested, *appears sad or worried*	Frequent to constant frown, clenched jaw, quivering chin, *distressed-looking face; expression of fright or panic*
Legs	Normal position or relaxed, *usual tone and motion to limbs*	Uneasy, restless, tense, *occasional tremors*	Kicking or legs drawn up, *marked increase in spasticity, constant tremors or jerking*
Activity	Lying quietly, normal position, moves easily; regular rhythmic respirations	Squirming, shifting back and forth, tense, *tense, or guarded movements; mildly agitated (e.g. head back and forth, aggression); shallow, splinting respirations, intermittent sighs*	Arched, rigid, or jerking, *severe agitation; head banging; shivering (not rigors); breath holding, gasping or sharp intake of breaths, severe splinting*
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint, *occasional verbal outburst or grunt*	Crying steadily, screams or sobs, frequent complaints, *repeated outbursts, constant grunting*
Consolability	Content, relaxed	Reassured by occasional touching, hugging, being talked to; distractible	Difficult to console or comfort, *pushing away caregiver, resisting care or comfort measures*

Non-italicized text denotes the original FLACC descriptors. Italicized text denotes behaviors that were added for the revised FLACC scale, improving validity for assessment of children with cognitive impairment.[34]



• **Figure 28.1** Faces pain scale.

Distraction methods are hypothesized to work by engaging children and redirecting their attention away from the pain, thereby reducing perceived pain intensity and inhibiting the neural activity that underlies pain perception.[52–58] Complementary and alternative medicine techniques such as acupuncture have also been described as potential treatments of acute pain in children.[59,60]

Recent studies have identified preoperative risk factors for worse postoperative pain, including patient behaviors such as catastrophizing and psychological and somatic symptoms such as depression and fatigue.[61–63] Additional research is needed to determine whether psychological and other nonpharmacologic interventions may be beneficial for this pain-vulnerable group of children.

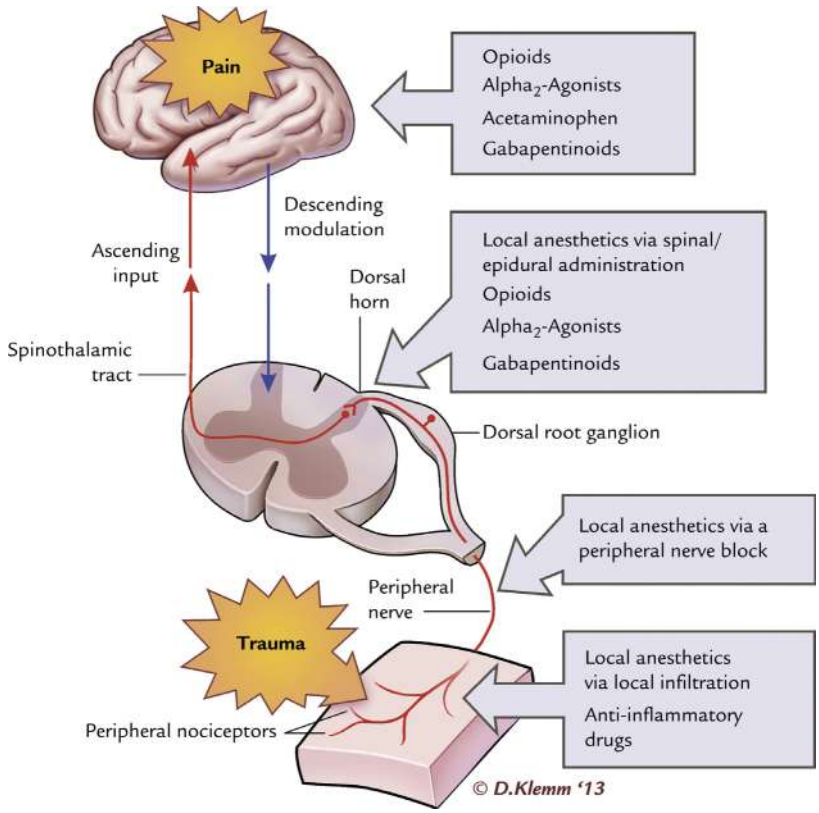
Pain Treatment Modalities

Acute pain in infants and children may result from several causes, including surgery, trauma, sickle cell vaso-occlusive episodes, and oncologic processes and treatments. Non-opioid analgesics can provide adequate control of mild pain with minimal side effects.[64] For moderate to severe pain, a multimodal strategy that incorporates non-opioid analgesics, opioids, and regional anesthesia is preferred. Multimodal analgesia involves multiple agents working synergistically at different biologic locations along the pain pathway (Fig. 28.2).[65] This allows improved pain control with reduced side effects (sedation, respiratory depression, nausea, pruritis, ileus) that can occur with the higher doses required when opioids are used alone for treatment of severe pain.[66,67] Patient factors such as comorbidities, developmental level, opioid use history, and ability to take oral medications must be considered along with pain cause, severity, location, and expected duration when developing an optimal analgesia plan.

Non-opioid Analgesics

Sucrose

Oral administration of glucose and sucrose can provide mild analgesia, as opioid peptides in the ventral striatum and cingulate gyrus may play a role in regulating positive responses to energy-rich food sources.[68,69] A Cochrane database review suggested that sucrose



• **Figure 28.2** The pain pathway and locations of action for various analgesics. (© David Klemm).

may be effective in reducing procedural pain in neonates.[70] Doses in the range of 0.01–0.1 g can be used to reduce procedural pain in infants younger than six months.[71]

Acetaminophen

Acetaminophen is commonly used in children to reduce or eliminate pain from a variety of conditions.[72] It can be administered via the oral, rectal, and intravenous routes. There is no evidence to suggest the superior analgesic effect of one route over another when appropriately dosed, and the oral route is the most cost effective.[73] The rectal and intravenous routes are used for patients unable to take oral medications, as is often the case in the perioperative period. Higher rectal doses (i.e. 30–40 mg/kg loading dose followed by 15–20 mg/kg maintenance doses at 4–6 h intervals in children over two years old) are required to produce therapeutic serum concentrations in the majority of patients, and there is large interindividual pharmacokinetic variability.[74,75] Intravenous acetaminophen has more predictable bioavailability and achieves maximum concentration more rapidly than rectal dosing, and therefore may be the preferred non-oral route for administration to hospital inpatients.[76]

While rare, hepatotoxicity is a dose-dependent risk with acetaminophen use.[77] Compared to older children, neonates exhibit decreased acetaminophen clearance because of renal and hepatic immaturity. Doses should be reduced, especially in preterm infants.[78] Another potential source of overdose is inadvertent administration from multiple sources, including over-the-counter cold remedies and fixed-dose opioid combinations, both of which often contain acetaminophen. All medications being taken by a patient, including those available without a prescription, should be carefully reviewed before recommending acetaminophen (Table 28.3).

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used in children and can be administered via oral, intravenous, or intramuscular routes. NSAIDs are an effective treatment for various pain states and have been shown to be more effective than opioids for mild traumatic musculoskeletal pain in children.[79] When used in the postoperative setting, NSAIDs can produce analgesia equivalent to a dose of opioid, and their use with or without additional opioids has been associated with less nausea, vomiting, respiratory depression, and other adverse events.[72,80,81] Ketorolac is commonly used in children and can be administered via intravenous or intramuscular routes.

The clinical significance of the effects of NSAIDs on platelet function remains controversial, which has led to its avoidance by some for procedures with a significant risk of postoperative bleeding. Known side effects, including bleeding, renal toxicity, and gastritis, are more likely to occur with prolonged administration and in the presence of coexisting disease. Adverse events are more common in neonates; NSAIDs should be used cautiously in patients less than six months of age and avoided in patients less than 21 days old or 37 weeks post gestational age.[82,83] Evidence from animal models has caused concern that NSAIDs may interfere with osteogenesis. However, studies of children receiving a short course of NSAIDs, including ketorolac, after spinal fusion or operative fracture repair do not appear to be at increased risk for bone nonunion.[84,85] Aspirin, a unique NSAID that irreversibly inhibits cyclooxygenase (COX)-1 and COX-2, should not be routinely used as an analgesic in patients under the age of 18 years because of the risk of Reye's syndrome, a serious acute encephalopathy.[86]

TABLE 28.3 Non-opioid Analgesic Dosing

Medication	Dose	Dosing Interval (h)	Maximum Daily Dose (mg/kg)	Maximum Daily Dose (mg)
Acetaminophen* (oral)	10–15 mg/kg	4–6	75	3000
Acetaminophen* (IV)	15 mg/kg	6	75	3000
Acetaminophen* (rectal)	30–40 mg/kg as loading dose, 15–20 mg/kg maintenance	6	75	3000
Ibuprofen^	5–10 mg/kg	6–8	40	2400
Ketorolac (IV)^,#	0.5 mg/kg	6	2	120
Celecoxib (oral)	10–25 kg: 50 mg >25 kg: 100 mg	12		400
Gabapentin (oral)	<50 kg: 15 mg/kg loading dose, 5 mg/kg maintenance >50 kg: 300–600 mg	8		
Pregabalin (oral)	<50 kg: no available evidence >50 kg: 50 mg	8–12		
Ketamine (infusion)	0.1–0.2 mg/kg/h	Continuous		
Diazepam (oral, IV)	0.05–0.1 mg/kg	6–8		

*Dose should be decreased in preterm and term neonates.

^Use with caution in neonates <6 months old.

#Avoid use in neonates <37 weeks post gestational age or 21 days postnatal age.

IV, Intravenous.

Gabapentinoids

The antiepileptic medications gabapentin and pregabalin have been used as adjunctive medications for the management of post-surgical pain with a neuropathic component, such as following posterior spinal fusion. While robust evidence for efficacy is currently lacking, one study did suggest improved pain control and decreased opioid use when gabapentin was used following posterior spinal fusion in pediatric patients.[87] No studies have examined the use of these drugs following other surgeries in children, but evidence in adults supports the use of gabapentin and pregabalin following large abdominal surgeries as well.[88]

Ketamine

Ketamine has been investigated as an adjunctive analgesic for pediatric inpatients with several painful conditions. When given as an intraoperative bolus, it has improved early postoperative pain scores, reduced opioid use, and decreased the incidence of emergence delirium.[72] Patients with episodes of acute or chronic pain from sickle cell disease or cancer may particularly benefit from a low-dose ketamine infusion.[89,90] These patients are at risk for poor pain control because of opioid tolerance and opioid-induced hyperalgesia, processes that may be reversed by ketamine's antagonism of the *N*-methyl-D-aspartate glutamate receptor.[91]

Muscle Relaxants

Diazepam is a benzodiazepine with muscle relaxant properties. It is commonly used to relieve pain from muscle spasms following orthopedic surgeries involving dissection through large muscle groups, such as posterior spinal fusion for scoliosis and periacetabular osteotomy for hip dysplasia.[92,93] Benzodiazepines cause sedation and respiratory depression, particularly when used concurrently with opioids. Thus respiratory monitoring should be employed when using them together at high doses.[94,95] Other muscle relaxants used in pediatrics include baclofen and tizanidine.

Tramadol and Codeine

Tramadol and codeine, both administered as prodrugs with little intrinsic activity, are metabolized to their active forms by the enzyme CYP2D6.[96] The active form of tramadol is a unique medication with opioid and non-opioid effects. In contrast, codeine is metabolized to morphine, with pure opioid effects. Both were previously used for the control of pain in children.[97,98]

Genetic variants of the CYP2D6 enzyme lead to wide variations in the serum concentrations of the active forms of these drugs. Slow metabolizers produce lower levels of active drug and experience poor pain control, while ultrarapid metabolizers quickly develop very high serum levels of the active drug and are at risk for adverse effects, including respiratory depression.[99] In response to several deaths in children with ultrarapid metabolism of codeine, the Food and Drug Administration (FDA) issued a 2017 warning advising against the use of both of these drugs in nursing mothers, all children younger than 12 years of age, and patients aged 12–18 years at risk for opioid-induced respiratory depression, including those with obstructive sleep apnea, obesity, lung disease, or following tonsillectomy.[100] Therefore codeine has been almost completely replaced by other oral opioid medications for use in pediatric patients. Because of its unique mechanism of action, tramadol still has a role for some pediatric patients with chronic pain. However, tramadol is often titrated to a target dose over days to weeks to prevent side effects such as somnolence and has limited use in the management of acute pain in children.

Opioid Analgesics

Stewardship During the Opioid Epidemic

A crisis of opioid misuse has afflicted the United States over the first two decades of the 21st century, with soaring rates of abuse and overdose deaths. While the opioid epidemic has received widespread attention, most legislative action and treatment programs have been aimed at adults. Unfortunately, children of all ages have also been affected, and anyone treating pediatric pain must be aware of the ways their patients may be affected by this national crisis.[101]

Opioid use during pregnancy has resulted in rising rates of neonatal abstinence syndrome (NAS), with about 32,000 infants now diagnosed per year in the United States. NAS may result in dysregulation of the central nervous, autonomic nervous, respiratory, and gastrointestinal systems, requiring a high level of neonatal care to prevent further morbidity. NAS also complicates pain management for affected infants undergoing painful procedures and may have additional long-term physical, psychological, and behavioral effects which have yet to be fully characterized.[102]

Toddlers and young children living in homes with opioid-using adults are at significant risk for accidental ingestion and overdose.[103] The increasing reservoir of unused opioids in the community has led to a nearly three-fold increase in pediatric opioid overdose deaths from 1999–2016.[104]

Substance use disorders often start in late childhood and adolescence, and the last 20 years have also seen a dramatic increase in opioid abuse and deaths in this population.[105] Even teenagers who are appropriately prescribed opioids for pain relief following surgical procedures are at risk for subsequent misuse and addiction to opioids and other substances.[106,107]

Despite these concerns, opioids are often needed to prevent unnecessary suffering in infants and children. They remain a fundamental component of appropriate pain control strategies for young patients in the postoperative setting and the management of chronic painful conditions such as sickle cell disease, cystic fibrosis, and cancer. To responsibly care for pediatric outpatients with pain, physicians and medical providers should take steps to reduce the chances of accidental or intentional misuse of opioids. Parents should be instructed to keep any opioids in the home safely, preferably locked, where children cannot reach them. Parents should also be told to safely dispose of opioids as soon as the prescribed patient no longer needs them, either at a local drug take-back site, by flushing them down the toilet, or by combining them with dish soap or kitty litter and throwing them in the garbage. Finally, physicians should attempt to reduce the reservoir of unused opioids in the community by prescribing the lowest number of doses that are expected to reasonably care for a patient's pain in the outpatient setting, especially for acute indications such as post-surgical pain.

Opioid Therapy

Opioids may be administered via oral, parenteral, intranasal,[108,109] and neuraxial routes. Opioid clearance is lower in neonates but reaches mature levels in the first six months of life.[110] Opioid-induced respiratory depression may be more pronounced in neonates and infants, as reflexive respiratory responses to airway

TABLE 28.4 Oral Opioid Analgesic Dosing Guidelines

Medication	Potency Relative to Morphine	Typical Starting Dose (mg/kg)	Typical Dose if >60 kg (mg)	Dosing Interval (h)
Morphine	1	0.3	15–20	3–4
Hydrocodone	1–1.5	0.1–0.2	5–10	4–6
Oxycodone	1–1.5	0.1–0.2	5–10	4–6

TABLE 28.5 Management of Opioid-related Side Effects

Adverse Effect	Initial Management	Secondary Management
Pruritus	Diphenhydramine, hydroxyzine	IV low-dose naloxone[166]
Nausea, vomiting	Ondansetron,	Promethazine, IV low-dose naloxone[166]
Urinary retention	Decrease opioid dose	Urinary catheterization
Respiratory depression	Decrease opioid dose	IV naloxone

IV, Intravenous.

obstruction and hypoxemia mature over the first year of life.[111] Children with obstructive or central sleep apnea are also at high risk for opioid-induced respiratory depression and sedation, and opioids should be started at roughly 50% of the dose for a typical patient of similar age and weight.[112] Starting oral doses for opioid-naïve patients without significant medical comorbidities are listed in Table 28.4. Intravenous opioids are chosen when patients cannot take oral medications or require rapid titration for severe uncontrolled pain.

High doses of opioids are associated with multiple adverse effects, including sedation, respiratory depression, nausea, vomiting, ileus, constipation, pruritus, and itching. These side effects can significantly prolong patient recovery and may be more unpleasant than the pain for which the opioids are being prescribed. Non-opioid analgesics and regional anesthesia should be used to the maximum extent possible in patients with poorly controlled pain, with the goals of reduced opioid requirement, better pain control, decreased side effects, improved functional level, and faster recovery. Management options for opioid-related side effects are shown in Table 28.5.[113]

Patient-Controlled Analgesia

Patient-controlled analgesia (PCA) can provide controlled, titratable, autonomous analgesia to children and adolescents. Several trials support the safety and efficacy of PCA in children older than six years.[114] PCA is now the standard method for delivering opioid analgesia for children with severe pain after surgery or in cases where the patient cannot tolerate medication by mouth, such as with chemotherapy-induced mucositis.[115] Patients with severe acute nonsurgical pain, such as sickle cell vaso-occlusive pain or acute worsening of cancer pain, may also benefit from the rapid titration that PCA allows.

Morphine, fentanyl, and hydromorphone are commonly used opioids for PCA. Because PCA-delivered demand boluses are relatively small and chosen to maintain analgesia, pain should be well controlled with a loading dose prior to the initiation of PCA. A continuous infusion of opioids may be paired with PCA to replace chronic opioid requirements or improve sleep patterns for the first night following particularly painful surgery.[116] Continuous infusions often lead to a higher amount of delivered opioids and may make nausea and sedation more likely. Therefore caution should be employed whenever a continuous infusion is used, particularly in patients at risk for respiratory depression.[117–119] Suggested PCA parameters for opioid-naïve patients without significant medical comorbidities are listed in Table 28.6. Continuous pulse oximetry and respiratory monitoring should be routinely employed with PCA, as large amounts of opioids may be delivered.[120]

For young children or those with cognitive impairment, the demand doses of opioids may be administered by a nurse (nurse controlled analgesia, or NCA) or a family member (PCA by proxy, or PCA-P). NCA and PCA-P eliminate a built-in safety mechanism of PCA, which is that the patient must be alert enough to self-deliver additional opioids. Parents must be educated to only deliver demand boluses if the patient is awake and in pain, as providing boluses to a sleeping patient may cause respiratory depression and opioid overdose.[121,122] Despite these risks, NCA and PCA-P can provide safe and effective pain relief when appropriate precautions are taken.[123]

TABLE 28.6 Patient-Controlled Analgesia Dosing Guidelines

Medication	Loading Dose	Demand Dose	Lockout Time (min)	Continuous Infusion
Hydromorphone	10–20 (μg/kg)	2–3 (μg/kg)	5–15	2–3 (μg/kg/h)
Morphine	0.05–0.1 (mg/kg)	0.01–0.02 (mg/kg)	5–15	0.01–0.02 (mg/kg/h)
Fentanyl	0.5–1 (μg/kg)	0.15–0.2 (μg/kg)	5–15	0.15–0.2 (μg/kg/h)

Regional Anesthesia

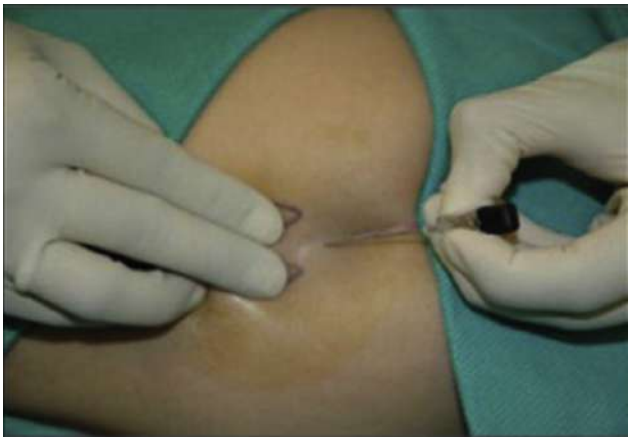
Regional anesthesia is an effective means by which to reduce postoperative pain and opioid use in pediatric surgical patients.[124] Versatile new techniques[125,126] and the adoption of enhanced recovery protocols that include regional anesthesia[127] have contributed to increased utilization. However, the most important factor behind increased use has been the widespread acceptance of regional anesthesia performed on pediatric patients under general anesthesia.

In adults, regional anesthesia is most often performed on awake or minimally sedated patients. Pain or paresthesia may suggest improper needle placement and potential nerve damage, while symptoms such as tinnitus may be early signs of local anesthetic systemic toxicity (LAST) from an inadvertent intravascular injection. General anesthesia may be avoided if surgical levels of regional anesthesia are achieved, which is especially beneficial for adults with high risk comorbidities. Conversely, children are more likely to be afraid of needles and invasive procedures and may not cooperate if fully awake or minimally sedated. Even if symptoms suggesting impending injury were elicited, young or developmentally immature patients may not be able to communicate these to the regionalist. An uncooperative patient may move while the needle is close to delicate structures, increasing the risk for damage.

Needle placement is more accurate with ultrasound visualization, allowing avoidance of nerves and vascular structures and reduction in the volume of local anesthetic needed to achieve the desired result.[128] Large multicenter studies of regional anesthesia in children have shown low complication rates (comparable to those seen in adult practice) and a reduced incidence of LAST and neurologic complications when performed under general anesthesia compared to minimally sedated or awake patients.[129–131] Therefore the performance of pediatric regional anesthesia under general anesthesia or deep sedation is now considered standard of care.[132,133]

Caudal Analgesia

One of the most commonly used pediatric regional anesthesia techniques is the caudal block, which can provide analgesia from the lumbosacral to midthoracic dermatome levels.[134] The caudal block is popular because of readily palpable landmarks, ease and speed of placement in infants and children, and low rates of failure or complications.[135] A needle with a blunt stylet is passed through the sacrococcygeal ligament into the caudal space (Fig. 28.3). A distinct "pop" is felt when the caudal space is entered. Ultrasonography has been described as a tool to assist in caudal placement.[136] Local anesthetics include bupivacaine (0.125%–0.25%) and ropivacaine (0.1%–0.375%), with volumes of 0.5–1.25 mL/kg (maximum volume 30 mL) depending on desired dermatomal level. The most commonly used dosing is 1 mL/kg of ropivacaine 0.2% or bupivacaine 0.25%.[137,138] Because of the difficulty in interpreting a negative test dose, the use of epinephrine 1:200,000 in the caudal solution is discretionary. If epinephrine is used, a heart rate increase of greater than 10 beats per min or any change in T wave morphology in the first minute after injection should be considered an accidental intravenous injection, and needle placement should be adjusted before further injection.[132]



• **Figure 28.3** Caudal block landmarks and placement technique.

Spinal Anesthesia

Former preterm infants are particularly susceptible to the risks of general anesthesia, and spinal anesthesia has been proposed as an alternative for procedures such as inguinal hernia repair.[139] However, this has not become routine practice because of a lack of provider familiarity with the technique and concerns over the duration of spinal anesthesia in cases of unexpectedly prolonged surgery.[140,141] Rates of apnea in the immediate postoperative period may be reduced with spinal anesthesia, but there is no overall impact on apnea incidence in the first 12 h. Therefore this technique does not reduce the need for extended observation of premature infants.[142] While concerns exist over potential neurotoxicity related to general anesthesia in young children, avoidance of a brief general anesthetic through the use of spinal anesthesia for hernia repair has not been found to have any impact on neurodevelopment, further limiting the applicability of this technique.[143,144]

Continuous Neuraxial Catheters

Continuous epidural analgesia is a commonly used technique in infants and children.[145,146] Epidural catheters may be placed in the thoracic, lumbar, or caudal regions. It is also possible to insert a catheter into the caudal space and thread it cephalad to the desired vertebral level, with location confirmation by ultrasound or epidurogram.[147] Bupivacaine and ropivacaine are frequently used local anesthetic solutions. Common additives to these solutions include opioids (e.g. fentanyl, morphine, or hydromorphone) and α2-agonists (e.g. clonidine). Standardized dosing parameters must be used in neonates, infants, and children to avoid local anesthetic-related systemic toxicity.[148] Suggested pediatric dosing regimens are listed in Table 28.7. Patient-controlled epidural analgesia can be used with continuous infusions of local anesthetic and patient-determined boluses to augment analgesia.[149]

Peripheral Nerve Blockade

Peripheral and truncal nerve blocks have played an increasing role in pediatric postoperative pain management.[131,147,150,151] In addition, these techniques have been described as an effective means of achieving analgesia in the setting of pediatric trauma.[152] Peripheral nerve blocks in children are typically performed under general anesthesia with the use of ultrasound guidance and have a low incidence of complications.[131] Head and neck, truncal, and upper and lower extremity blocks are frequently performed to provide analgesia in suitable candidates.

TABLE 28.7 Pediatric Epidural Dosing Guidelines

Medication	Drug Concentration	Starting Rate	Infusion Limits^
Bupivacaine	0.0625%–0.1%	0.1–0.2 mL/kg/h*	≤0.4 mg/kg/h
Ropivacaine	0.1%–0.2%	0.1–0.2 mL/kg/h*	≤0.4 mg/kg/h
Fentanyl	2–5 µg/mL		0.5–2 µg/kg/h
Morphine	5–10 µg/mL		1–5 µg/kg/h
Hydromorphone	2–5 µg/mL		1–2.5 µg/kg/h
Clonidine	0.5–1 µg/mL		0.5–1 µg/kg/h

*Volume should not exceed 10 mL/h in the thoracic space or 15 mL/h in the lumbar space in pediatric patients.

^Maximum dose should be reduced for thoracic epidurals or in neonates.

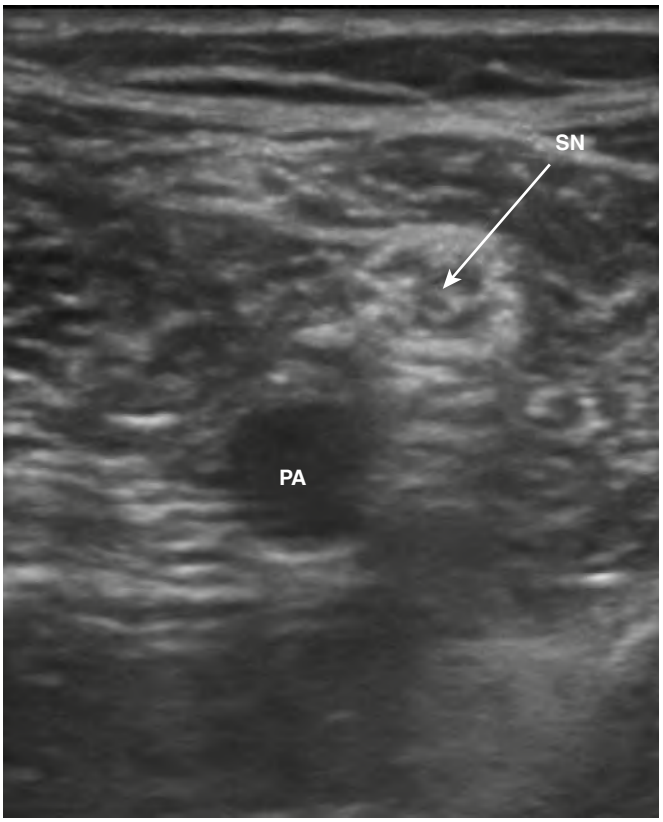
Indications and suggested dosing guidelines for these blocks have been included as a reference point in Table 28.8, although large variability in national dosing practice suggests a need to develop practice guidelines.[153]

Continuous Peripheral Nerve Blockade

Continuous peripheral nerve blocks (CPNBs) placed with ultrasonographic guidance may be used in pediatrics.[154] CPNBs provide effective pain control beyond the 12–16 h typically seen with a single injection block and reduce the need for opioids and their undesirable side effects for multiple days following surgery. CPNBs may be used in the outpatient setting with elastomeric pumps, a relatively inexpensive and easy-to-use method for providing a continuous infusion of local anesthetic with little operator requirement.[155,156]

Two large studies examining thousands of CPNBs placed for postoperative analgesia in children found low rates of failure or complications. The majority of these complications were related to minor catheter malfunction such as dislodgement, occlusion, or leakage.[156,157] Neither of these studies reported any cases with major complications such as neurologic damage, serious infection, or LAST. Superficial signs of infection are more common with catheters that remain in place for greater than three days, consistent with the evidence in the adult literature.[157,158]

The most common indication for CPNBs in pediatric surgical care is for older children undergoing painful orthopedic surgery of a single lower extremity.[156,157] Femoral nerve catheters have been used to facilitate same-day discharge following surgery of the distal femur or anterior knee, such as anterior cruciate ligament reconstruction.[159] Popliteal sciatic catheters for foot and ankle surgery result in fewer adverse effects compared to epidural catheters (Fig. 28.4).[160] Lumbar plexus catheters can provide unilateral analgesia following hip and thigh surgery.



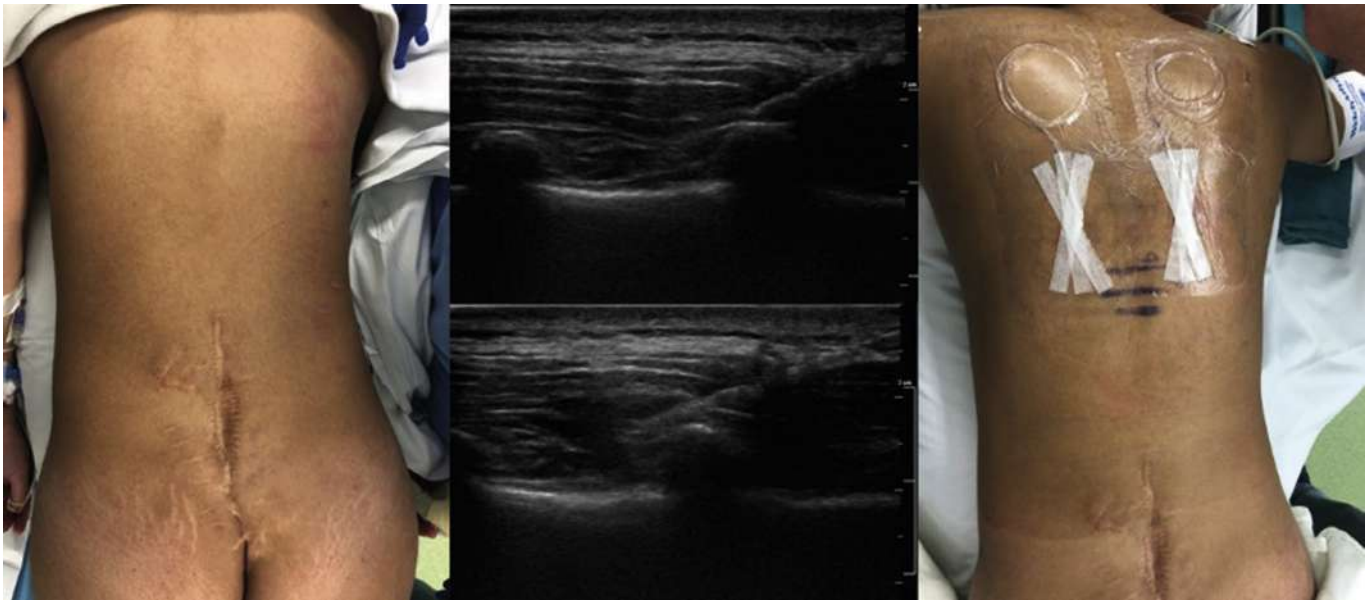
• **Figure 28.4** Sonographic anatomy of the sciatic nerve at the popliteal fossa *(arrow)*. *PA,* Popliteal artery; *SN,* sciatic nerve.

While less commonly used than lower extremity CPNBs, brachial plexus catheters may be used for pain control following upper extremity surgery. Interscalene catheters may be used for shoulder and proximal humerus surgery, such as rotator cuff repair,[161] while supraclavicular, and infraclavicular catheters can provide analgesia following elbow surgery or fracture repair of the radius, ulna, and distal humerus.

One of the most exciting recent advancements in pediatric regional anesthesia has been the introduction of truncal and fascial plane CPNBs, allowing for prolonged analgesia of the thoracic and abdominal walls. Examples include continuous transversus abdominis plane (TAP), paravertebral, and erector spinae plane (ESP) blocks. Compared to epidural catheters, these techniques carry a reduced risk of inadvertent dural puncture, sympathectomy, urinary retention, and neuraxial bleeding or infection and may allow earlier achievement of post-surgical recovery benchmarks such as walking and bladder catheter removal.[127] They may be used when neuraxial

TABLE 28.8 Commonly Performed Peripheral Nerve Blocks in Children With Suggested Dosing Guidelines and Example Indications

Technique	Dose (mL/kg)	Maximum Volume (mL)	Indications
Head and Neck Blocks			
Supraorbital and supratrochlear	0.1–0.15 mL/kg	5 mL	Scalp excision, frontal craniotomy
Occipital	0.1–0.15 mL/kg	5 mL	Scalp excision, occipital craniotomy
Infraorbital	0.1–0.15 mL/kg	5 mL	Nasal surgery, cleft palate/lip repair
Superficial cervical plexus	0.1–0.15 mL/kg	5 mL	Tympanomastoid surgery, cochlear implant
Auriculotemporal	0.1–0.15 mL/kg	5 mL	Tympanomastoid surgery
Suprazygomatic maxillary[167]	0.15 mL/kg	5 mL	Cleft palate/lip repair
Upper Extremity Blocks			
Interscalene	0.1–0.3 mL/kg	15 mL	Shoulder and proximal humerus surgery
Supraclavicular	0.1–0.3 mL/kg	15 mL	Elbow, forearm, hand surgery
Infraclavicular	0.2–0.3 mL/kg	15 mL	Elbow, forearm, hand surgery
Axillary	0.2–0.3 mL/kg	15 mL	Elbow, forearm, hand surgery
Median, radial, ulnar nerves	0.1–0.15 mL/kg	5 mL	Rescue/supplemental analgesia for wrist and hand surgery
Digital nerve	0.05–0.1 mL/kg	2–3 mL	Finger surgery
Lower Extremity Blocks			
Lumbar plexus	0.3–0.5 mL/kg	20 mL	Unilateral hip or proximal leg surgery
Femoral nerve	0.2–0.4 mL/kg	15 mL	Femur shaft fracture, knee surgery, anterior cruciate ligament repair
Adductor canal (saphenous nerve)	0.2–0.4 mL/kg	15 mL	Surgery involving the knee and medial lower leg or ankle
Lateral femoral cutaneous nerve	0.1–0.15 mL/kg	5 mL	Lateral thigh skin graft, muscle biopsy, or hardware removal
Sciatic nerve (intergluteal approach)	0.3–0.5 mL/kg	20 mL	Knee surgery
Sciatic nerve (popliteal approach)	0.3–0.4 mL/kg	15 mL	Knee surgery, foot/ankle surgery
Ankle block	0.1 mL/kg per nerve	1–3 mL per nerve	Polydactyly repair, foot foreign body removal
Trunk and Thorax Blocks			
Intercostal	0.05–0.1 mL/kg	1–3 mL	Thoracotomy, chest tube placement
Ilioinguinal/iliohypogastric	0.2–0.3 mL/kg	15 mL	Inguinal surgery
Rectus sheath	0.2 mL/kg	10 mL	Umbilical and epigastric hernia repair
Paravertebral[168]	0.3–0.5 mL/kg	15 mL	Thoracotomy, pectus excavatum repair
Erector spinae plane[125]	0.3–0.5 mL/kg	20 mL	Thoracotomy, laparotomy, hip surgery
Transversus abdominis plane[169]	0.3–0.5 mL/kg	20 mL	Laparotomy, appendectomy, kidney transplant
Quadratus lumborum[170]	0.3–0.5 mL/kg	20 mL	Lower abdominal, hip, and proximal leg surgery
Penile	0.1 mL/kg	10 mL	Circumcision, meatoplasty
Pudendal[171]	0.3–0.5 mL/kg	5 mL	Hypospadias repair



• **Figure 28.5** Ultrasound-guided placement of bilateral erector spinae plane (ESP) continuous nerve catheters at the T9 transverse processes in a patient with spina bifida undergoing laparotomy.

catheters are contraindicated or difficult to place, such as with spinal dysraphism or in patients with a history of spinal fusion for scoliosis (Fig. 28.5).[162] The location of needle placement for TAP and ESP CPNBs is relatively superficial, far from key structures, and easily compressible. Consequently, these techniques have been used when neuraxial catheters are avoided because of coagulopathy, including in patients undergoing a liver transplant.[163] Finally, while neuraxial catheters are only used for inpatients, truncal CPNBs may be used selectively in the ambulatory setting.[164,165]

Conclusion

The management of acute pain in children presents unique challenges. Specialized assessment tools, behavioral techniques targeted to patient developmental level, recognition of the widespread impact of the opioid epidemic, multimodal analgesic strategies, and increasingly versatile regional anesthesia techniques all play important roles in the optimal care of neonates, infants, and children. Continued advocacy, research, and innovation in this field are imperative to reduce suffering in these vulnerable patients further.

Key Points

- Pain control is necessary to prevent adverse hormonal, metabolic, cardiorespiratory, emotional, and behavioral effects in neonates and young children.
- Various measures of pain intensity are available for the pediatric population, with the selection of the correct scale based on the patient's age, developmental level, and ability to provide feedback.
- Non-opioid analgesics can relieve mild to moderate pain and decrease opioid-related side effects when used as part of a multimodal analgesic strategy for severe pain.
- Children of all ages have been significantly impacted by the opioid epidemic.
- PCA with opioids can be used effectively to control pain and improve patient satisfaction.
- Neuraxial and regional anesthesia techniques provide effective pain relief and can be safely performed under general anesthesia in infants and young children.
- CPNBs provide site-specific analgesia and have certain advantages over epidural catheters.

Low Back Pain Disorders

KHALID MALIK, ARIANA M. NELSON

Introduction

Musculoskeletal disorders are a common source of pain and disability globally and are ubiquitous in industrialized nations; among them, low back pain (LBP) is the most common.[1] Second only to respiratory tract infections, LBP is the most frequent reason for outpatient doctor visits and, as it often affects the young and the employed, is the most common cause of work related disability.[2] The rising expenditures of LBP, both the direct costs of care and the indirect costs of disability and lost productivity, amount to billions of dollars each year in the United States alone.[3] The reported lifetime incidence of LBP is highly variable, ranging from 13.8%[2] to 31%.[4] This discrepancy is likely because of the poorly defined and heterogeneous causes of LBP. The conditions causing LBP are protean, and the pain can originate not only from the various spinal components and the neural structures housed within the spinal column but also from the surrounding muscles, tendons, and ligaments. Additionally, pain can be referred from the abdominal and pelvic viscera and the adjacent joints. Thus the list of structures causing LBP is extensive and includes the intervertebral discs (IVDs), vertebral bodies, facet joints, spinal nerve roots (NRs), the spinal and paraspinal soft tissues, and the sacroiliac and hip joints. This unwieldy list of possible etiologies of LBP can be initially managed by categorizing these conditions into two broad groups: a) conditions that, if untreated, can be life threatening or can cause serious neurologic injury and b) conditions that are benign and self-limiting and are unlikely to cause neural damage.[5] The first group is typically comprised of *fractures and dislocations* of the spine, both primary and secondary; *tumors and infections* of the spinal and related neural structures; *inflammatory conditions* such as ankylosing spondylitis and rheumatoid arthritis; *metabolic conditions* such as Paget's disease; and *spinal deformities* such as scoliosis and kyphosis. The second category of spinal pain generators consists of a wide range of benign and self-limiting conditions that includes lumbar sprain and strain, myofascial pain syndrome (MFPS), herniated disc (HD), lumbar spinal stenosis (LSS), degenerative disc disease (DDD), internal disc disruption (IDD), lumbar facet syndrome (LFS), sacroiliac joint dysfunction (SIJD), spondylolysis, spondylolisthesis, and spinal instability (SI). In this book, we discuss the causes of LBP pertinent to the practice of pain medicine. This specific chapter discusses conditions causing LBP that can be linked to the dysfunction of the IVDs (DD) and include HD, LSS, DDD, IDD, and LFS. Other significant causes of LBP, e.g. pain of muscular and ligamentous origin, MFPS, SIJD, and SI, though associated with DD, frequently occur independently and are discussed elsewhere in this textbook. Conditions that are life threatening or can cause serious neurologic compromise, that is, the first group, are generally ruled out prior to a referral to a pain medicine physician and are beyond the scope of this chapter. LBP frequently radiates to the lower extremities either in dermatomal (radicular pain) or non-dermatomal (referred pain) distribution, and a brief discussion of both categories will be presented.

Lumbar Radicular Syndrome

Definition and Terminology

Pain, paresthesia, and numbness in a dermatomal distribution and a positive straight-leg raise (SLR) test, with or without accompanying signs of sensory loss, weakness, and diminished reflexes, are mediated by sensory spinal NRs (SSNRs) or dorsal root ganglia (DRG).[6] These symptoms of lumbar radicular syndrome (LRS) can be present in isolation. However, they are generally present in conjunction with LBP. The incidence of LRS in patients with LBP is reported to range from 12% to 40%.[2] Other terms used for LRS include *lumbar radiculopathy*, which inappropriately implies the presence of objective signs of NR damage-loss of sensation, muscle weakness, and diminished reflexes; *lumbar radiculitis,* which incorrectly proposes that an inflammatory process is primarily responsible for the radicular signs and symptoms; and *lumbar radicular pain*, which mistakenly assumes that pain is always the principal symptom. Hence, the descriptive term *LRS* may be the most accurate as it correctly suggests a constellation of clinical signs and symptoms of variable etiology secondary to the pathology or dysfunction of the SSNRs or DRGs. The term *sciatica* is also often used synonymously with LRS. However, this term incorrectly implies that the level of injury is at the peripheral nerve rather than the SSNR or DRG. Because of convergence and overlap of somatosensory input at the spinal and supra-spinal levels, pain from the various low back pathologies, e.g. IDD, FJS, SIJD, can refer to the lower extremities without the involvement of SSNRs or DRGs. This pain is non-dermatomal in distribution and typically radiates to the buttocks and lateral thighs; it rarely radiates below the knee joints into the legs and feet.

Etiology and Differential Diagnosis

LRS is caused when the impulses generated at the SSNR and DRG locations are perceived as pain, numbness, or tingling in areas innervated by the affected axons, i.e. in a dermatomal distribution (Fig. 29.1).[6] The pathologic processes causing LBP and LRS are similar, but there is obligatory involvement of SSNRs and DRG in LRS. Lesions in the IVD and spinal stenosis are the most common cause of LRS. Additionally, neoplastic, infectious, traumatic, metabolic, and vascular lesions discussed can also involve the SSNRs, DRGs, and the lumbosacral plexuses and can infrequently produce radicular signs and symptoms.[7] The entrapment neuropathies involving the sciatic nerve (e.g. the piriformis muscle and the ischial tunnel syndromes) can also generate pain and paresthesia in the lower extremity. However, these typically affect multiple dermatomes.[7] The somatic referred pain, because of interneuronal convergence within the spinal cord, in addition to being non-dermatomal in nature, has a deep aching quality and lacks the objective signs of NR involvement.

Clinical Features

Though pain is the predominant symptom, other features of radicular involvement include paresthesia, numbness, and weakness in the distribution of the involved NR. Radicular pain typically travels along a narrow band and is of sharp, shooting, and lancinating quality.[8] Objective signs include gait disturbances, loss of sensation, reduced muscle strength, and diminished reflexes involving the corresponding dermatome. HDs and the degenerative spinal conditions typically involve the lower lumbar NRs, whereas the more sinister causes of LRS, e.g. local tumor invasion, tend to involve more superior NRs with greater frequency.[9] Characteristic features of the various lumbar and sacral NR involvement include:

- S1: Pain, paresthesia, and numbness of the posterior part of the thigh, calf, and plantar surface of the foot, difficulty toe walking, weakness of plantar flexion, and loss of the plantar reflex.
- L5: Pain, paresthesia, and numbness involving the buttock, anterolateral aspect of the leg, dorsal surface of the foot and great toe, difficulty heel walking (steppage gait), and weakness of ankle and toe extension.
- L4: Pain, paresthesia, and numbness involving the anterior part of the thigh, knee, and upper medial portion of the leg, weakness of knee extension, and a diminished patellar tendon reflex.
- L3 and L2: Pain, paresthesia, and numbness involving the groin and inner thigh areas, weakness in hip flexion.
- Lower Sacral NRs: Decreased sensation in the buttock and perineal areas (i.e. saddle anesthesia) and autonomic dysfunction as indicated by bowel and bladder dysfunction (typically urinary retention and constipation followed by incontinence), and sexual dysfunction manifested as loss of erection in men and vaginal anesthesia in women.[10,11]

Clinical Tests of Nerve Root Irritation

Several tests can be performed to confirm the presence of NR irritation (Box 29.1). Passive SLR test or Lasègue test assesses the presence of worsening pain in the radicular distribution with ankle dorsiflexion of the extended lower extremity, which results from the traction of lower lumbar NRs that are drawn caudally between 1.4 and 4 mm.[12] Therefore a positive SLR suggests radicular pathology of the lower lumbar NRs (L4, L5, and S1). Radicular pain in the affected leg when the contralateral asymptomatic leg is similarly raised constitutes an X-SLR test. Although a positive SLR test is highly sensitive, X-SLR is more specific for lumbar NR irritation.[13] An increase in back pain during SLR is typically attributed to NR movement in lumbar spinal segments,[14] and a centrally HD can exclusively generate LBP with an SLR because of strain on the anterior theca.[15] Tripod test confirms positive SLR test in a patient in sitting position—with the patient seated, the knee is extended and the foot dorsiflexed. During a femoral stretch test, the patient is in a prone position, the knee is flexed, and the hip extended; it places the L2 and L3 NRs under tension and indicates irritation of these NRs.

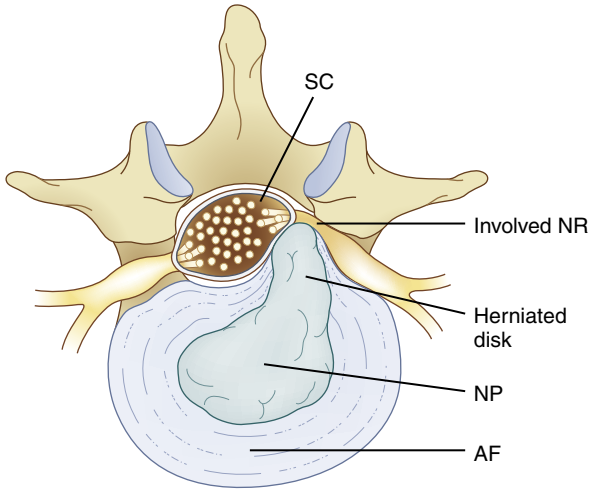
Lumbar Herniated Disc

History and Epidemiology

Although radicular symptoms have been known since ancient times, they were first attributed to "posterior displacement of the disc" by Goldthwaite in 1911.[16] The incidence of symptomatic HD is estimated to be 1% to 2% in the general population, for which approximately 200,000 lumbar discectomies are performed each year.[17]

Terminology

Disc herniation may be defined as the displacement of disc material beyond the confines of the IVD space (Fig. 29.2).[18] Although the nucleus pulposus (NP) is typically the principal component, other constituents (e.g. cartilage, bone, and disc annular tissue) also frequently comprise the HD material.[19] The various terms used to describe disc herniation include *herniated NP*, *ruptured disc*, *prolapsed disc*. However, the term *HD* seems most appropriate as it conveys the concept of displacement of any disc component regardless of source. HD is further classified based on the morphology of the herniated material.[18] A *protruded disc* is present when the neck (i.e. the distance between the edges of the base) of the herniated material is wider than the widest disc diameter in any given plane (Fig. 29.3). *Disc extrusion* is the opposite of disc protrusion in that the neck is narrower than the widest disc diameter in any given plane (Fig. 29.4). *Disc sequestration* is a type of disc extrusion whereby no continuity exists between the herniated material and the parent disc. HD is also classified based on the integrity of the overlying annulus fibrosus (AF). A *contained* herniation, in contrast to a *non-contained* herniation, is distinguished by the fact that the displaced disc material is covered by an intact annulus. Of note, the currently available diagnostic modalities, including computed tomography (CT), magnetic resonance imaging (MRI), and discography, are unable to accurately ascertain the integrity of the disc annulus, and these distinctions may be arbitrary. The terms *desiccation*, *fibrosis*, *narrowing*, *bulging*, *fissuring*, and *sclerosis* of the disc are also used. However,



• Figure 29.2 Schematic depiction of disk herniation. *AF*, Annulus fibrosus; *NP*, nucleus pulposus; *NR*, nerve root; *SC*, spinal cord.

At the L5-S1 level, there is left-sided disk extrusion, and the L4-5 disk shows desiccation and a high-intensity zone; the remaining disks appear normal.

they suggest degenerative disc processes and do not reflect disc herniation.[18]

Pathophysiology

Since Mixter and Barr first reported alleviation of radicular symptoms after removal of herniated disc material in 1934, HD is thought to be the most common cause of LRS.[20] Data from animal studies indicate that NR compression impairs nutrition and can cause ischemic injury,[21,22] and deformation of the affected NR by HD fragments are often evident on diagnostic imaging studies in human patients with radicular symptoms.[23] Therefore mechanical compression of the NRs by the herniated disc material (see Fig. 29.2) has been commonly acknowledged as the preeminent source of LRS. However, clinical studies have shown that NRs exposed to mechanical deformation and HD material for prolonged periods produced pain while similar NR deformation without exposure to HD material caused no pain.[23] Furthermore, HD material retrieved from patients at the time of discectomy has demonstrated the presence of inflammatory mediators,[24,25] and in animal models, the application of the NP, and not the epidural fat, to the NR produced physiologic and anatomic evidence of radiculopathy.[26] The presence of clinical and electromyographic evidence of LRS has also been demonstrated in patients with normal findings and no pressure effects on spinal imaging.[27] Taken together, these observations suggest that inflammatory mediators and inflammation rather than mechanical compression play a central role in LRS because of HD.

Natural History

The natural history of HD is favorable, and most patients (over 60%) experience significant improvement in their symptoms within the first few months. However, a substantial minority (between 20% to 30%) will fail to improve.[28] Clinical improvement is usually accompanied by resolution of HD on spinal imaging.[29] Large extruded discs decrease in size more rapidly and with greater frequency than smaller disc protrusions and bulges.[30] Physiologic regression of the HD is thought to be via phagocytic processing by macrophages, which are more prevalent in the outermost layers of HD material.[31] Therefore the paradox of larger herniations diminishing more rapidly can be explained by the greater surface area available for phagocytosis in a large extruded disc.

Clinical Correlations

Most lumbar disc herniations occur at the lower lumbar levels, with the L4/5-disc level being the most common (59%), followed by the L5/S1 (30%) and L3/4 (9%) disc levels.[32] Herniation at these levels produces typical radicular signs and symptoms in the affected dermatomes, while centrally HDs may primarily cause LBP with both being exacerbated by SLR.[15] Large, often central, disc herniations can cause neurologic compromise and cauda equina syndrome (CES).

Cauda Equina Syndrome

CES is caused by compression, typically acute compression, of the spinal NRs comprising the cauda equina in the lumbosacral spine. The overall incidence of CES is low, affecting approximately 4/10,000 patients with LBP.[33] CES is most frequently caused by a massive midline disc herniation,[10,11] or smaller disc herniation in a previously stenotic spine.[10,11] Rare causes of CES include spinal metastases, hematoma, epidural abscess, traumatic compression, acute transverse myelitis, and abdominal aortic dissection. Almost 70% of patients with CES also have a history of chronic LBP, but CES is the primary complaint in the remaining 30% of the affected population.[32] These patients, typically seen within 24 h of the onset of their symptoms (Box 29.2), usually present with bilateral but often asymmetric lumbar radicular pain (LRP) and less frequently with LBP. The pain is often accompanied by weakness in both feet, gait disturbances (secondary to pain and weakness), abdominal discomfort (because of urinary retention), urinary overflow incontinence, or bowel incontinence. Objective signs include motor and sensory deficits, diminished reflexes, and positive SLR test, often present in lower extremities. Symptoms of particular significance are diminished sensation in the buttocks and perineum (saddle anesthesia), diminished sphincter tone, and evidence of urinary bladder retention on examination. In approximately 10% of patients with signs and symptoms suggestive of CES, the cause is compression of the spinal cord at more superior levels, i.e. at the thoracic or even the cervical spinal cord.[34] These patients have weakness of the lower extremities, similar to lesions at lower spinal levels, but experience higher levels of sensory loss, corresponding to the level of spinal cord involvement, and may have increased tone and reflexes in the lower extremities.[35] MRI is the "gold standard" for diagnosis of CES, and imaging of the entire spine (lumbar, thoracic, and cervical) is often performed because of the possibility of spinal cord compression at higher levels.[34,35] Once the diagnosis is made, treatment involves high dose intravenous steroids and urgent decompressive surgery to reduce permanent neurologic injury and resulting disability.[32]

• BOX 29.2 Clinical Signs and Symptoms of Cauda Equina Syndrome

Features in the Clinical History

Radicular pain in both lower extremities; pain in one leg may be greater
Isolated low back pain is rare
Complaint of weakness in one or both legs and feet
Gait disturbances because of pain and weakness
Abdominal discomfort as a result of urinary retention

Features in the Clinical Examination

Motor and sensory deficits in the lower extremities
Diminished lower extremity reflexes
Positive straight-leg raise and crossed straight-leg raise tests
Saddle anesthesia
Diminished sphincter tone
Evidence of urinary bladder retention

Treatments for Herniated Discs

Because of the favorable natural history, herniated discs are typically managed expectantly with symptomatic treatment in the absence of neurologic deficits.[35,36] Other specific treatments for HD include a variety of injections and minimally invasive or larger-scale surgical interventions.

Injections for Herniated Disc

Epidural steroid injections (ESIs) have been used to treat HDs for more than 50 years. Traditionally, a posterior interlaminar (IL-ESI) approach is used, and the injectate reaches the anterior

• BOX 29.3 Predictors of Favorable Outcomes of Conservative Noninvasive Treatment of Herniated Disks

Negative crossed straight-leg raise test
Absence of leg pain on extension of the spine
Return of neurologic function within 12 weeks of onset
Absence of stenosis on spine imaging
Favorable response to epidural steroid injections
Patient with 12 years of education
Motivated and otherwise healthy patient
Absence of comorbid psychologic condition
Absence of workers' compensation claim

portion of the spinal canal near the HD by flowing through the circumferential epidural space around the thecal sac. Transforaminal epidural steroid injections (TF-ESIs) have the theoretical advantage of delivering the injectate directly to the anterior epidural space. Fluoroscopic guidance can improve the precision with which the injectate is deposited in the epidural space.[37] The literature is replete with case series and uncontrolled studies, both in support of and against the efficacy of ESIs. However, a review of the randomized controlled trials (RCTs) of IL-ESI for LRP show ESIs to be more beneficial than control treatments, particularly in the short term, and TF-ESIs were found to be superior to IL-ESIs.[38,39] ESIs are discussed in detail in Chapter 65.

Predictors of Outcome with Expectant and Non-invasive Treatments for HD: Predictors of a favorable outcome from conservative treatments include 1) a negative X-SLR test; 2) absence of leg pain with spine extension; 3) absence of degenerative disc changes on spinal imaging; 4) favorable response to ESIs; 5) resolution of any neurologic deficits within 12 weeks; 6) a motivated, otherwise healthy patient; 7) more than 12 years of education; 8) absence of workers' compensation claims, and 9) absence of comorbid psychologic disorder (Box. 29.3).[40]

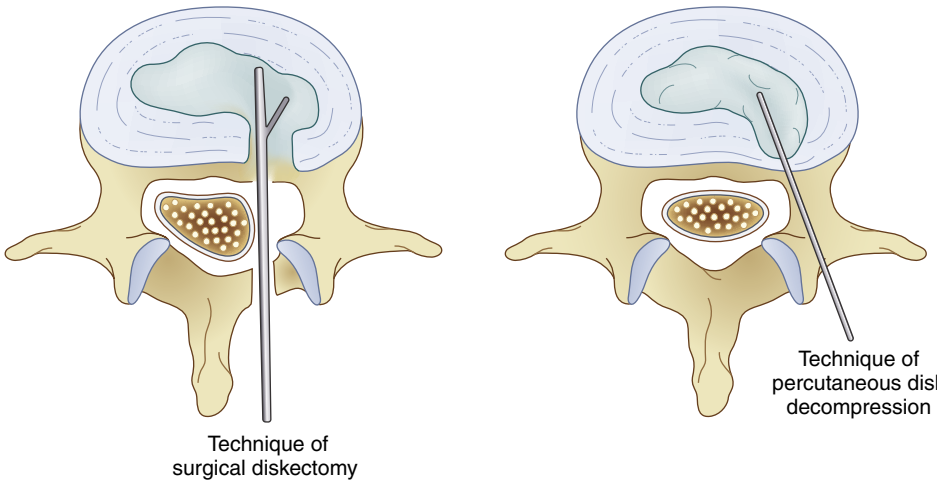
Minimally Invasive Treatments for Herniated Discs

Percutaneous disc decompression (PDD) was developed following the success of intradiscal injection of chymopapain for LRP from an HD. Positive results of the intradiscal chymopapain injections suggested that the dissolution of non-herniated intranuclear disc contents may resolve the HD symptoms without directly targeting the HD material (Fig. 29.5). However, chymopapain injections are rarely performed in the United States because of the complications of unintentional injection of this substance into the subarachnoid space and the rare occurrence of severe allergic reactions. During PDD, non-herniated NP tissue is removed, which is postulated to reduce intradiscal pressure that allows inward collapse of the HD fragment. This therapeutic intervention is likely effective in the presence of an intact AF, i.e. when the herniation is assumed to be contained, presumably when the HD fragment is smaller than 4 mm.[41] Based on the principles of joint endoscopy, PDD was initially conducted by using large-bore endoscopes, 7 mm or greater in internal diameter, which were used to remove the NP material. However, these early endoscopes were cumbersome to operate and had the added risk of trauma to the disc annulus and, hence, were quickly abandoned. The technique of automated percutaneous lumbar discectomy (APLD) used a smaller introducer cannula (2.5 mm in internal diameter), and the nuclear material was removed with a suction and cutting technique. Later, a variety of lasers were used to vaporize the nuclear material. These laser disc decompression devices had smaller cannulas, less than 3 mm in internal diameter, and often included a fiberoptic channel for observation. The technique of disc Nucleoplasty® used a smaller (1.5 mm, 17 gauge) introducer needle and bipolar radiofrequency (RF) energy to create small channels, removing the nuclear material. A percutaneous discectomy technique with the proprietary name of DeKompressor® uses 1.5 and 1.0 mm (19 gauge) outer cannulas and a probe that rotates to remove the disc material. A modified intradiscal electrothermal therapy (IDET) catheter (Acutherm®) aimed to induce localized thermal lesioning and shrinkage at the base of the HD material.

Despite its use spanning several decades, evidence supporting the use of the various PDD techniques is lacking. In one study, MRI of patients before and after APLD showed no difference in the size of HDs at six weeks.[42] Although animal[43] and cadaver studies[44] have shown a reduction in disc pressure after PDD. No evidence exists of high intradiscal pressure in patients with HDs, or its reduction after PDD procedures. Furthermore, the amount of nuclear material removed is variable for the various PDD techniques, ranging from 4 to 5 gm for APLD, 1 gm for Nucleoplasty® and DeKompressor® devices, variable for the various laser procedures, and unknown for the Acutherm® device. Removing large amounts of disc material has been linked to disc collapse and accelerated disc degeneration.[45] However, studies correlating disc pressure and outcomes with a specific amount of nuclear material removed suggest that the optimum amount of disc material that should be removed is unknown. Therefore it may be prudent to remove the least amount of disc material possible to achieve the most beneficial results. Similarly, the use of smaller-gauge introducer cannulas would limit the annular damage and should be preferentially used. Removing nuclear contents from within the disc protrusion itself via a more lateral percutaneous approach has also been suggested.[41] Discography followed by a post-discography CT scan to assess the size and location of the HD and the integrity of the disc annulus has also been proposed prior to the PDD. This practice has been linked to improved outcomes.[46] Two RCTs of APLD showed success rates of 29%[47] and 33%.[48] However, no such trials support the use of laser disk decompression, Nucleoplasty®, DeKompressor®, and Acutherm®, and their use remains anecdotal.

Operative Treatments for Herniated Discs

A detailed discussion of the various surgical procedures for HD is beyond the scope of this chapter. Classic discectomy, first popularized by Mixter and Barr in 1934,[20] is the most popular procedure performed for HD. This technique fundamentally includes laminectomy and release of ligamentum flavum to access the epidural space, removal of the HD fragment, and annulotomy to remove the non-herniated disc material (see Fig. 29.5). Several variations of this technique exist, which differ in the extent of laminectomy and ligamentum flavum release and annulotomy performed during the procedure. The micro-discectomy procedure is less invasive and aims to minimize the surgical trauma and limit the potential for NR injury and epidural scarring. Although surgery is commonly performed for HD,[17] little high-quality evidence exists in its support. A prospective trial comparing surgical and non-surgical treatments for HD showed superior outcomes in surgically treated (92%) than the nonsurgically treated patients (61%) at one year.[49] However, these results deteriorated over time, with differences between the groups becoming less significant at four years and insignificant at ten years. This study was also criticized for lacking careful randomization and blinding, a large crossover



• **Figure 29.5** Schematic depiction of surgical discectomy and percutaneous disk decompression.

of patients to the surgical group, insensitive outcome measures, and small sample size.[50] Another frequently cited study in support of operative treatments is a non-randomized and observational study with similar results at one and five years but slightly favorable results for surgical treatment at ten years (56% vs. 40%, $P = 0.006$).[51] The spine patient outcomes research trial (SPORT)[52] showed primary outcomes to be in favor of surgery at all observation periods. However, these differences were not statistically significant, and the main benefit of the surgery was the faster resolution of pain. It appears that the main reason to undergo surgery is the urgency with which a patient wishes to achieve pain relief over the following two to four months.[53] However, the need for surgery is absolute in patients with CES,[32] and surgical treatment is generally necessary for patients with progressive motor deficits. In contrast, other indications for surgery, including intractable pain and poor response to conservative therapy, appear relative.[54] The results of micro-discectomy have been reported to be superior to those of traditional discectomy.[56] Although patients with "sciatica" of more than 12 months duration have been shown to have less favorable results after surgery,[57] the full effects of a potential delay in operative treatment, while nonsurgical treatment is attempted, remain unknown. Overall, the lack of consensus and variability of adherence to indications for surgery is demonstrated by the nearly 20 fold difference in surgery rates in otherwise demographically similar United States populations.[55]

Lumbar Spinal Stenosis

Terminology and Etiology

LSS is defined as the clinical syndrome of neurogenic claudication or radicular symptoms from narrowing of the spinal canal, neuroforaminae, and/or lateral recess generally assumed to be from compression of the neural elements.[58] Though LSS has been recognized for some time, its modern descriptions first appeared in medical literature in 1954.[57] LSS is typically classified (Table 29.1) into congenital and acquired varieties, with the latter being the most common. Congenital or developmental LSS is generally idiopathic in nature but rarely can be from developmental bone dysplasia such as achondroplasia. Acquired LSS is most frequently degenerative in nature, and the less common causes include metabolic disorders such as Paget's disease, trauma, surgery, spinal tumors, and spinal deformities. LSS has also been classified by anatomic criteria into central stenosis because of narrowing of the spinal canal and lateral stenosis because of narrowed neural for aminae and/or lateral recess.[58]

Pathophysiology

The most common, the acquired degenerative variety, of LSS is characteristically because of disc degeneration and its sequelae. The typical lesions include 1) loss of disc height, 2) AF bulging, 3) facet joint hypertrophy, 4) thickening and redundancy of the ligamentum flavum, and 5) local osteophyte formation.[59] Therefore the stenotic changes are typically at the level of the IVDs, and one or several vertebral motion segments may be involved (Fig. 29.6). Central stenosis can cause compression of the NRs of the cauda equina, whereas lateral stenosis typically results in compression of the exiting spinal NRs. The L5 NR is most commonly involved (75%), followed by the L4 (15%), L3 (5.3%), and L2 (4%) NRs.[60] The capacity of the lumbar spinal canal is significantly greater during flexion and reduced during extension. Therefore the symptoms of LSS are typically worse during lumbar extension.[61] Notwithstanding, degenerative changes of LSS are prevalent in older adults[62] and are frequently also seen in asymptomatic individuals.[36] Direct

TABLE 29.1 Classification of Lumbar Spinal Stenosis

Etiologic Classification	
Congenital	Idiopathic
	Achondroplastic
Acquired	Degenerative

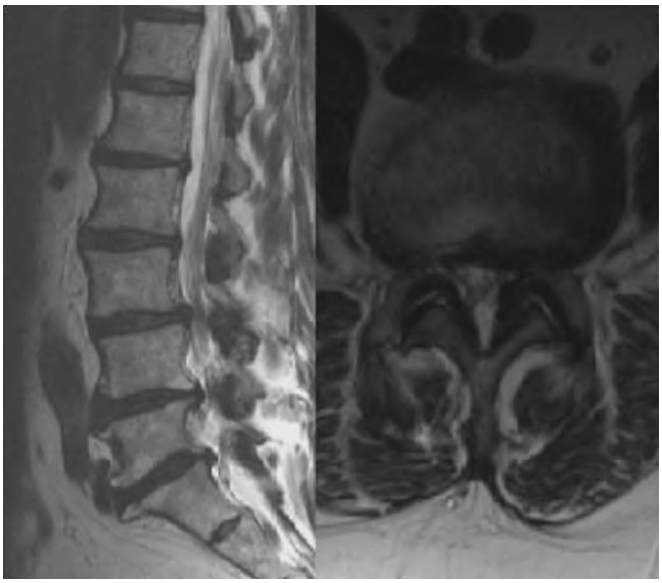
Lateral stenosis	Lateral recess stenosis
	Neural foraminal stenosis



• **Figure 29.6** T2-weighted sagittal and axial magnetic resonance images of multilevel lumbar spinal stenosis.

compression and/or ischemia of the neural structures is generally thought to be responsible for the clinical manifestations, and in contrast to HD, the role played by the inflammatory changes is less clear.[63] The degenerative changes that result in spinal stenosis can also give rise to SI, degenerative spondylolisthesis, and spinal deformities, including degenerative scoliosis, which can further exacerbate spinal narrowing.

Clinical Considerations

- *Neurogenic claudication*: The typical manifestations of neurogenic claudication include pain radiating to both lower extremities—posterolateral aspect of the thighs and legs—which is exacerbated with standing, walking, and lumbar extension and is relieved by sitting. The pain is often associated with numbness and heaviness or weakness of the lower extremities. These symptoms must be distinguished from claudication of vascular origin, and this possibility should be entertained in the presence of signs related to vascular insufficiency.[64] In contrast to vascular claudication, the pain of neurogenic claudication can be present with standing only and can be eased by walking in a flexed position, such as leaning on a walker or shopping cart.[65]
- *Radicular pain*: Radicular symptoms unrelated to any activity can be a sign of NR involvement. This usually reflects lateral stenosis and can be present with or without symptoms of neurogenic claudication.[66]
- *Axial pain*: Axial pain is more reflective of disc, facet joint, or sacroiliac joint pathology. It may indicate SI and is unlikely to be the leading feature of LSS.[67]
- *Clinical signs*: Patients with LSS tend to walk with a forward flexed gait and often maintain this "stooped posture" position while standing with the loss of lumbar lordosis and decreased range of lumbar extension. Because of the slow and chronic nature of the progression of LSS, the SLR test is infrequently positive, and the sensorimotor deficits are less pronounced. In a study of patients with LSS, a sensorimotor deficit in the lower extremity was seen in 30% of patients (most commonly in the L5 NR distribution), a decreased or absent plantar reflex was present in 43%, and a diminished patellar reflex was noted in 18% of the patients; the SLR test is positive in only 10%–23% of patients.[68]

Natural History and Treatment Options

Even though LSS was initially thought to be unrelentingly progressive,[70] its natural history can be defined by intermittent pain flares, or it may remain relatively unchanged over time.[71,72] Because of its seemingly progressive nature and poor prognosis, LSS was treated in the past with early surgical interventions.[70] However, nonsurgical treatments have been shown to effectively control the symptoms.[72,73] Surgical treatment of LSS typically provides superior control of the symptoms initially,[74] but the benefits seem to decline over time.[75] The prevalence of this condition in older adults and the frequent presence of other comorbid conditions often make these patients unsuitable for major surgical intervention. Moreover, delaying surgery for a trial of nonsurgical treatment, even with severe stenosis, has been shown to have minimal detrimental effect on the final surgical outcomes.[76] Therefore in the absence of progressive neurologic deficits or CES (rare in spinal stenosis), nonsurgical treatments are prudent, and surgery should be reserved for patients who have failed appropriate trial of non-operative therapies.

Non-operative Treatments

Non-operative treatments for LSS, including medications, activity modification, bracing, and physical therapy, are discussed later in the chapter. ESIs, particularly IL-ESIs, are effective in the short term treatment of acute pain exacerbations and can provide symptomatic control of episodically worsening symptoms of neurogenic claudication.[77] Fluoroscopically guided TF-ESIs appears to be a treatment better suited for radicular symptoms secondary to LSS and have been shown to have both short term and long-term efficacy.[78,79]

Operative Treatments

Wide laminectomy performed at the stenotic levels is the standard procedure for surgical decompression of LSS.[80] It involves broad removal of the spinal laminae and ligamentum flavum extending laterally from pedicle to pedicle. Extensive removal of the posterior spinal elements can result in SI, which can be avoided by the preservation of the pars interarticularis and the lateral halves of the facet joints. Extensive decompressive surgery, typically performed for complex stenosis and degenerative spondylolisthesis, may result in significant SI. The post-decompressive instability may be avoided by fusion performed with or without instrumentation.[80] The various approaches to lumbar decompression and fusion have included the traditional posterior lumbar inter-body fusion (PLIF) and, more recently, anterior lumbar inter-body fusion (ALIF), lateral lumbar inter-body fusion (LLIF), and transforaminal lumbar inter-body fusion (TLIF).[81] These approaches are frequently combined, and the anterior and lateral approaches (LLIF and TLIF) can reduce the amount of surgical muscle dissection and minimize the nerve manipulation required to access the vertebrae, discs, and nerves. Lately, surgical techniques involving minimal decompression, such as laminotomy, fenestration, and laminoplasty, are increasingly used to preserve spinal stability and avoid post-decompressive fusion.[82] However, these minimally

decompressive techniques can be accompanied by higher rates of restenosis.

Degenerative Disc Disease

Lumbar disc degenerative changes most clearly seen on magnetic resonance (MR) imaging include 1) disc desiccation; 2) reduced disc height; and 3) disc bulging. Often referred to as DDD, these changes are frequently linked to LBP; however, they are also considered age-related physiologic variants.[83] To further comprehend DDD one must first understand the basic disc anatomy, physiology, and age-related changes in the disc.

Anatomy and Physiology of the Intervertebral Disc

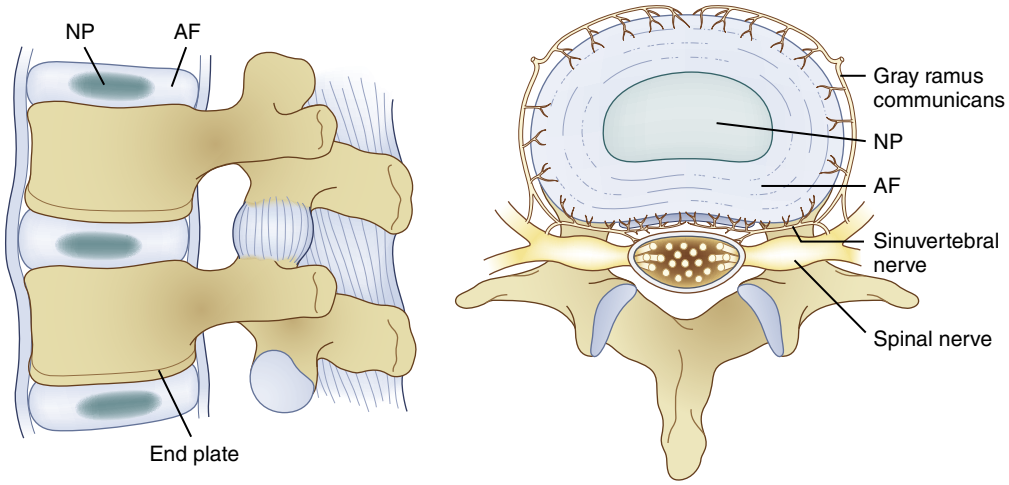
Healthy IVDs are an integral component of the spinal column as their collective plasticity engenders spinal flexibility that is vital to the agility enjoyed by vertebrates. The IVD is a doughnut shaped structure interposed between the adjacent vertebral bodies and can be grossly compartmentalized into an outer rim, the AF, the inner NP, and the cartilaginous endplates (Fig. 29.7). This distinction, most obvious at the lumbar levels, decreases with advancing age. Both NP and AF are sparsely populated by cells of variable origin that maintain the disc function and integrity. The NP is inhabited by chondrocyte-like cells found in clusters, whereas AF is populated by fibrocyte-like cells.[84] The abundant intercellular disc matrix is different for the NP and AF. In the NP, the matrix is jelly-like and has a high concentration of water and proteoglycans, whereas in the AF, the matrix is firmer and has high collagen content. The collagen fibers in the AF are arranged as interlacing lamellae, which are firmly attached to the adjacent vertebral bodies.[84] Due to their central pivotal position, the IVDs are exposed to intense compressive forces that can vary instantaneously, with postural changes and weight bearing, from negative to extreme positive pressures. However, a healthy IVD is strikingly resilient, transcending the adjoining vertebral bodies, as it maintains the critical gap between the adjacent vertebral bodies and relieves the loading stress on the contiguous structures, i.e. the spinal ligaments and the facet joints.[85] These axial compressive loading forces are borne directly by the NP, which because of its inelasticity, are dispersed as the lateral stretch of the tensile AF collagen fibers.[86] The incompressibility exhibited by the NP is largely because of its high water content, which is maintained in turn by the hydrostatic pressure generated by its high proteoglycan content.[84] Apposite NP proteoglycan concentration is maintained by a delicate balance between the anabolic activities of the NP cells and the enzymatic activities of NP matrix metalloproteinases (MMPs).[87] The IVD is largely avascular, and the metabolic requirements of cells in NP and AF are met almost exclusively by diffusion to and from capillary plexuses located in the outer AF and the adjacent vertebral bodies across the avascular cartilaginous end plates.[88] This arrangement is tenuous at best, and the disc cells, especially in the NP, function in a precarious anaerobic environment.[89] The IVD also lacks scavenger cells, and the degradative products of disc macromolecules, therefore, accumulate over time and alter the normal cell and matrix interactions.[90] Therefore the state of hydration, the compressibility of the NP, and the disc itself can be altered by a host of factors influencing metabolic activities within the disc.

Vascularity and Innervation of the Intervertebral Disc

IVD is the largest avascular structure in the body and is also scantly innervated. The vascularity and innervation in a normal IVD are limited to the outer one-third of the AF, and the NP lacks completely any blood supply and innervation.[84,91] Innervation of the outer third of the AF, mainly mechanoreceptors, is by plexuses along the anterior and posterior longitudinal ligaments (see Fig. 29.7).[92] The posterior plexus receives its input from the sinuvertebral nerve and the gray rami communicans, the latter also contributing to the anterior plexus. The sinuvertebral nerve receives its contributions from the ventral rami and the gray rami communicans.[92] Therefore a normal disc has rich autonomic connections and is innervated by multiple spinal segments, an arrangement that explains the diffuse and non-specific nature of the pain originating from the IVDs, akin to the pain from abdominal viscera such as appendix and spleen.

Pathophysiology of Degenerative Disc Disease

Degenerative changes within the disc are commonly seen in asymptomatic individuals, especially with advancing age. However, extensive and often isolated degenerative disc changes are also seen in younger patients with LBP (see Fig. 29.4).[93] Therefore degenerative disc changes may represent both a painless physiologic consequence of aging and also a pathologic and painful



• **Figure 29.7** Schematic representation of normal intervertebral disk components and innervation. *AF*, Annulus fibrosus; *NP*, nucleus pulposus.

phenomenon.[94] A host of factors have been shown to influence early and progressive disc degeneration, including genetic predisposition, diminished blood supply (from causes such as smoking and vascular insufficiency), increased mechanical stress (such as from repeated heavy lifting, contact sports), obesity, and traumatic injury to the cartilaginous end plate.[95–99] These factors can imbalance the tenuous intradiscal milieu, both in the NP and in the AF. In the NP, such imbalances can cause dysfunction (senescence) and decline (apoptosis and necrosis) of the NP cell population, enhanced MMP activity, and increased cytokine or inflammatory mediator content.[100–102] These changes would reduce the NP proteoglycan and water content, diminish its hydrostatic pressure, and would render the NP compressible, exposing the AF to direct axial compression.[86] The axial stress to the AF would eventually lead to its stress failure and loss of collagen, and development of AF fissures that spread outward toward the periphery.[103] These NP and AF structural changes affect the biomechanical properties of the entire disc and cause it to shrink and become less plastic.[104]

Clinical Significance of Degenerative Disc Changes

The reduced disc height and lessened disc pliability can alter the disc and spinal dynamics and can increase the stress loading across the disc itself and the adjacent spinal and paraspinal structures. Consequently, the disc and the contiguous facet joints, muscles, and ligaments, following the local injury and repair responses, can undergo a variable degree of inflammatory changes, increased vascularity and innervation, fibrosis, sclerosis, hypertrophy, new bone formation, and arthritic changes. Several well-recognized painful LBP syndromes can be distinctly linked to degenerative disc changes, including HD, IDD, LFS, LSS, SIJD, MFPS, and Modic changes seen in the adjacent vertebral bodies.[105–107] The symptoms can also arise from the involvement, either from direct pressure or because of the inflammatory changes, of the neural structures housed within the spinal column. Although most of the LBP syndromes have been described individually, they can also be linked directly or indirectly to DDD. However, to further complicate the diagnostic algorithm, the degree of degenerative disc change evident on imaging studies correlates poorly to the symptoms of LBP experienced by patients.[108]

Internal Disc Disruption

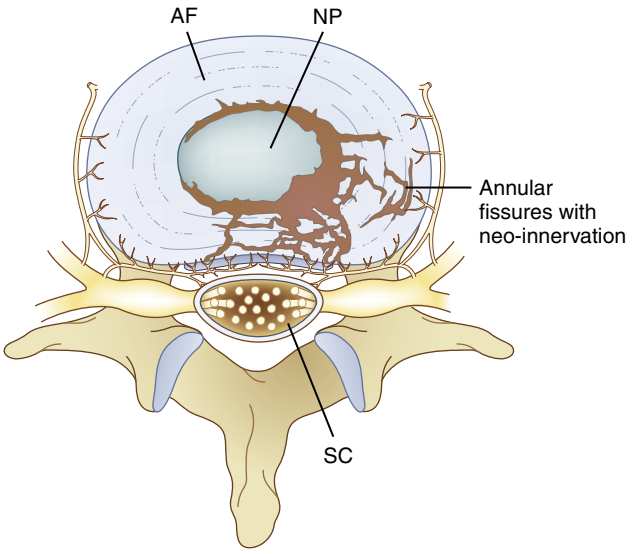
The role played by the disc itself as a source of LBP is poorly understood and, because of minimal innervation of healthy nonpainful discs, has remained controversial.[83] The ambiguity of this source of low back pain is illustrated by the many terms used to describe a painful disc: *IDD*, *discogenic pain*, and *painful DDD,* among others.

Historical Background

Though the concept of IVD as a source of pain was first espoused as early as 1947,[109] the term *IDD* was not used until 1986.[110] The term was coined based on the observation that discs producing pain upon contrast injection during discography, which at that time was the most common diagnostic method for diagnosing an HD, often appear morphologically intact on plain x-rays. Therefore a diagnosis of IDD was rendered almost entirely based on subjective pain responses generated during provocative discography. This exclusively subjective criteria, confounded by a host of psychosocial and somatization influences, led to intense controversy.[111] The validity of provocative discography was seriously challenged, showing a high false-positive rate of 37%.[112] However, these results were widely criticized,[113] and a subsequent study showed a false-positive rate of 0%.[114] As a result of continued scrutiny from the medical community,[111] provocative discography is now assessed using stringent criteria that were adopted to reduce false-positive rates. The International Spine Intervention Society criteria for provocative discography include 1) concordant pain response; 2) presence of at least one disc level with no pain on provocation (the control disc level); and 3) evidence of disc disruption on post-discography CT scan (one or more annular tears extending to the outer AF).[115] To improve the specificity of provocative discography, pressure manometry is often used, and the pressure discography can ostensibly identify painful discs with minimal stimulation.[116]

Pathology of Internal Disc Disruption and Discogenic Pain

Positive pain response on provocative discography has been linked to a host of disc lesions.[117–124] Specimens of discs from patients with concordant pain on discography have been shown to contain vascularized granulation tissue fissures that extend from the NP to the outer AF (Fig. 29.8).[122–124] These granulation tissue zones correlate with the annular fissures seen on post-discography CT scans,[122] and the high-intensity zones seen on MR imaging.[123] In a healthy disc innervation and vascularity are limited to the outer one-third of the AF, but discs with positive pain on provocative discography are highly vascular and richly innervated.[92,118] The nerve fibers found along the AF fissures consist of two distinct varieties:[122] 1) nerve fibers accompanying neovascularization, which are likely vasoregulatory, and 2) free nerve endings, which penetrate deep into the inner AF and NP, are high in substance P, and are likely nociceptors.[118,119] These granulation tissue zones are abundantly infiltrated with mononuclear cells and exhibit strong expression of nerve growth factors, which may contribute to nerve ingrowth and accelerated disc degeneration.[121,124] These discs are also high in inflammatory mediators[120] that can sensitize



• **Figure 29.8** Schematic depiction of lesions of internal disk disruption. *AF*, Annulus fibrosus; *NP*, nucleus pulposus; *SC*, spinal cord.

the neo-nociceptors and maintain a state of hyperalgesia within the affected disc. Thus the pain generated can be aggravated with mechanical stress, such as axial loading, and can be elicited with minimal stimulation on discography, i.e. a chemically sensitized disc instead of a mechanically sensitized disc, which requires higher pressures.[125] Innervation of the disc by nociceptors, presence of inflammatory mediators and inflammatory cells, and the abundance of sympathetic connections at the spinal cord level provide a ready substrate for the origin of discogenic pain. However, it remains uncertain whether IDD is a distinct disease entity or if it denotes early-onset, progressive and painful DDD. Factors discussed above that predispose to early and progressive DDD are also central to the etiology of IDD. However, there is no test currently available that can objectively and reliably detect the pathologic lesions of IDD. Regrettably, the subjective concordant pain response on disc provocation, coupled with morphologic abnormalities seen on post-discography CT scan, currently remains the only means of diagnosing IDD. In addition to the disc lesions described, often causing chronic LBP, acute forms of disc injury causing intense and abrupt LBP have also been described.[126]

Clinical Findings

The exact incidence of IDD in patients with LBP is unknown. However, a preliminary study showed that the incidence of IDD in a group of patients with chronic LBP was as high as 40%.[127] Another study showed that 73% of the patients with severe acute LBP had greater than 70% pain relief after intradiscal injection of local anesthetics.[126] This study indicated that acute disc pathology is responsible for the equally high incidence of severe acute LBP. Both studies claimed that the incidence of disc related pain was greatest in patients younger than 40 years of age, and the pain was located primarily in the low back and buttock regions. The onset of pain was precipitated by a torsion injury of the low back and was exacerbated by axial loading such as with prolonged sitting and standing. Although the pain experienced from disc pathology is characteristically axial in nature, it may also refer to the lower extremities in a non-dermatomal distribution.[128]

Treatments for Discogenic Pain

Treatments for IDD and painful DDD are principally palliative in nature as the available treatments cannot reverse the pathologic changes described above. Among the variety of minimally invasive treatment options available are several disc-heating modalities. Intradiscal electrothermal therapy (IDET) involves heating the posterior AF by a percutaneously placed heating coil.[129] Based on joint arthroscopy, IDET aims to shrink the AF collagen and coagulate the neo-nociceptors. However, its exact mechanism of purported effects is not clear.[130,131] The outcome studies of IDET are mixed, and the reported efficacy ranges from minimal benefit[132] to highly successful.[129] The theoretical basis for surgical treatments for IDD and discogenic pain rests on the complete removal of the painful disc followed by fusion of the adjacent vertebral bodies. However, the results of spinal fusion for discogenic pain using the various techniques discussed previously are also mixed, raising serious doubts about the efficacy of spinal fusion.[133] Loss of spinal mobility from fusion has also been linked to accelerated disc degeneration at the adjacent spinal levels. Artificial disc replacement was introduced to obviate some of the problems associated with spinal fusion surgery. However, outcome studies of disc arthroplasty show results similar to spinal fusion with the added problems of device longevity and high complication rates.[134] Treatments that can restore the disc matrix composition prior to the irreversible damage to the disc and the contiguous structures have been proposed and include biologic treatments such as gene therapy, tissue engineering techniques, and stem cell transplantation.[135,136] However, these therapies remain experimental and are not reimbursable by insurance. The anaerobic disc environment, the immense pressures sustained by the disc, and the ubiquitous presence of the inflammatory mediators likely render the disc environment hostile to this class of interventions. In summary, the currently available treatments for discogenic pain are mainly symptomatic or questionably efficacious. They can also cause substantial complications and cannot restore the disc function or prevent further deterioration, leaving ample room for additional research and new treatment modalities.

Lumbar Facet Syndrome

There is a detailed discussion on the pathogenesis, diagnosis, and treatment of facet syndrome in Chapter 31 of this textbook. In this chapter, we will present a succinct overview to complete the discourse on LBP syndromes.

Anatomy

The lumbar facet or zygapophyseal joints (LFJs) are synovial joints composed of an articular surface, synovial membrane, fibroadipose meniscoid, and fibrous capsule.[137] These paired joints are located dorsally at the junction of the lamina, pedicle, and the base of the transverse process. Each joint is composed of two articular processes, the superior and the inferior, which project from the corresponding vertebrae. The orientation of facet joints is distinct at the lumbar, thoracic, and cervical levels, with the LFJs having a curved and oblique profile. The medial branch (MB) of the posterior primary ramus traverses the base of the superior articular process (SAP) at its junction with the transverse process to innervate both the facet joint at the same level and the vertebral level below. Each facet joint receives innervation from its corresponding vertebral level and the vertebral level above. The course of the MB is relatively fixed as it originates from the dorsal ramus, proximally at the base of the SAP, and passes under the mamillo-accessory ligament. The L5 dorsal ramus passes over the sacral ala at the base of the sacral SAP.[138] The fibrous capsule and the synovium of the LFJs are richly innervated by nociceptive fibers.[139]

Historical Background

LFJs were first proposed as a potential source of pain in the early 1900s,[16] and the term *facet syndrome* was introduced as early as 1933.[140] Several investigators have since reproduced pain in the low back and the proximal leg by injecting hypertonic saline (a physiologic irritant) into the facet joints.[141–143] The relief of pain in patients with chronic LBP by intra-articular facet joint injections of local anesthetic and steroids was first reported by Mooney and Robertson in 1976.[142]

Pathophysiology

Degenerative changes in the facet joints frequently follow DD and accompany degenerative changes in the discs and the neural canals, contributing variably to the patients' overall LBP. However, the exact cause of pain originating from the LFJs is often undetermined, and isolated facet joint pathology is rare. The known

• BOX 29.4 Pathologic Lesions That Can Cause Lumbar Facet Syndrome

Systemic inflammatory arthritides
- Rheumatoid arthritis
- Ankylosing spondylitis

Degenerative arthritic changes
Villonodular synovitis
Synovial cysts
Infections
Microtrauma
- Microfractures
- Capsular and cartilaginous tears

Meniscoid and synovial entrapment
Joint subluxation

causes of independent facet joint pathology include systemic inflammatory arthritides, e.g. rheumatoid arthritis and ankylosing spondylitis, synovitis, and infections (Box 29.4).[144] Microtrauma to the LFJs, including microfractures and capsular and cartilaginous tears, have also been observed in postmortem studies.[145] However, these are undetectable by routine imaging studies, and their role in causing chronic LBP is unknown.[145] Meniscoid and synovial entrapment and joint subluxation are other proposed causes of pain potentially originating from LFS.[146] Notwithstanding, the degenerative arthritic changes, often accepted as the most frequent source of LFS, are observed both in symptomatic and asymptomatic individuals. Moreover, the correlation of degenerative arthritic changes visible on imaging studies and the outcome of diagnostic facet joint injections is poor.[147]

Diagnosis

The typical features of LFS include unilateral or bilateral LBP, frequently referred to as the buttocks, groin, hip, or thighs but infrequently present below the knee joints (Box 29.5).[148] The pain is often exacerbated by arching or twisting movements and with prolonged standing or sitting, and it is reportedly relieved by forward flexion, rest, and walking. Pertinent physical examination findings include painful limitation in low back extension, absence of neurologic deficits, a negative SLR test, and localized paravertebral tenderness over the facet joints. However, many investigators report a lack of consistent clinical findings in patients who respond positively to diagnostic facet joint injections.[149] Even though some have suggested a correlation between the arthritic findings on imaging and the pain relief from diagnostic injections,[150] the imaging findings are generally unable to reliably predict facet joints as a source of pain.[151]

• BOX 29.5 Clinical Features of Lumbar Facet Syndrome

Low back pain
Pain referred to the groin, hip, and posterior aspect of the thigh but rarely below the knees
Pain exacerbated by twisting and extension of the low back region but relieved by forward flexion
Pain with prolonged sitting or standing and relieved by rest and walking
Localized tenderness over the facet joints
Lack of neurologic signs
Normal straight-leg raise test

Diagnostic Injections for Lumbar Facet Syndrome

Despite the various controversies, analgesic response to targeted, low-volume, intra-articular, local anesthetic facet joint injections, or medial branch blocks (MBBs) currently remains the only accepted standard for establishing pain originating from LFJs.[148,149,152] The suspected painful facet joints injected are either those found most tender on the physical examination or, in the absence of any localizing signs, the lowermost joints, i.e. the L5/S1 and L4/5 joints, because these joints are most commonly affected.[149] Fluoroscopic guidance and the use of the coaxial needle insertion technique are often considered essential for intra-articular needle placement.[149] The injectate volume is generally less than 2 mL as larger volumes can cause capsular injury and leakage of contrast material into neural foramina and epidural space, resulting in loss of diagnostic specificity. A small volume of contrast medium (0.2 to 0.3 mL) may also be injected prior to the local anesthetic injection to adequately delineate the joint space. MBBs performed by injecting a small volume (<1 mL) of local anesthetic at the junction of the transverse and the SAP (the "eye of the Scottie dog") have been shown to have equal diagnostic sensitivity.[149] Injection of a small volume of contrast medium prior to the local anesthetic MBBs, has been advocated to confirm the correct needle placement and rule out intravascular needle tip location. MBBs are also useful when the joint entry is challenging, e.g. in patients with severely degenerated joints or after non-fusion spine surgery, and are preferable prior to the MB rhizotomy as they allow direct testing of the nerves targeted for the subsequent neurotomy. Avoidance of systemic analgesics, or the use of only short-acting drugs, and the resumption of pain provoking activities after the diagnostic injection, can facilitate the evaluation of the analgesic response after the diagnostic blocks. Local anesthetics of different duration, used on two separate occasions (double comparative blocks), with the patient reporting corresponding duration of pain relief, can enhance diagnostic specificity.[152] Determined by a single set of diagnostic injections, the prevalence of LFS varied from low of 7.7% to high of 75% in a group of patients with chronic LBP. However, it varied from 15% to 40% when the more stringent double comparative block criteria were used.[152] In addition to the wide variation in the reported prevalence, a placebo response rate of almost 40% was reported when a single set of diagnostic blocks was employed.[153] Therefore double comparative blocks are generally recommended for appropriate diagnosis of LFS to avoid the unacceptably high false-positive response rate of the single diagnostic procedure.

Therapeutic Interventions for Lumbar Facet Syndrome

Lumbar Facet Joint Injections: Based on the practice of intra-articular injection of steroids in knees and shoulders, intra-articular lumbar facet steroid injections were first performed in 1976.[142] Confirmation of LFS by diagnostic blocks, prior to the therapeutic LFJ injections, is rarely practiced.[154] Pain relief from therapeutic LFJ injections is reported mainly in observational studies with success (pain relief of greater than six months) rates varying between 18% to 63%.[152] However, the few prospective controlled trials of LFJ injections have failed to show therapeutic

efficacy.[152,155] Therefore although it is a common intervention, LFJ injections for LBP are inadequately supported, and the typical steroid dosages used (e.g. 20 to 30 mg of methylprednisolone per joint) remain empirical.

Facet Denervation

Denervation of a painful facet joint, referred to as facet rhizotomy, neurotomy, or ablation, is accomplished by lesioning of the MB at the painful vertebral level and one level above. Although chemical neurolysis and cryoablation have been employed, thermal radiofrequency ablation (RFA) of the targeted MB is the most frequently used technique. Because the distal circumferential radius of an RF lesion is markedly shorter than the median radius, RFA is typically performed by placing an electrode parallel to the path of the target MB, i.e. along the base of the SAP.[156] Optimal electrode positioning is confirmed both radiologically and by appropriate sensory and motor testing (discussed in Chapter 31) prior to the lesion creation. The size of RF electrodes used varies between 18 and 22 gauge, the temperatures range between 80°C and 90°C, and the duration of RF lesioning can last from 60 to 90 s. Larger probe size, longer duration, and higher temperatures can produce larger lesions with a greater likelihood of thermally coagulating the target MB. Routine use of 18 gauge electrodes with a 1 cm exposed tip, lesioning duration of 120 s, and temperature of 80°C have been recommended by some authors.[157] In addition to the several observational studies reporting the efficacy of RFA for LFS, three RCTs of its efficacy are available; while two demonstrated improved chronic LBP following the procedure, the third showed no benefit.[157]

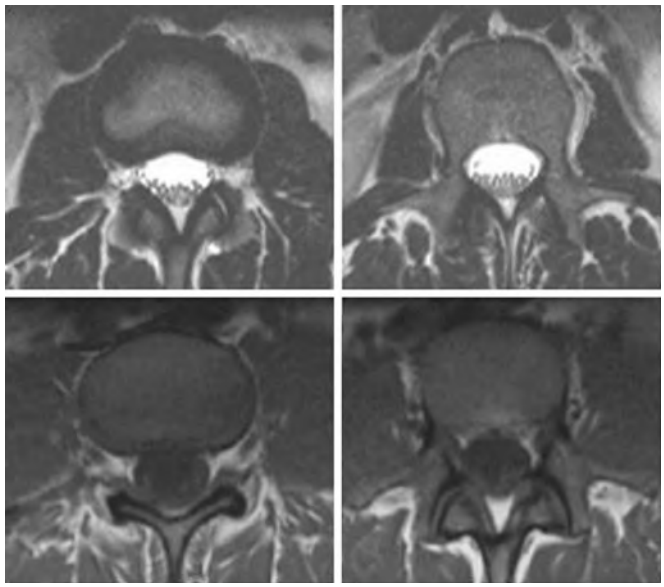
Diagnostic Studies for Low Back Pain

The diagnostic studies employed to ascertain the etiology of LBP can be broadly grouped into imaging modalities, discography, diagnostic blocks, electrodiagnostic studies, and laboratory studies. These studies are detailed in other sections of this book, and only the most pertinent information pertaining to the imaging, electrodiagnostic, and laboratory tests are relayed below.

Imaging Studies

- *Magnetic resonance imaging*: MRI is considered the gold standard in determining the etiology of low back and radicular pain (Figs. 29.9 and 29.10). MRI offers the best resolution of pathologic lesions in the spinal canal, spinal cord, neural foraminae, NRs, and disc spaces and allows evaluation of the entire spine.[69] In patients with a history of previous spine surgery, a contrast-enhanced MRI is recommended to differentiate between scar tissue and possible recurrent disc herniation. Limitations of the MRI include lengthy examination time, claustrophobia, and its effects on metallic bodies. MRI is contraindicated in patients with pacemakers, certain aneurysm clips, or other metallic objects in the body. MRI is the most common imaging modality used to diagnose an HD and LSS as the findings are characteristic and easy to visualize but are also frequently present in older[62] and/or asymptomatic individuals.[158,159] Therefore it is critical that the radiologic abnormalities identified are correlated with the patient's clinical evaluation. The degenerative disc changes seen on the MRI can include disc desiccation (loss of T-2 disc signal intensity), disc bulging, and loss of disc height. As stated, these MR findings are also common in asymptomatic individuals and are of limited value in the diagnosis of painful DDD and IDD.[93,108] Loss of T-2 signal intensity, indicating loss of NP water content (see Fig. 29.4), often referred to as "black disk disease," may be the only indication of early IDD.[160] A high-intensity zone in the posterior AF on the MRI (see Fig. 29.4) has been shown to indicate the presence of a tear in the posterior disc annulus and is closely correlated with positive pain on provocative discography.[123] Nevertheless, the overall correlation of results between discography and the MR features for the diagnosis of IDD has ranged between 55%[161] to almost 100%.[162]
- *Computed tomography*: Although MRI is considered the gold standard spinal imaging modality, CT scan of the spine can be

• **Figure 29.9** Normal T2- and T1-weighted midline sagittal magnetic resonance images of the lumbar spine.



• **Figure 29.10** Normal T2- and T1-weighted axial transdiscal and interdiscal magnetic resonance images of the lumbar spine.

• **Figure 29.11** Normal anteroposterior and lateral plain X-ray images of the lumbar spine.

a valuable and even preferable tool for the evaluation of bony spinal details, e.g. diagnosis of spinal fractures, bony tumors, and abnormalities of the facet joints and lateral recesses. However, in the evaluation of the spinal canal, CT is unable to distinguish between certain lesions (e.g. between an HD or neoplasm), and its routine use for this purpose is discouraged.[163] CT combined with myelography has a resolution comparable to that of MRI. Therefore CT-myelogram can reliably diagnose spinal canal lesions when MRI is contraindicated.[163]

- *Plain radiography*: Plain x-rays of the spine are the most cost-effective and readily available of the imaging techniques. Typical views performed include the anteroposterior, lateral, and oblique spinal images. Plain X-rays of the spine can reveal various bony abnormalities. However, the soft tissue details are difficult to discern (Fig. 29.11). Though spinal fractures and deformities are readily appreciated, the plain X-ray findings of lumbar lordosis, transitional vertebrae, and disc space narrowing are common in asymptomatic individuals.[164] As compared to other modalities, plain radiographs do not permit sectional imaging, and thus sagittal and axial views are not possible. Therefore the "routine" ordering of spinal roentgenograms for LBP is not recommended.[165] Flexion and extension spinal films are often performed, typically after spinal fusion surgery, to evaluate segmental instability as a source of pain. However, the correlation between abnormal vertebral motion and pain symptoms is poor.[166]
- *Myelography*: Though a common test in the past, myelography without spinal CT is an infrequently performed test. It is utilized to detect spinal canal lesions when other studies yield conflicting information, are not available, or are contraindicated.
- *Bone scan*: Increased uptake of the radioactive isotopes by metabolically active inflammatory or neoplastic tissues (disc, bone, ligaments) can help identify lesions such as discitis, osteomyelitis, arthritic conditions, and stress fractures, which are otherwise difficult to ascertain on routine imaging.

Electrodiagnostic Studies

Electrodiagnostic studies, including electromyography (EMG) and nerve conduction velocities (NCV), are useful in establishing the radicular nature of symptoms when the clinical features are inconclusive or are indistinguishable from other syndromes such as peripheral neuropathy. In contrast to the imaging studies, the combined results of EMG and NCV have higher specificity for the diagnosis of LRS.[167] However, EMG and NCV cannot determine the etiology of LRS, the results correlate poorly to the anatomic level of the radicular lesions ascertained, and their routine use is not recommended.[36] Somatosensory evoked potentials (SSEPs) can pinpoint the site of nerve dysfunction, and their use is generally limited to ascertaining the location of intraoperative nerve injury.

Laboratory Tests

The various hematologic and serologic tests such as complete blood count, erythrocyte sedimentation rate, C-reactive protein, rheumatoid factor, antinuclear antibodies, HLA-B27 antigen, and urinalysis are useful when spinal infections and inflammatory and rheumatologic disorders are suspected.

Symptomatic Treatments for Low Back Pain

Various remedies that aim to provide symptomatic relief of pain and improve function, despite the etiology, are used extensively to manage LBP. These strategies are briefly discussed below:

- *Medications*: Multiple categories of medications employed for the management of LBP, often in variable combinations, include nonsteroidal anti-inflammatory drugs (NSAIDs), acetaminophen/paracetamol, opioids, oral steroids, muscle relaxants, membrane stabilizers (e.g. gabapentinoids), and neurotransmitter reuptake inhibitors (e.g. serotonin-norepinephrine reuptake inhibitors, tricyclic anti-depressants). NSAIDs are by far the most commonly used drugs and have been shown to have efficacy in the management of acute radicular symptoms.[168] Acetaminophen and NSAIDs are particularly helpful in providing symptomatic relief of acute flares of LBP. Opioids are widely prescribed for various LBP conditions. However, because of the significant potential for abuse and the chronic nature of the LBP syndromes, the use of opioids should be limited to short courses and only for acute exacerbations of LBP.[169] Systemic corticosteroids are prescribed, both orally and parenterally, for the various LBP syndromes, particularly for an acute disc herniation. However, evidence supporting this practice is lacking.[170,171] Calcitonin has been found to be beneficial for LSS resulting from Paget's disease.[172]
- *Physical therapy*: Physical therapy modalities, both active and passive exercises, are routinely advocated to improve function and reduce pain. Active exercises, deemed more effective, can boost muscle strength and conditioning, while passive maneuvers aim to increase range of motion, increase flexibility, and reduce stiffness.[173] Regularly performed active exercises can also promote weight loss, promote cardiovascular fitness, and improve tolerance of other exercise programs. Flexion-based exercises, e.g. stationary bicycle and inclined treadmill, may be helpful in LSS by increasing the cross-sectional area of the spinal canal and improving microcirculation of the neural elements.[174] Aquatic therapies, particularly those that stretch hip flexors and hamstrings and strengthen the core abdominal and trunk muscles, may also be useful in LSS.[174] The overall role of physical therapy for the treatment of various LBP syndromes remains uncertain.[40]

- *Psychological treatments*: Behavioral therapy, especially cognitive behavioral therapy and biofeedback, have been shown to have modest efficacy in patients with chronic LBP.[175]
- *Activity Modification*: To promote natural healing and recovery, avoidance of aggravating activities, and relative rest, is recommended during acute flare-ups of the various LBP syndromes. However, the potential for deconditioning and stiffness limits recommendations of prolonged inactivity.[169] Instead, a continuation of activities within the limits imposed by the pain is recommended as it results in faster recovery.[176]
- *Bed rest*: Though a common treatment in the past, prolonged and strict bed rest is no longer advocated for the management of LBP conditions because of its multiple potential harmful effects.[176,177]
- *Bracing*: Lumbar bracing, including rigid, semi-rigid, and soft braces and binders, are other methods of immobilizing a painful spine; lumbar binders propose to reduce loads across the lumbar spine. These devices may reduce pain by limiting motion and can provide symptomatic relief. However, the potential for deconditioning and stiffness, along with insufficient evidence supporting their use, limits their recommendation.[178] Overall, to avoid deconditioning and stiffness, the use of braces and binders, particularly the rigid braces, should be limited only to short periods.
- *Traction*: Once a mainstay treatment for LBP, particularly for HD, traction, both in its continuous or intermittent forms, remains unproven and is no longer a popular therapy.[179] Vertebral axial decompression (VAX-D®), a proprietary modality based on traction principles, remains untested.
- *Acupuncture*: Although some studies have shown the effectiveness of acupuncture for chronic LBP, it lacks clear scientific support from rigorous trials.[180]
- *Miscellaneous Treatments*: Chiropractic manipulations, massage therapy, magnets, transcutaneous electrical nerve stimulation, and ultrasound application, often employed for the management of low back and radicular pain, remain unsubstantiated.

Diagnostic Challenges in Patients With Low Back Pain

With their shared etiology, predisposed to by DD, most low back and radicular pain syndromes, including the DDD, HD, LSS, IDD, LFS, SIJD, and even the ubiquitous sprains and strains, can be present concurrently. Despite their distinct pathologic lesions, as discussed earlier in this chapter, these LBP syndromes likely have analogous overall patterns of cyclical injury and repair.[181] The injury sustained by the various spinal and paraspinal structures secondary to DD invokes local tissue inflammatory reactions. These reactions herald the subsequent repair cycles characterized by granulation, endothelial, neural, and fibrotic tissue infiltration. These injury and repair cycles likely correspond to the remissions and relapses characteristic of chronic LBP and plausibly also explain the poor correlation of symptom severity and imaging findings. The presence of many concomitant LBP syndromes and the variability in the pain caused can result in multiple concurrent, asymmetrically present, and vacillating pain generators, which are inconsistently linked to the morphologic changes observed. Hence, the precise recognition of these diverse pain generators in a patient with LBP is challenging. The limitations of the most frequently employed test for LBP (the spinal MRI) were alluded to earlier in this chapter, i.e. the abnormalities can be elucidated in both symptomatic and asymptomatic individuals.[158,159] Other frequently employed tests such as the diagnostic local anesthetic blocks and provocative and/or local anesthetic discography are also compromised by their subjective nature and the fact that the placebo effect can result in low specificity and high false-positive rates. Hence, the accuracy with which pertinent pain generators can be elucidated in patients with LBP rests on the keen awareness of their concomitant presence and vacillating nature. The spinal imaging modalities in this context can define the extent of the disc and the contiguous spinal and paraspinal structural involvement from DD. Armed with this background, a meticulous clinical evaluation could delineate the plausible pain generators. Pertinent diagnostic blocks and provocative tests, corroborating the clinical and the radiologic findings, can further enhance the diagnostic accuracy and pinpoint targets for surgical and minimally invasive interventions. However, although ordering tests selectively and correlating their results with clinical findings should prevent inappropriate diagnoses and improve outcomes,[35] the precise source of LBP can remain elusive.

Approach to Managing Patients With Low Back Pain

The extensive list of conditions causing LBP, alongside the diagnostic impediments discussed, necessitate a clear approach to managing patients with LBP. Indiscriminate diagnostic workup is not only costly but would also engender results that may be unrelated and misleading. Therefore in 1994, the Agency for Health Care Policy and Research (AHCPR) developed guidelines to identify and treat, at first, only the conditions deemed life threatening and/or that can cause neurologic compromise. Conferring the AHCPR guidelines, these "specific" conditions (i.e. malignancies, inflammatory conditions, traumatic injuries, and CES), defined at the outset of this chapter, can be recognized by systematic clinical evaluation of these patients.[35] The signs and symptoms indicative of the "specific" LBP conditions, referred to as "red flags" (Table 29.2) cited in the AHCPR publication, include:[35]

- *Extremes of age*: Patients younger than 20 years old often present because of congenital and developmental anomalies, while those over 50 are at higher risk of developing neoplasms, pathologic fractures, infections, and life threatening extra-spinal processes as a cause of their LBP.
- *Duration of symptoms*: Compared to chronic LBP (pain greater than three months), symptoms of less than three months duration, acute and subacute LBP, can indicate a more sinister etiology.
- *History of trauma*: History of significant trauma, or a less serious injury in older patients and those with serious medical conditions, may result in simple or pathologic fractures that may require further workup.
- *Constitutional symptoms*: Fever, chills, malaise, night sweats, and unexplained weight loss suggest a serious underlying disorder such as malignancy or infection.
- *Systemic illness*: History of cancer, recent bacterial infections (e.g. serious respiratory or urinary tract infections), intravenous drug abuse, immunosuppression (e.g. infection with human immunodeficiency virus, organ transplantation, and chronic corticosteroid use) could increase the likelihood of pathologic fractures, epidural and vertebral body abscesses, and metastasis.
- *Unrelenting pain*: Pain of benign etiology is typically relieved with rest and supine position, especially at night, while pain from serious pathologic conditions can be unrelenting, worse at night, and unresponsive to rest and analgesics.
- *Cauda equina syndrome*: The signs and symptoms of CES are discussed earlier in the chapter (Box 29.2).

TABLE 29.2 "Red Flags" in the Clinical History of Patients With Low Back and Radicular Pain

Red Flag	Implications
Red Flags in the History	
Age younger than 20 years	Congenital and developmental disorders, spondylolisthesis
Age older than 50 years	Malignancy, pathologic fractures, infections, AAA
Short term symptoms of < three months	More serious etiology
Trauma	Fractures
Fever, chills, malaise, night sweats, weight loss	Malignancy, osteomyelitis, abscess, fracture
History of cancer, HIV, chronic steroid use, IV drug abuse, immunosuppression	Malignancy, osteomyelitis, abscess, fracture
Unrelenting pain	Malignancy, osteomyelitis, abscess, fracture
Incontinence, saddle anesthesia, bilateral neurologic symptoms	Cauda equina compression
Red Flags in the Physical Examination	
Fever	Malignancy, osteomyelitis, abscess
Motor weakness, diminished reflexes, saddle anesthesia, weak anal sphincter	Cauda equina compression
Spinous process tenderness	Fracture

AAA, Abdominal aortic aneurysm; *HIV*, human immunodeficiency virus; *IV*, intravenous.

Contemporary algorithms for managing LBP,[5] consistent with the AHCPR recommendations, recommend first excluding specific disorders by identifying "red flags" in the patient's history and physical examination. In their presence, to rule out these specific conditions, the patients are offered further diagnostic workup and possible intervention, while their absence translates to a diagnosis of non-specific LBP (NsLBP). Though by definition, NsLBP denotes an unknown etiology, the pain in these patients is customarily assumed to be from "degenerative" conditions with favorable natural history. Self-limiting and expected to resolve spontaneously, NsLBP is managed expectantly; i.e. the patients are not afforded diagnostic tests or specific treatments but rather preventative strategies and generic therapies for the symptomatic relief of pain and disability.[5,35,36] In the absence of a suitable recovery during the period of expectant management, which typically occurs over a period of six to eight weeks, NsLBP patients may be offered further diagnostic workup and interventions. Such intercepts are subjective and adopted variably across different clinical practices.

Limitations of the Current Approach

The "specific" disorders are uncommon (< 5%), and over 95% of the patients with LBP will ostensibly have "non-specific" causes. Hence, following the current methodology, a vast majority of the patients presenting with LBP will undergo no diagnostic workup, receive no specific treatment, be provided no clear explanation for their symptoms, and be given no express recommendations for the prevention or further deterioration of their condition. Even in instances in which diagnostic workup and specific treatments were to be provided, in the absence of the expected recovery, these decisions can be uncertain, deferred, or eschewed altogether. Consequently, many patients seek alternate care methodologies and are lost to follow up. The designation of LBP to "specific" and "non-specific" groups, based only on the clinical criteria, can also be subjective and interpreted variably by the diverse providers involved.[182] Remarkably, when the "specific" disorders are excluded, the LBP caused can be from a range of well-defined conditions we examined earlier in this chapter and are discussed elsewhere in this book. Notwithstanding the distinct pathophysiology and natural history, many of these "non-specific" conditions have existing treatments and explicit preventative strategies, and others, with their greater understanding over the recent years, may have looming treatment options. Additionally, though considered self-limiting, these "non-specific" conditions can be progressive and irreversible and may cause significant long-term pain and disability. Paradoxically, the "specific" disorders are not invariably progressive, nor will they necessarily lead to neurologic injury and/or demise, e.g. certain compression and non-displaced spinal fractures, stable deformities, chronic inflammatory, and metabolic conditions, and even some neoplasms, necessitate only careful monitoring and supportive care. Hence, cataloging LBP to "specific" and "non-specific" groups might rest on arbitrary criteria, which can leave a vast majority of patients with LBP with unclear management strategy or understanding of their symptoms. Such lack of guidance could also result in incapacitating pain and disability from the irreversible progression of these conditions. Therefore an alternative strategy based on a clear understanding of these conditions, which would improve patient satisfaction, optimize care and prevention, and will have superior outcomes, is desirable. One such, ostensibly conflicting approach is to attempt to determine the cause and offer specific therapies and preventative strategies to all the patients with LBP. With superior knowledge of the causative conditions, meticulous clinical evaluation, and the targeted use of the diagnostic tests, the costs of indiscriminate and "routine" diagnostic testing could be curtailed. For instance, patients suspected of omnipresent sprains, strains, and MFPS would undergo no diagnostic testing, as no testing is available to confirm these conditions. Following this strategy, the patients could be informed of the possible nature of their LBP, lessening their discontent, and specific therapies and preventative strategies can be initiated early in the course of these otherwise progressive conditions. By way of example, early recognition of DD is vital, even though specific treatments that can arrest or reverse early DD are currently not available because specific preventative strategies (e.g. explicit work related lifestyle modifications) could be introduced early to slow the progression of DD to subsequent advanced LBP syndromes.

Treatment Challenges, Prevention, and Future Directions

The diagnostic impediments mentioned above are confounded by substantial treatment challenges in patients with LBP. The available treatments, discussed under the various chapter subheadings, can be summarized as a range of surgical, minimally invasive, conservative, traditional, and alternative therapies.

These therapies are offered by diverse providers with varied backgrounds who tend to prefer their own methodologies or field of treatment. Consequently, analogous conditions are often treated by profoundly different approaches, which can lead to an immense variability in the care provided.[182] Furthermore, the available treatments aim mainly to provide symptomatic relief, improve strength and flexibility, reduce inflammation, and in the surgical interventions, in particular, provide neural decompression and spinal stability. Crucially, therapies aimed to resolve early DD and restore disc matrix composition prior to the irreversible damage to the disc and the contiguous structures are not well-developed. Consequently, the symptomatic relief afforded by many treatment modalities is typically either incomplete or short-lived as it does not address the underlying DD. In particular, low back surgery can cause worsening LBP, which is proportionate to the extent and the number of low back surgeries performed.[183] As "regenerative" therapies are nascent and traditional treatments lack efficacy, early initiation of specific preventative strategies to curb DD and stop the progression of disc and contiguous structural injury is vital. Premature DD can originate from a myriad of genetic and environmental influences. Polymorphism at various connective tissue gene loci can render the IVD vulnerable to injury and specific occupational and lifestyle external influences predisposing to DD, as discussed earlier in the chapter. Hence, individuals with specific phenotypes who are exposed to precipitating environmental influences are especially prone to early DD and must be identified. Furthermore, recognition of early DD prior to significant disc injury and any symptoms is feasible, as MRI can discern early loss of NP proteoglycan and water content.[184] Screening high-risk individuals could reveal early DD and premature disc damage so that early preventative actions can be taken. Although fiscal impact renders screening MRI impractical at the present time, similar preventative measures can be adopted in patients with new onset LBP to curb the progression of DD, which may lessen the overall burden of LBP on the individual patient and greater society.

Key Points

- LBP often emanates from spinal and paraspinal structures, but it may also refer to adjacent joints or even viscera.
- LBP in any particular patient is often caused by multiple, variable, asymmetric, and vacillating pain generators.
- Causative conditions of LBP are managed by cataloging those that are potentially life threatening and/or can cause neurologic compromise and those that are presumed to be self-limiting.
- Despite carrying low mortality burden, the self-limiting conditions that cause LBP can be progressive, irreversible, and may result in long-term pain and disability.
- Many distinct low back syndromes notably have a shared primary origin that derives from dysfunction of the IVDs.
- The general pattern of most painful primary etiologic processes is similar in that tissue injury is followed by inflammatory changes and fibrotic repair.
- Injury and repair cycles that result in chronic LBP often originate in an initial injury to the disc and then progress to painful episodes with remissions and relapses consistent with the pattern of tissue injury and repair.
- The tests available for the diagnosis of these LBP syndromes, particularly the array of imaging studies, give only a snapshot of the evolving pathologic processes and generally are unable to clearly pinpoint the primary pain generators.
- Expertise in the conditions causing LBP, meticulous clinical examination, and confirmation of the disease state with available diagnostic tests are all necessary to appropriately assess patients with LBP.
- The treatments available for the management of various low back conditions, even those publicized as regenerative, cannot reverse or even arrest the underlying causative pathologies.
- Currently available treatments generally provide symptomatic relief with variable efficacy, but because of an absence of effect on etiologic processes, the relief provided is typically partial and/or temporary.
- Surgical treatments often provide inadequate pain relief and, in addition to their invasive nature and high complication rate, may also result in worsened LBP.
- Pertinent indication for spine surgery, especially in the context of non-specific LBP, is progressive neurologic compromise and not LBP.
- As treatments cannot mitigate the pathologic processes causing the various LBP syndromes, a clear understanding of their prevention by measures adopted early in vulnerable patient populations and in afflicted patients to minimize progression remains paramount.

Buttock and Sciatica Pain

GRAHAM WAGNER, ARIANA M. NELSON, STEVEN P. COHEN, ZACHARY L. McCORMICK

Buttock pain can originate from a heterogeneous collection of pathologic conditions. Similar to low back pain, the precise diagnosis and treatment of pain in this region can be challenging. This chapter focuses on pain largely experienced in the buttock region *and* originates below the lumbosacral junction. Pain generators can be intrinsic to the buttock region, such as the sacroiliac joint complex (SIJC), coccyx, piriformis muscle and sciatic nerve (SN), ischiogluteal bursa, and other muscles in the hip girdle and pelvic region, as well as referred from other regions such as the viscera of the abdomen or pelvis. Pain experienced in this region can also be caused by disorders originating in the lower back, such as radiculopathy and facetogenic pain, which are discussed in other chapters of this textbook. Less common but nonetheless important causes of buttock pain, such as fracture, infection, and neoplasm, are also beyond the scope of this chapter.

Sacroiliac Joint Complex (SIJC) Pain

Epidemiology

Pain generated by the SIJC is an underappreciated source of the presenting complaint of low back pain (LBP), with a reported prevalence rate ranging between 10% and 33% in individuals with a suspected mechanical etiology predominantly below L5.[1,2] However, the diagnosis of SIJC pain depends on the diagnostic criteria, with more stringent criteria resulting in lower prevalence rates based on the response to injections. In a review by Kennedy et al. using ≥50% pain relief based on single blocks yielded prevalence rates between 60% and 65% in three studies. Based on the more stringent criteria of ≥75% pain relief with double-blocks, prevalence rates ranged from a low of 10% to a high of 33% based on five studies.[2]

Etiology

The sacroiliac joint is a diarthrodial synovial joint, and pain in this region may arise from numerous bony and soft tissue structures, including the fibrous joint capsule, the sacral and iliac bones (sacral degeneration generally occurs after degenerative changes in the ilium), adjacent muscles (e.g. latissimus dorsi, gluteus maximus and medius, erector spinae, iliacus, rectus femoris), and ligaments located both anterior and posterior to the articulation. Soft tissue, periosteum, and the joint capsule all contain nociceptors. Therefore all potential sources of pain. Although the ligamentous connections in the SIJC contain the greatest surface area and are most likely to be injured with trauma, the density of nociceptors is greatest in the joint capsule.[3] Because of the myriad potential pain generators within and surrounding the sacroiliac joint (SIJ) region, the SIJC may be more appropriate.

SIJC pain may result from repetitive stress or traumatic inciting events. Several studies that examined the causes of injection-diagnosed SIJC pain found that a specific inciting event was reported in 40% to 50% of cases, with the most common antecedents being motor vehicle collisions, falls, cumulative stressors, and pregnancy.[4–6] Pregnancy is associated with SIJC pain because of anterior weight gain, change in posture, hormone-induced relaxation of the ligaments in the last trimester, and trauma to the pelvis associated with childbirth. A prospective study performed in 355 parturients found a LBP prevalence rate of 49%, while another study conducted in 1500 pregnant women with new-onset LBP reported that 79% stemmed from SIJ dysfunction based on functional testing.[7,8] Of note, the reported prevalence in parturients may be overestimated, as dual diagnostic blocks cannot be performed during pregnancy. Leg length inequality has also been implicated as a potential etiology of SIJC pain, as leg length inequality has been shown to asymmetrically distributes loads across the SI joints. Forces are increased on the side of the longer leg and increase with greater leg length inequality.[9] An additional source of SIJC pain is prior surgery. Surgically induced SIJC pain may be difficult to distinguish from lower lumbar pathology, although timing and pain referral patterns may provide clues. Clinical studies evaluating prevalence rates based on response to diagnostic injections after spinal fusion have reported rates between 32% and 43%, being more common after fusion to the sacrum.[10] SIJC pain after fusion can result from accelerated joint degeneration, ligamentous disruption, or simply increased mechanical stress because of load transfer to adjacent segments below the fusion (particularly with a fusion to the sacrum).

Extra-articular vs. Intra-articular Pathology

SIJC pain may be classified as extra- or intra-articular (bone, fibrous capsule, articular cartilage, synovium) and can have different causes (Table 30.1). In studies that have evaluated the response to SIJ injections, one large retrospective study found combination intra- and extra-articular injections to be superior to intra-articular blocks,[11] one found extra-articular injections to be better for immediate pain relief,[12] while a small study designed to evaluate the accuracy of ultrasound injection study reported no difference in short-(24 h) or intermediate- (four weeks) term outcomes.[13] A more recent multi-center, double-blind, randomized trial comparing fluoroscopically guided to landmark-based SIJ blocks[14]

TABLE 30.1 Causes of intra- and Extra-articular SIJ Pain

Intra-articular	Extra-articular
Arthritis (e.g. osteoarthritis, rheumatoid)	Trauma/fractures
Spondyloarthropathy	Ligamentous injury
Trauma	Myofascial pain
Infection	Enthesopathy
Cystic disease	Pregnancy
	Cystic disease

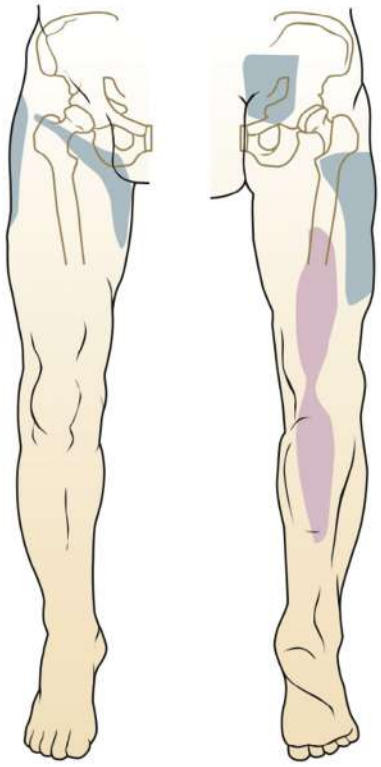
found no differences in immediate pain relief (reflecting prevalence) or one month outcomes between intra-articular and extra-articular local anesthetic and steroid injections. However, those who received intra-articular blocks fared better on some outcome measures at three months. Individuals with intra-articular SIJ pain are more likely to be older and present with insidious onset, bilateral symptoms, and evidence of joint degeneration on imaging. In contrast, those with extra-articular SIJ pain are more likely to be younger, have unilateral pain, report a specific inciting event, and have more prominent tenderness.

Nociceptive fibers and receptors containing calcitonin gene-related peptide and substance P immunoreactive free nerve endings have been noted in the interosseous and anterior ligaments of the SI joint by Szadek and colleagues.[15] Given their findings, the authors recommended extra- as well as intra-articular approaches to diagnostic SI joint injections.

Presentation

The SIJ is the largest axial joint in the body, and consequently, presentation depends on the part of the joint that is injured (i.e. upper vs. lower joint, dorsal vs. ventral joint, ligaments vs. articular surface vs. joint capsule). Multiple studies have shown that SIJC pain is most likely to be concentrated below the L5 spinal level near the posterior superior iliac spine, with upper joint pathology causing pain in the upper buttock region and lower joint pathology causing pain in the lower buttock.[16,17] In a retrospective study, 94% of individuals experienced buttock pain, and 72% had pain in the lower lumbar region.[18] Half of the patients reported pain extending into the lower extremity, with 28% experiencing pain extending below the knee. Fourteen percent had radiation into the groin. Buttock pain extending into the posterolateral thigh is one of the most common presentations (Fig. 30.1). A study by Cohen et al.[5] found that 35% of patients who underwent sacral lateral branch nerve (SLBN) radiofrequency ablation (RFA) experienced pain in their thigh(s). A two part study that sought to determine SIJC referral patterns in asymptomatic volunteers and patients with LBP found the most common presentation to be unilateral buttock pain extending to the posterior and sometimes lateral thigh,[19] while others have found the presence of groin pain to most accurately distinguish SIJC pain from other mechanical sources of LBP. It should be noted that groin pain is a more common presenting symptom in intra-articular hip pathology than in SIJ pain or trochanteric bursitis, although the three conditions are often concurrent.[6,16,20]

Whereas most studies examining SIJC pain referral patterns have been based on maps drawn from patients who respond to intra-articular injections or from pain patterns induced by capsular distension, some investigators have also examined pain patterns based on soft tissue SIJC injections, for example, local



• **Figure 30.1** Pattern of pain from sacroiliac joint syndrome. (From Benzon HT. Pain originating from the buttock: sacroiliac joint dysfunction and piriformis syndrome. In: Benzon HT, Raja S, Molloy RE, et al. (eds). *Essentials of Pain Medicine and Regional Anesthesia*. New York: Elsevier Churchill Livingstone; 2005:356–365.)

anesthetic injection into the dorsal ligaments. In a study of 50 patients who achieved at least 70% pain relief from extra-articular injections, the authors found that the upper ligamentous part of the SIJC generated pain near the posterior superior iliac spine with radiation to the groin, while pain emanating from the middle and lower portions of the SIJC was most prominent in the mid- and lower buttock regions,[16] induced pain from all sections often spread into the posterolateral thigh, but infrequently below the knee. SIJC pain may also occur concurrently with other sources of LBP, with one study finding that 75% of individuals with axial LBP, herniated disc, or lumbar stenosis had radiologic evidence of SIJ arthritis.[21]

Multiple studies have sought to evaluate the predictive value of physical examination findings in establishing the SIJ(s) as the primary pain generator using response to low-volume diagnostic blocks as the reference standard. These studies have generally found that single provocative maneuvers, alignment tests, and mobility assessments possess low sensitivity and specificity for identifying a painful SIJ. However, a systematic review that included 18 studies found that a combination of three provocative tests has sufficient discriminative power.[22,23] The maneuvers provide value in confirming the diagnosis when the symptoms suggest SI joint complex dysfunction and other causes of pain have been eliminated.

Physical examination of the patient with SIJC pain usually revealed tenderness over the posterior aspect of the joint and sacral sulcus. There were no neurologic symptoms such as numbness or weakness. There are several provocative maneuvers designed to stress the SIJC and elicit concordant pain, including the FABER (flexion, abduction, and external rotation), Patrick's test,

Gaenslen's test, Yeoman's (extension) test,[24,25] sacroiliac or posterior shear test, Gillet's test,[25,26] thigh thrust test, pelvic distraction test, and pelvic compression test. Fortin's finger test is also helpful in diagnosis, but it should probably be described as part of the history. Given the complexity of the lumbar, sacral, and pelvic anatomy, SIJC provocative maneuvers often stress structures that are in close spatial and mechanical proximity to the SIJ. This adds complexity to interpreting positive results and necessitates three positive provocative maneuvers to reasonably assure SIJC involvement in a patient's pain.

FABER-Patrick's test (Left SIJC exam) (Fig. 30.2)

- Position: Supine.
- Maneuver: The left leg near the ankle is placed in front of the right thigh above the knee.
- The physician placed one hand over the right iliac crest while the other hand pushed over the medial aspect of the left knee.
- Positive test: Pain over the left SIJ region (also back, buttock, groin)
- Comment: Test stresses the SIJC *and* hip joint, as well as the posterior elements of the lower lumbar spine. Pain because of intra-articular hip pathology, a more common cause of groin pain, is experienced on the side with a flexed hip/knee. Pain originating in the lower lumbar spine, a more common cause of LBP, can be experienced in either laterality.

Gaenslen's Test (Left SIJC exam) (Fig. 30.3)

- Position: Supine. Left leg and lower thigh hanging off the examination table.

• **Figure 30.2** FABER-Patrick's test, left side.

• **Figure 30.3** Gaenslen's test, left side.

- Maneuver: The examiner flexed the right hip and right knee (i.e. the hip joint was maximally flexed). The examiner presses downward over the left thigh (the hip joint is hyperextended).
- Positive test: Pain in the left SIJ.
- Comments: The test stresses both SIJs simultaneously by counter-rotation at the extreme range of motion of the joint. The test also stresses the hip joint and stretches the femoral nerve (the examiner should ensure the absence of hip pathology or conditions affecting the femoral nerve to diagnose SIJ syndrome).

Yeoman's Test (also called Extension Test) (Fig. 30.4)

- Position: Prone.
- Maneuver: The examiner placed one hand above the anterior aspect of the knee and elevated it slightly; the other hand pressed downward over the crest of the ilium.
- Positive test: Pain over the posterior SIJ region.
- Comments: The hip is extended, and the ipsilateral ilium is rotated. The test stresses the SIJ and extends the lumbar spine, and stresses the femoral nerve. It is more specific and reliable than other tests.

Gillet's Test (Fig. 30.5)

- Position: Standing.
- Maneuver: One of the examiner's thumbs was placed on the second sacral spinous process, and the other thumb was placed on the posterior superior iliac spine (PSIS).
- Normal SIJ: The PSIS moves inferior to the S2 spinous process when the patient maximally flexes the hip.
- Dysfunctional or fixed SIJ: PSIS remains at the level of the S2 spinous process or moves superior to the sacrum.

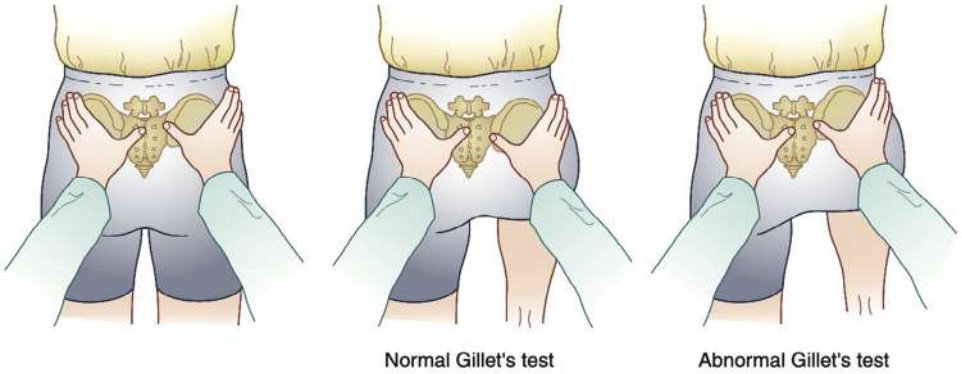
Sacroiliac Shear Test (Fig. 30.6)

- Position: Prone.
- Maneuver: The palm of the examiner's hand was placed over the posterior iliac wing. The shear thrust is directed inferiorly, producing a shearing force across the SIJ.
- Positive test: Pain in the location of the SIJC.

Thigh Thrust Test (Fig. 30.7)

- Position: Prone.
- Maneuver: The patient's hip was flexed to 90°, and the knee was flexed to 90°. The practitioner positions the patient's knee under his or her axilla and applies direct downward pressure through the femur.
- Positive test: Pain over the ipsilateral SIJ region (also back, buttock, groin).

• **Figure 30.4** Yeoman's test, left side.



• **Figure 30.5** Gillet's test. (From Benzon HT. Pain originating from buttock: sacroiliac joint syndrome and piriformis syndrome. In: Benzon HT, Raja SN, Molloy RE, et al. (eds). *Essentials of Pain Medicine and Regional Anesthesia*. 2nd ed. Philadelphia: Elsevier; 2005).

• **Figure 30.6** Sacroiliac Shear test.

• **Figure 30.7** Thigh Thrust test.

- Comment: This test stresses the SIJC *and* hip joint as well as the posterior elements of the lower lumbar spine. Thus this examination can overlap with intra-articular hip pathology, a more common cause of groin pain, and lumbar facet joint pain, a more common cause of LBP.

  Pelvic distraction Test (Fig. 30.8)
- Position: Prone.

• **Figure 30.8** Pelvic Distraction test.

- Maneuver: The practitioner is facing the patient. The physician placed the left hand over the patient's right ASIS and the right hand over the patient's left ASIS. Firm pressure was applied outward.
- Positive test: Pain over the symptomatic SIJ region (also back, buttock, groin).

  Pelvic compression Test (Fig. 30.9)

• **Figure 30.9** Pelvic Compression test.

• **Figure 30.10** Fortin's Finger test, right side.

- Position: lateral decubitus. Pelvis aligned perpendicular to the floor.
- Maneuver: The practitioner is facing the patient. The practitioner places overlapping hands over the patient's superior ASIS. The firm pressure was applied downward.
- Positive test: Pain over the symptomatic SIJ region (also back, buttock, groin).

Fortin's Finger Test (Fig. 30.10)

- Position: Standing.
- Maneuver: Patient points to their area of maximal tenderness.
- Positive test: If the area of maximal tenderness is greater than the PSIS, this indicates that the SIJC is the source of pain.
- Comment: Is not a part of the actual physical exam but rather the patient's historical account.

Radiographic evaluation of the joint rarely aids diagnosis other than in the setting of trauma or an underlying rheumatologic condition such as spondyloarthropathy (e.g. ankylosing spondylitis). However, using fluoroscopy to assess whether Fortin's point truly overlies the SIJ space has higher sensitivity than physical examination maneuvers alone.[27] X-ray and computed tomography (CT) can show changes to the joint space, bone erosions, subchondral sclerosis, and bony malalignment. Magnetic resonance imaging (MRI) can show intra-articular fluid signal, soft tissue and bone edema, fatty infiltration, and joint erosions, while bone scan can show active areas of increased metabolic uptake. CT has low sensitivity and specificity, and radionucleotide bone scans have low sensitivity but high specificity in patients with positive diagnostic blocks.[28] To date, there have been no studies showing an association between x-ray or MRI findings and pain of the SIJC using a reference standard such as a diagnostic injection,[29–31] but in patients with inflammatory spondyloarthropathies, there is an association between SIJ pathology on MRI, buttock pain, and positive response to nonsteroidal anti-inflammatory drugs (NSAIDs).[32] Diagnostic local anesthetic block of the joint is considered the standard criterion for SI joint pain, although complex innervation patterns and technical limitations prevent it from being considered a gold standard.[6,33,34] Provocation of pain on injection of the SIJ alone is not a suitable criterion for the diagnosis of SIJC as the putative source of buttock pain.[6]

Treatment

In individuals with correctable pathology, such as leg length discrepancy, malalignment, or muscle weakness, addressing the underlying etiology with guided exercise, manual therapy including manipulation, or shoe lifts may be beneficial,[35–37] and there is some evidence supporting medications such as anti-depressants, NSAIDs, and opioids for short-term benefit. However, none have been specifically studied in individuals with SIJC pathology.

Only a handful of prospective studies have evaluated the efficacy of steroid injections for SIJC pain. These studies have shown benefits for both intra-[38] and extra-articular injections,[39,40] but all have been characterized by short-term follow up (≤2 months) and small numbers (<25 patients). Studies that have compared intra- and extra-articular injections have yielded mixed findings,[11–13] suggesting that the injection location should be targeted toward the suspected pain generators (i.e. into the ligaments in young people with suspected extra-articular pathology vs. between the bony interface in older people with arthritis). In individuals with injection-confirmed SIJ pain who fail to derive intermediate- or long-term benefits, placebo-controlled and observational studies indicate that SLBN RFA may provide benefits lasting between six months and one year.[41] Since the lateral branches targeted by RFA innervate the posterior ligaments but not the joint capsule, individuals with extra-articular pathology may be more likely to benefit. This is supported by a study evaluating SLBN RFA outcome predictors whereby older individuals, who are more likely to suffer from arthritis, were more prone to fail treatment.[5]

Arthrodesis has been used for decades to treat SIJC pain resulting from fractures, instability/dislocations, and secondary to degenerative changes. Among these indications, SI joint arthropathy is one of the most controversial, with the available studies being confounded by poor selection criteria, diverse outcome measures, and various forms of bias. Recently, there has been a surge in the use of minimally invasive SIJ fusion techniques to treat individuals who have failed conservative management, with results from observational and prospective randomized trials showing benefits for up to two years.[42]

Technique of Sacroiliac Joint (SIJ) Injection

For diagnostic injections, patients were asked to stop their pain medication on the day of the procedure. Sedation is not recommended by the American Society of Anesthesiologists or Spine Intervention Society[43] and has been shown in a large, randomized crossover study to increase the false-positive rate of diagnostic SIJ injections.[44] Light sedation (low dose intravenous or oral benzodiazepine) may be administered to anxious patients or those with a history of vasovagal episodes. Contraindications to the injection include infection in the area and bleeding diathesis. Allergy (not anaphylaxis) to contrast media may require pretreatment with antihistamines and steroids, whereas allergy to local anesthetics may require identification of the appropriate local anesthetic to be used for the procedure. The use of imaging is recommended during SIJ injection to ensure intra-articular needle placement, as blind injections rarely result in correct needle positioning and may increase the risk of complications.[14,45,46]

Fluoroscopy-Guided SIJ Injection

Fluoroscopy is considered the standard of care for intra-articular SIJ injection, as it detects both intra-vascular and intra-articular needle placement. However, this image guidance modality does not guarantee successful joint access. Therefore more challenging anatomy may require CT guidance.[46,47]

The technique for SIJ injection has been described.[48,49] The target point typically lies along the inferoposterior aspect of the joint, in the area 1 to 2 cm cephalad from its most caudal end.[48]

• **Figure 30.11** Sacroiliac joint injection. Note the spread of the dye along the joint.

Although in individuals with suspected extra-articular pathology, the most painful area may be targeted, such as the cephalad portion of the dorsal ligaments.[50]

Once the needle was within the joint, a small amount of contrast was injected to demonstrate intra-articular spread (Fig. 30.11). The response of the patient to the injection of contrast media is noted as either "no pain," "unfamiliar pain," or "similar pain" than the pain complaint.[6] After appropriate contrast spread, a solution of steroid and local anesthetic is injected. Because the capacity of the SIJ is small and distension may exacerbate pain or rupture the joint capsule, a maximum volume of 2 to 3 mL has been recommended for intra-articular SIJ injections.[48,51] Spillage of injectate outside the SIJ is acceptable because some of the pain receptors are located outside the joint. Some practitioners advocate specifically for intra-articular *and* extra-articular injectate placement because of the known innervation throughout the SIJC, as described above.

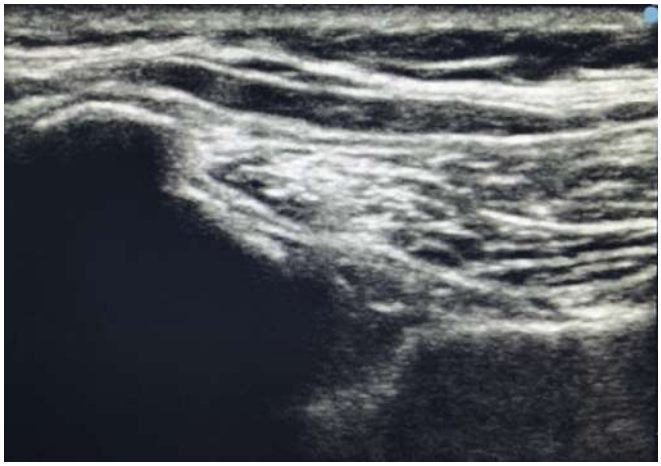
Other approaches include placement of the needle at the inferior end where the posterior and anterior joints overlap if a markedly lucent zone is noted in that area.[48] The midportion of the joint can also be cannulated, although the joint capsule typically extends only about one-third of the way up from the caudad border.[52] Finally, the superior aspect of the joint can be accessed using a cephalo-caudad approach.

After the procedure, the patient should be observed for 15 to 30 min to determine the analgesic response and monitor for complications. The local anesthetic has an immediate effect, but the anti-inflammatory effect of depo-steroid develops over 2 to 5 days, sooner for non-particulate formulations. Guidelines vary regarding the cutoff for designating a block as positive, with some using ≥75% pain relief, others using ≥50%, and still, others advocate an even lower cutoff as the United States Food and Drug Administration and IMMPACT guidelines consider ≥30% pain relief to be a clinically meaningful response.[53,54] Because SI joint pain typically coexists with other musculoskeletal conditions and there is no reliable alternative to treatment, using a less stringent cutoff, such as 50%, as advocated by the international facet guidelines for diagnostic injections, will maximize access to care. Provocative maneuvers can be repeated to assess the improvement. Transient weakness in the ipsilateral leg is because of the spillage of the local anesthetic onto the sacral nerve roots or the SN. Other complications include bleeding, infection, exacerbation of pain, fever, transient difficulty voiding, and allergic reactions to components of the prep solution or injectate.

Ultrasound-Guided SIJ Injection

The feasibility of ultrasound-guided SI joint injections was initially shown by Pekkafahli et al.[55] and was further described by Harmon and O'Sullivan.[56] A curvilinear low-frequency transducer (4 to 6 MHz) was placed perpendicular to the skin over the distal sacrum in the midline in a cross-sectional view (short axis) to identify the sacral hiatus. The probe was moved laterally until the lateral edge of the sacrum came in view and then moved the cephalad to find the medial aspect of the iliac bone. At this site, the SIJ appeared as a hypoechoic wedge-shaped structure (Fig. 30.12). The target area for injection was at the level of the second sacral foramen, which was approximately 2 to 3 cm above the caudal pole of the SI joint. A 22 gauge needle was inserted and advanced in-plane with a lateral and anterior trajectory into the joint. Pop is felt once the synovial joint penetrates. The visible spread of injectate outside the joint indicates periarticular rather than intra-articular placement.

The accuracy of this technique was also assessed. Klauser et al. evaluated ultrasound-guided SIJ injection in cadavers at two levels of the joint by comparing approaches at the level of the first sacral foramen versus those at the second sacral foramen.[57] CT examination showed 90% of the needles at the lower level to be within the SIJ versus 70% at the upper level. The same procedure resulted in an intra-articular placement rate of 100% in both locations (eight in the lower and two in the upper site) when performed in live patients. Jee and colleagues showed an improved ability to avoid intra-vascular structures but a lower intra-articular accuracy rate (87%) with ultrasound versus fluoroscopy (98%).[58] De Luigi et al. found 48/50 (98%) of ultrasound injections to be intra-articular with fluoroscopic confirmation,[59] while Perry et al. found 15/17 (88%) to be intra-articular based on cadaveric dissections.[60] Successful ultrasound injection may be largely related to factors such as body habitus and practitioner experience; for example, Pekkafahli et al. noted marked improvement with operator experience, from a 60% success rate in their first 30 injections to a 94% success rate in their second 30 injections.[55] The successful placement of ultrasound-guided SIJ injections has not



• **Figure 30.12** Ultrasound visualization of the left SIJ. *White arrow*, Ideal needle trajectory; *SIJ*, sacroiliac joint. (Credit: Ariana Nelson, MD.)

been universal. One cadaveric study by Stelzer et al. showed a significantly higher rate of intra-articular injections with fluoroscopy versus ultrasound.[46]

Computed Tomography-Guided SIJ Injection

Injection of the SIJ has been described under CT guidance.[61–63] Success rates from CT-guided injections range from 75% to 92% in the literature.[61,63] The increased radiation exposure and lack of availability of CT in pain clinics restrict the wider application of this approach.

Palpation-Guided SIJ Injection

Palpation-guided intra-articular injections have been shown to be extra-articular in most cases, with one study finding that contrast spread was more likely to be epidural than intra-articular.[45,64,65] In three studies that examined the accuracy of landmark-guided injections, the range for intra-articular spread was between 8% and 22%.[14,45,64] Yet, landmark-guided injections have been reported to result in good pain relief in uncontrolled studies.[66] In a large, randomized, double-blind study by Cohen et al., landmark-guided injections were associated with comparable benefits to fluoroscopically guided injections at one month. However, three months intra-articular injections at three months were superior in some outcome measures.[14] However, some complications were more frequent in the landmark-guided group, and the generally positive results might not be generalizable to a primary care provider population. Palpation guidance cannot be recommended for diagnostic purposes and should not be routinely utilized for therapeutic purposes.

Efficacy and Effectiveness of SIJ Injections

The effectiveness of SIJ injections has been examined in studies, meta-analyses, and reviews with a discordant interpretation of results (Table 30.2).[2,67] Four controlled trials have investigated corticosteroid SIJ injections; all demonstrated some degree of benefit.[38–40,67]

TABLE 30.2 Efficacy and Effectiveness of Sacroiliac Joint Injections

Observational studies				
Lilliang et al.[71]	Prospective case series (n = 39)	Intra-articular SIJ injection with 40 mg triamcinolone (fluoroscopically guided)	67% had 50% relief for over six weeks, the average duration of relief was 37 weeks	SIJ pain diagnosed by a positive response to dual SIJ injections; history of lumbosacral fusion predicted short duration of relief
Chou et al.[4]	Retrospective case series (n = 54)	Intra-articular SIJ injection with 12 mg betamethasone and anesthetic	28% of patients had ≥80% pain relief at two weeks	Dual diagnostic blocks with ≥80% pain relief as diagnostic criteria
Laslett et al.[22]	Prospective case series (n = 58)	Intra-articular SIJ injection with 40 mg triamcinolone and anesthetic	67% of patients had 50% pain relief at six weeks	Dual diagnostic blocks with ≥75% pain relief as diagnostic criteria
Irwin et al.[100]	Retrospective case series (n = 42)	Intra-articular SIJ injection with 80 mg methylprednisolone or 6 mg betamethasone and anesthetic	43% of patients had ≥50% pain relief at one month	Dual diagnostic blocks with ≥70% pain relief as diagnostic criteria
Borowski et al.[11]	Retrospective chart review (n = 120)	Intra-articular injection of local anesthetic and steroid versus intra-articular *and* extra-articular injection of local anesthetic and steroid	At three months, 13% of the intra-articular subgroup and 31% of intra-articular and extra-articular subgroup had a >50% drop in VAS or described ADLs as "greatly improved"	
Murakami et al.[12]	Prospective, unrandomized, case series, n = 50	25 patients with intra-articular SIJ injection of 2% lidocaine, 25 patients with extra-articular SIJ injection of 2% lidocaine	Improvement rate of 96% in the extra-articular group and 62% in the intra-articular group by the Japanese Orthopedic Association "restriction of activities of daily life" scoring system	There was no steroid used in either injection, and longer term improvement was not assessed
Hartung et al.[13]	Prospective, unrandomized, case series, n = 14 (20 SIJs), patients with MRI confirmed active sacroiliitis	20 SIJ injections with steroid and gadolinium performed under ultrasound	At 28 days, no clinically significant difference in the groups was seen, though a significant decrease of mean NRS was seen on both groups (NRS decrease of 2.5 in both groups)	60% of SIJ injections under ultrasound were not positioned within the intra-articular space as confirmed with MRI post-gadolinium

ADLs, Activities of daily living; *CT*, computed tomography; *MRI*, magnetic resonance imaging; *NRS*, numeric rating scale; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *SIJ*, sacroiliac joint; *VAS*, visual analog scale.

Multiple uncontrolled studies have also indicated that corticosteroid SIJ injections can provide clinically meaningful pain reduction in patients with and without spondyloarthropathies.[61,68–74]

Techniques of Denervation of the Nerves of the SIJC

Blockade of the L4 medial branch nerve, L5 dorsal ramus, and lateral branch nerves of S1-S3

As noted, the posterior margin of the SIJ and posterior ligaments are innervated by the L5 dorsal ramus and the lateral branches of S1, S2, and S3, with contributions from S4 in some people, and infrequently from L4 (i.e. during sacralization of L5). Because the lateral branches innervate the posterior ligaments but not the joint capsule or ventral ligaments, they cannot be considered diagnostic. However, they are often employed to predict response to radiofrequency (RF) ablation of the same nerves.[75] In two successive studies, Dreyfuss et al. showed that multi-site multi-depth blocks were superior to single-site, single-depth blocks in response to experimental pain provocation of the dorsal ligaments and posterior SIJ capsule.[76,77]

The technique of blocking the L4 medial branch nerve, L5 dorsal ramus, and-S1-S3 lateral branches has been described.[75,77] The patient is instructed to engage in their normal activities and maintain a pain diary to monitor pain relief. In instances where

a dual block paradigm is used, the second block is typically performed with a different anesthetic than the first block to assess the duration of anesthesia that is concordant with that expected (i.e. shorter with lidocaine than bupivacaine, in general). Local coverage determinations may dictate the necessary pain relief to progress to RF lesioning, but 50% to 80% relief is a common threshold because of frequent concomitant pain generators and the inability to target the joint capsule or ventral ligaments.

Radiofrequency Denervation of the SIJC

Transient pain relief from intra-articular steroid injections may require permanent denervation of the nerve supply of the SIJC. Although chemical neurolysis with phenol can be performed, such intervention is rarely used because of possible leakage of the agent with unintended neurolysis of adjacent neural structures, as previously described, the SIJ communicates with the S1 and S2 foramina in a proportion of individuals, and there may also be defects in the anterior capsule that allow direct communication to the region of the lumbosacral plexus. RF ablation of nerves results in controlled and predictable neurolysis.

Complete pain relief after lesioning of the lateral branches at the posterior aspect of the SI joint is unlikely because innervation of the ventral aspect of the joint is not destroyed. However, the posterior aspect of the joint is a more frequent source of pain than the ventral aspect, and numerous investigators have carefully delineated the predominant dorsal innervation of the SI joint.[33,50,78]

The dorsal ramus of either strip lesioning or the periforaminal technique, the dorsal ramus of L5, should be lesioned, in addition to the lateral branches of S1-3 and potentially S4. An RF cannula was placed at the lateral margin of the superior articular process, where it met the sacral ala, as described previously. Because the lesion created by conventional RF is smaller and positioned along the active tip of the probe, the needle trajectory should ideally be oriented nearly parallel to the path of the nerve to maximize the chances of neural destruction when using conventional RF. On the lateral fluoroscopic image, the needle tip should be no further anterior than the anterior third of the superior articular process (SAP).[48] When using cooled RF, the electrode should be inserted in a perpendicular fashion. Internally cooled electrodes result in larger, more circular lesions, and the tip should be situated no more anterior than the midpoint of the SAP to avoid lesioning the segmental nerve root.[79] It has previously been argued that conventional RFA of the L5 dorsal ramus could be safer than water-cooled RFA, but this is speculative. This was investigated by Kapural et al., who retrospectively reviewed 100 cases of RF ablation of the SIJ.[80] Among these patients, 82 had cooled RF of the L5 dorsal ramus, whereas others had conventional RF. The rate of acute complications was not higher in the water-cooled RF group, but this sample size was likely too small to effectively evaluate complications.

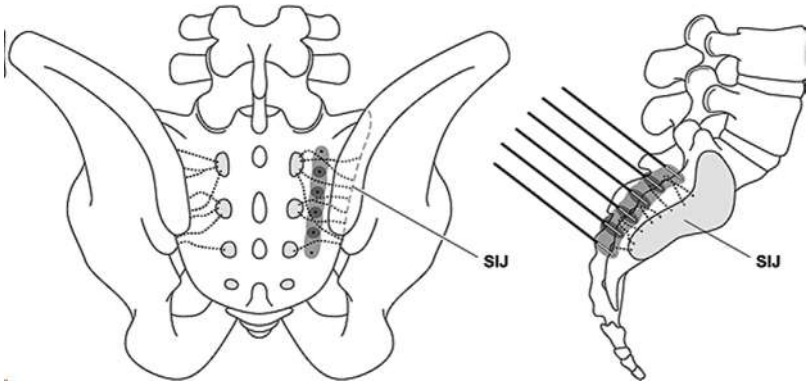
Strip Lesioning of the Sacral Lateral Branch Nerves

RF ablation of the terminal fibers supplying the posterior SIJC (again, contribution from the lateral branches of the posterior rami of S1-S3 +/– L5/S4) can result in analgesia in patients who previously responded to diagnostic SIJC injections.[81] Because the lateral branches targeted for denervation innervate the posterior ligaments, some experts have advocated extra-articular injections,[50] or prognostic multi-site, multi-depth lateral branch blocks[77] as a prognostic tool before RFA. However, studies have found that intra-articular injections may also provide significant predictive value,[82] possibly because of spillover of local anesthetic.

One technique for thermal RF denervation of the dorsal ligament component of the SIJC utilizes two probes to create a bipolar strip lesion.

Although numerous techniques utilizing bipolar lesions have been described, the palisade bipolar strip lesion technique will be outlined here, as it has been shown to capture 100% of the lateral branch nerves 97.5% of the time.[81] In the palisade technique, the patient is positioned prone, and the C-arm is aligned for an anteroposterior image. RF probes (20 g, 10 mm active tip) were placed 10 mm apart in a straight line approximately 4 mm lateral to the lateral border of the posterior sacral foramina from superior to S1 to inferior to S3 (S4 if the inferior border of the SIJ extends caudally beyond S3),[83] and all of the sites were anesthetized with 0.5% 2% lidocaine (Fig. 30.13). In studies where this technique was utilized,[81,83] the RF probe was heated to 90° for 180 s.

Another bipolar strip lesioning technique, referred to as the PSN lateral crest, could be expected to provide similar results to the palisade bipolar technique.[81] In which RF probes are placed along the lateral sacral crest from the first to third sacral tubercles.[84] After all of the sites are anesthetized with 0.5 mL 2% lidocaine, bipolar lesions are created with 17 g two-tined RF probes placed approximately 15 mm apart at 90° for 180 s.[81] This method was originally described for use with ultrasound guidance, and with accurate placement could theoretically provide similar effectiveness



• **Figure 30.13** Palisade treatment of sacroiliac joint (SIJ) pain. A row of straight radiofrequency (RF) cannulae are inserted to contact the dorsal sacral surface perpendicularly between the S1-S3 foramina and the SIJ line. Bipolar RF lesions generated between adjacent cannulae produce a continuous palisade lesion across the region where sacral lateral branch nerves (dotted lines) travel from the sacral foramina to the SIJ. (Left) Needle view. (Right) Lateral view. (From Cosman ER Jr, Gonzalez CD. Bipolar radiofrequency lesion geometry: implications for palisade treatment of SIJ pain. *Pain Pract*. 2011;11(1):3–22.)

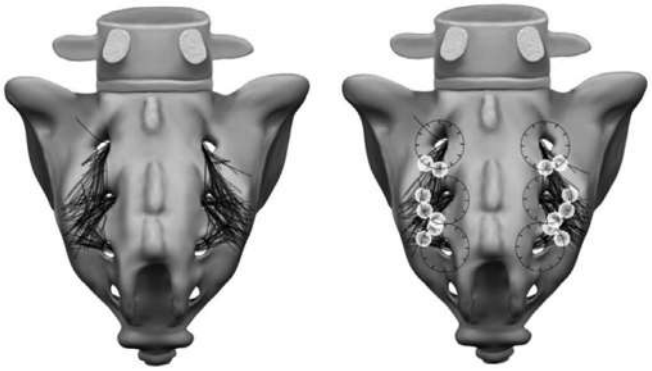
to fluoroscopically guided techniques, although outcomes research is yet to be conducted.

If a monopolar technique[82,85] is utilized, the size of the monopolar lesion can be increased by injecting fluid before the RF lesion is applied.[86] Using *ex vivo* chicken samples, Provenzano et al. noted that pre-injection of fluid other than water increased the lesion size. Hydroxyethyl starch and hypertonic saline resulted in the largest lesions, followed by 0.9% NaCl and lidocaine. Increasing the volume from 0.5 mL to 3 mL did not significantly change the size of the lesion. Similar findings were noted with bipolar lesioning.[87] Three percent NaCl appears to be ideal in that it increases the size of the lesion between the electrodes while diminishing the spread of tissue destruction beyond the electrodes.

Periforaminal Radiofrequency Lesioning of the Sacral Lateral Branch Nerves

Variations of the periforaminal RF technique have been performed with traditional thermal RF[50,75,82,88–90] and water-cooled RF.[5,85,91–93] The water-cooled technique was recently described by Stout et al.[94] With the patient in a prone position, the C-arm is aligned for an anteroposterior image. For the S1-S3 or S4 lateral branches, cooled RF probes (17 g, 4 mm active tip) are placed 10 mm lateral from the center of the sacral foramina, along the dorsal surface of the sacrum at 4:30 and 6:00 for S1; at 2:30, 4:00, and 5:30 for S2; and at 1:00 and 2:30 for S3 on the right; the corresponding mirror targets for the left are at 6:00 and 7:30 for S1; at 6:30, 8:00, and 9:30 for S2; and at 9:30 and 11:00 for S3.[94] Their placement of the RF probes takes into consideration the variability in the course of the nerves and alignment of the posterior sacral foramen vis-à-vis the SIJ and has been shown to capture all medial branches in 95% of SIJC specimens.[81] When the S4 foramen is observed to be at a comparable level in the longitudinal plane to the lowest part of the SI joint (i.e. afferent innervation is likely to be entering the foramen), it may be targeted as well. If the S4 foramen is caudal to the inferior aspect of the ipsilateral SIJ, there is likely little utility in performing a periforaminal lesion (Fig. 30.14). On lateral fluoroscopic images, the needle tip should not be anterior to the posterior sacrum to avoid intra-foraminal positioning. For the L5 dorsal ramus, motor stimulation was applied at 2 Hz at 2 V to verify the absence of muscle contraction in a radicular distribution (motor stimulation is not required for the sacral levels). All of the sites were anesthetized with 2% lidocaine (0.5 mL), and lesioning began at 60°C for 150 s (water-cooled RF). It is often customary to inject 0.5 mL of a mixture of local anesthetic and steroid after the lesioning for postoperative analgesia and prevent neuritis.

In a cadaver study, Roberts et al. showed that bipolar and water-cooled RF lesions captured 100% of the known course of the lateral branches with the greatest frequency, up to 97% and 92% of the time, respectively. In contrast, conventional monopolar was only able to capture 100% of the known course of the lateral branches approximately 12% of the time.[81]



• **Figure 30.14** The figure on the *left* shows the course of the sacral lateral branches as determined by cadaveric study. The figure on the *right* shows all lateral branches from all specimens with clockface overlay and an 8 mm lesion size. (From Stout A, Dreyfuss P, Swain N, Roberts S, Loh E, Agur A. Proposed optimal fluoroscopic targets for cooled radiofrequency neurotomy of the sacral lateral branches to improve clinical outcomes: an anatomical study. *Pain Med*. 2018;19(10):1916–1923.)

Efficacy and Effectiveness of Radiofrequency Denervation of the Dorsal Sacral Nerves and Lateral Branches

The effectiveness of SIJ injections has been examined in studies, meta-analyses, and reviews with somewhat discordant results[95,96] (Table 30.3). Multiple randomized, controlled trials have shown the superiority of RF denervation of the L5 dorsal ramus and the S1-S3 lateral branches over sham procedures.[82,85,91] Water-cooled periforaminal and bipolar RF have been shown to be associated with a higher success rate than conventional monopolar RF.[5,66,81] However, not all studies have shown effectiveness with RF ablation. van Tilburg et al. failed to show the efficacy of conventional RF versus a sham procedure,[89] and Juch et al. failed to show the superiority of conventional RF and exercise therapy to exercise therapy alone,[97] although it should be noted that procedural and methodologic shortcomings in both studies have questioned the validity of the results.[98,99]

Coccydynia

Epidemiology and Etiology

Coccydynia, defined as pain in the region of the coccyx, is an infrequent cause of buttock pain with poorly characterized and underreported epidemiology.[108] Thus its prevalence is thought to be low. Women are more likely to be affected than men, and the prevalence is highest in middle-aged women.[109] Obesity and complications or instrumentation during childbirth are also associated with coccydynia.[108,110–112] Trauma is commonly associated with tailbone pain,[111,113] while ankylosing spondylitis[114] and tumors of the bone or pelvis[115,116] are less commonly reported. Maigne et al. reported that 69% of 208 patients with chronic coccydynia reported a history of prior trauma. Within that series, bony outgrowths, anterior and posterior subluxation, and hypermobility were all identified as predisposing conditions.[111] Minor trauma, such as prolonged sitting on hard or irregular surfaces, may be a predisposing factor.[117] Radicular or visceral pain may also contribute to referred pain in the region of the coccyx.

Anatomy

The coccyx is a small but complex structure located at the distal end of the sacrum, connected to the sacrococcygeal articulation. It comprises three to five fused bony spinal segments (Fig. 30.15). Anteriorly, the coccyx provides attachments for the anterior sacrococcygeal ligaments and fibers of the levator ani muscle, while posteriorly, the gluteus maximus and posterior sacrococcygeal ligaments attach. Between individuals, there is significant variability

Author	Study Design	Treatments	Results	Comments
Explanatory Studies				
van Tilburg et al.[89]	Prospective, randomized, controlled, double blinded study, n = 51	Conventional RF of L5 dorsal ramus and cooled RF of S1–4 lateral branches versus sham procedure	No significant difference between groups at three months	SIJ pain confirmed by positive intra-articular block; crossover allowed at three months
Patel et al.[85]	Prospective, randomized, controlled, blinded study, n = 51	Cooled RF of the L5 dorsal ramus and S1–3 lateral branches versus sham procedure	At three months, mean NRS −2.4 in the treatment group and −0.8 in sham, ODI −11 in the treatment group, +2 in sham; effect persisted at nine months	Patients with axial back pain and a positive response to dual lateral branch blocks; crossover allowed at three months
Cohen et al.[82]	Prospective, randomized, controlled study, n = 28	Conventional RF of L4 medial branch and five dorsal ramus and cooled RF of S1–3 lateral branches versus sham procedure	Pain scores improved at one month (2.4 in the treatment group, 6.3 in the sham group); benefit persisted at six months	SIJ pain confirmed by positive intra-articular block; crossover allowed at one month
Mehta et at.[101]	Prospective, randomized, controlled, double blinded study, n = 17	Strip lesion with Simplicity of S1–3 dorsal peripheral nerves and conventional RF of L5 dorsal ramus versus sham procedure	At three months, mean NRS −4.7 in the treatment group and −0.3 in sham. Similar results at six months	SIJ pain confirmed by positive intra-articular block
Pragmatic Studies				
Dutta et al.[102]	Prospective, randomized, comparative, study, n = 30	Pulsed RF of the L4, L5 dorsal rami, and S1–S3 lateral branches versus intra-articular steroid injection	Mean pain relief similar and improvement in ODI in both groups at one month, with significantly greater pain relief with RF at three and six months	SIJ pain confirmed by positive intra-articular block
Juch et al.[97]	Prospective, randomized, controlled study, n = 228	Various techniques of RF at various locations with exercise therapy versus exercise therapy alone	No significant difference in NRS at three months	SIJ pain confirmed by intra-articular injection. Results clouded by methodologic concerns
Martinez et al.[103]	Prospective, randomized, controlled study, n = 60	Palisading bipolar RF (needle distance 1 cm) versus palisading bipolar RF (needle distance >1 cm) versus dual SIJ steroid injections	All groups had ≥ 50% pain reduction at one month. At three months, only both RF groups had ≥ 50% pain reduction. At 12 months, only the >1 cm RF group had had ≥ 50% pain reduction	
Salman et al.[90]	Prospective, randomized, comparative, study, n = 15	Conventional RF of the L4, L5 dorsal rami, and S1–S3 lateral branches versus intra-articular steroid injection	53% of patients in the RF group obtained >50% pain reduction	Unable to analyze the control group because of a small number of participants
Zheng et al.[104]	Prospective, randomized, controlled, n = 155	Palisading bipolar RF versus celecoxib	Mean VAS −1.9 at three months and −2.2 at six months with RF group over the control group	Prior diagnosis of ankylosing spondylitis
Observational Studies				
Stelzer et al.[105]	Retrospective chart review, n = 109	Cooled RF of the L5 dorsal ramus and S1–3 lateral branches	Mean VAS −4.0 at one month with similar results seen at six and 12 months	All patients had positive blocks of SIJ *or* medial/lateral branches

in structure,[118] and mobility[119] of the sacrococcygeal articulation, as well as dimensions and angulation[120,121] of the coccyx itself.

Sensory innervation of the coccyx is primarily derived from the sacrococcygeal plexus, which originates from the lower sacral nerve roots. Anteriorly, this is comprised of the coccygeal nerves and the ventral rami of S4 and S5, while the dorsal rami of S4 and S5 and the coccygeal nerves contribute to innervation.[122] The sacrococcygeal plexus innervates the following anterior structures: the pubococcygeus muscle, ischiococcygeus muscle, coccygeus muscle, and a portion of the levator ani, external anal sphincter, sacrococcygeal and coccygeal ligaments, sacrococcygeal joint, and coccygeal periosteum. Posterior structures innervated by the sacrococcygeal plexus include the dorsal periosteum, overlying skin, and soft tissue.[122–126]

Sympathetic anatomic innervation from the paravertebral sympathetic trunk contributes to the ganglion impar, located on the ventral surface of the coccyx, and visceral pain from the rectum may refer to this region via nociceptive input from the ganglion impar.[127] Pain from other pelvic viscera may also refer to the coccygeal region via the hypogastric plexus or pelvic splanchnic nerves.[122]

Aside from being the insertion point of muscles, tendons, and ligaments, the coccyx supports pelvic floor and anal function and provides structural support in the sitting position in conjunction with the ischial tuberosities.[108]

Presentation

Coccydynia classically presents as pain in the region of the tailbone, but other aspects of the history may be helpful, including pain with sitting, reclining, defecation, or intercourse.[108] Acute onset after a posterior fall could indicate a traumatic etiology. Tenderness to palpation over the coccyx is often present but not requisite, as pain of radicular or visceral origin can refer to this region. Hypermobility of the sacrococcygeal articulation can be diagnosed via rectal examination. Imaging with plain film radiographs, CT,

• **Figure 30.15** Posterior view of the bony sacrococcygeal junction. *Red arrow*, sacrococcygeal articulation. (From White TD, Folkens PI. Pelvic girdle: sacrum, coccyx, & os coxae. In: TD White, PI Folkens (eds). *The Human Bone Manual*. 1st ed. Burlington, MA: Academic Press; 2005: 241–253.)

or MRI may help in diagnosing fractures, dislocations, cysts (pilonidal, Tarlov), or masses.

Treatment

Conservative treatment of coccydynia can be initiated with mechanical support such as modified wedge-shaped, "U"-shaped, or donut cushions that offload pressure over the tender region. Adjusting seating surfaces and workplace ergonomic changes may also offer benefits. Cold and heat therapies are reasonable options. Pharmacologic therapy with NSAIDs and, to a lesser extent, tricyclic anti-depressants have been studied, but the studies were small and the data inconsistent.[128,129] Topical analgesics have been shown to be beneficial in arthritis but have not been studied directly in this patient population. As in other pain states, opioid therapy should only be considered after the failure of conservative therapy and should be used cautiously outside of the acute phase.

Physical therapies, such as massage, manual manipulation, and modalities have been utilized with varying degrees of success. It is thought that these therapies may relieve pain because of inflammation, muscle spasm, ligament pain, and dislodgement of the coccyx.[108] Maigne et al. compared intrarectal manipulation to shortwave diathermy, with significantly more patients experiencing ≥50% pain relief in the intrarectal manipulation group at one and six months.[130] In 2015, Lin et al. compared extracorporeal shockwave therapy to physiotherapy (short wave diathermy or inferential current) with significantly greater mean pain relief in the former group, but no difference in Oswestry disability index scores at eight weeks.[131]

Regarding interventional procedures, there are a myriad of described treatments of coccydynia, most commonly injection of steroids and local anesthetics. There is no clear consensus on the best target for injection, although it is generally accepted that because of the close proximity of the pelvic viscera anteriorly, fluoroscopic or ultrasound guidance should be utilized. Overall, the body of literature surrounding treating coccydynia is low to very low quality because of small sample sizes and methodologic shortcomings. In 1991, Wray et al. randomized 120 patients to receive steroid injections or manipulation. They reported a mean pain reduction of 60% in the steroid group versus 85% in the manipulation group, and the follow up period was unclear in their report.[132] In a small study of 14 patients, Mitra et al. reported that 50% of patients experienced at least 50% pain relief with steroid and local anesthetic injections over and around the coccyx at three weeks.[133] Pulsed radiofrequency treatment of the posterior coccygeal nerves innervating the coccyx was performed in ten patients with a mean improvement in pain of 75% at six months.[134] A study evaluating thermal radiofrequency ablation of the posterior coccygeal nerves in nine patients reported a mean improvement in pain of 55%, with follow up varying between two months and two years.[135] In this study, conventional radiofrequency ablation was found to be superior to pulsed RF, and those who responded to prognostic blocks fared better than those who did not receive pretreatment local anesthetic blocks.

The ganglion impar, which is the terminal pelvic segment of the sympathetic trunk lying just anterior to the coccyx and accessed via the sacrococcygeal articulation, has also been a target for intervention in patients with pain referred from the pelvic viscera, typically in the setting of malignancy. Gunduz et al. performed ganglion impar blocks in 19 patients, with 95% experiencing ≥50% pain relief at a mean follow up of 17 months.[136] Thermal radiofrequency ablation of the ganglion impar has also been described, with a mean improvement at six months in 10 patients, being 66% for pain and 50% for function.[137] Chemoneurolysis of the ganglion impar has also been described in case reports and small case series, the largest of which showed 73% mean pain relief at four months in 28 patients treated with CT-guided ethanol injections.[138,139] It must be noted that a major potential complication of ganglion impar ablation is anal sphincter incompetence, so a thorough risk/benefit discussion with the patient is imperative.

Neuromodulation has also been used to treat chronic coccydynia. Improvement in pain with stimulation of the sacral nerve roots via the sacral hiatus in the epidural space has been described.[140] Stimulation of the S3 nerve root via the S3 foramen[141] and stimulation of the thoracic dorsal columns,[142] both of which were effective in providing pain relief.

For patients with pain refractory to more conservative measures, surgical coccygectomy is the last resort treatment option. While numerous studies have reported significant benefits of coccygectomy (more than half of all patients in every published study have derived benefit), the majority of these studies were retrospective, observational, and uncontrolled, thus limiting the ability to draw firm conclusions from their results.[135] As with non-operative interventions for coccydynia, the body of literature for surgical intervention is low to very low quality because of small sample sizes and methodologic shortcomings.

Piriformis Syndrome

Epidemiology

Piriformis syndrome (PS) was first described[143] in 1947 and is relatively uncommon, generally reported as affecting only 5% to 8% of a population. However, the prevalence may be as high as 36% in patients who are referred for back or leg pain.[144–147] It should

be considered in the differential diagnosis of patients who present with unilateral buttock and/or leg pain. However, because its clinical presentation often overlaps with other sources of buttock pain, it is commonly misdiagnosed.[144,147,148]

Anatomy of the Piriformis Muscle and the SN

The piriformis muscle originates from the anterior surface of the S2-S4 sacral vertebrae, the capsule of the SIJ, and the gluteal aspect of the ilium near the iliac spine.[149] The broad origin of the muscle tapers becomes smaller in caliber and tendinous as it courses through the greater sciatic foramen and inserts on the piriformis fossa on the medial aspect of the greater trochanter of the femur (Fig. 30.16). The piriformis is typically innervated by the superior gluteal nerve,[150] and the principal function of the muscle is to abduct and externally rotate the femur. Neurovascular structures close to the piriformis muscle include the posterior femoral cutaneous nerve, gluteal nerves, gluteal vessels, and the SN, most relevant to our discussion.[151]

Formed from the ventral rami (L4-S3) of the lumbosacral plexus, the SN is approximately 2 cm in diameter as it exits the pelvis via the greater sciatic foramen. This large mixed nerve contains motor fibers that supply the posterior thigh, hip, and knee, and sensory fibers that supply the entire surface of the leg distal to the knee, except for the anteromedial calf and medial aspect of the foot.[151] Typically, the SN passes inferior to the piriformis muscle, but deviations in this anatomic relationship are relatively common, and prevalence rates have been described as 6% or up to 22%.[152–155] The Beason and Anson classification system[156] describes these six possible anatomic relationships between the piriformis muscle and the SN (Table 30.4). According to a recent study, the prevalence of the most common relationship types A (the entire SN passes inferior to the piriformis muscle), B (the SN is split, with a portion piercing the piriformis and a portion passing inferior to the muscle), and C (the SN is split, with a portion passing superior to and a portion passing inferior to the piriformis) were 74%, 22%, and 3%, respectively (Fig. 30.17).[157] Anatomic variants are thought to increase the likelihood of developing PS, given that an abnormal course of the SN or smaller divisions would be more susceptible to compression or irritation from muscular hypertrophy than a large-caliber undivided SN.[152,158,159] Indeed, variability in morphometric measurements of the lower limbs correlates with anatomic variations in the relationship of the piriformis muscle with the SN.[144] However, the significance of variant anatomy regarding the likelihood of developing PS is disputed, given the results of a cadaveric surgical case series and a prospective MRI study on living patients,[160] both of which showed similar rates of aberrant anatomy in patients with or without symptoms of PS.

(From Benzon HT, Katz JA, Benzon HA, et al. Piriformis syndrome: anatomic considerations, a new injection technique, and a review of the literature. *Anesthesiol*. 2003; 98:1442–1448.)

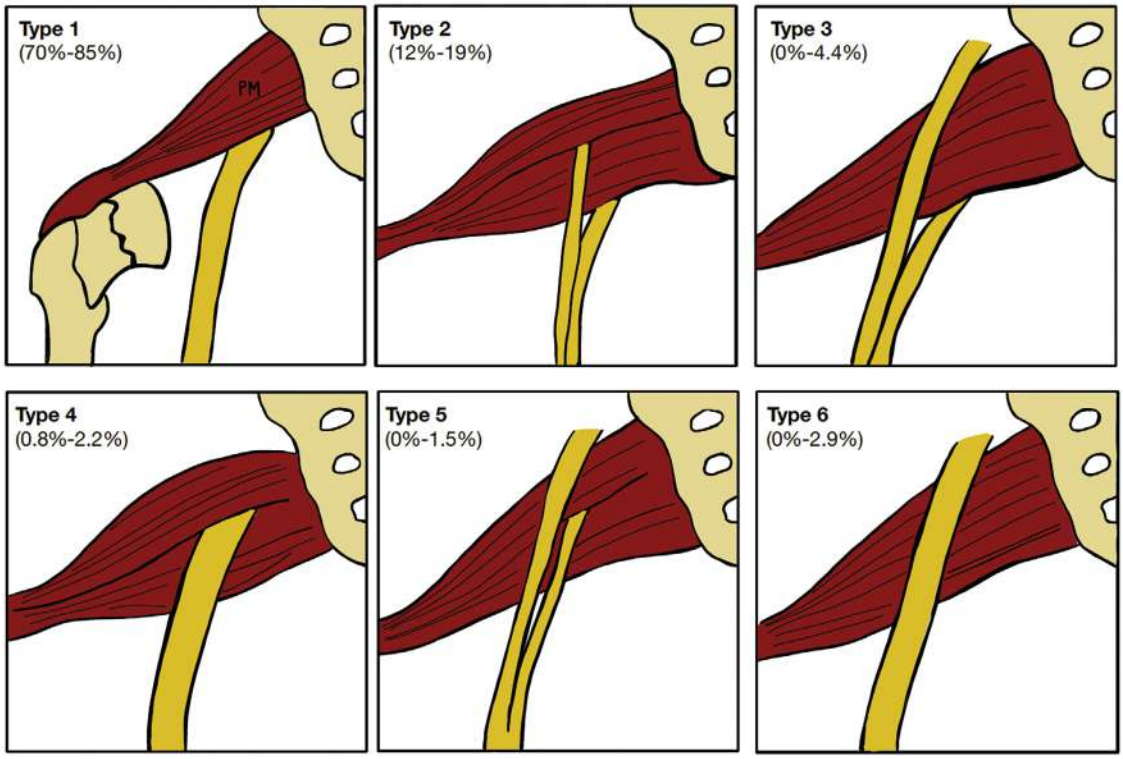
TABLE 30.4 Beason and Anson Classification for the Anatomic Relationship between the Sciatic Nerve (n.) and Piriformis Muscle (m.)

Beason and Anson Classification		
Normal anatomy	Type 1	Undivided sciatic n. passes inferior to undivided m
Proximal division	Type 2	One division passes through, and one inferior to m
Aberrant route	Type 3	One division passes inferior and one superior to m
	Type 4	One division passes inferior and one superior to the m
Normal division	Type 5	Sciatic n. passes through the m
Aberrant route	Type 6	Sciatic n. passes superior to the m

Pathophysiology

The clinical presentation of PS likely has a somatic component, from myofascial pain in the buttock musculature, and depending on the relationship between the muscle and nerve, in some cases, a neuropathic component is present from irritation or compression of the SN. Affected patients had a median age of 50,[161] and females were more affected than males. Risk factors for PS include pelvic/buttock trauma,[147] hypertrophy or spasm of the piriformis or gemelli muscles,[149] female sex assigned at birth, pregnancy, anatomic variants in the relationship between the piriformis and SN, true or apparent leg length inequality (at least 0.5 inches in difference),[154] obesity, hypertonicity, lumbar hyperlordosis, infection, and mass effect from space occupying lesions.[161]

Although a history of trauma can be elicited in 50% of cases of PS,[162] trauma isolated exclusively from the piriformis muscle is rare. Instead, the reported injury is generally mild and deemed to be a sequela of heavy manual labor or strenuous athletic activity that often occurs several months prior to the onset of pain. However, the pathophysiologic relationship between physical stress and muscle pain that occurs months later is debatable. Because of diffuse muscular involvement, some authors now favor the



• **Figure 30.17** Beason and Anson types for the relationship of the piriformis muscle and the sciatic nerve. (Credit: Sophie Sha.)

term "deep gluteal syndrome" rather than PS.[163] However, both terminologies describe a syndrome in which trauma leads to the release of inflammatory mediators, including histamine, bradykinin, and serotonin, which then irritates the buttock musculature and/or the SN.[152,164] This irritation then leads to further spasm or inflammation of the musculature in a classic pain cascade cycle that leads to chemical or anatomic irritation of the SN as it passes between the piriformis muscle and the bony pelvis.[165]

Presentation

In a review of 55 studies, the most common features of a patient with PS were:[166]

- buttock pain
- external tenderness over the greater sciatic notch
- aggravation of pain with prolonged sitting
- augmentation of pain with maneuvers that increase tension on the piriformis muscle

Patients with PS tend to describe pain centered on the buttock and extending from the origin of the muscle at the sacrum to the insertion of the muscle on the medial aspect of the greater trochanter.[144,147,152] Pain is often aggravated by prolonged sitting, especially on hard surfaces or with motor activity involving the affected limb, as in driving or biking, and when rising from a seated position.[144,147] Radiation of pain to the ipsilateral distal leg is thought to be present if the SN is significantly irritated.[147,152]

Physical examination may reveal pelvic tilt, a palpable spindle-shaped mass in the buttock, and tenderness to external palpation or on pelvic/rectal examination, given the proximity of the piriformis to the lateral pelvic wall. The pain can be aggravated by the Valsalva maneuver or flexion, adduction, and internal rotation (FAIR) of the hip-maneuvers that stretch the muscle. If the hip is flexed over 90°, the piriformis is elongated with external rotation, and thus the heel-contralateral knee maneuver may reproduce pain. However, the use of these physical exam maneuvers is not always reliable.[167]

Although PS is a clinical diagnosis, it is also a diagnosis of exclusion from other sources of buttock pain. Therefore diagnostic modalities such as electromyography (EMG), CT, and MRI may assist in diagnosis. EMG can demonstrate a delay in the patient's H-reflex during the FAIR maneuver compared with the patient's H-reflex in an anatomically neutral position.[168] Patients with PS more consistently have electrophysiologic abnormalities in the peroneal H-reflex (prolongation by three standard deviations for definitive diagnosis)[169] than the tibial nerve H-reflex.[170] Although imaging is often negative, CT and MRI may demonstrate enlargement of the piriformis muscle. Magnetic resonance neurography is a more sensitive modality for detecting signal changes in the SN under a hypertrophied piriformis muscle. However, this imaging modality is not universally available, and most insurance companies do not routinely authorize its use.[171] Lastly, ultrasonographic diagnosis of PS is an emerging technique that is being increasingly utilized. Patients with symptomatic PS will demonstrate increased thickness and cross-sectional area of the muscle than asymptomatic individuals.[172,173]

Treatment

As with most pain syndromes, the initial treatment is conservative. Oral nonsteroidal anti-inflammatory medications (NSAIDs) and muscle relaxants are used to reduce inflammation and muscle spasms, respectively, and can be used in conjunction with a course of physical therapy (PT) to improve therapeutic effects. Conventional PT consists of FAIR of the hip followed by pressure applied to the piriformis muscle.[144,147] Exercises such as hip flexion, adduction, and external rotation (ADD stretch), hip flexion, external rotation,

and adduction (ExR stretch) increase the piriformis length by 30% to 40% compared to conventional PT. Treatment with NSAIDs, muscle relaxants, and PT is successful in 75% to 80% of patients.[174]

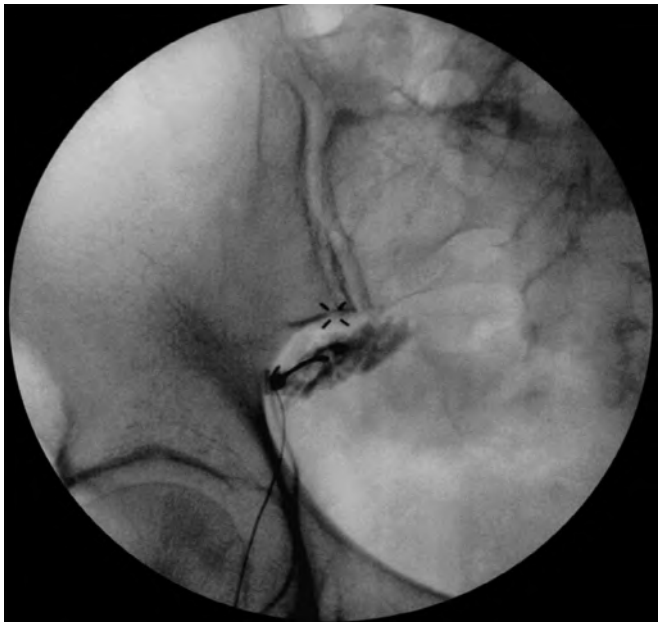
Techniques of Piriformis Muscle and Perisciatic Nerve Injections

The remaining subset of patients are candidates for injection therapy,[175] which can consist of medication administration or dry needling.[176] Injections are typically performed with image guidance, and fluoroscopy, ultrasonography,[177,178] and EMG are often used either alone or in combination.[179] CT and MRI guidance are other options and can better target the tendinous portion of the external rotators of the hip,[180] but their use is infrequent because of increased radiation exposure and logistical difficulties, respectively.

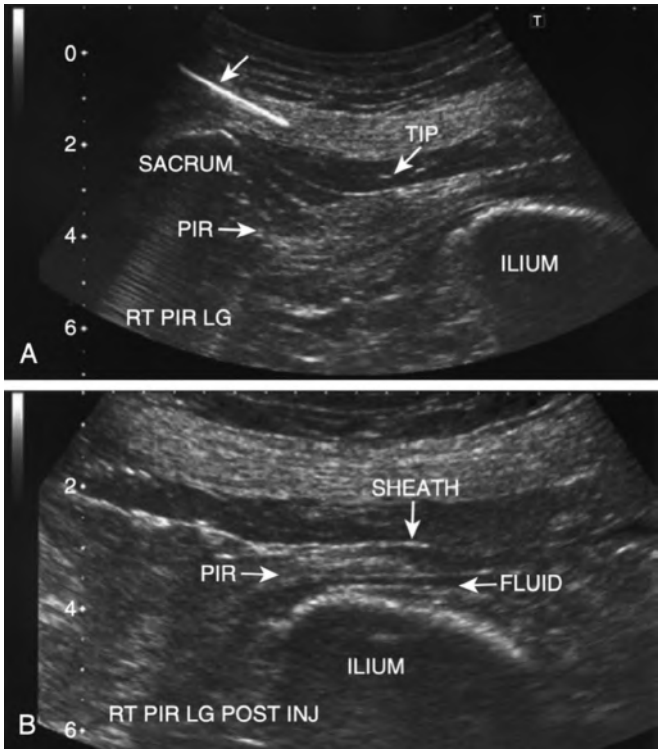
Fluoroscopy is the most commonly used method for image-guided injections. After positioning the patient prone, the needle was advanced coaxially into the muscle belly of the piriformis at 1 to 2 cm lateral and 1 to 2 cm caudal to the inferior border of the SIJ. Contrast dye can then be applied, and if an appropriate myogram is visualized, the injectate is administered (Fig. 30.18).

In addition to fluoroscopy,[152,179] EMG can be used to identify a motor-evoked response from the SN. The needle can then be withdrawn at least 0.3 cm to administer a portion of injectate perisciatically. Then, the needle can again be withdrawn an additional 1 cm to the belly of the piriformis muscle and the remaining injectate administered.[152]

Pain providers offering piriformis injections are increasingly using ultrasound guidance,[181] which is considered more accurate[182] and avoids radiation or contrast exposure. Several ultrasound-guided methods exist, most of which rely on the identification of the inferior/lateral border of the sacrum. Subsequently, the pain providers scanned laterally with the ultrasound probe from the sacral hiatus until the piriformis is identified as a hyperechoic mass deep to the gluteus maximus and an ovoid-shaped SN visible either adjacent to or embedded within the muscle.[177] An alternate approach identifies the PSIS and the posterior inferior iliac spine and then scans inferiorly from the lateral sacrum to the greater sciatic notch plane (Fig. 30.19).[178] Ultrasound can also guide needle placement and the administration of medications, or simply needle placement for dry needling technique.[176,183] Studies have found no difference in pain or satisfaction outcomes when the piriformis is injected with fluoroscopic versus ultrasound guidance.[184]



• **Figure 30.18** Fluoroscopic image of the insulated needle in the piriformis muscle with the muscle being outlined by the injected radiopaque dye.



• **Figure 30.19** **(A)** Longitudinal ultrasound view of the piriformis during needle placement using a medial-to-lateral approach parallel to the long axis of the transducer. The proximal end of the needle has been digitally enhanced to highlight the needle trajectory. **(B)** Post-injection tenogram at the level of the greater sciatic foramen. Anechoic injectate (FLUID) within the piriformis tendon sheath lies superficial and deep to the hyperechoic tendon. *RT PIR LG*, Right side, piriformis, longitudinal view; *TIP*, needle tip. (From Smith J, Hurdle MF, Locketz AJ, et al. Ultrasound-guided piriformis injection: technique description and verification. *Arch Phys Med Rehabil*. 2006;87:1664–1667.)

The injectate is typically composed of a particulate steroid formulation combined with a local anesthetic. In a randomized, double-blind study performed in 47 patients with PS, there was no difference in pain scores up to three months after injection in patients who received local anesthetic only versus local anesthetic with steroid.[185]

Patients may also receive botulinum toxin if the response to steroids and local anesthetics is transient. The use of botulinum toxin to treat refractory PS is supported by randomized controlled and observational studies.[186] The toxin blocks the release of acetylcholine at the neuromuscular junction, resulting in prolonged relaxation, which causes increased fatty infiltration of the piriformis and concomitant reduction in thickness and volume of the muscle.[171,187] The duration of the effect depends on the rate of neuromuscular sprouting and reinnervation of the muscle. However, botulinum toxin typically confers relief for greater than six weeks[188] and lacks the side effects of steroid administration, making it an attractive alternative injectate. Risks of botulinum injection include plexopathy, polyradiculoneuritis, and local psoriasiform dermatitis.[189–191]

The most invasive option for the management of PS includes surgical release, in which the distal piriformis tendon is resected

at the femoral insertion site to decompress the SN. Other musculature of the buttocks can compensate for the loss of this muscle function, and surgery has become less invasive with advances in technique[192] surgical management is effective in approximately 75% of patients.[193] If symptoms recur, they are typically because of incomplete tendon release or scar/hematoma formation.[194]

Non-Piriformis Muscle Pain

Pathology involving muscles besides the piriformis may present as low back and/or buttock pain. Mechanical pain involving muscles and other soft tissue in the buttock may manifest as a dull, aching pain worsened by weight bearing, activities, and sometimes sitting. Depending on the source of pain and the anatomic location of the SN in relation to the structure, patients may also experience true sciatic neuropathy, or "pseudo sciatica," which presents as pain extending into the posterolateral thigh region.

There are reports of pain derived from the gemelli-obturator internis muscle complex, which consists of the obturator internis muscle and bursa, superior and inferior gemelli, and the tendinous insertion of the complex on the greater trochanter. The obturator internis originates from the pelvic surface of the obturator membrane and the surrounding bones. The superior and inferior gemelli originate from the ischial spine and tuberosity, respectively, and are inserted on the medial aspect of the greater trochanter after merging with the tendon of the obturator internis. Pain arising from the gemelli-obturator complex may manifest as an aching pain in the retrotrochanteric region that extends into the hip and posterolateral thigh.[195,196]

In some individuals, movement may bring the SN into juxtaposition with the obturator-gemelli complex (i.e. tendon). An anatomic study performed in cadavers and human volunteers showed that internal rotation of the hip could result in deviation of the nerve course, causing symptoms of sciatic neuropathy.[195,197]

Tendonitis, muscle tears, and spasms of the quadratus femoris can manifest as buttock pain, groin pain, hip pain, and "sciatica," depending on the anatomic relationship with the SN or its branches.[198–200] The gluteal muscles and their tendinous insertions are also a potential source of buttock and lateral hip pain.[201–203] The gluteus maximus, which extends and laterally rotates the hip, is the largest muscle in the buttock-hip region, originating from the sacrotuberous ligament and inserting into the iliotibial band. The gluteus medius muscle arises from the ilium, attaches to the lateral greater trochanteric, and functions to stabilize the femur and pelvis during weight bearing. Pathology of the gluteus minimus, which originates from the external iliac fossa and inserts on the anterior facet of the greater trochanter, most often occurs in conjunction with disorders involving the gluteus medius tendon. The gluteus minimus is involved in internal hip rotation and abduction. For muscles, activities that involve their function may exacerbate pain from overuse injuries, while activities that stretch the muscles may worsen pain arising from muscle spasms.

The treatment of muscle pain depends on the pathology and may consist of rest for overuse injuries, stretching exercises for muscle spasms, PT and exercises to address biomechanical precipitating factors, and nonsteroidal anti-inflammatory drugs for inflammatory processes. Injections have also been employed for both diagnostic and therapeutic purposes.[199,204] In refractory cases of SN entrapment, surgical decompression may be indicated.[198]

Trigger point injections may be considered when myofascial pain is suspected. This concept and technique are discussed in Chapter 68. For non-piriformis trigger point injections, studies have found greater short-term benefit with the injection of substances than dry needling, with little difference in outcomes between injectates.[205,206]

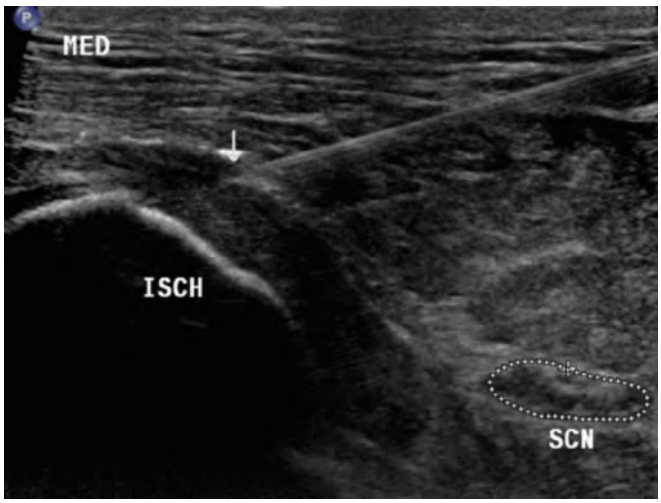
Ischial Bursitis

In ischial bursitis, also termed ischial-gluteal bursitis, the fluid-filled sac (the non-pathologic bursa contains minimal fluid) that separates the ischial tuberosity from the gluteus maximus muscle becomes inflamed. Although the epidemiology is unknown, it is estimated to account for less than 1% of cases of low back or buttock pain. Risk factors for ischial bursitis include obesity, autoimmune diseases, excessive or inappropriate exercise, and a sedentary lifestyle characterized by long periods of sitting; hence, the colloquial nickname "weaver's bottom."[207] The typical presentation of ischial bursitis is gluteal or upper posterior thigh pain, often provoked or exacerbated by exercise or prolonged sitting. On physical examination, tenderness to palpation was a prominent objective sign. MRI can be helpful in the diagnosis and may show low or intermediate signal intensity on T1 and T2 hyperintensity in the region of the ischial bursa.[208] The treatment of ischial bursitis is symptom-oriented and may include ergonomic modification, PT, NSAIDs, and steroid injections.[209] Surgical resection of the bursa may be performed for refractory cases.[210]

Techniques of Ischial Bursa Injection

Ischial Bursa Injection Under Ultrasound

The patient was positioned in the contralateral decubitus position. With an ultrasound-guided injection, the ischial tuberosity was palpated, and a curvilinear probe was placed axially over the ischial tuberosity. In this view, the ischial tuberosity, hamstring tendons, gluteus maximus, and SN can all be visualized (Fig. 30.20). Flexion of the knee and hip decreases the distance between the bursa and skin compared to hip and knee extension. Using a sterile technique, the needle is passed through the skin in an in-plane approach, traversing the gluteus maximus toward the ischial tuberosity. When the needle tip is clearly visualized in



• **Figure 30.20** Ultrasound image demonstrating a needle within the ischial bursa. The gluteus maximus muscle is above the needle tip, and the hamstring tendon origin is below the needle tip. The *arrow* indicates the needle tip; the top is superficial; the bottom is deep; the left is medial *(MED)*, and the right is lateral. *ISCH*, Ischium; *SCN*, sciatic nerve. (From Wisniewski SJ, Hurdle M, Erickson JM, Finnoff JT, Smith J. Ultrasound-guided ischial bursa injection: technique and positioning considerations. *PMR*. 2014;6(1):56–60.)

the region of the ischial bursa, an injectate of local anesthetic and particulate steroid is administered into the bursa.[211]

Ischial Bursa Injection Under Fluoroscopy

A fluoroscopically guided ischial bursa injection was performed with the patient in the prone position and the fluoroscope image intensifier oriented in the cephalocaudad position. A 22 or 25 gauge Quincke needle was introduced perpendicular to the skin on the inferior portion of the buttock and directed in a coaxial fashion toward the ischial tuberosity. After contact with the bone, the needle was withdrawn 1 mm, and contrast dye was administered. If vascular uptake is absent and a fill pattern consistent with a filling of the ischial bursa is noted, then an injectate of particulate steroid and local anesthetic is administered.

Summary Comments

Much like pain in the lower back, pain in the buttock is derived from numerous anatomic pain generators (Table 30.5). When considered as an entity separate from LBP, the benign sources of buttock pain include the SIJ and associated structures, termed the SIJC, the coccyx and associated soft tissues, the deep external hip rotator muscles including the piriformis muscle along with the SN, and other soft tissues of the buttock region. The diagnosis and management of these pain generators differ markedly and are discussed in detail in this chapter.

TABLE 30.5 Presentation of Different Etiologies of Buttock Pain

Condition	Historical Findings	Pain Pattern	Physical Exam Findings	Imaging/Diagnostic Findings
Sacroiliac joint complex pain	Trauma to back or pelvis Spinal deformity Prior spinal surgery Leg length discrepancy Patient points to pain over the PSIS or sacral sulcus May be pain with walking, prolonged sitting, rising from sitting Female gender Onset during pregnancy or childbirth	Pain largely below L5 level Radiation to the groin or posterior thigh to the upper calf	Three or more positive physical exam findings Tenderness to palpation over the posterior joint, PSIS, sacral sulcus Absence of neurologic signs	Imaging is typically normal or shows mild osteoarthritis Plain film radiographs and CT may show changes to the joint space, bone erosions, subchondral sclerosis, and bony malalignment MRI can show intra-articular fluid signal, soft tissue and bone edema, fatty infiltration, and joint erosions Radionucleotide bone scan can show active areas of increased metabolic uptake
Piriformis pain	Trauma to pelvis or buttocks Overuse (athlete, laborer) Leg length discrepancy Pain with prolonged sitting, particularly on hard surfaces, or rising from a seated position	Pain in the buttocks radiating to the greater trochanter If the sciatic nerve is irritated, radiating pain down the posterior ipsilateral thigh	Tenderness to palpation in the buttocks; may have a palpable tender point Provocative maneuvers include hip flexion, adduction, and/or internal rotation Numbness in the ipsilateral leg is rare Normal reflexes	MRI may show an enlarged piriformis, the relationship of the muscle to the sciatic nerve, or localized inflammation CT may show traumatic sequelae, pelvic visceral or soft tissue masses EMG - fibular H-reflex may be prolonged
Coccydynia	Trauma to the tailbone Prolonged sitting on hard surfaces	By definition, pain is in the area overlying or immediate to the coccyx Pain may be vague if referred from the pelvic viscera or sacral nerve roots	Tenderness to palpation over the coccyx or sacrococcygeal junction Hypermobility of the coccyx on rectal exam Dislodgement of the coccyx	Plain film radiographs, CT, or MRI, may help in diagnosing fracture, dislocation, cysts (pilonidal, Tarlov), or masses
Ischial bursitis	Exacerbated by prolonged sitting ("weavers bottom"), or exercise Might be concomitant with obesity, sedentary lifestyle, or autoimmune disease	Pain in the lower buttocks over the ischial tuberosity Proximal posterior thigh pain	Tenderness to palpation over the ischial tuberosity Pain with end-range hip flexion	Ultrasound may show fluid within the bursa MRI may show bursitis or proximal hamstrings/gluteal tendinopathy
Non-piriformis muscle pain	Dependent on the structure(s) involved: may be pain with activity, weight bearing, or sitting Trauma to the gluteal region	Dependent on the structure(s) involved: pain may be in the deep or superficial gluteal musculature, at the attachments on the greater trochanter, radiation into the hip or lateral thigh. If the sciatic nerve is irritated, radiating pain down the posterior ipsilateral thigh	Dependent on the structure(s) involved: may exhibit tenderness to palpation of the deep or superficial gluteal musculature over the posterior or greater trochanter May exhibit pain with internal rotation or hip flexion	Ultrasound may show tendinopathy or hematoma Plain film radiographs and CT may show fracture MRI may show tendinopathy or another soft tissue injury

CT, Computed tomography; *EMG*, electromyography; *MRI*, magnetic resonance imaging; *PSIS*, posterior superior iliac spine.

Key Points

- The causes of pain localized to the buttocks are diverse and often challenging to diagnose.
- The SIJC consists of the SIJ and anterior and posterior stabilizing ligaments. The sensory innervation of these structures is complex.
- The SIJC pain is felt in the SIJ area and can radiate to the lateral hip, posterolateral thigh, posterior leg, and groin.
- The common tests that confirm the presence of SIJC pain include the FABER-Patrick, Gaenslen, Yeoman, Gillet, sacroiliac shear, pelvic distraction, pelvic compression, and thigh thrust tests.
- The diagnosis of SIJC pain is based on the patient's history, symptoms, physical examination maneuvers, elimination of the other causes of buttock pain, and a positive response to an SIJ injection.
- Relief from the SIJ or SIJ *and* periarticular injection with local anesthetic and steroids can be temporary. More prolonged relief can be obtained by thermal RF lesioning of the SIJ or the lateral branches of the primary ramus of the L5-S3 nerves. The literature supports periforaminal RFA and sacral lateral crest strip lesion RFA techniques as successful methods to relieve pain from the SIJC.
- Coccydynia most commonly occurs after trauma, with women more often affected than men.
- Visceral pain may refer to the area of the coccyx via the ganglion impar, hypogastric plexus, or pelvic splanchnic nerves.
- Interventional treatment for coccydynia can be performed with sacrococcygeal joint injection, radiofrequency ablation of the coccygeal nerves, ganglion impar injection or radiofrequency ablation, and surgery with coccygectomy.
- PS is located in the buttocks and radiates to the ipsilateral hip. It may radiate to the leg if the SN is compressed or irritated.
- Physical examination signs to confirm PS include the Pace, Lasègue, and Freiberg signs.
- The diagnosis of PS is usually based on the presence of the above symptoms and positive provocative tests.
- Perisciatic and piriformis muscle injections of steroids and local anesthetics may result in relief that lasts several months. If the relief is transient, injections of botulinum toxin may provide longer relief.
- Non-piriformis muscle pain may present similar to PS, as an aching pain that worsens with sitting or movements, with or without sciatica, depending on the relationship of the gemelli-obturator muscle complex with the SN.
- Similar to PS, injections may be indicated for diagnostic and therapeutic purposes in individuals who fail to respond to conservative therapy.
- Ischial bursitis, also known as "weaver's bottom," typically presents as an aching pain in the lower buttock region and worsens with sitting or certain activities. Treatments include NSAIDs, ergonomic modification, PT, and steroid injections.

Facet Pain: Pathogenesis, Diagnosis, and Treatment

STEVEN P. COHEN, JAVIER DE ANDRÉS ARES

Introduction (Importance of the Problem)

Low back pain (LBP) and neck pain represent two of the five leading causes of medical disability worldwide. More than 75% of patients reporting spine pain are between 18 and 65 years old, thereby adding to the burden through lost productivity and wages.[1] Although the prevalence of LBP varies greatly throughout the literature, some lifetime prevalence estimates are as high as 84%–90%.[2,3] The five year recurrence rate of LBP may be as high as 69%.[4] The lifetime prevalence rate of neck pain has been estimated to be approximately 67%.[5,6] In 2016, LBP and neck pain expenditures were estimated at $134.5 billion, an increase of 44.4% from 2013.[7]

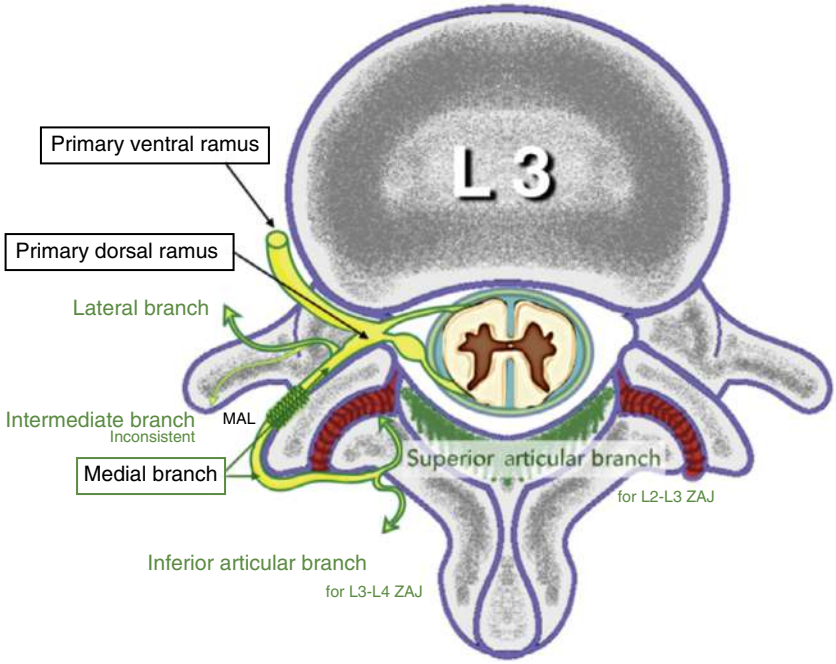
Anatomy and Function

The spine is usually composed of seven cervical, 12 thoracic, and five lumbar vertebrae. The z-joints are paired structures situated posterolateral to the vertebral body. In conjunction with the intervertebral disk, they make up what is commonly known as "the three-joint complex." Together, these joints support and stabilize the spine and prevent injury by limiting motion in all planes. The lumbar z-joints are diarthrodial synovial joints formed from the superior articular process of one vertebra and the inferior articular process of the vertebra above. The volume capacity of these joints is approximately 1–1.5 mL in the lumbar region and 0.5–1.0 mL in the cervical region.[8] The articular surfaces are covered by hyaline cartilage and contain a fibrous capsule. The fibrous capsule is approximately 1 mm thick and forms mostly collagenous tissue arranged in a transverse fashion to provide resistance to forward flexion.[9,10] The superior and inferior joint borders are formed by the fibrous capsule. There is also a small meniscoid structure inside the joint composed of connective tissue rim or adipose tissue.[11] In the lumbar spine, the multifidus muscle serves as the posterior joint border, and the ligamentum flavum replaces the fibrous capsule at the anterior border.[11,12] The position of the joint relative to the sagittal and coronal planes helps determine the role the joint plays in protecting the spine against excessive motion. Joints oriented parallel to the sagittal plane (e.g. upper lumbar spine) provide little resistance to backward and forward shearing forces, but limit excess rotation, flexion, and extension. Joints oriented closer to the coronal plane (e.g. thoracic spine and lower lumbar spine) will allow less rotation, flexion, and extension but protect against shearing forces. The cervical z-joints are inclined at approximately 45° from the horizontal plane and angled 85° from the sagittal plane. This alignment prevents excessive anterior translation and assists the disks in weight bearing.[12,13]

The mamillo-accessory ligament (MAL) is a fibrous connective band that extends from the mammary process to the accessory process (Fig. 31.1).[14] The importance of the MAL lies in the fact that they provide a fibrous tunnel through which the lumbar medial branch of the T12–L4 dorsal rami course.[15] This protects the medial branch but may interfere with nerve anesthetization during medial branch blocks and neurotomy during radiofrequency ablation.[16] The MAL can also become ossified, becoming a hypothetical source of medial branch entrapment, particularly at lower lumbar levels.[17]

The medial branch of the posterior rami supplies sensory and proprioceptive innervation to the facet joint. Each exiting spinal nerve splits into ventral and dorsal rami. The ventral ramus is the largest of the two branches and is the primary source of motor and sensory fibers. The posterior ramus divides into the lateral, intermediate, and medial branches. In the lumbar region, the lateral branch innervates the paraspinal muscles, thoracolumbar fascia, and sacroiliac joint, and supplies variable sensory fibers to the skin overlying the spinous processes. The small intermediate branch supplies the longissimus muscle. The medial branch is the largest branch of the posterior primary ramus and innervates the lumbar z-joint, multifidus muscle, interspinal muscle and ligament, and periosteum of the neural arch. Each medial branch gives rise to an ascending and a descending branch, innervating half of two adjacent z-joints.[12] Therefore to block sensory input from a single z-joint, two adjacent medial branches must be anesthetized.

Facet joints are imbued with rich innervation containing encapsulated (Ruffini-type endings, Pacinian corpuscles), unencapsulated, and free nerve endings.[18] In addition to being a potential pain generator, the z-joint capsule is thought to serve in a proprioceptive capacity as well, as evidenced by the presence of low threshold, rapidly adapting mechanosensitive neurons. In addition to substance P and calcitonin gene-related peptide, a substantial percentage of nerve endings in the facet capsules contain neuropeptide Y, which is indicative of the presence of sympathetic efferent fibers.[19] Nerve fibers have been found in subchondral bone and intraarticular inclusions of facet joints, thus signifying that facet-mediated pain may originate in structures besides the joint capsule.[20] Inflammatory mediators, such as prostaglandins,[21]



• **Figure 31.1** L2 Schematic drawing of the branches of the L2 dorsal ramus. Note that the L2 medial branch participates in the innervation of L2-L3 z-joint and L3-L4 z-joints. *MAL*, Mamillo-accessory ligament; *ZAJ*, zygapophysial joint.

and the inflammatory cytokines interleukin-6 and tumor necrosis factor-α[22] have been found in facet joint cartilage and synovial tissue in degenerative lumbar spinal disorders.[23]

Lumbar Facet Joints

The lumbar facet joints are aligned laterally to the sagittal plane and vary in angle. In an anatomic study published in 1940 by Horwitz and Smith,[24] the authors found that the L4–5 z-joints tended to be more coronally positioned (almost 70° with respect to the sagittal plane), whereas the L2–3 and L3–4 joints were likely to be oriented more parallel (<40°) to the sagittal plane. In posterior studies,[9,25] investigators have found that the upper lumbar facet joints (T12–L2) are oriented closer to the midsagittal plane of the vertebral body (mean range, 26° to 34°), whereas the lower facet joints tend to be oriented away from the plane (40° to 56°). Approximately 80% of the facet joints are curved in the upper lumbar spine and 20% are flat. In the lower lumbar spine, these numbers are reversed.[24] Studies by Grobler and colleagues[26] and Boden and associates[27] found a positive association between degenerative spondylolisthesis and more sagittally oriented lower lumbar facet joints. The inferior articular processes of L5 combine with the superior articular processes of the sacrum to form the L5–S1 facet joints.

Sensory innervation of the facet joints is derived from the medial branches arising from the posterior primary rami at the same level and the level above the facet joint.[8,28] The medial branches of L1–L4 run across their respective transverse processes one level below the named spinal nerve (e.g. L4 crosses the transverse process of L5) and traverse the dorsal leaf of the intertransverse ligament at the base of the transverse process. The nerve then proceeds along the junction of the superior articular and transverse processes, courses underneath the MAL, and splits into multiple branches as it crosses the vertebral lamina (Fig. 31.1). Calcification of the MAL can be a source of nerve entrapment,[29] most commonly occurring at L5 (20%) and L4 (10%). At L5, the dorsal ramus itself is amenable to blockade.[30,31] Some authors have claimed that a branch from the S1 nerve root can run cephalad to supply a portion of the L5–S1 facet joint, although this is controversial.[32,33] It is important to appreciate the distances between the posterior rami proper and the medial branch (since the objective of diagnostic blocks and neurotomy is to target the medial branch selectively). Shuang found that the distance between the branch point of the dorsal ramus and the upper edge of the root of the transverse process (i.e. target point for the medial branch) averaged 3.5 (SD 1.2) mm, 3.6 (SD 1.4) mm, 3.5 (SD 1.3) mm, 3.4 (SD 1.2) mm, and 1.9 (SD 0.9) for L1 to L5, respectively. The L5 distance was significantly shorter than the L1–L4 distance.[34] The extensive spread of local anesthetic in soft tissue (i.e. 0.5 mL covers an area of 6 cm^2) highlights the lack of specificity for medial branch blocks.

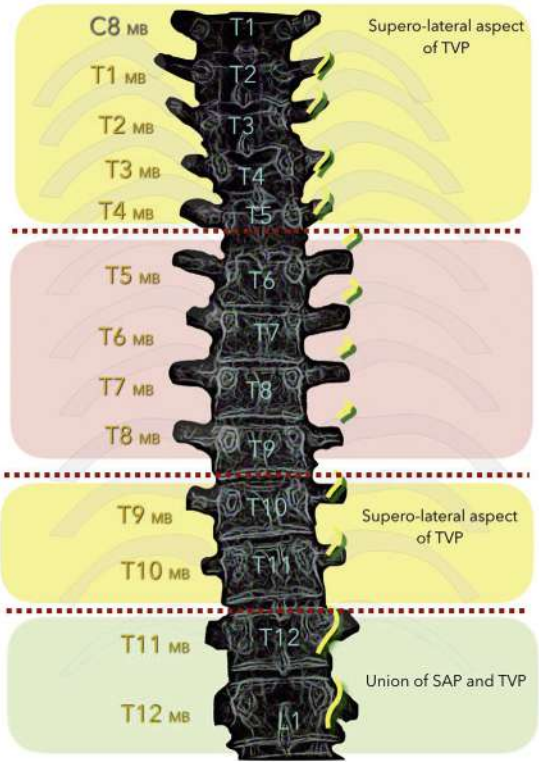
Thoracic Facet Joints

The thoracic z-joints are vertically oriented, with the anterior portion located more cephalad.[9,35,36] The frontal orientation permits lateral flexion at the expense of axial rotation. In the low thoracic spine, the angle transitions from a predominantly frontal orientation to the characteristic sagittal orientation of the lumbar facets. This transition generally occurs between T11–12 and T12–L1.[11,25] A study by Masharawi[13] showed that thoracolumbar facet joints were positioned in an oblique plane. In the transverse plane, facets T1–T11 were positioned with an anterior inclination of approximately 25° to 30° from the frontal plane. The transverse orientation of lower thoracic facet joints is highly variable.[10] Unlike the lumbar facet joints, where tropism is unusual,[9,37] asymmetry is the rule rather than the exception in the thoracic spine, with the right side generally oriented more vertically and frontally than the left.[10] The normal angles of z-joints gradually increase as they transition downwards toward

the lumbar spine by converging to the frontal plane, more so in the sagittal than the transverse plane.[38]

Sensory innervation of the thoracic facets is comparable to that in the lumbar spine, with innervation derived from the medial branch at the same level and level above. Exceptions to this rule sometimes occur at the uppermost thoracic z-joints, whereby the medial branches from C7 and C8 may travel caudad to levels as low as T3.[39] In a cadaveric study by Chua and Bogduk,[40] the authors showed that the thoracic medial branches assume different courses depending on the level. This study asserts that the T1–3 and T9–10 medial branches can be found on the superolateral edge of the transverse process of the subjacent vertebrae (T2–4 and T10–11, respectively). The relationship with osseous structures has implications for treatment. In the mid-thoracic region, the T4–T8 levels contain substantial inter and intraspecimen variability, with facet joint innervation often arising directly from the dorsal ramus rather than the medial branch and frequently traversing the intertransverse space without consistent bone contact.[41]

Because the thoracic medial branches also swing laterally to circumvent the multifidus muscle, motor stimulation of the multifidus muscle cannot be used reliably to confirm needle placement during radiofrequency (RF) treatment. In none of the 84 medial branch dissections did the authors[41] find the nerve crossing the junction between the superior articular process and the transverse process, as occurs in the lumbar spine. Instead, the superolateral corner of the transverse process was noted to be a more accurate target point for diagnostic blockade and denervation (Fig. 31.2). A recent study suggested that the posterior rami in the thoracic spine may send a branch, termed the "descending branch," to the facet joint before the bifurcations of the medial and lateral branches.[42]



• **Figure 31.2** Schematic drawing depicting the theoretical courses of thoracic medial branches. Note that from T1 to T4 and T9 to T10, the medial branches cross the superior lateral quadrant of the transverse process. In the mid-thoracic area, from T5 to T8, there is no consistent relationship between the facet joint nerve supply to any bony structure, so the medial branches appear to be suspended in the intertransverse space.

Cervical Facet Joints

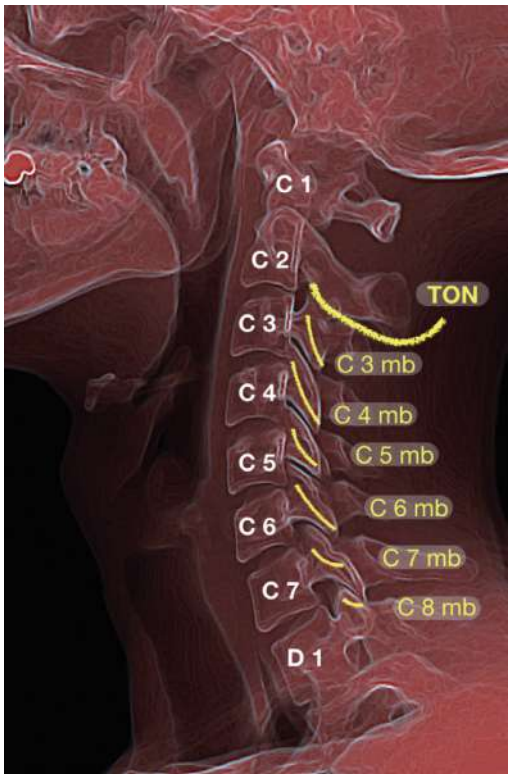
To facilitate the complex motions of the neck, the position and shape of the cervical z-joints change greatly from the base of the occiput to the cervicothoracic junction.[25,43,44] The occiput sits on the C1 articular processes in an orientation nearly parallel to the axial plane. The superior articular process at C3 faces posteromedially, with a 70° angle in the sagittal plane and a 45° angle in the transverse plane. The relative position of the C2–3 facet inhibits rotation and serves to anchor the C2 vertebra as a rotational pivot for the atlantoaxial joint (C1–2). Between C3–4 and C7–T1, the facet joint orientation transitions to the more posterolateral position of the C7 superior articular process. The most frequent site of this transition is the C5–6 joint. The position of the z-joints at this level allows flexion, extension, rotation, and lateral bending. Because of the enhanced mobility of this segment, the C5–6 level is also the most prone to facet dislocations and spondylosis. The shapes of the C3–6 facet joints tend to be round and almost flat, whereas the C6–T1 z-joints are elliptical with a more concave surface. The combination of shape and orientation at the cervicothoracic junction is designed to maximize stability.

Innervation of the cervical z-joints is more complicated than that of the lumbar and thoracic levels. Similar to the lumbar and thoracic z-joints, the C3–4 to C7–T1 facet joints receive dual innervation from the medial branches at the same level and one level above.[45] In some individuals, there are dual medial branches at a single level, which most commonly occurs at C4 and C5. The medial branches curve around the waists of the articular pillars at their respective levels then branch out to supply two joints. The tight fascia and tendons of the semispinalis capitis muscle ensure that the medial branches cling closely to the periosteum, thereby making their position more predictable. In a lateral projection, the medial branches lie near the center of the articular pillars at midcervical levels (Fig. 31.3).[46–48]

The innervation of C2–3 is slightly more complicated. This uppermost facet joint receives the majority of its innervation from the C3 dorsal ramus. The C3 dorsal ramus is normally divided into two separate medial branches. The larger superficial branch is also known as the third occipital nerve, and the inferior branch is termed the deep medial branch. Some innervation of the C2–3 level is also derived from the C2 dorsal rami, which may form five distinct branches, the largest of which is the greater occipital nerve.[48,49] Along with the upper cervical z-joints themselves, the dorsal rami and its branches can be a source of cervicogenic headache.[50,51]

Pathophysiology

Osteoarthritis (OA) is the most important cause of facetogenic pain. In most cases, facet joint arthropathy is a product of years of repetitive strain and low-grade trauma. This is illustrated by the strong association between facet arthropathy and increasing age.[52–56] Studies have demonstrated that intervertebral disk degeneration virtually always precedes facet changes in the lumbar spine.[57] In some cases, an inciting event or pathology can be identified, but the etiologic relationship between the identified inciting event and pain is not always clear. For example, in the lumbar spine, Okonkor et al.[57] found that 52% of 1069 patients with positive lumbar facet blocks



• **Figure 31.3** Schematic drawing of the cervical medial branches (mb). Note how the medial branch of C5 crosses the center of the articular pillar, while branches above and below C5 cross their articular pillars at more cephalad locations.

reported an inciting event, with motor vehicle collisions, sports injuries, and falls being the most common.

Preceding trauma is especially common in the cervical spine, particularly whiplash injuries.[47,51,58] This can result in chronic neck, head, and shoulder pain secondary to hyperflexion and rotation.[59,60,61]

Cadaveric and Laboratory Studies

Ianuzzi and coworkers[62] found that joint moments occurring with any given motion correlate with the magnitude of joint displacement and tend to be greatest at the L4–5 and L5–S1 joints. At the three most caudal joints (L3–S1), contralateral bending was associated with greater capsular strain than ipsilateral bending. In contrast, the L1–2 and L2–3 joints undergo greater strain during ipsilateral flexion. For the upper three facet joints, the maximum joint displacement and the greatest strain were associated with lateral bending. For the two lowest joints, the greatest degree of strain occurred during forward flexion (Table 31.1).

Later work provided evidence that spinal fusion can lead to accelerated degeneration at adjacent levels.[63–67]

The z-joints may respond to repetitive strain and inflammation by filling with fluid and distending, thereby stretching the capsule.[68] Pain from capsular inflammation can spread beyond the joint area because of compression of the exiting nerve root, especially with foramina that are already narrowed by facet joint hypertrophy, osteophytes, or herniated intervertebral disks.[69–72] Inflammatory cytokines released from facet joint tissue may also contribute to the radicular symptoms in patients with spinal stenosis.[73] Facet joint pain can manifest in a radicular pattern, which is supported by a study that found that the presence of foraminal and central stenosis was positively associated with lumbar medial branch radiofrequency ablation (RFA) outcomes.[74] Irritation of the capsule may also cause reflex spasms of the paraspinous muscles.[69,74,75]

Several experiments conducted by groups of investigators established the pathophysiologic basis for persistent lumbar facet pain. These studies showed that injection of pro-inflammatory and algesic mediators into facet joints resulted in inflammatory changes, leading to sensitization of nociceptors.[76–80] Later work by Chen et al. showed the presence of C and Aδ fibers in the cervical facet joint capsules of goats.[81] C fibers were more prevalent in the dorsolateral aspect of the z-joint capsule, where tendons and muscles attach.

Human Studies

The intervertebral disk and paired facet joints work in concert with changes in any part of the three-joint unit, altering the motion and function of the others. Degenerative disk disease (DDD) has been shown to result in concomitant changes in the facet joints.[82–84] In the reverse scenario, degeneration and motion abnormalities of the facet joints can induce and accelerate intervertebral disk degeneration.[85–87] Multiple studies have examined the relationship between DDD and facet joint OA and concluded that DDD generally precedes facet arthritis[57,88,89] and that facet arthropathy is most pronounced at spinal levels with advanced DDD.[57,88]

The spinal musculature also works collectively with z-joints, controlling movements and stabilizing the vertebral column.[90,91] Paraspinal muscles provide proprioceptive feedback for proper alignment and biomechanics.[91,92] Aging decreases paraspinal muscle mass,[93] which could compromise these functions and contribute to z-joint OA. Patients with chronic LBP seem to have impaired spinal proprioception[94] and a decrease in paraspinal muscle mass.[95] A study by Kalichman demonstrated an association between decreased paraspinal muscle density and the presence of lumbar z-joint OA,[93] while other conditions that can contribute to or cause z-joint OA include degenerative scoliosis[96] and spondylolisthesis.[97]

Several cases of lumbar facetogenic pain secondary to traumatic dislocation from rapid deceleration injuries have been reported, mostly at L5–S1.[60,61,98–102] The purported mechanism of injury in these cases was hyperflexion, rotation, and distraction.[60] Twomey et al. dissected the lumbar spines of 31 patients who died of trauma and noted occult bony fractures in the superior articular process or subchondral bone plate in 35% of subjects and facet capsular or articular cartilage damage in 77% of cases.[103]

For chronic posttraumatic neck pain, the cervical z-joints have been estimated to account for up to 60% of cases.[45] However, trauma is responsible for a relatively small percentage of chronic neck pain, with the prevalence ranging from 13%–42%.[104]

Prevalence

The prevalence of facet joint pain varies greatly in the literature. Among patients with axial spine pain, the proportion of patients with facetogenic pain is higher in the cervical and thoracic regions than in the lumbar region. The problem with estimating the prevalence of facet joint pain is that in the absence of any objective reference standard (e.g. imaging), one must rely on subjective diagnostic procedures such as medial branch blocks or intraarticular injections, which are subject to high technical failure rates (e.g. between 29% and 38% per joint, and from 46% to 64% per

TABLE 31.1 Motions Associated With the Largest Intervertebral Angulation and Strain for the Lumbar Facet Joints

Facet Joint Level	Movement Associated With Maximal IVA	Largest Strain
L1-2	Right bending	Right bending
L2-3	Left bending	Right bending
L3-4	Right bending	Right bending
L4-5	Forward flexion	Forward flexion
L5-S1	Extension	Forward flexion

IVA, Intervertebral angle.

procedure in the lumbar spine).[105] There is also a wide variation in the interpretation of blocks (e.g. the threshold of pain relief required to designated a block as positive), with uncontrolled blocks subject to significantly high false positive and false negative rates.[106] Many studies also conflate two different concepts: z-joint arthropathy, which may or may not be painful, and z-joint pain, which may or may not be produced by arthropathy.[107]

The prevalence of LBP stemming from lumbar facet joints is low and is greatly affected by the age of the cohort being tested (i.e. much higher in older individuals) and both the cutoff threshold and number of blocks.[108] In a non-enriched population in which double blocks are employed and cutoff thresholds exceeding 75% are used, the prevalence of lumbar facetogenic pain among individuals with axial LBP is approximately 10%–15%. The prevalence of z-joint-related cervical pain is estimated at 50–55%, increasing to approximately 60% in patients whose neck pain is caused by whiplash. In the thoracic spine, the prevalence is estimated to be between 40% and 50%.[109]

The prevalence of lumbar facetogenic pain is shown in Table 31.2. Earlier studies (1999–2000) by Schwarzer et al.,[55,110,111] Revel et al.,[112] Manchikanti et al.,[113,114,116] and Dreyfuss et al.[115] are not included in the table (Tables 31.2 and 31.3).

Diagnosis

History

Facetogenc pain tends to be insidious and progressive,[127] except for whiplash injuries that follow an acute, traumatic event.[128,129] Young patients with LBP or neck pain are more likely to present with centralized pain that is more indicative of disc disease,[130] while older patients are more likely to have facetogenic pain as the primary pain generator.[9–20] The direct association with age is consistent with the concept that facet pain is a chronic degenerative disorder that coexists with DDD[57] rather than an acute inflammatory process.

Pain Referral Patterns

The distribution and radiation of pain from the facet joints have been derived from relief with LA blocks, pressurization of the facet joints, and stimulation of the medial branches innervating the specific joints. The majority of these studies have failed to demonstrate any reliable pain referral patterns.[131–134]

An important part of the clinical workup is differentiating z-joint pain from other sources of pain.[135,136] A study by DePalma et al.[122] demonstrated that the presence or absence of thigh pain significantly correlated with the source of chronic LBP for varying ages (i.e. thigh pain increased the likelihood of facetogenic vs. discogenic pain in older people). In contrast, the presence of hip/girdle pain or leg pain did not discriminate between discogenic pain, z-joint pain, or sacroiliac joint pain. As previously noted, discogenic pain was more prevalent in younger patients, while z-joint pain was more prevalent in the elderly.[52]

When the existing data are synthesized, certain pain patterns emerged (Figs 31.4–31.6). The joint capsule appears to be more likely to generate pain than the synovium or articular cartilage. A great deal of overlap exists between neighboring facet joints and between discs and facet joints. All lumbar levels are capable of producing groin pain, which is most common at lower levels.[30,72,99,132,137–149] Pain from the upper lumbar facets tends to extend into the flank, hip, and upper lateral aspect of the thigh, whereas pain from the lower lumbar levels is likely to penetrate into the thigh, usually laterally and posteriorly. Infrequently, the L4–5 and L5–S1 facet joints can provoke pain in the lateral part of the calf and rarely in the foot. Patients with osteophytes, synovial cysts, or facet hypertrophy may also have radicular symptoms. Unilateral pain or pain in the paraspinal distribution is more likely to be associated with pain from the facet or sacroiliac joints than with discogenic LBP.[150]

Clinical studies have been conducted in normal volunteers and patients with suspected cervical facet pain to determine pain referral patterns.[151–154] From C2–3, the pain pattern generally extends rostrally to the upper cervical region and suboccipital area. Infrequently, symptoms extend toward the ear or further up the scalp. From C3–4, pain is referred to the upper and middle posterior aspect of the neck, with occasional radiation to the lower occiput. From C4–5, the most common referral pattern is to the lower posterior cervical region, although in many people, it extends to the middle posterior aspect of the neck and suprascapular region. Pain from C5–6 typically radiates to either the suprascapular region or lower part of the neck but sometimes extends to the shoulder joint or midposterior neck region. From C6–7, pain is usually referred to the upper or lower neck area. Pain from the C7–T1 z-joint most frequently extends further down into the midscapular area.

Other joints that can cause cervical pain or headaches are the atlanto-occipital joint and atlanto-axoid joints. Both show highly variable patterns, which may extend over the suboccipital region and the head and face.[155]

Similar work has been done for thoracic z-joints. The pain referral patterns were as follows: pain from the C7–T1 and T1–T2 z-joints typically radiate into the suprascapular region and superior angle of the scapula. Pain extending into the midscapular region may originate from either C7–T1, T1–2, or T2–3, and pain from the T11–12 z-joint generally extends into the paravertebral region around the site of injection around the iliac crest area (Fig. 31.6).[153,156]

Physical Examination

As with historical findings and pain referral patterns, physical examination has limited value in diagnosing facet pain and is more valuable in ruling out other causes of pain. Among the available physical examination findings, the presence of *paraspinous muscle*

TABLE 31.2 Results of Lumbar Facet Joint Pain Prevalence Studies Conducted with Either Placebo-Controlled or Comparative Local Anesthetic Blocks

Author, Year	Patients	Interventions	Results	False Positive Rate and Comments
Manchikanti et al.[117] 2004	397 pts with chronic LBP without neurologic deficits	Pts rec'd MBB with 1% lidocaine. All pts who obtained ≥75% pain relief underwent confirmatory blocks with 0.25% bupivacaine. A (+) response was ≥80% relief lasting longer with bupivacaine.	198 (50%) of pts obtained a (+) response to lidocaine blocks, with 124 reporting definite pain relief with bupivacaine, for a 31% prevalence rate	FP rate, 27%. Mean age, 47 years.
Manchikanti et al. [118] 2007	117 consecutive patients with chronic LBP after lumbar surgical interventions	MBB performed with 1% lidocaine, 0.25% bupivacaine, 0.5 mL. At least 80% of pain relief from block.	Prevalence = 16% (9%–23%)	FP rate = 49% (39%–59%). in patients with failed back surgery syndrome
Manchukonda et al.[119] 2007	303 patients with chronic LBP of at least three months duration following a motor vehicle accident	MBB performed with 1% lidocaine, 0.25% bupivacaine, 0.5 mL. At least 80% pain relief with the ability to perform previously painful movements.	Prevalence = 31% (27%–36%)	FP rate= 27% (22%–32%)
Kavita et al.[120] 2008	Retrospective analysis of 303 patients with chronic lumbar and/or cervical pain divided by age groups (Group I: 18–30 years, II: 31–40 years, III: 41–50 years, IV: 51–60, V: 61–70 years, VI: greater than 70 years old)	Facet joint pain was initially assessed in all patients by diagnostic blocks using 1% lidocaine, followed by 0.25% bupivacaine if the responses to lidocaine were positive on two separate occasions, usually separated by three to four weeks. A positive response was defined as: 1) at least an 80% reduction of pain, 2) the ability to perform previously painful movements (as assessed using a verbal numeric pain rating scale), 3) pain relief from a block lasting at least 2 h when lidocaine was used and at least 3 h when bupivacaine was used.	The prevalence of facet joint involvement in lumbar spinal pain ranged from 18% (in Group II: 31-40 years) to 44% (in Group IV: 51-60 years), with significant differences noted when Group II and Group III were compared to other groups, and with higher rates in Group V.	Overall FP rate 45% (36%–53%) Group I: 40% (20%–60%) Group II: 50% (26%–74%) Group III: 45% (30%–60%) in Group IV: 30% (12%–47%) Group V: 64% (43%–84%) Group VI: 43% (16%–69%)
Manchikanti et al.[121] 2010	181 patients with chronic low back pain	MBB performed with 1% lidocaine, 0.25% bupivacaine, 0.5 mL. Compared, 50% pain relief with 80% pain relief.	50% pain relief Prevalence = 61% (53%–81%) 80% pain relief Prevalence = 31% (26%–35%)	50% pain relief FP rate = 17% (10%–24%) 80% pain relief FP rate = 42% (35%–50%)
DePalma et al.[122] 2011	Retrospective evaluation of 156 patients with CLBP were assessed for the source of chronic LBP (discogenic pain, facet joint pain, and sacroiliac joint pain)	MBB performed with 1% lidocaine, 0.5% bupivacaine. Concordant relief for 2 h for lidocaine and 8 h for bupivacaine with 75% pain relief as the criterion standard	Prevalence = 31%	Study evaluated various structures implicated in LBP with controlled diagnostic blocks

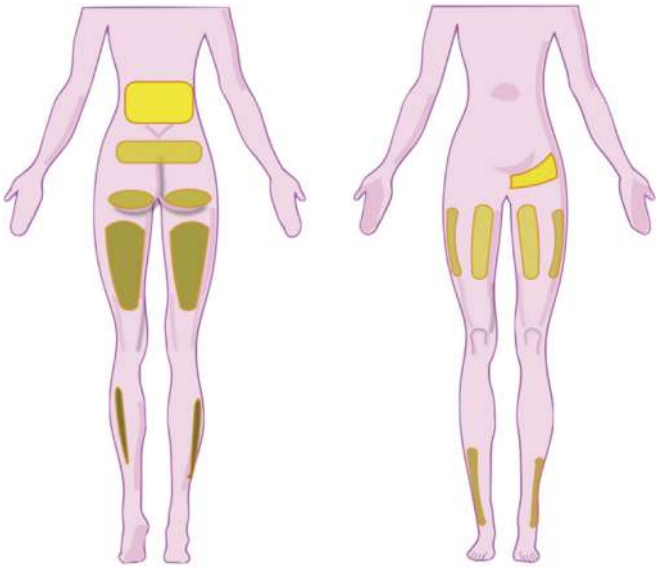
The false positive (FP) rate, if not mentioned, was determined by dividing the number of patients who obtained pain relief with the lidocaine screening block but not with the confirmatory block by the total number of blocks. *LA*, Local anesthetic; *LBP*, low back pain; *MBB*, medial branch block; *pts*, patients; *rec'd*, received.

The prevalence of lumbar facetogenic pain is shown in Table 31.2. Earlier studies (1999-2000) by Shwarber et al.,[55,110,111] Revel et al.,[112] Manchikanti et al.,[113,114,116] and Dreyfuss et al.[115] are not included in the table.

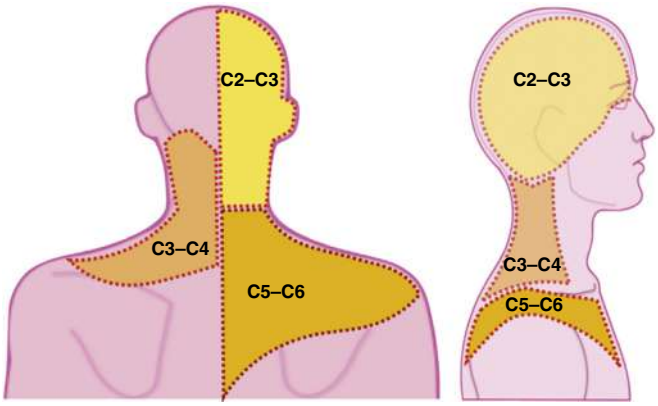
TABLE 31.3 Results of Cervical and Thoracic Zygapophyseal Joint Pain Prevalence Studies Conducted With Either Placebo-Controlled or Comparative Local Anesthetic Blocks

Author, Year	Patients	Interventions	Results	False Positive Rate and Comments
Barnsley et al.[41,47] 1993	47 pts with chronic neck pain >3 months after MVA	Pts rec'd cervical MBB with 0.5 mL of either 2% lidocaine or 0.5% bupivacaine. Pts with positive block rec'd other agent. A (+) response required longer pain relief with bupivacaine.	27 pts had longer relief with bupivacaine than with lidocaine, for a 60% prevalence rate.	13 pts (27%) had a (+) response to both LAs but in excess of the expected duration. Average age, 41 years. Female-male ratio, 1:1. All but three pts involved in litigation.
Barnsley et al.[123] 1995	50 pts with chronic neck pain of >3 months duration after a whiplash injury from MVC	Pts rec'd cervical MBB with 0.5 mL of either 2% lidocaine or 0.5% bupivacaine at random. Pts with a (+) block rec'd the complementary anesthetic. A (+) response required longer pain relief with bupivacaine.	27 pts who completed the study met the criteria for a (+) painful joint, for a 54% prevalence rate.	Ten pts (20%) had longer pain relief with lidocaine than with bupivacaine or no pain relief with repeated blocks. Average age, 41 years. Female-male ratio, 1.5:1. C2-3 and C5-6 most frequently affected levels.
Lord et al.[51] 1996	68 pts with chronic neck pain of >3 months duration after a whiplash injury from MVA	Pts rec'd diagnostic C2-3 blocks to rule out those with third occipital headache. Placebo-controlled cervical facet blocks below C2-3 were done with 0.5 mL of either 2% lidocaine or 0.5% bupivacaine. If (–), other levels were then attempted. If (+), pts rec'd either NS or other LA at random and then had a third block with the remaining agent.	31 of 52 pts (60%) who completed the study had cervical facet pain at C2-3 or below, for a 60% prevalence rate. Among pts with HA as the dominant Sx, 50% prevalence of C2-3 facet joint pain. In pts without C2-3 facet pain, the prevalence of lower cervical facet pain was 49%.	Average age, 41 years. Female-male ratio, 2:1. C2-3 and C5-6 most commonly affected levels.
Manchikanti et al.[124] 2002	46 pts with chronic thoracic pain (>6 months) without neurologic Sxs	Pts rec'd MBB with 1% lidocaine followed by confirmatory blocks with 0.5% bupivacaine. A (+) response was ≥80% concordant pain relief.	22 of 36 pts with (+) lidocaine blocks had longer relief with confirmatory bupivacaine blocks, for a 48% prevalence rate.	FP rate, 58%. Average age, 46 years.
Manchikanti et al.[125] 2002	106 pts with chronic neck pain with or without HA or upper extremity pain	Pts rec'd diagnostic blocks with 0.5 mL of 1% lidocaine followed by 0.5 mL of 0.25% bupivacaine two weeks apart.	64 of 81 pts with (+) lidocaine blocks had longer relief with confirmatory bupivacaine blocks, for a 60% prevalence rate	40% FP rate. Mean age, 43 years. Female-male ratio, 2:1. 15% of pts had previous neck surgery.
Manchikanti et al.[117] 2004	500 pts with chronic neck, thoracic, and/or LBP without neurologic Sxs. 255 pts had cervical Sxs, and 72 pts had thoracic Sxs	Pts rec'd MBB with 1% lidocaine followed by confirmatory blocks with 0.25% bupivacaine. A (+) response was ≥80% relief lasting longer with bupivacaine. Minimum of two levels blocked based on pain patterns.	55% prevalence rate of cervical facet joints in pts with cervical spine pain. 42% prevalence rate of thoracic facet joints in pts with thoracic pain.	FP rate of 63% for cervical and 55% for thoracic MBB. Average age, 47 years. Female-male ratio, 2:1 for both cervical and thoracic.
Manchukondet al.[119] 2007	251 patients with chronic neck pain of at least six monthsduration. Non-specific with no radicular component	1% lidocaine 0.25% bupivacaine 0.5 mL volume	Pain relief ≥80% with the ability to perform previously painful movements	Prevalence = 39% (32%–45%) FP rate= 45% (37%–52%)
Yin and Bogduk[126] 2008	84 patients with chronic neck pain of at least three months duration	4% lidocaine 0.75% bupivacaine 0.5 mL	100% pain relief with duration of response concordant with the anesthetic used	

HA, headache; *MVC*, motor vehicle collision; *MVA*, motor vehicle accident; Sxs, symptoms.



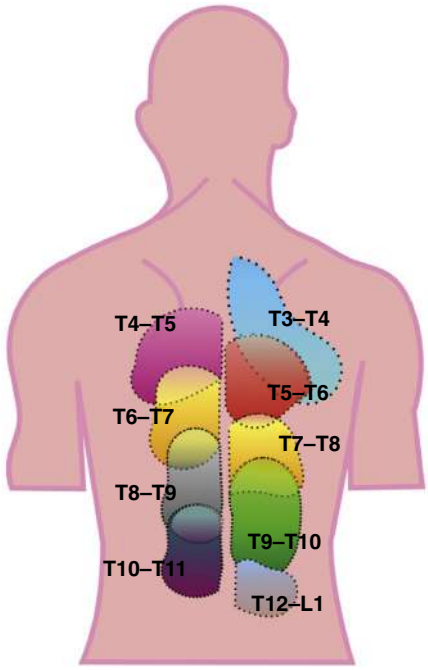
• **Figure 31.4** Pain referral patterns from the lumbar facet joints. The most common referral patterns extend from the darkest (low back) to the lightest regions (flank and foot) in descending order. The following key is listed in order of affected frequency (i.e. low back to foot). The facet levels next to each location represent the zygapophyseal joints most associated with pain in each region. Low back: L5-S1, L4-5, L3-4; buttock: L5-S1, L4-5, L3-4; lateral thigh area: L5-S1, L4-5, L3-4, L2-3; posterior thigh area: L5-S1, L4-5, L3-4; greater trochanter: L5-S1, L4-5, L3-4, L2-3; groin: L5-S1, L4-5, L3-4, L2-3, L1-2; anterior thigh area: L5-S1, L4-5, L3-4; lateral lower leg area: L5-S1, L4-5, L3-4; upper back area: L3-4, L2-3, L1-2; flank: L1-2, L2-3; foot: L5-S1, L4-5. (Adapted from Cohen, SP, Raja SN. Pathogenesis, diagnosis, and treatment of lumbar zygapophysial facet joint pain. *Anesthesiology*. 2007;106:591–614.)



• **Figure 31.5** Pain referral patterns from the cervical facet joints. (Adapted from Bogduk N, Marsland A. Cervical zygapophysial joints are a source of neck pain. *Spine*. 1988;13:615.)

tenderness on palpation is probably the only sign weakly indicative of facetogenic pain.[157,158] This finding is likely because of sensitized musculature rather than actual strain on the facet joints.

Despite the limited value of physical examination in diagnosing facet pain, many research studies and clinicians still rely on provocative maneuvers to select patients for facet interventions. A study showed that patients who responded to intraarticular injections were more likely to have back pain associated with groin or thigh pain, paraspinal tenderness, and reproduction of pain with



• **Figure 31.6** Pain referral patterns from the thoracic facet joints. (Adapted from Dreyfuss P, Tibiletti C, Dreyer SJ. Thoracic zygapophysial joint pain patterns. A study in normal volunteers. *Spine*. 1994;19:809.)

extension rotation maneuvers.[145] Pain radiating below the knee was a negative predictor.

Larger and more methodologically sound studies have failed to validate "lumbar facet syndrome" or the provocative maneuver commonly known as "facet loading." Prospective studies of patients with chronic LBP could not correlate any historical or physical findings associated with a positive response to facet injections.[145,159] In both studies, only a small percentage (10% and 15%, respectively) of patients responded to diagnostic blocks. A randomized, placebo-controlled study of 80 patients with chronic LBP by Revel et al. found seven factors to be associated with response to facet joint anesthesia: age older than 65 years and pain not exacerbated by coughing, not worsened by hyperextension, not worsened by forward flexion, not worsened when rising from forward flexion, not worsened by extension rotation maneuvers, and well relieved by recumbency.[112] However, subsequent investigations failed to corroborate these findings.[160]

Very few studies have investigated the history and physical findings most consistent with cervical and thoracic facet pain. One study found that a blinded therapist specializing in manipulation could correctly diagnose symptomatic cervical facet joint pain in patients with positive diagnostic cervical MBBs through the perceived passive displacement of the joint and its resistance to displacement.[161] However, a subsequent study conducted using controlled blocks as the "gold standard" for cervical z-joint pain found that although manual examination had a sensitivity of 88%, low specificity (39%) precluded its use as a valid diagnostic tool.[162] The majority of cervical facet prevalence studies have been conducted on whiplash victims, thereby making it difficult to draw conclusions in non-trauma patients. A Delphi study from an expert panel identified 12 indicators of lumbar joint pain. Those that reached the highest levels of consensus were a positive response to facet joint injection, localized unilateral LBP, positive medial branch block, paraspinal tenderness, absence of radicular

features, pain eased by flexion, and pain, if referred, located above the knee.[163] A study by Laslett found seven characteristics suitable for selecting patients for interventions involving the lumbar z-joints: 1) age 50 years or greater, 2) pain relieved when walking, 3) pain improved by sitting, 4) paraspinal pain predominance, 5) Modified Somatic Perception Questionnaire score exceeding 13, 6) positive extension rotation test, and 7) absence of centralization during repeated movement testing.[53] Recently, a meta-analysis by Usunier et al. identified four clinical tests that predicted cervical facet joint pain: passive intersegmental motion testing; mechanical sensitivity; pain consistent with cervical zygapophyseal joint referral patterns; and, based on a single study, a positive extension rotation test.[164] However, the sensitivity and specificity of these tests were poor.

Radiologic Findings

The prevalence of facet joint disease observed on radiologic imaging is dependent on the age of patients, presence of symptoms, imaging modality, and threshold used for designating an examination as "abnormal." In LBP patients, the prevalence of degenerative facet disease on computed tomography (CT) ranges from 40% in some studies[165] to 85% in others.[166,167] Studies comparing the sensitivity and specificity of MRI and CT in detecting facet degenerative changes are not uniform (Table 31.4).[88,169,170] In a study of 14 patients with DDD, those younger than 40 years showed minimal osteoarthritic changes of the lumbar facets.[88] The prevalence of facet pathology increased significantly in patients older than 60 years. In asymptomatic volunteers, the incidence of lumbar facet degeneration ranges from 8% to 14%.[168,171,172]

The use of radiologic imaging as a predictor of response to diagnostic facet blocks has been conflicting. Although some studies have found a positive association between CT, MRI, and other imaging modalities and response to facet blocks,[165,173] an equal number have not.[54,146,166,133,174]

Recent studies have focused on newer imaging modalities.[175,176,177] A study by Rosen showed a positive correlation between the severity of degenerative disk and facet disease on PET/MRI using an 18-F FDG radiotracer.[178] However, Lehman and Diehm more recently demonstrated poor concordance between peri-facet joint signal changes and facet joint pain.[179] In a study by Yolcu and Lehman comparing hybrid imaging techniques (PET/CT, PET/MRI, and single-photon emission computed tomography [SPECT]/CT) to evaluate back and neck pain because of suspected z-joint arthropathy, the authors concluded that while they are promising, increased radiation exposure and higher costs must be considered.[180]

In summary, the literature does not support the routine use of radiologic imaging as a means of diagnosing facet pain. The lack of an association between imaging findings and facet joint pain is consistent with other musculoskeletal pain disorders such as knee and hip osteoarthritis.[181,182,183]

Diagnostic Blocks

The poor correlation between historical, radiologic, and physical examination findings and zygapophyseal pain has led to widespread acceptance of the use of diagnostic blocks to confirm facet joints as primary pain generators.[184] Although MBB and intraarticular injections are widely touted to be equally effective diagnostic tools,[185] the evidence for this claim is based on two studies, neither of which used a crossover design, controlled blocks, or prescreened patients for z-joint pain.[148,186] Several factors undermine the diagnostic validity of MBB. In a cadaveric study done in the late 1930s, Kellegren showed that injection of 0.5 mL of fluid spread into an area encompassing 6 cm^2 of tissue.[187] Cohen and colleagues demonstrated that reduction in LA volume in cervical MBBs from 0.5 to 0.25 mL decreased aberrant spread to other potential pain generators, including spread to the intervertebral foramen, by over 50%.[188] Because of the short distance between branches of the dorsal rami, even low-volume medial branch blocks are likely to block the lateral and intermediate branches. Since these nerves supply afferent innervation to multiple potential pain-generating structures, including the paraspinal muscles, ligaments, sacroiliac joints, and skin, MBB can relieve pain even in the presence of non-pain-generating z-joints. False positive rates have been reported to be as high as 63% in the cervical region, 53% in the thoracic region, and 27% in the lumbar facet region.[117] However, the higher prevalence (true positive) rates in the neck and midback should theoretically result in a lower false-positive rate. False negative responses are also a concern as they can limit access to care and result from intravascular uptake of the LA, procedure-related pain, and failure of patients to distinguish between pain from the procedure and their baseline pain. Considering the low sensitivity of aspiration and intermittent fluoroscopy, some advocate using "real-time" fluoroscopy to detect intravascular uptake during MBB.[189]

Although intraarticular facet injections may be more theoretically accurate in diagnosing facet pain, these blocks can be technically challenging and fraught with limitations. Injection of >2 mL of fluid can rupture the joint capsule and lead to extravasation of LA onto other pain-generating structures, leading to false positive blocks. Depending on the point of extravasation, these structures can include the epidural space, intervertebral foramen, ligamentum flavum, and paraspinal musculature.[68,149]

Medial Branch Block Versus Intraarticular Injection

The argument supporting a prognostic procedure that targets the nerves rather than the joints themselves is supported by a multicenter case-control study demonstrating better radiofrequency ablation outcomes in patients who undergo medial branch blocks rather than intraarticular injections.[190]

A study by Ackerman and Ahmad randomized 46 patients with axial LBP and a positive SPECT scan to receive either intraarticular injections or MBB using 0.7 mL of LA and steroid. Twelve weeks after treatment, 61% of the intraarticular injection group experienced a positive outcome, which favorably compared with 26% in the MBB group.[191] It is difficult to draw conclusions based on these comparative studies because of the multitude of design flaws. The most prominent ones are the lack of a definitive diagnosis in the study populations and that only one study[186] evaluated immediate post-procedure pain relief. Studies investigating the prevalence and false positive rates in chronic LBP patients (Table 31.2) have generally found comparable diagnostic values for MBB and intraarticular injection. None of the three placebo-controlled studies evaluating the outcome of lumbar RF denervation after intraarticular injections to "confirm" the presence of facetogenic pain demonstrated definitively positive outcomes.[192,–194] In contrast, most studies that screened patients with lumbar MBB demonstrated a primary positive outcome.[195] In a prospective, randomized study comparing lumbar facet cryodenervation success rates between patients who underwent medial branch and pericapsular lumbar facet screening blocks, Birkenmaier and associates[196] found superior outcomes up to six months after the procedure in the MBB group. However, the excessive volumes used during both diagnostic procedures, the absence of

TABLE 31.4 Prospective Clinical Trials Evaluating Intraarticular Steroid Injections for Lumbar and Cervical Facet Joint Pain

Authors, Year, Methodology Score	Patients and Interventions	Results	Comments
Carette et al.[220] 1991; MQ score = five	97 pts with chronic LBP who reported immediate relief after injections of 2 mL of steroid and saline (n = 49) or saline (n = 48) into the L4-5 and L5-S1 lumbar z-joints.	42% of pts who received steroids and 33% who rec'd placebo reported marked improvement for up to three months (not significant). At six months, the steroid group reported less pain and disability. Only 22% of pts in the steroid group and 10% in the placebo group had improvement through six months.	Differences between groups at six months reduced when co-interventions were taken into account. NS is known to provide pain relief greater than that expected from a placebo.
Marks et al.[149] 1992; MQ score = three	86 pts with chronic LBP were randomized to receive either 1.5 mL of steroid and LA MBB or intraarticular injections (2 mL at the lowest level).	Pts who rec'd facet joint injections had better pain relief than did those who underwent MBB at all follow ups, but this was significant only at one month.	Flaws include no true control group, failure to identify pts based on diagnostic injections, no monitoring of co-interventions, and lack of a blinded observer.
Barnsley et al.[221] 1994; MQ score = five	41 pts with chronic neck pain following MVA were randomized and received an injection of either 1 mL of 0.5% bupivacaine or 5.7 mg of betamethasone into painful cervical z-joints diagnosed by comparative LA MBB.	Less than half the pts reported relief for more than one week, and fewer than one in five reported relief for more than one month. The median time to return of 50% of the preprocedure pain was three days in the steroid group and 3.5 days in the LA group.	All pts had neck pain following a whiplash injury. Some pts with long-lasting benefit in both groups.
Fuchs et al.[218] 2005; MQ score = one	60 pts with chronic LBP were randomized to either 1 mL of HA or steroid into the three lowest facet joints at weekly intervals for six weeks.	Pts who rec'd HA injections experienced a 40% decrease in pain scores vs. a 56% reduction in those who rec'd steroid (not significant). The greatest pain reduction was observed after three months in the HA group and after one week in the steroid group.	Inclusion criteria included at least moderate facet degeneration on radiologic imaging. Flaws include lack of a control group, failure to identify pts based on diagnostic injections, no monitoring of co-interventions, and multiple injections.
Pneumaticos et al.[222] 2006; MQ score = three	47 pts with chronic LBP and radiologic evidence of lumbar z-joint abnormalities were randomized in a 2:1 ratio to undergo intraarticular LA and steroid injections (3 mL) based on SPECT scans or physical examination.	One month after injection, 87% of pts with (+) SPECT had significant pain improvement vs. 12.5% of pts with (–) SPECT and 31% of pts who underwent injections based on physical examination.	Differences remained significant at three months but not six months. No functional assessment was done. The use of SPECT was cost effective.
Kennedy et al.[225] 2018; MQ score = three	28 subjects with confirmed z-joint pain via dual comparative medial branch blocks were randomized to receive either intraarticular corticosteroid (triamcinolone 20 mg) or saline via fluoroscopic guidance.	There was no statistically significant difference in the need for radiofrequency ablation between groups, with 75% of the saline group and 91% of the corticosteroid group receiving neurotomy. No difference was observed in the mean time to radiofrequency neurotomy between saline (6.1 weeks) and corticosteroid (6.5 weeks) groups.	Corticosteroid injections into the lumbar z-joints were not effective in reducing the need for radiofrequency neurotomy in those with z-joint pain confirmed by medial branch blocks.
Cohen, et al.[105]2018; MQ score four	229 patients were randomized in a 2:2:1 ratio to receive intraarticular facet injections with LA and steroid, medial branch blocks with LA and steroid, or saline.	Mean reduction in average numeric rating scale pain score at one month was 0.7 ± 1.6 in the intraarticular group, 0.7 ± 1.8 in the medial branch block group, and 0.7 ± 1.5 in the placebo group; P = 0.993. The proportion of patients with positive blocks was higher in the intraarticular (54%) and medial branch (55%) groups than in the placebo group (30%; P = 0.01). Radiofrequency ablation was performed on 135 patients (45, 48, and 42 patients from the intraarticular, medial branch, and saline groups, respectively). The mean reduction in average pain score at three months was 1.8 ± 2.3 in the intraarticular, 1.8 ± 2.4 in the medial branch, and 0.7 ± 1.5 in the control group (P = 0.025). At three months, the proportions of positive responders in the intraarticular, medial branch block, and placebo groups were 51%, 56%, and 24%, respectively (P = 0.005).	This study establishes that facet blocks are not therapeutic. The higher responder rates in the treatment groups suggest that facet blocks might provide prognostic value before radiofrequency ablation.

The methodologic quality (MQ) score is based on the five point Jadad scale.[223] A score of three or higher indicates high methodologic quality.

HA, Hyaluronic acid; *LA*, local anesthesia; *LBP*, low back pain; *MBB*, medial branch block; *MVA*, motor vehicle accident; *NS*, normal saline; *pts*, patients; *rec'd*, received; *SPECT*, single-photon emission computed tomography; *z-joint*, zygapophyseal (facet) joint.

controlled blocks, and the lack of proven validity for pericapsular injections detract from the authors' conclusions.

The most recent randomized study published in 2018 by Cohen et al.[105] compared the therapeutic and prognostic value of intraarticular blocks and medial branch blocks performed with bupivacaine and steroids and sham injections. Among patients in the intraarticular and medial branch block groups who experienced a positive block but failed to derive long-term (≥3 months) relief, radiofrequency ablation was performed. In the sham group, radiofrequency ablation was performed in all non-responders. The authors determined that the strongest factor associated with a positive radiofrequency ablation outcome was a positive outcome from a true diagnostic block, with medial branch and intraarticular injections having comparable prognostic value. The difference in radiofrequency ablation outcomes between the treatment groups and the control group was small but statistically and clinically meaningful. Finally, the authors found no meaningful benefit at one month or subsequent time points between either of the true injections and the placebo.

Intraarticular injections can be technically challenging, especially in the steep, frontally oriented thoracic facet joints.[197] In addition, MBB involves anesthetization of the nerves to be lesioned and hence may serve as a "dry run" before definitive treatment, similar to performing a selective nerve root block before surgical decompression. Multiple guidelines, including those by the 14 participating federal and international organizations,[185] have endorsed lumbar medial branch blocks but not intraarticular injections based on face validity,[107] target-specificity,[24] and construct validity,[198] as a selection tool for medial branch neurotomy.[150] Given the lack of evidence for intraarticular injections as a superior diagnostic tool and the technical ease of performing MBB, MBB is recommended as the prognostic tool of choice for subsequent medial branch denervation.

False Positive Blocks

Numerous studies have found a high false positive rate for diagnostic facet blocks that appear unaffected by the type of block used (i.e. intraarticular or MBB). Published rates have ranged from 25% – 40% in the lumbar spine,[114,117,185,198] 58% in the thoracic spine,[124] and 27%–63% in the cervical spine.[47,117,125,161,199] A study showed high specificity and marginal sensitivity of serial local anesthetic cervical MBBs with lidocaine and bupivacaine.[200] Although high specificity will result in a low false positive rate, the low sensitivity predisposes patients to false negative diagnoses, thereby reducing access to care.

Reasons for false positive facet blocks are multifactorial and include a placebo response (18%–32%) to diagnostic interventions, use of sedation, liberal use of superficial LA, and spread of injectate to other pain-generating structures.[201] The International Facet Joint Guidelines Committee,[185] the American Society of Anesthesiologists,[202] and the Spine Intervention Society[203] all recommend against the routine use of sedation. Dreyfuss et al. used postprocedural CT scans following 120 fluoroscopically guided lumbar MBBs to assess the specificity and spread of contrast material.[31] Two target points were chosen: one at the superomedial border of the transverse process and a second lower site midway between the upper border of the transverse process and the MAL. In 16% of injections, contrast material was noted to spread into the intervertebral foramen or epidural space, which was more common at the upper target point. In all cases, distal spread into the cleavage plane between the multifidus and longissimus muscles was noted. The injectate volume (0.5 mL) bathed the target in every case, leading the authors to conclude that lower volumes may be adequate. In a study of 24 patients undergoing cervical MBB, Cohen et al. investigated the spread of LA (0.5 mL versus 0.25 mL) mixed with contrast agent.[188] MBBs were performed in either the prone or lateral position. CT scans were conducted following MBBs to assess aberrant spread. Blocks performed in the 0.25 mL group resulted in aberrant spread to untargeted adjacent levels and into the intervertebral foramina less than half as often as those in the 0.5 group. There were six "missed" medial branches in the 86 blocks performed, which were evenly distributed between the groups. These findings indicate that lower volumes may enhance specificity without affecting sensitivity.

To reduce the amount of superficial anesthetic used for MBB, Stojanovic et al. introduced a single-needle technique whereby multiple medial branches are blocked via a single skin entry point.[204] In a prospective crossover study comparing the single-needle and conventional multiple-needle techniques, the authors found that the single-needle technique required significantly less superficial LA, resulted in less procedure-related pain, and was faster to perform than the multiple-needle approach.[205] With regard to the final needle position, spread of contrast material, and postprocedural pain relief, no differences were noted between the two techniques.

False Negative Blocks

Similar to false positive blocks, false negative blocks may result from many factors. The prevalence of false negative blocks can never be known for certain in the absence of a pathognomonic reference standard, but in a retrospective study by Derby et al.,[206] the false negative rate (determined by a subsequent positive block using 70% pain relief as the cutoff) was 47% in individuals who obtained <50% relief and 47.1% in those who experienced 50%–69% relief, with 75% of these patients achieving ≥50% pain relief after radiofrequency ablation. One study estimated the incidence of false negative lumbar MBBs attributable to non-medial branch aberrant innervation to be approximately 11%.[150] A person whose facet joints are innervated by nerves other than the medial branches can theoretically respond to intraarticular blocks but fail to derive relief with technically successful medial branch neurotomy. Venous uptake of LA was reported to occur in 8% of lumbar facet blocks in one study,[31] and 33% in another.[149] In one of these studies, even after the needle was repositioned following vascular uptake, the injection of LA failed to prevent pain from capsular distention in 50% of subjects.[149] This has led some purists to advocate aborting medial branch blocks when intravenous uptake is detected.[149] In a study involving more than 1400 lumbar MBBs in 456 patients, Lee et al. found a 6.1% rate of uptake of LA, which was detected in 34% of the patients by aspiration and in 59% by spot fluoroscopy.[207] Digital subtraction angiography is considered the reference standard for detecting intravascular uptake during medial branch blocks. One large study found a 19% incidence of vascular uptake with digital subtraction, compared with 11% using real-time contrast administration and 6.7% with aspiration. One of the biggest causes of false negative blocks is the failure of patients to properly distinguish procedure-related pain from their index pain, which underscores the need for proper patient education (Box 31.1).

How Many Blocks Should Be Performed Before Radiofrequency Denervation?

Many experts and organizations advocate performing multiple diagnostic blocks to reduce the high false positive rate.[208,209,210] There are two problems with this argument. First, reducing the

• BOX 31.1 Interventions That May Reduce the Incidence of False Positive and False Negative Lumbar Facet Blocks

1. Perform placebo-controlled blocks or, if not possible, comparative local anesthetic blocks.
2. Aim for a lower target point on the transverse process.
3. Reduce the injectate volume to 0.5 mL or less.
4. Be judicious with the use of superficial anesthesia.
5. Consider a single-needle approach.
6. Consider using guidance with computed tomography when doing intraarticular injections in patients with severe spondylosis.
7. Avoid the use of sedation or opioids.
8. Use dye to identify vascular uptake and confirm spread to neural targets.
9. Use small needles to reduce procedure-related pain.

false positive rate is important when trying to establish "efficacy" but may be counterproductive when one's objective is "effectiveness," which seeks to maximize outcomes under real-life conditions. To illustrate this point, many controlled studies evaluating RF denervation have screened hundreds of patients to enroll several dozen subjects. Although the results of a positive study are cited many times, the ultimate outcomes of hundreds of patients excluded from participation remain unknown. Second, many of these "false positive" blocks may include "false negatives."[148,211–213] Although performing multiple blocks will reduce the false positive rate, it will inexorably increase the false negative rate, which reduces access to care. Eliminating placebo responders may not only be impossible but also impractical since the benefits experienced from a positive "sham" intervention are indistinguishable from those experienced with a "true" intervention.[214]

In an attempt to determine the ideal number of diagnostic blocks under "real-life" circumstances, Cohen and colleagues performed a randomized, comparative cost effectiveness study in which 151 patients were allocated in an equal ratio to receive lumbar facet RF denervation without MBB, after a positive response to one MBB performed with bupivacaine, or only after a concordant response to comparative blocks performed in random order with lidocaine and bupivacaine.[215] Predictably, a higher RF success rate was found in the double-block group, which is consistent with the use of this treatment paradigm in clinical efficacy trials. However, the overall number of patients who experienced a successful outcome at three months was significantly higher in the zero-block group (n = 17) than in the single- (n = 8) and double-block (n = 11) groups. Moreover, the cost per effective treatment and the overall costs in the zero-block group were less than half of those in the other two groups. The results of this study are bolstered by theoretical computations that have determined that "double blocks" are not cost effective at current reimbursement rates.[216]

Similar comparative effectiveness studies have not been performed for cervical facet joint pain.[217] However, because the relative reimbursement rates between diagnostic blocks and RF denervation are comparable in the neck and facetogenic pain accounts for a higher proportion of chronic neck pain than chronic LBP, these results are likely to be reliably extrapolated to cervical facet joint RF denervation. The use of a single block is advocated by the International Lumbar Facet Guidelines Committee.[185] These guidelines also advocate a personalized approach, such that an older person with paraspinal tenderness and severe facet joint degeneration on anticoagulation could receive RF ablation without a screening block. In contrast, double blocks should be considered in a clinical trial or a young athlete with a diffuse pain phenotype.

Intraarticular Steroid Injections: Are They Diagnostic, Therapeutic, Or Both?

There is controversy regarding the use of intraarticular LA and steroid injections to diagnose and treat facet pain.[218] In uncontrolled studies, success rates in individuals undergoing intraarticular steroid injections range from 18%–63%, with most of these studies being conducted in patients who did not undergo diagnostic screening blocks.[105,143,148] Unlike medial branch blocks, which may result in false positive diagnoses by blocking non-medial branch nerves, and false negative diagnoses in patients with non-medial branch innervation, intraarticular injections technically meet the criteria for a "diagnostic" intervention. However, the high technical failure rate (which can lead to false positives and false negatives) and significant procedure-related pain in technically challenging blocks (which can lead to false negatives) undermine the diagnostic value of intraarticular injections.[185]

The results of controlled trials evaluating the diagnostic and therapeutic value of intraarticular injections have been mostly negative (Table 31.4).[105,144,186,218–223] A single-blind, triple crossover study[224] that compared lumbar intraarticular placebo injections, sham (needle placement outside of the joints without injection) procedures, and verum injections found equivalence between true and placebo injections and partial equivalence between verum and sham procedures, with a high placebo response. The authors concluded that a single intraarticular lumbar facet injection had little diagnostic value. In a large study, Lilius et al.[219] found no significant differences in the outcomes of 109 patients who received large-volume (8 mm) LA and steroid injected into two lumbar facet joints, the same mixture administered around the joints, or physiologic saline. In another study comparing intraarticular steroid and saline in 97 patients with chronic LBP, Carette et al. found a statistically significant benefit only at the six month mark in the steroid group.[220] Barnsley et al. randomized 41 patients with chronic neck pain following an MVA to receive 1 mL of either intraarticular bupivacaine or betamethasone under double blind conditions.[221] The median time to return of 50% of the patient's pre-injection pain was three days in the steroid group and 3.5 days in the LA group, with less than half of the patients reporting pain relief lasting longer than one week. All patients in this study were prescreened for cervical z-joint pain via comparative MBB.

Basic science studies demonstrating inflammatory mediators around degenerated facet joints form a theoretical underpinning for the potential benefit of intraarticular steroids.[16,17] There is some evidence to support this assertion, as evidenced by several prospective and observational studies that evaluated low to intermediate volume (1–3 mL) LA and steroid intraarticular lumbar facet joint injections performed in more than 160 patients with axial LBP.[176,191,222,223] In these studies, patients with positive SPECT findings experienced better pain relief (>75% success rate) than those with no SPECT findings (<40% success rate) up to three months after injection. In two earlier studies that monitored patients for six months post-injection, the beneficial effect wore off after three months.[218,222] However, two recent high quality studies have also questioned the therapeutic efficacy of intraarticular joint injections. A double blind, placebo-controlled study by Kennedy et al.[225] used comparative medial branch blocks as the diagnostic

criterion to enroll 28 patients with lumbar facetogenic pain. The authors found that corticosteroids injected into the z-joints were ineffective in reducing the need for radiofrequency neurotomy, although their primary endpoint changed. A two phase, placebo-controlled trial by Cohen et al.[105] (FACTS study) randomized 229 patients in a 2:2:1 ratio to receive intraarticular lumbar facet injections, medial branch blocks, or a placebo. The main conclusions of this study are as follows.

- The failure rate of intraarticular injections is substantial, 29% per technical joint.
- The strongest factor associated with a positive RFA outcome was a positive diagnostic block.
- Medial branch blocks and intraarticular injections had comparable prognostic value for radiofrequency ablation, with both being superior to placebo injections.
- Intraarticular facet injections are not therapeutic in most people.

Diagnostic/Prognostic Blocks

Diagnostic blocks involve technical acumen and variables such as an understanding of anatomy and the literature, communication skills (i.e. explaining to patients to engage in normal activities and discount procedure-related pain), and interpretation of what is often conflicting information. Diagnostic blocks help practitioners choose patients who are likely to benefit from radiofrequency denervation. The basic problem is that they rely on subjective measures over short periods. Although blocks may refine the selection and improve outcomes, they rarely provide a definitive diagnosis.

Treatment

Conservative Treatment and Pharmacotherapy

A multimodal approach for the treatment of facetogenic pain is essential. Although many patients seen in interventional pain medicine clinics will receive a procedural approach to therapy, there is value in conservative therapy, medical management, and, when indicated, psychotherapy. Pharmacotherapy, psychotherapy, and non-interventional integrative treatments of spinal pain have been investigated, but no study has evaluated these alternatives specifically in patients with facet pain. Currently, the international facet joint guidelines recommend at least three months of conservative care before proceeding with procedural interventions.[185]

Regenerative Treatments

In the past 10 years, numerous studies have been performed to evaluate treatment options in which the body's own healing armamentarium could be used to treat degenerative pathologies such as facetogenic spinal pain. These treatments aim to potentiate and assist the normal healing process of the body in damaged tissues. Many substances have been studied to determine whether the normal course of tissue degeneration can be altered.

- Platelet-rich plasma (PRP): PRP is a concentrate of whole blood centrifuged to obtain plasma rich in growth factors and platelets acquired from autologous blood. The basis for PRP is that platelets are essential in anabolic healing processes.[226,227,228] Although several studies have demonstrated benefit from intraarticular PRP, large, randomized controlled studies are lacking.[229–231]
- Mesenchymal signaling cells: Mesenchymal signaling cells (MSCs) are cells capable of proliferation and differentiation into cells that promote tissue regeneration.[232] They are present in several tissues (blood, adipose tissue, and muscle) and possess both immunomodulatory and anti-inflammatory effects.[233] They can be harvested from bone marrow or adipose tissue. No study has evaluated the injection of MSCs into facet joints, although promising results have been obtained for other synovial joints.[234]

Guidelines by the American Society of Interventional Pain Physicians reported that the level of evidence for regenerative treatments for lumbar facet joint pain was IV out of V, based on mostly low quality studies.[235] The authors concluded that regenerative therapies should be provided to patients as a stand-alone treatment or in conjunction with other therapies, following diagnostic evidence of pathology likely to respond to therapy. Recent studies have also evaluated biologic replacements for degenerated and painful facet joints.[236] Several scaffold-based approaches are currently being investigated, with some clinically available for the knee and other large joints. New 3-D printers are capable of producing shape-specific cartilage to replace facet joint cartilage.[237] Despite these promising strategies, the evidence supporting biologic and surgical replacement therapies are weak to non-existent.

Therapeutic Medial Branch Blocks

In a series of prospective, randomized evaluations of repeated therapeutic MBB with LA, LA plus sarapin, LA plus steroid, and LA plus steroid and sarapin, Manchikanti et al. reported significant relief of lumbar,[238] thoracic,[239] and cervical facet pain,[240] in more than 85% of individuals in all groups for up to two years. Patients were screened with comparative LA blocks, but the studies lacked a placebo or sham group, and a large percentage of patients were on opioids. No differences were found with the addition of either steroids or sarapin to LA. Although a small percentage of patients may derive long-term benefits from diagnostic MBB either from a placebo response, from "breaking the cycle of pain," or, in rare instances, from the anti-inflammatory effects of steroids on a medial branch trapped beneath the MAL, most studies have failed to corroborate these findings.[137,185]

Several other studies have evaluated the therapeutic potential of MBBs. In a non-randomized, placebo-controlled study, Dias da Rocha et al.[241] found that in 52% of 104 patients who responded to lidocaine MBB, two-thirds experienced persistent relief at three months. However, older randomized trials comparing MBB to IA injections[148,186] found sustained benefit at 1 month in only a small percentage of patients. More recently, a large, well-designed placebo-controlled study comparing MBB with LA and steroids, IA injections with LA and steroids, and placebo injections found no significant difference between groups at the one month follow up, with only 11% of MBB patients experiencing at least a two point reduction in average back pain score.[105] The concept that blocking the medial branch with or without steroids can lead to sustained pain relief is also inconsistent with randomized controlled trials evaluating RFA in patients who responded to MBB with significant but short-term benefits. Among the several trials evaluating medial branch RFA that reported the number of patients who obtained persistent pain relief from MBB, only the study by Nath et al.[243] noted a substantial percentage of patients who obtained prolonged relief. Overall, the international facet joint guidelines assert that there is little supporting evidence for the prolonged benefit from MBB.[185]

Pulsed Radiofrequency of the Medial Branch and Facet Joint

Pulsed radiofrequency (pRF) is a non-invasive technique that has been used for the treatment of chronic pain. The conceptual appeal of pRF is that it acts via the creation of an electrical field, beneficial alterations in gene expression, and enhancement of descending modulatory systems, resulting in minimal nerve damage.[244] Unlike conventional RF, which injures nerves that can lead to deafferentation pain (in nerves containing A-β fibers), muscle weakness (in nerves containing motor fibers), and neuroma formation (which can result in ectopic discharges), pRF is frequently used as a treatment for neuropathic pain, in which nerve damage is the underlying cause of the pain.[245–250]

Two clinical trials compared the conventional RF with pRF. Kroll and colleagues[251] randomized 50 patients who achieved >50% relief after two MBBs to continuous RF or pRF. Although no significant differences between groups were found at the three month follow up, a comparison of within-group differences revealed greater improvements in pain and disability in conventional RF patients. This study was underpowered to detect between-group differences. In the second study, Tekin et al.[252] randomized 60 patients with a positive response to a single MBB to either sham RF (LA only), pRF, or continuous RF. All groups, including the LA only group, showed improvements in pain and disability. However, the magnitude of improvement and duration of benefit was significantly greater in the continuous RF group. A randomized, double blind study was conducted by Çetin et al.[253] comparing continuous radiofrequency neurotomy to pRF in 118 patients with injection-confirmed lumbar facet joint pain. The authors found that continuous radiofrequency was superior to pRF in both the short and long term for pain reduction and satisfaction. In summary, the current state of evidence does not support pRF in the treatment of facet joint pain.

Radiofrequency Denervation (see also Chapter 66 Radiofrequency Treatment)

Although percutaneous rhizotomy was first described by Rees in 1971,[255] the technique of percutaneous RF lesioning is generally credited to the neurosurgeon Norman Shealy.[256,257] For lumbar facet RF denervation, most studies report sustained relief in 50%–80% of patients without previous back surgery,[158,258] whereas 35%–50% of subjects with failed back surgery syndrome obtain prolonged relief.[158,259–261] In the only study comparing outcomes of cervical z-joint denervation in operated and non-operated spines, Cohen et al. found no difference in success rates between patients with failed neck surgery syndrome and those who had never undergone surgery.[157] Reasons by which prior surgery might predispose patients to treatment failure include altered anatomy, greater baseline disease burden including opioid use, and a higher incidence of false positive diagnostic blocks.[185]

Lumbar Radiofrequency Neurotomy

Several randomized and numerous uncontrolled studies have evaluated the effectiveness of lumbar and cervical radiofrequency neurotomy and reported variable results. These studies are summarized in Table 31.5.

A key flaw in many studies is the failure to select patients based on placebo-controlled or even comparative LA blocks, which are now acknowledged to be inferior to placebo controls. Although double blocks are often impractical and will inevitably result in a lower overall success rate with a higher total cost, elimination of "false positive" responders is ideal for studies that seek to establish efficacy. Because the anatomy of the lumbar spine makes it more difficult to position electrodes to create large lesions that enhance the likelihood of capturing the target nerve, practitioners should ideally insert the cannulas at a sharp cephalad-medial angle so that they are situated near parallel to the medial branches. In most randomized trials evaluating lumbar facet RFA, electrode positioning was suboptimal, including the Leclaire,[193] Gallagher,[192] van Kleef,[195] van Wijk[194], and MINT studies.[262] However, some may construe these findings as evidence that RF denervation is a fundamentally flawed treatment. A more plausible interpretation is that they indicate a strong need to optimize RF denervation techniques and better identify candidates likely to obtain positive outcomes. Among randomized studies, those that have employed more stringent selection criteria (i.e. lower enrollment rates) and utilized optimal lesioning strategies are more likely to report positive outcomes.

Thoracic Radiofrequency Neurotomy

As noted above, an older observational study performed in 40 patients reported an 83% success rate for thoracic medial branch RFA at a mean follow up of 31 months.[263] Other small, retrospective studies have reported success rates of 40% and 68% at variable follow ups. The main challenge with thoracic facet RFA is the highly variable locations of the thoracic medial branches.[41] This is one reason aggressive lesioning strategies such as bipolar RFA, cooled RFA, and creating multiple lesions have been advocated.[264,265]

Cervical Radiofrequency Neurotomy

Only three randomized, double blind trials have evaluated percutaneous RF denervation for cervical facet pain (Fig. 31.7). Lord et al. randomized 24 patients with whiplash injury following an MVA and a positive response to diagnostic, placebo-controlled cervical MBB to receive either cervical medial branch denervation or a sham procedure.[129] Patients with pain stemming solely from the C2-3 z-joint were excluded. A series of three blocks were performed to diagnose cervical facet pain, including a placebo block. A block was deemed positive if the patient had complete, concordant relief each time an LA was used but no relief with saline. At each level, two to three lesions were created. The mean time for a return to 50% of baseline pain was 263 days in the RF group and eight days in the placebo group. At 27 weeks, seven patients in the RF group and one patient in the control group remained pain free. Five of the patients in the RF group had numbness in the territory of the treated nerves, but none considered it troublesome.

In a 2004 study, Stovner et al.[266] randomized 12 patients in whom cervicogenic headache was diagnosed based on clinical symptoms to receive either cervical facet RF denervation or a sham procedure. Although the authors performed medial branch and greater occipital nerve blocks, the results were not used to select patients. The study was halted early secondary to the failure to enroll the subjects. At the three month follow up, four of six patients in the RF denervation group obtained a meaningful clinical response versus two of six patients in the sham group. At six months, no differences were noted between the groups. The results of sham denervation in this study are comparable to those of a previous uncontrolled study that evaluated RF for cervicogenic headache in which patients reported a 34% reduction in symptoms.[267] In 2021, van Eeerd et al. randomized 76 patients to cervical MBB with bupivacaine and sham RFA or medial branch RFA. Patients were selected based on clinical presentation and radiographic findings, without prognostic blocks. Through 6-month follow-up, the benefits favoring the RFA group for pain and patient global impression of change did not significantly differ from the MBB

TABLE 31.5 Outcomes Studies Assessing Medial Branch Radiofrequency Denervation for Lumbar, Thoracic, and Cervical Facet Joint Pain

Study, Year	Number and Type of Patients	Follow Up Period and Methodologic Scores	Results	Comments
Gallagher et al.[192] 1994	41 pts with chronic LBP who obtained "clear-cut or equivocal" relief from single intraarticular facet joint injections with LA and steroid. 18 pts with a good response and six pts with an equivocal response underwent RF denervation. 12 pts with a good response and five with an equivocal response underwent sham denervation.	• Six months • MQ = 2 • CR = 6	Significant differences in pain scores were noted only between patients with a good response to LA blocks who underwent true RF denervation (n = 18) and those with a good response who underwent sham treatment (n = 12) through six months.	Did not define "good" or "equivocal" response. Anatomic landmarks were not well described. Observers were not blinded. Electrode not placed parallel to the nerve. In "Methods" stated that only LA was used, but in abstract stated that LA and steroids were used
Lord et al.[51] 1996	24 pts (12 per group) with chronic neck pain after MVA. Included pts with a (+) response to placebo-controlled diagnostic blocks. Randomized to undergo true RF at 80°C for 90 s or 37°C (placebo treatment) between C3 and C7 according to response to diagnostic blocks.	• Three months (12 months in pts with persistent relief) • MQ = 5 • CR = 8	The mean time to return 50% of preoperative to pain was 263 days in the RF group and eight days in the placebo group. At 27 weeks, seven points in the RF group and one in the control group remained pain free.	Excluded pts with solely C2-3 facet pain. Five pts in the RF group reported numbness in the territory of treated nerves.
van Kleef et al.[195] 1999	Subjects were 31 pts with chronic LBP who obtained ≥50% pain relief after a single MBB (one dropout). Compared true denervation with sham.	• 12 months • MQ = 5 • CR = 8	After three months, nine of 15 pts in the lesion group vs. four of 16 in the sham group had ≥50% pain relief. At one year f/u, seven of 15 in the lesion group and two of 16 in the sham group had ≥50% relief.	Used 0.75 mL of injectate for diagnostic blocks. Electrode not placed perpendicular to the target nerve. Used multifidus rather than sensory stimulation to identify the medial branch. Used 60 s lesions.
Leclaire et al.[193] 2001	Subjects were 70 pts with chronic LBP who obtained "significant" pain relief lasting >24 h after a single intraarticular facet injection of lidocaine and steroid (four dropouts). Compared true denervation with sham.	• 12 weeks • MQ = 4 • CR = 8	At four weeks, there were modest improvements in Roland-Morris (P = 0.05) and VAS (P = NS) pain scores, but not the Oswestry score. No difference in any outcome measure at 12 weeks.	Did not define "significant pain relief" with diagnostic injection. Inclusion criterion of >24 h pain relief is inconsistent with the pharmacology of lidocaine. Performed two lesions, each for 90 s. Anatomic landmarks not noted. Electrode not placed parallel to the nerve.
Stovner et al.[266] 2004	12 pts with unilateral cervicogenic HA received comparative LA blocks and a greater occipital nerve block. Randomized to cervical facet RF or sham procedure.	• 24 months • MQ = 4 • CR = 7	At three months, four of six RF pts had a meaningful clinical response (≥30% improvement), as did two of the six in the sham group. Six months after the procedure, no differences were noted between groups.	The RF group had a better response to diagnostic blocks. Able to recruit only 12 pts in 2.9 years. Excluded pts with ongoing litigation. Diagnostic blocks were not used to select RF patients.
Van Wijk et al.[194] 2005	81 pts with chronic LBP who obtained ≥50% pain relief after two-level intraarticular facet injection of LA (no dropouts). Compared true denervation with sham.	• 12 months • MQ = 5 • CR = 7	No significant difference at three months for combined outcome measure (pain score, physical activity, and analgesic intake). The global perceived effect was greater in the treatment group at three months.	Improvement in pain scores persisted throughout the 12 month f/u. Used 60 s lesions.

TABLE 31.5 Outcomes Studies Assessing Medial Branch Radiofrequency Denervation for Lumbar, Thoracic, and Cervical Facet Joint Pain—cont'd

Study, Year	Number and Type of Patients	Follow Up Period and Methodologic Scores	Results	Comments
Tekin et al.[252] 2007	60 chronic LBP pts with ≥50% relief from a single MBB at either L1-3 or L3-5 received either sham, pulsed RF, or RF denervation.	• 12 months • MQ = 4 • CR = 8	Continuous RF was better than pulsed RF and sham for pain. No significant difference between sham and pulsed RF. Regarding improvement in disability, continuous RF and pulsed RF were better than sham.	Used 0.3 mL diagnostic MBBs. The proper technique was used for MBB and RF.
Nath et al.[243] 2008	40 pts with chronic LBP with ≥80% relief from three LA facet blocks.	• Six months • MQ = 4 • CR = 6	RF group fared better than the control group for all outcome measures, though benefits were modest.	40 of the 376 screened were randomized. Created six empirical lesions without stimulation.
Civelek et al.[271] 2012	100 patients with LBP were randomized to receive a medial branch block or radiofrequency neurotomy.	• 12 months • MQ = 2 • CR = 4	Medial Branch block was more effective at one month than radiofrequency, but at six and 12 months, RFA pts had better results.	Myriad methodologic flaws including lack of blinding, suboptimal RF technique, and lack of prescreening with diagnostic MBB.
Lakemeier et al.[242] 2013	56 patients with axial LBP were randomized in a double blind fashion to intraarticular steroids with sham RFA or medial Branch RFA.	• Six months • MQ = 1 • CR = 4	Both intraarticular and RFA groups improved with no significant differences between them.	Methodologic flaws in the study included intraarticular block rather than MBB screening; suboptimal RFA technique; permitted analgesic co-interventions.
Moussa et al.[272] 2016	A prospective randomized controlled trial where 120 patients with injection-confirmed lumbar facet joint pain were randomly divided into three groups: radiofrequency coagulation of the facet joint capsule, radiofrequency denervation of the medial branches, and sham radiofrequency lesioning.	• Three years • MQ = 4 • CR = 8	Both RF groups > control group. RF of the facet joint capsule = RF of the medial branches through 1-year, but superior to RF of the medial branches after one year.	Use of RFA not validated for capsular denervation. All groups also received a local anesthetic and steroid injection. Two lesions were created in the capsule, three along the medial branches. Used small electrodes with a short heating time.
Van Tilburg e al.[273] 2016	A randomized placebo-controlled double blind multi-center trial was performed in 60 patients with chronic LBP. The active group was treated with radiofrequency and the sham with lidocaine and placebo RFA.	• Three months • MQ = 4 • CR = 6	No difference between groups.	Required less than 50% pain relief for a positive block; 79% of blocks positive. Suboptimal technique (perpendicular electrode orientation, short heating time). Permitted co-interventions.
Juch et al.[262] 2017	The MINT study consisted of three pragmatic multi-center, nonblinded randomized clinical trials that evaluated the effectiveness of RFA treatments for participants with chronic LBP. The facet joint trial contained 251 participants.	• 12 months • MQ = 3 • CR = 6	Radiofrequency denervation combined with a standardized exercise program resulted in no clinically important improvement in chronic LBP compared with a standardized exercise program alone.	Myriad flaws included >70% positive rate for diagnostic blocks, that patients with a negative block in one study proceeded to blocks for another study, permitted psychological and exercise co-interventions, and suboptimal technique.

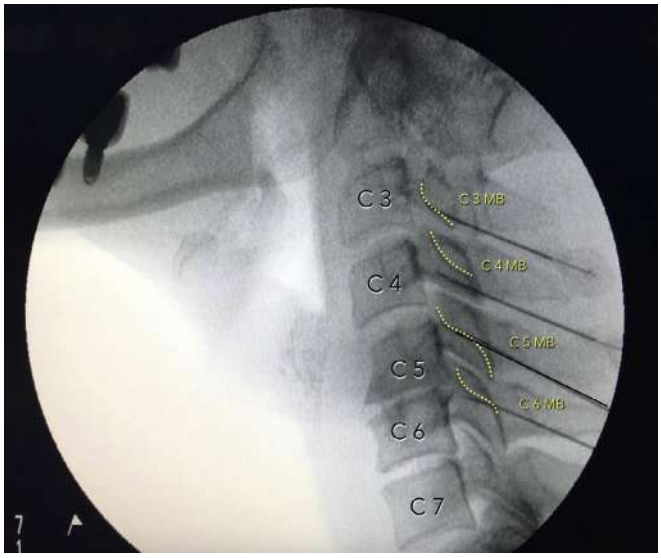
TABLE 31.5 Outcomes Studies Assessing Medial Branch Radiofrequency Denervation for Lumbar, Thoracic, and Cervical Facet Joint Pain—cont'd

Study, Year	Number and Type of Patients	Follow Up Period and Methodologic Scores	Results	Comments
Kennedy et al.[225] 2018	This double blind, controlled trial randomized 24 patients to receive intraarticular corticosteroid (triamcinolone 20 mg) or saline via fluoroscopic guided injection.	• Six weeks • MQ = 4 • CR = 8	Corticosteroid injections into the lumbar facet joints were ineffective in reducing the need for radiofrequency neurotomy of the medial branches in those with facet joint pain confirmed by comparative medial branch blocks.	Pain scores and function were not recorded. Diagnostic MBB was performed with 0.2 mL.
Cohen et al.[105] 2018	This multi-center randomized study randomized 229 patients in a 2:2:1 ratio to receive intraarticular facet injections with bupivacaine and steroid, medial branch blocks, or saline.	• Three months • MQ = 5 • CR = 9	No long-term benefit for intraarticular steroids or MBB. Individuals who received MBB or IA injections had a greater reduction in pain after RFA.	This study confirmed the lack of long-term efficacy for intraarticular and medial branch facet blocks but supports their use as prognostic tools.

The methodologic quality (MQ) score was based on the five point Jadad scale.[223] A score of three or greater indicates high methodologic quality. The clinical relevance (CR) score was based on patient selection parameters and description of the RF technique (zero to nine scale) as described by Geurts and colleagues.[319]

f/u, Follow up; *HA*, headache; *LA*, local anesthetic; *LBP*, low back pain; *MBB*, medial branch block; *MVA*, motor vehicle accident; *NS*, not significant; *pts*, patients; *rec'd*, received; *RF*, radiofrequency; *VAS*, visual analog scale.



• **Figure 31.7** Lateral view of obliquely-placed electrodes targeting the cervical medial branches. Note that the electrodes are inserted in a cephalad direction in the center of the articular pillar, after which they may be adjusted based on stimulation parameters. *MB*, Medial branch.

group, but the benefits lasted longer (median duration of benefit 42 vs. 12 months).[268] In an open-label prospective study comparing cervical z-joint RF results between litigant and non-litigant patients with whiplash injuries, Sapir and Gorup found no significant differences between groups in one year outcomes.[269] Potential reasons for limited RF success rates for chronic neck pain and cervicogenic headache include technical difficulty denervating the frequently affected C2–3 facet joint, concomitant sources of head pain, and lack of specificity for diagnostic injections. As noted above, the higher pre-test probability of neck pain arising from the facet joints (i.e. lower false positive rate and higher false negative rate) and a greater likelihood of nerve capture during RFA (electrodes can be placed parallel to the nerve in a smaller area) have led some investigators to forego any diagnostic blocks. As a prelude to their randomized, controlled trial that did not utilize prognostic blocks, van Eerd et al.[270] performed a retrospective review of 65 patients who underwent a modified posterolateral RFA procedure based solely on clinical findings. The rationale for performing RFA without a diagnostic block is based on 1) the lower false positive rate in the cervical spine because of a higher prevalence rate of facetogenic pain in individuals with neck pain than in those with LBP; 2) the lower variability in location for the cervical than the lumbar medial branches; and 3) the greater ease in targeting them with electrodes oriented parallel. The authors reported a 55% success rate at the two month follow up. However, in their follow up sham-controlled trial using the same approach, the authors found no significant differences between the group that received RFA and those who received medial branch blocks and placebo RFA, through with both groups achieving >50% success rates.[268]

Outcome studies on cervical radiofrequency denervation are summarized in Table 31.5.[271–273]

Use of Neurostimulation

Generally, a threshold of 0.5 V or less is deemed sufficient to create a lesion that encompasses the target nerve, although the margin of error can be increased using techniques that enhance lesion size. Although sensory stimulation may indicate close proximity to the target nerve at this voltage, many patients perceive concordant stimulation at 0.5 V or less even when the electrode is purposefully placed in muscle, as during a sham procedure. In a prospective study involving 61 patients, Cohen and colleagues[274] found no correlation between the mean sensory threshold and lumbar RF denervation outcomes. Although one might construe this to mean that sensory stimulation is not necessary, it should be emphasized

that sensory thresholds in these patients were recorded only after repeated electrode adjustments. In addition to nerve proximity, other factors that can affect sensory stimulation include age, sex, inherent pain perception, analgesic therapy, the use of sedation, and the presence of comorbidities such as diabetes. An alternative or complement to sensory stimulation in the lumbar and cervical spine regions is to elicit multifidus or other paraspinal muscle contraction since the medial branch that innervates the lumbar facet joint also supplies this paraspinal muscle. The 2020 International Lumbar Facet Joint guidelines[185] provided a grade C recommendation for sensory stimulation and a grade B recommendation for motor stimulation. In the cervical spine, there is a reported case of permanent head drop in a patient who underwent bilateral cervical medial branch RFA without the use of motor stimulation.[275]

Meta-analysis on Radiofrequency Denervation

Several meta-analyses of radiofrequency denervation have reached different conclusions. A meta-analysis published in 2014 by Poetscher et al.[276] concluded that RFA of lumbar facet joints was more effective than placebo and possibly more effective than steroid injections. A 2015 Cochrane systematic review by Maas et al.[277] concluded that there was no high quality evidence suggesting that RF denervation provides pain relief or functional improvement in patients with chronic LBP. They also found that the quality of evidence for RF denervation in chronic LBP ranged from very low to moderate. In 2017, a meta-analysis by Lee et al.[278] concluded that conventional radiofrequency denervation resulted in significant reductions in LBP originating from the facet joints in patients with a positive response to diagnostic blocks over 12 months when compared with sham procedures or epidural nerve blocks. Manchikanti et al. performed several systematic reviews evaluating cervical[279] and lumbar[280] facet radiofrequency denervation. In the cervical spine, the authors concluded that there was level II for the long-term effectiveness of radiofrequency neurotomy. In the lumbar area, they found moderate evidence supporting radiofrequency neurotomy for chronic LBP.

Another comprehensive systematic review published by Schneider[281] in 2019 sought to determine the effectiveness of lumbar medial branch thermal radiofrequency neurotomy based on different selection criteria and procedural techniques. The authors found that the best outcomes were achieved when patients were selected based on high degrees of pain relief from dual medial branch blocks, using a technique employing parallel electrode placement.

Factors Associated With Outcome

In a multi-center study, Cohen et al. identified factors associated with successful RF treatment in 192 patients who underwent lumbar facet denervation after a single positive MBB.[158] Among the 15 variables analyzed, only paraspinal tenderness was found to predict successful treatment. Factors associated with failed treatment included increased pain with hyperextension and axial rotation (i.e. facet loading), duration of pain, and previous back surgery. The latter two variables have been associated with treatment failure for RF denervation and a host of other LBP interventions including epidural steroid injections and surgery.[282–284] A study performed on the cervical spine by the same group of investigators found similar results. The only variable associated with a positive outcome was paraspinal tenderness. Factors associated with a negative outcome included opioid use, radiation to the occiput, and pain worsened by extension rotation maneuvers.[157] Streitberger et al.[285] performed a prospective study in 275 individuals and found that depression was associated with a shorter duration of benefit after lumbar medial branch RFA. In a retrospective study involving 111 people by Conger et al.,[286] the authors found that a larger Cobb angle and older age foretold lumbar medial branch RFA treatment success. More recently, Cohen et al.[287] performed a prospective observational study in 318 patients to determine predictors of treatment results for minimally invasive low back interventions in general, including medial branch RFA. They found that older age, shorter duration of pain, lower baseline pain scores and functional disability, absence of secondary gain, absence of concomitant pain and psychiatric conditions, and having less non-organic (Waddell) signs were associated with treatment success. A negative correlation between Waddell signs and facet treatment outcomes was previously reported by Lilius et al.[219] for lumbar facet intraarticular steroid injections.

Repeating Radiofrequency Denervation

When pain returns following RF denervation, which typically occurs between six months and one year, neurotomy can be repeated with similar efficacy.[288,289] In the cervical spine, the success rate for repeated RF denervation may be slightly higher than that in the lumbar spine. One systematic review reported a 59% success rate for repeat lumbar medial branch RFA based on two studies and an 88% repeat success rate for cervical medial branch RFA based on five studies.[290] The international lumbar facet guidelines[186] recommend repeating lumbar facet RFA in individuals who obtain at least three months of meaningful relief, up to twice per year, without repeating the prognostic block if the recurrence is similar to the pre-RFA pain pattern.[185]

High Intensity Focused Ultrasound Ablation and Other Novel Forms of Denervation

An alternative approach to RFA is high intensity focused ultrasound (HIFU) ablation, guided by magnetic resonance.[291,292] HIFU is a novel non-invasive technique whose target point is the entire facet surface, whereby nerve endings terminate to innervate the joint. Advantages of this technique include its non-invasive nature and that it does not entail radiation exposure.[293] Several other non-radiofrequency mediated forms of denervation have been described, including laser irradiation,[294] cryoablation,[295] and phenol, and alcohol injection,[296] some of which are limited by their lack of precision, which can theoretically result in extravasation of neurolytic substances into the intervertebral foramen, which can lead to numbness and/or weakness. However, there have been no randomized trials evaluating efficacy.

Surgery

Surgery is occasionally performed to treat facet arthropathy despite a lack of evidence supporting fusion for degenerative spinal disorders.[297,298] Not surprisingly, the results of studies evaluating the use of lumbar z-joint blocks to predict outcomes of lumbar arthrodesis are discouraging. The three studies that compared surgical outcomes between facet block responders and non-responders failed to show a difference between groups.[299–301] Bough and associates[131] conducted a retrospective review of 127 facet joints surgically removed from 84 patients in an attempt to correlate histologic evidence of facet degeneration with a provocative response to preoperative facet arthrography. Although the authors found the positive predictive value of concordant pain reproduction to be 85%, the negative predictive value was only 43%, which led them to conclude that provocative facet arthrography was of little value as a presurgical screening tool. In a prospective case series,

Lovely and Rastogi[302] found that 83% of 23 patients who responded to bracing and three facet blocks achieved 90% or greater pain relief after fusion surgery at the latest follow up. However, the large volumes used per block, the failure to exclude placebo responders, and the lack of a comparison group undermine the conclusions that can be drawn. Patients with lumbar z-joint pain might respond to arthrodesis because some surgeons, either purposefully or inadvertently, perform medial branch rhizotomies during pedicle screw placement. More recently, percutaneous fusion and open facet arthroplasty[303] have recently been used to treat facet joint pain, but there are no prospective outcome data for either procedure. In summary, there is no convincing evidence to support any surgical intervention for lumbar z-joint pain other than that resulting from a traumatic dislocation.

Complications

Serious complications are uncommon after facet interventions.[304] The metabolic and endocrine sequelae of intraarticular facet joint steroids have not been studied. However, based on extrapolation from epidural steroid injections, one would expect suppression of the hypothalamic-pituitary-adrenal axis for up to four weeks depending on the steroid used and elevated glucose levels for less than one week.[305,306] Although infrequent, a host of infections has been associated with intraarticular injections, including septic arthritis, epidural abscess, and meningitis, but these infections are rare following RF denervation.[307,308,309] Reports of spinal anesthesia and post-dural puncture headache have been published but are preventable using imaging in multiple views.[310,311]

A prospective study described complications associated with more than 7400 patient encounters and more than 43,000 individual facet injections in the cervical, thoracic, and lumbar spine,[312] with no serious complications reported. Intravascular injection was detected in 11.4% of patients overall, with the highest incidence in the cervical region (20%). In less than 1% of cases, patients experienced vasovagal reactions, bruising, and nerve root irritation. Catastrophic injuries have been reported, including a posterior circulation stroke during a C1–2 intraarticular steroid injection that was thought to be because of microvascular injury from accidental injection into the vertebral artery, and a case of head drop after bilateral cervical medial branch RFA.[275,313]

Numbness and dysesthesia have been reported after RF denervation but tend to be transient and self-limited. Burns are rare with RFA and may result from electrical faults, breaks in the insulation of electrodes, generator malfunction, and theoretically from the creation of large lesions in a thin individual with little soft tissue overlying the target nerve.[314] The most common complication following facet joint RF is neuritis, with a reported incidence of less than 10% in the lumbar spine but higher in the upper cervical spine.[315] In one study, the post-administration of corticosteroids or pentoxifylline was found to reduce the incidence of postprocedural pain following RF denervation.[316] However, a subsequent large retrospective study failed to find a reduction in neuritis in individuals administered post-RFA steroids vs. those who did not. Notably, one study found that steroids administered pre-RF lesioning reduced lesion size.[317,318]

Guidelines or Recommendations of Best Practice

Many pain societies have tried to establish guidelines to promote the best way to select patients and perform radiofrequency denervation. Below is a brief summary of the international working group guidelines for lumbar facet joint pain.[185]

1- Consensus Practice Guidelines on Interventions for Lumbar Facet Joint Pain From a Multispecialty, International Working Group

Authors: Cohen et al.

Societies: 12 international societies and the United States Depts. of Defense and Veterans Affairs

Designs: A modified Delphi method was used to answer 17 questions for guideline development. The USPSTF was utilized to grade the level of evidence and strength of recommendations.

Year: 2020

Recommendations:

1. There are no pathognomonic physical examinations or historical signs that can reliably predict the response to facet joint blocks in individuals with mechanical chronic LBP, although paraspinal tenderness may be weakly associated with a positive block.
2. There is weak or no evidence supporting the use of image tests for identifying painful lumbar facet joints prior to lumbar MBB or IA facet joint injections.
3. A three month trial of different conservative treatments is recommended before facet joint interventions.
4. CT or fluoroscopy (lower costs, faster time, and less radiation exposure than CT) is recommended for lumbar MBB. However, ultrasound may be helpful in patients in whom radiation exposure may be associated with potential harm (e.g. pregnancy) or in patients without obesity when radiographic or radiologic imaging is unavailable.
5. MBBs have limitations as a diagnostic tool related to aberrant lumbar facet joint innervation. They provide better predictive information for medial branch RF denervation than intraarticular injections.
6. MBB should be a prognostic screening test of choice before lumbar facet RFA. Intraarticular injections of corticosteroids may be of therapeutic value for certain populations in whom there is acute inflammation and in whom denervation may be relatively contraindicated but are unlikely to provide long-term benefit in most people.
7. Sedation should not be routinely administered for diagnostic or prognostic facet injections without reasonable indications.
8. Lumbar MBBs should be performed with ≤0.5 mL (total volume) to reduce spread to adjacent structures.
9. The routine use of therapeutic facet injections should be discouraged. However, in patients who are at risk of adverse consequences from RF denervation (e.g. young athletes, older individuals on anticoagulation therapy or with implantable cardiac devices) or in whom there is a strong likelihood of success (e.g. individuals who obtained prolonged relief from previous diagnostic injections with or without steroids), it may be reasonable to add steroids to a block to derive intermediate-term relief.
10. A ≥50% reduction in pain relief should be considered as a positive prognostic block to maximize access to care.
11. A single block is recommended as a prognostic block before RF denervation because of the significant false negative rate of blocks.
12. Creating larger lesions with reduced lesion variability may increase the likelihood of capturing the medial branch.
13. Near parallel placement of traditional electrodes (non-cooled electrodes) is recommended to maximize nerve capture.
14. Sensory stimulation is recommended when single lesions are anticipated; when multiple lesions are planned, the evidence for sensory stimulation is inconclusive. Motor stimulation should always be performed.

15. Recommendations for Avoiding Complications:
    a. Vascular penetration: Aspirating and visualizing the spread of contrast on real-time fluoroscopy while performing MBB can reduce false negative results. Non-heparin anticoagulants should be continued in the peri-procedural period for patients undergoing lumbar MBB or RF denervation.
    b. Procedural pain and numbness: Injection of steroids through the cannula after ablation may reduce pain and discomfort following RF denervation.
    c. Injury to the spinal cord or nerves: Adequate visualization of needles in true anteroposterior, oblique, and lateral views and absence of sensorimotor responses in a radicular distribution in response to test stimulation prior to RF may also reduce the probability of injury to the spinal cord and spinal nerve roots.
    d. Degeneration of spinal anatomy and musculature: Physical therapy regimens aimed at restoring the function of paraspinal muscles before and after RF denervation are recommended.
    e. Impact on implanted devices: Use of bipolar RF mode is preferable, along with consulting the device manufacturer and the specialist team that implanted the device.
    f. Tissue burns: Positioning large monopolar ground pads in an optimal location and orientation may prevent tissue burns.
    g. Impact on spinal instrumentation: Ensure that the RF cannula is not in contact with a pedicle screw to avoid thermal injury to tissues surrounding the implanted spinal hardware. Previous spine surgery is associated with a higher rate of false positive blocks and lower RFA success rate.
16. There should be different standards in selecting patients for radiofrequency ablation in clinical trials and clinical practice.
17. The lumbar medial branch RFA can be repeated on recurrence of baseline pain in patients who experience a minimum of three months of improvement (preferably six months improvement for multiple procedures) following a previous RF denervation.

Conclusions

Pain originating from the facet joints has long been recognized as a potential source of back and neck pain. The three most caudal lumbar facet joints, L3–4, L4–5, and L5–S1, are exposed to the greatest strain and are thus more prone to pathology. In patients with chronic neck pain, the C2–3 and C5–6 facet joints are most commonly affected clinically, while radiologic studies have shown that C3–4, C4–5, and C2–3 undergo the most degeneration. The exact prevalence of facet disease is unclear but maybe as high as 10%–15% in patients with axial LBP, 49%–60% in patients with chronic neck pain, and 42%–48% in patients with axial mid-back pain. By the age of 60 years, more than half of all symptomatic individuals will experience significant lumbar facet joint degeneration, with similar proportions in other spine regions.

No discrete historical data for physical findings are pathognomonic for facet arthropathy in any region. Paraspinous muscle tenderness appears to be the only physical examination finding reliably associated with a positive response to diagnostic blocks and RF of the medial branches; however, its specificity is unknown. The referral patterns for pain arising from the facet joints at different levels and different structures (e.g. facet joints and disks) overlap considerably. Reports on the correlation between CT and MRI evidence of facet arthropathy and the response to diagnostic lumbar facet blocks are conflicting. Since the facet joint is innervated by medial branches arising from the posterior rami of the spinal nerve at the same level and a level above the joint, LA blocks of these nerves have been advocated for diagnostic and prognostic purposes. Intraarticular facet injections with LA have been proposed as an alternative method for diagnosing facet joint pain, although the existing data suggest that MBB is a better predictive tool for RF denervation outcomes. Similar to other blocks, the potential for false positive and false negative results needs to be considered, and steps should be implemented to reduce their incidence.

Studies evaluating the long-term outcomes of RF denervation have demonstrated efficacy in well-selected patients.

Key Points

- Facet joints are an important source of axial spinal pain and are more common in individuals with neck and mid-back pain than in those with LBP.
- Facetogenic pain is often referred into the head, shoulder, and scapula in the cervical region, laterally in the thoracic region, and into the upper legs and sometimes groin in the lumbar region. There is a significant overlap between cervical facet levels and other spinal structures, such as the intervertebral discs.
- Facetogenic pain is more prevalent in elderly patients; in the cervical spine, whiplash is a common cause of facet joint pain.
- Facetogenic pain cannot be reliably identified using imaging modalities. Paraspinal tenderness is weakly predictive of response to facet interventions but has low specificity.
- Both medial branch blocks and intraarticular injections can be used to identify painful joints and select patients for radiofrequency ablation. There is some evidence that medial branch blocks are a better prognostic tool before radiofrequency ablation. Although intraarticular injections may theoretically confer greater diagnostic value than medial branch blocks, the high technical failure rate limits their utility.
- Steps that may reduce the false positive rate include limiting the volume of superficial anesthetic, avoiding procedural sedation, reducing block volumes, using a single-needle technique, and avoiding patients with poorly controlled psychopathology.
- Neither intraarticular injections nor medial branch blocks are likely to confer long-term benefits in a significant percentage of the population.
- To optimize access to care in light of the potential for false negative injections, more liberal selection criteria, such as using a single block and a 50% cutoff threshold, are recommended in clinical practice. In clinical trials, more rigorous criteria may be employed.

Neurosurgical Approaches to Pain Management

MARSHALL T. HOLLAND, AHMED M. RASLAN, KIM J. BURCHIEL

Neurosurgeons have a long history of surgical treatment for pain, particularly cancer pain. The notion that sectioning pain pathways could achieve pain control was first introduced by Spiller and Martin[1] in 1912, and was followed by the development of a whole array of surgical procedures aimed at interrupting ascending pain signals throughout different parts of the central nervous system.

Two major approaches are used when targeting the brain or the spinal cord to treat pain. The first is a nondestructive approach that uses either electrical stimulation of brain targets, which is thought to modulate the process of pain perception, or pharmacologic agents, which are introduced into the ventricular or intrathecal spaces to target pain-modulating receptors. Targets for electrical stimulation include the peripheral nerves, spinal cord, thalamic nuclei, periventricular gray (PVG) matter, periaqueductal gray (PAG) matter, and motor cortex. Currently, the pharmacologic agent of choice for intrathecal or intracerebroventricular (ICV) injection is morphine or other opiates. In general, nondestructive procedures are used for non-malignant pain. However, intrathecal opioids are also used for the treatment of cancer pain.

The second approach is a destructive approach, which is used with the goal of interrupting signals that lead to the perception of pain at various levels. Neuroablation can be performed on cellular complexes, such as nuclei or gyri, or on tracts to either disrupt the ascending sensory signals or destroy the limbic pathways involved in the emotional processes associated with pain.

This chapter discusses several approaches within the two broad categories of neurosurgical procedures for pain: (1) neuroablation and (2) neuromodulation, which is further subdivided into electrical and pharmacologic neuromodulation. Each broad category is further discussed based on the level of the nervous system that is being intervened.

Neuroablation

Cerebral Neuroablation

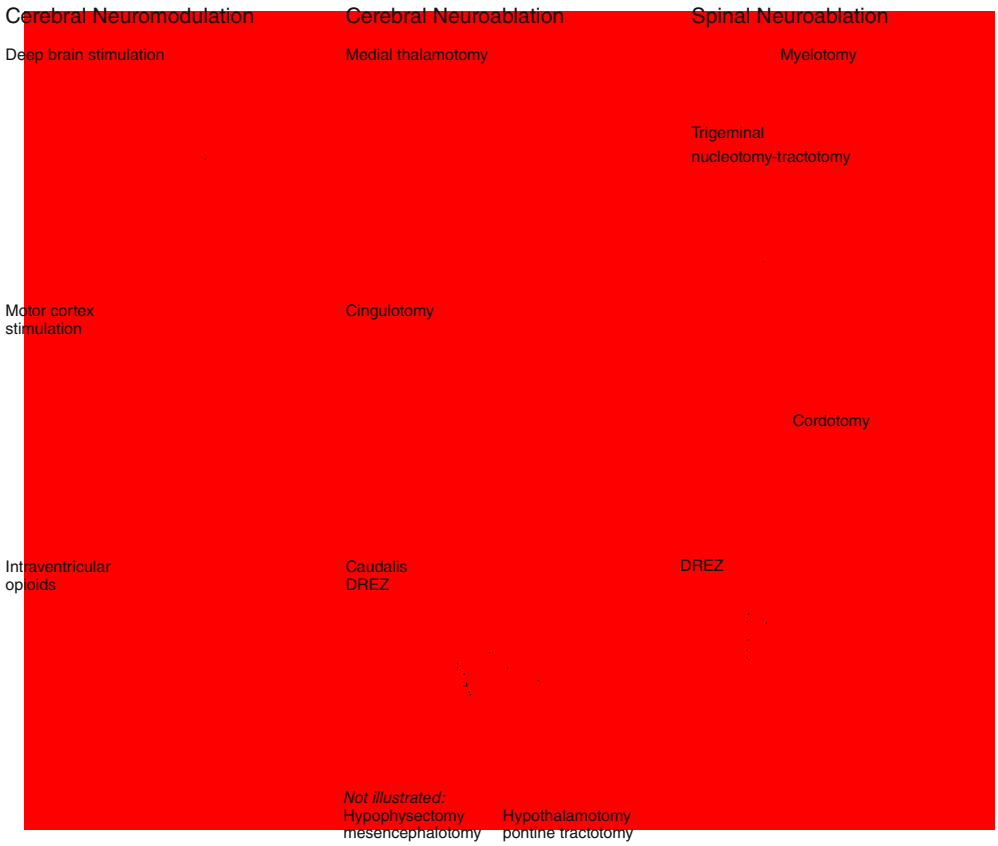
Historically, many procedures fall into this category, including mesencephalotomy, pontine tractotomy, and hypophysectomy. We focus on procedures that we believe have more than what could be considered purely historical significance.

Medial Thalamotomy

Stereotactic thalamic neuroablative surgery for pain is relatively safe with respect to deep brainstem structures, and because of the wide involvement of many thalamic nuclei in pain processing, it has been considered a part of the pain surgery armamentarium.[2] The first structure targeted for neuroablation was the ventral caudal (Vc) nucleus, as defined by Hassler.[3] However, it was soon recognized that neuroablation of the Vc nucleus was associated with significant deafferentation pain phenomena. The work of Mark and colleagues led to the belief that targeting the medial thalamic nuclei was more effective in managing pain.[4] Nuclear targets for neuroablative medial thalamotomy are (1) the centralis lateralis, (2) the centrum medianum, and (3) the parafascicularis. Several pain syndromes, including cancer pain, central and peripheral deafferentation pain, spinal cord injury, malignancy, arthritis, and neurogenic pain associated with Parkinson's disease, have been successfully treated by medial thalamotomy. Frank et al. reported the overall success rate of medial thalamotomy to be 52%,[5] with cancer pain being the main condition treated. Jeanmonod et al.[6] and Young et al.[7] used radiofrequency and gamma knife treatment, respectively, and reported a 60% success rate in achieving pain control. The ideal target lying between the three main medial thalamic nuclei (listed above) has yet to be determined, although the centrum medianum nucleus is the most frequently targeted. Deep brain stimulation (DBS) of the medial nuclei does not usually produce a conscious sensory response, and lesioning does not induce sensory loss. The published literature on medial thalamotomy is inconsistent regarding the target, guidance technique, patient population, and lesioning method used. Therefore the actual success rate of medial thalamotomy is challenging to assess. However, in general, the procedure is considered to be effective in treating nociceptive pain, with recent data pointing to some success in relieving neuropathic pain.

Stereotactic Cingulotomy

Cingulotomy refers to stereotactic lesioning of the anterior cingulate gyrus. Le Beau performed the first open cingulotomy to treat intractable pain in 1954,[8] which is believed to cause relief by altering a patient's emotional reaction to painful stimuli by interrupting the Papez circuit[9] and increasing tolerance to the subjective and emotional feelings of pain.[10,11] Cingulotomy is performed with standard stereotactic protocols, usually under general anesthesia. Bilateral lesions are made in the anterior aspect of the cingulate gyrus, and the success of the procedure is directly related to the extent of ablation of the cingulum (Fig. 32.1).[1] A suitable stereotactic cingulotomy candidate is a terminally ill patient with widespread metastatic disease that has extended to



• **Figure 32.1** Diagrammatic representation of cerebral neuromodulation and neuroablation procedures and spinal neuroablation procedures. *DREZ*, Dorsal root entry zone. (Adapted with permission from Raslan AM, McCartney S, Burchiel KJ. Management of chronic severe pain: spinal neuromodulatory and neuroablative approaches. *Acta Neurochir Suppl*. 2007;97:33-41. With kind permission from Springer Science and Business Media.)

the musculoskeletal system, where intrathecal or intraventricular administration of opiates is difficult. Emotional factors associated with pain would favor the selection of a stereotactic cingulotomy procedure. Stereotactic cingulotomy has been used to treat nonmalignant pain with a success rate of approximately 25%.[12] Stereotactic cingulotomy involves the ablation of sufficient anterior cingulate gyrus volume, which is usually achieved by producing at least two lesions with a wide surface area and non-insulated tip electrode. The procedure is generally safe, with few minor side effects. Pillay and Hassenbusch reported on a series of 12 patients in whom seven had satisfactory pain relief.[13] Cingulotomy is rarely used today, mainly because of its narrow indication, advances in the medical management of terminal cancer patients, and the widespread use of neuroaugmentive procedures.

Caudalis Dorsal Root Entry Zone (Brainstem Level)

Following the introduction of stereotaxis in the 1960s, the use of open ablative brain and brainstem surgery was almost abandoned. Siqueira first reported the performance of the caudalis dorsal root entry zone (DREZ) procedure in two patients.[14] Gorecki et al. at Duke University[15,16] later adopted the technique and expanded its indications. In the caudalis DREZ procedure, the caudal portion of the spinal trigeminal nucleus, along with the overlying trigeminal tract, is destroyed. Similar to spinal DREZ surgery, the objective is to destroy the cells of second-order neurons thought to be hyperactive in trigeminal deafferentation pain, thereby achieving pain relief (Fig. 32.1). The main indications for the caudalis DREZ procedure are ophthalmic postherpetic neuralgia and trigeminal anesthesia dolorosa. In cases of neuropathic facial pain in which all other medical and surgical modalities are ineffective, the caudalis DREZ procedure may represent a last resort. The procedure is rarely performed, and potential risks include ipsilateral limb ataxia and weakness.

Spinal Neuroablation

The first report of surgical disruption of spinal pain pathways was presented by Spiller and Martin in 1912. They sectioned the anterolateral quadrant of the spinal cord to interrupt the transmission of pain signals via the spinothalamic tract (anterolateral system) and to relieve pain on the contralateral side of the body caudal to the lesion.[1]

Several decades ago, open surgical sectioning of the spinothalamic tract (anterolateral cordotomy) to control pain was a common procedure in many neurosurgical centers. The procedure is mainly used to treat somatic nociceptive pain, usually from cancer. However, factors such as the debilitated state of cancer patients resulting in poor tolerance of open spinal cord surgery, together with high complication rates, meant that the procedure was not an ideal solution to the problem of cancer pain.

Currently, spinal cord targets for destructive procedures to treat pain include (1) the *spinothalamic tract* (anterolateral column), where destruction can alleviate somatic nociceptive pain below the level of the neck (e.g. anterolateral cordotomy), (2) the *trigeminal*

spinal nucleus, which is disrupted to treat trigeminal neuropathic pain (e.g. trigeminal tractotomy-nucleotomy ["caudalis DREZ"]), (3) the *midline ascending polysynaptic visceral pain pathway*, which is used to treat visceral pain, particularly pelvic pain (i.e. midline myelotomy), and (4) the DREZ, primarily to treat deafferentation pain in the upper extremity (i.e. DREZ procedure; Fig. 32.1). The role of each of these procedures in contemporary surgical pain management is reviewed.

Anterolateral Cordotomy

Anterolateral cordotomy refers to lesioning, sectioning, or other disruption of the lateral spinothalamic tract (LST), which is located in the anterolateral quadrant of the spinal cord. The procedure was historically performed in the upper thoracic spine via an open posterior approach and, less commonly, high in the cervical spine.[17] The spinal cord anterolateral ascending pain transmission system carries information about pain and temperature from one side of the body. The tract is formed by the central processes of nociceptive neurons in the dorsal horn that cross the spinal cord in the anterior commissure, ascend in the anterolateral column to the brainstem, and relay in the thalamus. Lesions of the anterolateral tract produce a contralateral deficit in pain and temperature sensation in two to five segments below the level of the cordotomy. Fibers in the LST have a somatotopic arrangement, with the sacral segments arranged posterolaterally and the cervical segments anteromedially.[18] The corticospinal (pyramidal) tract lies posterior to the LST with the white matter in between. The ventral spinocerebellar tract overlies the LST, and a lesion that damages the spinocerebellar tract may cause ipsilateral ataxia of the arm. Autonomic pathways for vasomotor and genitourinary control and reticulospinal fibers that subserve ipsilateral automatic respiration are also part of the anterolateral quadrant of the spinal cord. A patient with hemibody somatic cancer pain localized caudal to the cervical and upper thoracic areas represents the best candidate for a cordotomy procedure.[19]

From the beginning of the 20th century until the late 1960s to early 1970s, cordotomy was an open procedure undertaken at the mid to high thoracic levels since these sites largely avoided the complications of upper limb ataxia and sleep apnea.[20] Introduction of the minimally invasive percutaneous approach for cordotomy by Mullan et al. mitigated some of the neurologic risks and made it possible for the procedure to be performed on patients in poor general health.[21,22] In the mid-1980s and early 1990s, advances in opioid pharmacology, as well as the introduction of reversible and testable neuroaugmentive techniques, reduced the perceived need for spinal destructive procedures for pain control and led to a major reduction in the number of cordotomies performed by neurosurgeons worldwide. These neuroaugmentive procedures are expensive, particularly given the short life expectancy of many of the candidates, and are not uniformly effective.

Kanpolat et al. first introduced the concept of computed tomography (CT)-guided cordotomy, which allowed for a safer, selective, and more effective procedure.[23–25] In 1995, Fenstermaker and associates[26] performed anterior CT-guided lower cervical cordotomy through the disk space to avoid sleep apnea (a modification of Gildenberg et al.'s anterior low cervical percutaneous cordotomy).[27] CT-guided cordotomy is typically performed as a percutaneous procedure via a lateral approach to the spinal cord at the level of C2. However, the anterior cervical transdiscal approach can also be used; in a clinical study, this approach was used to control cancer pain in six of eight patients with pulmonary-pleural malignancy while avoiding sleep apnea.[28]

Currently, the CT-guided cordotomy procedure involves lumbar puncture and injection of a water-soluble dye into the patient's intrathecal space. After 30 min, a cervical CT scan was performed. These and subsequent scans were used to direct the cordotomy electrode into the anterolateral quadrant of the ipsilateral spinal cord. The electrode is insulated throughout the entire shaft except for the tip (2 mm in length and 0.3 to 0.4 mm in diameter). After measurement of the skin-dura distance and local anesthesia of the lateral cervical region, an electrode was introduced from the lateral side of the neck opposite the C2 foramen into the anterolateral quadrant of the spinal cord. Electrophysiologic testing is essential to ensure complete entry into the spinothalamic tract while avoiding the corticospinal tract. Radiofrequency lesions are performed until adequate hypoesthesia is achieved in the contralateral hemibody, or at least in the region of pain. CT-guided cordotomy has a higher success rate and fewer complications than traditional approaches. Control of cancer pain has been reported in more than 95% of the cases. Procedural complications may include weakness, hypotension, dysesthesia, mirror-image pain, ataxia, incontinence, and sleep apnea. Contemporary CT-guided cordotomy complications tend to be both minor and transient.[29]

An evidence-based review concluded that the case for cordotomy is somewhat unique among all cancer pain procedures in that it has the most supportive evidence.[30] The review used the Grading of Recommendations, Assessment, Development, and Evaluations (GRADE) system, and a recommendation for cordotomy was given. The GRADE system produces recommendations that are independent of the level of evidence.[31]

Trigeminal Tractotomy-Nucleotomy (Spinal Level)

Sensory information from the 5th, 7th, 9th, and 10th cranial nerves is carried by the trigeminal tract and branches into the trigeminal tract spinal nucleus. It extends caudally into the spinal cord to C2.[32] The trigeminal tract is considered a target for surgical treatment of facial pain,[33] and the history of procedures with this target is similar to cordotomy in that initial open procedures evolved toward less invasive stereotactic operations. Crue et al. and Hitchcock developed a stereotactic technique to lesion the trigeminal tract and nucleus via radiofrequency, named trigeminal nucleotomy.[34,35] As with CT-guided cordotomy, CT is used when performing the trigeminal tractotomy-nucleotomy (TR-NC) procedure today. Indications include anesthesia dolorosa, postherpetic neuralgia, neuropathic facial pain, facial cancer pain, and either glossopharyngeal or geniculate neuralgia.[25,36] The procedure can be considered, in some ways, a mini-caudalis DREZ procedure. The nucleus caudalis DREZ operation involves the same concept as the TR-NC procedure but includes the destruction of the substantia gelatinosa (Rexed laminae II and III) of the nucleus caudalis. Pain relief from TR-NC is reported to be complete or satisfactory in 80% of cases. Complications include ataxia from injury to the spinocerebellar tract (usually temporary) and contralateral hypoalgesia if the spinothalamic tract is included in the lesion.[25,34,36,37]

Extralemniscal Myelotomy

The extralemniscal myelotomy (ELM) procedure was first described by Hitchcock, who initially aimed to destroy the decussating fibers of the spinothalamic tract in the anterior commissure of the spinal cord to control pain in the neck and both arms.[38] ELM was achieved by creating a lesion in the central medullary region at the cervicomedullary junction. Unexpectedly, the ELM procedure also seemed to control pain caudal to the level of the

lesion. Schvarcz added the term "extralemniscal" to "myelotomy" because of the contention that the lesion incorporated an ascending polysynaptic nociceptive pathway.[39] Subsequently, the presence of such a tract has been confirmed anatomically. Several authors have presented reports of midline "punctuate" ELM via open procedures to interrupt this pathway at various spinal cord levels. The polysynaptic ascending pathway is thought to carry visceral nociceptive information and lies deep to the midline dorsal column.[40–42] The concept of CT guidance, previously applied to cordotomy and TR-NC procedures, has also been applied to ELM by Kanpolat et al., thus developing the image-guided ELM procedure used today.[36]

ELM is currently conceived as a pain control procedure for pain of visceral origin, including pelvic malignancy or cancer pain in the lower part of the trunk and lower extremities with a predominant visceral pain component. The procedure appears to be safe. However, pain relief results are not as good as those achieved with cordotomy and TR-NC procedures.[17]

Dorsal Root Entry Zone Lesions

With the introduction of the gate control theory in the 1960s, attention was drawn to the spinal dorsal horn as the initial physiologic substrate for pain modulation.[43] The dorsal horn and DREZ were then reconsidered as targets for neuromodulation (spinal cord stimulation) and neuroablation. In 1972, Sindou first attempted cervical DREZ destruction for neuropathic deafferentation pain in the upper extremity secondary to brachial plexus avulsion.[44] Nashold et al. soon followed and introduced the use of radiofrequency lesions to perform DREZ disruption.[45] Laser and ultrasound have also been used to damage the DREZ.[46,47] When large-fiber afferents (touch, position sense) in peripheral nerves or dorsal roots are altered, there is a reduction in the inhibitory control of the dorsal horn.[48] This situation is presumed to result in the excessive firing of the dorsal horn neurons, which is thought to be the cause of deafferentation pain and can be controlled by DREZ lesioning.[49] The technical details of the procedure and its variants are beyond the scope of this chapter, but DREZ lesioning is performed as an open surgical procedure under general anesthesia and often accompanied by intraoperative neurophysiologic monitoring. Surgical candidates include patients with brachial plexus avulsion, Pancoast's tumor with brachial plexus invasion combined with a good general condition and reasonable life expectancy, pain caused by spinal cord or cauda equina lesions, and pain accompanying spasticity after plexus or cord injury.[44] A general prerequisite for the DREZ procedure is a lack of functional use of the limb where the DREZ procedure is performed because complete sensory denervation of the limb will render it functional even if there is residual motor power. When patients are carefully selected, and the lesions are accurately performed, the success rate can be as high as 90% (with follow up success rates reported for up to four years). Complications and side effects include cerebrospinal fluid fistula, meningitis, ataxia, increased neurologic deficits, and dysesthesias.[50]

Neuromodulation

Electrical Neuromodulation

Central Electrical Neuromodulation

Deep Brain Stimulation

Pool first observed and reported on the analgesic effects of septal stimulation in the frontal and lateral forniceal columns while performing psychosurgery in the 1950s.[51] Heath and Mickle and Pool et al. subsequently reported the pain-relieving effect of septal and near-septal stimulation in nonpsychiatric patients.[52,53] Mazars and coauthors and Reynolds first reported pain relief from thalamic stimulation in 1960.[54,55]

Neurostimulation of the brain to relieve pain was thus introduced decades before what has become the main contemporary indication for DBS, that is, the treatment of movement disorders.[56] However, these early reports only set the stage for the eventual application of DBS for pain relief. In the mid-1960s, Melzack and Wall's gate theory[43] provided a logical rationale for DBS of the sensory thalamus to control pain. Shortly afterward, Reynolds reported on the analgesic effect of focal brain stimulation in rats (stimulation produced analgesia).[55] In the early 1970s, Hosobuchi and associates[57,58] and Richardson and Akil[59,60] were the first to report on stimulation of the human thalamus and PVG and PAG matter for pain control. Although stimulation of the thalamic sensory nuclei produced paresthesia in painful areas, consistent pain relief was not achieved. Similar results were produced by stimulation of the internal capsule.[61,62] Stimulation of the PVG and PAG typically did not produce paresthesia but did induce a sense of "warmth." High-intensity PVG/PAG stimulation produced unpleasant and sometimes overwhelming sensations, such as those of impending doom or terror. The centromedian-parafascicular complex was also targeted by Andy[63] as a stimulation site to treat pain, and this stimulation likewise did not produce paresthesia.

Despite reports describing the use of DBS to treat chronic pain in the 1970s and the early 1980s, data to support the technique never reached contemporary evidentiary standards. The use of DBS for pain control has failed to gain much acceptance in the neurosurgical community, and the use of DBS electrodes as pain control implants has never achieved United States Federal Drug Administration (FDA) approval. The lack of data to support the procedure is due, in part, to the small number of patients treated, inconsistent target localization, heterogeneity of the pain diagnoses treated, and failure to mount a prospective randomized trial that was sufficiently powered to answer the question of efficacy. The mechanism of pain relief by DBS is poorly understood but appears to be dependent on the site. The thalamus and PVG/PAG are the most commonly[64] targeted sites for DBS implants for pain. Hosobuchi et al.[58] suggested that the pain-relieving effect of PVG and PAG stimulation might involve endogenous opioid receptors based on their studies that found that the pain-relieving effect of DBS could be reversed by naloxone. Evidence supporting this mechanism of action of PAG/PVG DBS is inconsistent. Some investigators supported this concept, whereas others disagreed. Currently, it is postulated that the pain-relieving effect of PAG/PVG DBS is because of activation of multiple supraspinal descending pain modulatory systems, both opioid and nonopioid.[64] Pain relief resulting from stimulation of the ventral posterolateral (VPL) nucleus and ventral posteromedial (VPM) nucleus (Vc nucleus in the European Hassler terminology), the major sensory nuclei of the thalamus, is poorly understood. Inhibition of spinothalamic tract neurons[65] and activation of dopaminergic mechanisms have both been proposed.[66] The most accepted hypothesis is that thalamic stimulation activates the nucleus raphe magnus of the rostroventral medulla, which results in activation of a suprasegmental descending endogenous pain inhibition system.[64]

Meticulous patient selection, with classification of pain (i.e. nociceptive or neuropathic) and informed DBS target selection, should help improve the outcome of DBS for pain. Clinical case series (class III evidence) observations suggest that PVG/PAG

stimulation seems more effective in treating somatic nociceptive pain. This is consistent with the opioid-mediated effects of PAG/PVG stimulation. It has also been suggested that VPL and VPM (Vc) stimulation is more effective in treating neuropathic pain, a gate theory-based concept.[67] In the absence of controlled trials to prove efficacy, definitive conclusions regarding the ideal target for any particular pain syndrome remain elusive. Furthermore, many patients have mixed neuropathic/nociceptive pain, which suggests that the DBS target to control pain should be individualized according to the patient. Some authors have suggested placing two electrodes simultaneously in the sensory thalamic nucleus (Vc) and the PVG.[68] Another target, the anterior cingulate nucleus, has been tested and may produce better overall results.[69,70]

For some pain syndromes (e.g. thalamic infarction-induced pain), target selection is simpler, given that thalamic stimulation is impossible.[70] Chronic neuropathic pain conditions treated by DBS include anesthesia dolorosa, post-stroke pain, thalamic pain, brachial plexus avulsion, postherpetic neuralgia, postcordotomy dysesthesia, spinal cord injuries, and peripheral neuropathy pain. Nociceptive pain conditions treated by but not limited to DBS include failed back surgery syndrome, osteoarthritis, and cancer pain.[71]

Another target of interest for patients with post-stroke pain is the ventral striatum/anterior limb of the internal capsule.[71] Unfortunately, a recent randomized study failed to achieve a >50% decrease in pain compared to the control (sham) population. However, upon further analysis, the researchers showed significant improvement in the affective sphere of pain.[72]

DBS for chronic pain is similar to DBS for other indications (movement disorders) in that surgeons have several targets that are applicable to the general problem (Fig. 32.1). DBS target locations are often indirectly derived from the Schaltenbrand and Bailey atlas or measured directly from the patient's CT or magnetic resonance imaging scans. The location of these targets can be confirmed intraoperatively by macrostimulation, microelectrode mapping, or intraoperative imaging. To best judge the benefits of stimulation and help fine-tune stimulation parameters following final electrode implantation, a trial period of approximately one week is often a prerequisite. The complications of DBS for pain relief are similar to those of movement disorders. Typically, they are related to (1) brain injury from bleeding or inadvertent trauma as a result of electrode insertion, (2) infection, (3) hardware failure, or (4) transient site-specific side effects related to overstimulation or unintentional stimulation of neighboring areas. The latter might produce diplopia, seizures, nausea, paresthesia, or headaches.

Overall, DBS surgery is a safe procedure with a relatively low risk of complications or unintended neurologic sequelae. However, data supporting its efficacy are limited. Currently, DBS for pain control is an extraordinary treatment that may be applicable to only a few chronic pain conditions. DBS implantable hardware is not approved by the FDA for pain control procedures, and many insurance carriers do not authorize implantation. Given the tremendous interest in and application of DBS for movement disorders, whether DBS for pain will be substantially resurrected at some point remains to be seen.

Motor Cortex Stimulation

In 1954, Penfield and Jasper observed that stimulation of the precentral (motor) gyrus elicited sensory responses when the corresponding portion of the adjacent postcentral gyrus had previously been resected.[73] They treated burning pain on one side of the body by postcentral gyrectomy, and when the pain recurred, they performed precentral gyrectomy, which then controlled the pain. In 1955 White and Sweet attempted surgical resection of the postcentral gyrus for relief of central pain and reported 13% pain relief.[74] It was not until 1971, after the publication of the gate theory in 1965, that Lende et al. re-explored the motor cortex as a potential site for pain control. In an attempt to treat central neuropathic facial pain,[75] they performed two cases of precentral and postcentral gyrectomy of the facial cortex. These reports formed the basis for establishing a link between the precentral and postcentral areas and pain control surgery.

By the 1980s the cumulative failure of other procedures, both modulatory and destructive, to fundamentally alter neuropathic pain made it clear that the development of an innovative methodology to surgically treat pain was critically needed. Exploration of the motor area as a target site is under way. Hardy et al. stimulated the rat medial prefrontal cortex with a resultant significant elevation in nociceptive response latency.[76,77] Hosobushi implanted electrodes in subcortical somatosensory areas for control of dysesthetic pain, and from this study, it was concluded that somatosensory stimulation could be effective in the treatment of leg pain.[78] In 1991 Tsubokawa et al. first introduced epidural stimulation of the motor cortex as an option to treat central deafferentation pain. His group had tried postcentral gyrus (sensory) stimulation and found that it was either ineffective or exacerbated the pain. They demonstrated that epidural MCS inhibited abnormal thalamic neuronal burst activity and increased regional blood flow to the cortex and thalamus.[79] Primarily, Tsubokawa et al. used MCS for central deafferentation pain syndromes, such as post-stroke pain.[79,80] The mechanism of action of MCS is still poorly understood. However, the work of Garcia-Larrea, Peyron, and coworkers[81–83] has shed some light on its mechanism of action. Positron emission tomography and electrophysiologic studies have demonstrated that MCS increases blood flow to the ipsilateral thalamus, cingulate gyrus, orbitofrontal cortex, insula, and brainstem, with some correlation between increased thalamic and brainstem blood flow and efficacy of pain relief. The increased blood flow to the ipsilateral sensory thalamus was greater than that to the motor (ventrolateral) thalamus. It does not appear that an intact somatosensory system is absolutely necessary for the clinical benefits to be realized, an important discovery allowing the use of this technology for stroke and other deafferentation states.[81–83] As with many forms of chronic stimulation, habituation seems to occur, which is more likely with the use of high frequency stimulation. The patient selection process for MCS is of paramount importance (as it is for all pain-relieving surgeries), and in this case, the debate continues. Neuropathic pain is more responsive to this form of therapy than nociceptive pain. Attempting to predict the best candidates for MCS can be challenging, and Yamamoto et al. introduced a pharmacologic classification of post-stroke patients based on their pain relief response to escalating doses of intravenous thiamylal and morphine. They concluded that patients with a good response to thiamylal or ketamine and a poor response to morphine were the best candidates for MCS.[84] Several neurogenic pain syndromes have been treated by MCS, including thalamic pain, bulbar post-stroke pain (which typically occurs with "Wallenberg's syndrome"), facial neuropathic and deafferentation pain, and phantom and brachial plexus avulsion pain.[85,86] Treatment of central post-stroke pain following thalamic infarction or thalamic or putaminal bleeding

by MCS was reported by Tsubokawa et al. to achieve good to excellent pain control in 65% of cases (follow up >12 months), with no seizures observed.[79,80] Katayama and associates extended the indications to include bulbar pain secondary to "Wallenberg's syndrome" and reported on four patients initially treated by VPL thalamic stimulation that resulted in increased pain. Three other patients were later treated by MCS, with a greater than 60% reduction in pain in two patients and greater than 40% in one patient.[87] Treatment of neuropathic facial pain appears to be one of the most promising indications for MCS, which may be related to the breadth of facial representation over the motor cortex. Several reports have described neuropathic facial pain treatment using MCS. Raslan et al. all treated trigeminal neuropathic pain with MCS and reported pain relief in approximately 60% of patients for up to 12 months.[86,88–93] Peripheral deafferentation pain and brachial plexus avulsion pain have also been treated by MCS, with variable results. Movement disorders are an active area of ongoing MCS research.[85] MCS has been shown to improve the symptoms of thalamic hand syndrome, action tremors, intention myoclonus, and Parkinson's disease.

MCS involves the implantation of epidural electrodes over the motor cortex (Fig. 32.1), which can be localized by (1) radiologic landmarks of the central sulcus, (2) intraoperative somatosensory evoked potentials with an observation of "phase reversal" over the central sulcus, (3) intraoperative stimulation of the cortex with concurrent electromyographic monitoring of the relevant muscle groups contralaterally, and, more recently, (4) the use of neuronavigation systems to localize either the central sulcus or the precentral gyrus. Some authors even recommend the use of functional magnetic resonance imaging for targeting, especially with infarctions involving the motor cortex.[94] A trial period of MCS is usually required, followed by implantation of a permanent system if the trial produces adequate relief. Complications of MCS include intraoperative seizures, stimulator pocket infection, epidural bleeding, subdural effusion, and "tolerance" to stimulation with diminished analgesia over time.

Unfortunately, long-term studies with extended follow up have shown poor chances of meaningful and sustained pain relief outcomes.[86,95] Therefore the procedure is rarely covered by insurance and is not commonly performed in the United States.

Spinal Cord Stimulation (SCS)

Approved by the FDA in 1989 as part of the treatment paradigm for chronic pain, SCS represents a safe and effective therapy, particularly for neuropathic pain. Indications include neuropathic pain with a spinal origin, CRPS, peripheral neuropathic pain, and anginal pain. Evidence for this has been borne out via randomized controlled trials and systematic reviews.[96–98]

Patients undergo a trial period of stimulation in which a percutaneous lead is placed into the extradural space. Stimulation was performed using an external generator. Typically, following a trial period of three to seven days, it is determined whether the trial is deemed successful based on the patient's perception of satisfactory pain relief. The trial lead is then removed, and the patient may undergo permanent implantation surgery.

Most commonly, these systems focus on the stimulation delivery of paresthesia-inducing frequencies. More recent research has focused on the investigation of novel waveforms including 10,000 Hz high frequency stimulation and "burst stimulation."[99–102] Randomized control trials have shown mixed results of the superiority of these novel waveforms.[102,103] Most recently, the concept of "closed loop" SCS has come to the forefront. This treatment paradigm uses feedback via a sensing arm to extract an actionable biomarker signal (evoked compound action potentials) that allows the device to self-adjust with the potential to maximize therapeutic efficacy.[104] This technology will need to be evaluated over time with well-designed outcome studies.

Dorsal Root Ganglion (DRG) Stimulation

Stimulation of the DRG is an alternative form of neuromodulation that is most effective for the treatment of CRPS type 2. This was evidenced by the pivotal FDA trial revealing DRG stimulation to be superior to SCS.[104] The procedure involves the placement of the epidural stimulator into the neuroforamen adjacent to the DRG. Similar to most neuromodulatory interventions, a trial period of stimulation is utilized as a confirmatory test prior to permanent implantation.

Peripheral Nerve Stimulation (PNS)

There is sparse evidence for the use of the peripheral nervous system, dependent on the nerve of interest that is being stimulated. In general, this intervention involves the placement of a stimulating electrode near the nerve. Similar to other neuromodulation procedures, a successful stimulation trial must precede permanent implantation. Recent recommendations have been produced by the Congress of Neurological Surgeons surrounding the deployment of occipital nerve stimulation (ONS).[105] Additionally, studies have explored the use of occipital nerve stimulation for trigeminal neuropathic pain.[106,107] Presently, nerve stimulators are being placed in the femoral and sciatic nerves for post-amputation pain and in the tibial nerve for foot pain.

The topics of SCS, DRG stimulation, and PNS are discussed in detail in Chapter 71.

Pharmacologic Neuromodulation

Intraventricular Opioids

Studies showing the direct analgesic effects of opioids applied in the ventricular region and around the medulla of the central nervous system[108,109] led to the work of Leavens et al. in 1982, in which human ICV use of morphine was first reported.[110] The profound analgesic response to intrathecal morphine coupled with its widespread clinical use for lower body pain suggested the need for more rostral injection sites to control pain in the head, neck, and upper extremity regions. Although cervical intrathecal opioid injection sometimes results in respiratory depression, it is possible to deliver a small amount of ICV morphine without respiratory dysfunction or dysautonomia. Opioid receptors are abundant around the wall of the third ventricle and aqueduct, as well as in the PVG and PAG. In Leavens et al.'s 1982 report, 1 mg of morphine was used to treat patients with intractable cancer pain, resulting in profound analgesia and no respiratory depression or neurologic changes.[110] In a report on 82 patients, Lazorthes and associates recommended nine specific guidelines for the ICV use of morphine: (1) chronic pain secondary to inoperable malignant tumors in patients with terminal cancer, (2) pain not relieved by medical treatment and, in particular, the development of serious side effects from using oral or systemic morphine, (3) intractable bilateral, midline, or diffuse pain not appropriate for percutaneous or open surgical interruption of nociceptive pathways, (4) chronic pain of somatic nociceptive origin (neurogenic pain was a contraindication), (5) upper body pain secondary to cervicothoracic cancer, (6) chronic pain of the lower half of

the body (subdiaphragmatic) only after failure of or contraindication to conventional intrathecal spinal opioid administration, (7) absence of general risks for complications, such as coagulation disturbances, cutaneous infection, and septicemia, (8) informed consent from the patient and family, and (9) the presence of a favorable domestic environment (e.g. physician, nurse, or family) for ambulatory surveillance and chronic ICV morphine treatment. The authors recommended that when the topography of the pain involved a transitional area (e.g. lower thoracic, diaphragmatic, or upper abdominal region), ICV morphine could be indicated if the patient fails a more standard intrathecal morphine trial.[111]

Surgically, the implantation of a chronic ICV morphine infusion system involves placement of a catheter into the lateral ventricle near the foramen of Monro to deliver drugs near target receptors in the periaqueductal parenchyma of the midbrain (Fig. 32.1). The analgesic latency of ICV morphine administration was between 15 and 30 min, and the effect lasted for a mean of 28 h. Excellent or good pain relief rates range from greater than 50% to 97%, and side effects include somnolence, nausea, confusion, and respiratory depression, which are usually transient. Finally, Lazorthes et al. reported tolerance in three of 82 patients.[111]

The increased effectiveness of oral opioids has diminished the need for ICV morphine administration. However, the technique remains relatively simple and effective and is a viable option for patients with intractable pain of malignant etiology, following oral opioid failure and when pain is diffuse or cephalic in topography.[112]

Intrathecal Opioids

The main advantage of intrathecal opioid administration is the ability to achieve therapeutic efficacy via a smaller dose without the side effects induced by peripheral administration.[113,114] Similar to neuromodulation, patients undergo a trial prior to proceeding with a permanent implant. This approach involves accessing the intrathecal space via the lumbar cistern and advancing an intrathecal catheter up to the mid-thoracic spine. The catheter is then connected to a programmable pump with a reservoir that was placed in the abdominal adipose layer. The reservoir requires scheduled refills of medication, the frequency of which is determined by the patient's infusion rate, medication concentration, and reservoir capacity.[115]

Beyond opioids, multiple medications have been used by providers to treat chronic pain via the intrathecal route. These medications include clonidine, ziconotide, benzodiazepines, and tricyclic anti-depressants, among others.[116] The most commonly used drugs are clonidine and ziconotide. The potential advantage of non-opioid medications is the decrease in the potential for unwanted side effects, development of dependency, and risk of medication withdrawal in the event of a pump failure.[117] Intrathecal therapies are further discussed in Chapter 72.

Summary

Neurosurgical procedures to treat intractable pain have gone through an evolutionary process, dictated in part by technologic advances, scientific discovery, and changes in the survival rates of patients with chronic pain, especially those with cancer pain. Irreversible ablative procedures are used much less frequently today, yet they remain the procedures of choice on occasion. Depending on the physiologic substrate and pain topography, multiple brain and spinal cord regions can be targeted to treat chronic pain. Neuromodulation by either electrical stimulation or pharmacologic manipulation is generally the preferred approach to treat chronic pain.

Key Points

- Neurosurgical treatments for intractable pain are usually reserved as the last option for the treatment of intractable pain.
- These interventions can be either ablative or neuromodulatory, which can be divided into pharmacologic and electrical.
- Neurosurgical procedures can be performed at either the spinal or cerebral level. Spinal spinothalamic ablation (cordotomy) is the most studied and performed neurosurgical ablative procedure, and it is very effective in treating unilateral somatic cancer pain.
- Opioid use has limited the indications for ablative procedures, but there are still defined but limited indications for spinal ablative procedures that are confined to cancer-related pain.
- Spinal neuromodulation (i.e. SCS and intrathecal opioid devices) is widely used to treat chronic spinal pain.
- Advances in spinal cord stimulation include high frequency and burst stimulation and "closed loop" SCS.
- PNS involves the placement of the electrode near the nerve. Studies have shown a beneficial effect of occipital nerve stimulation. Clinically, electrodes are placed in the femoral and sciatic nerves for post-amputation pain and in the tibial nerve for foot pain.
- Clinical intrathecal therapies involve mainly opioids, ziconotide, and baclofen.
- Cerebral ablation of pain pathways or centers is rarely performed. However, cerebral neuromodulation procedures, such as deep brain stimulation and motor cortex stimulation, may have limited indications and utility that are usually related to central pain and neuropathic pain.

Evaluation and Treatment of Cancer-Related Pain

DERMOT FITZGIBBON, MARGARET HSU

Introduction

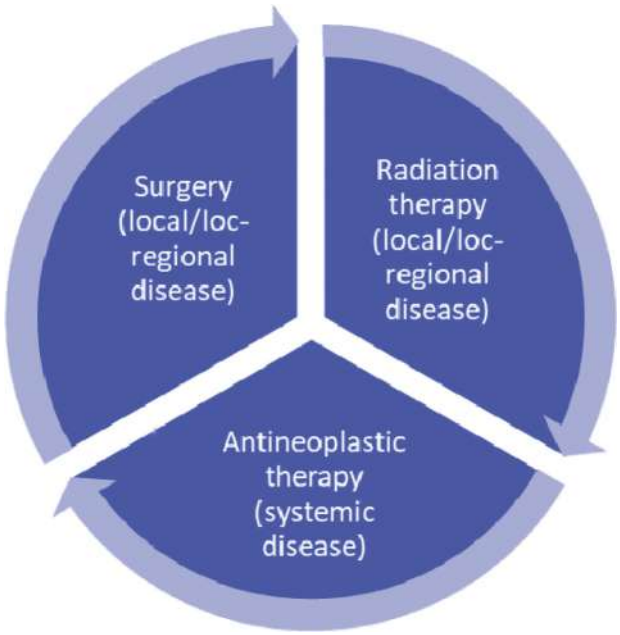
Cancer is a disease process that results when cellular changes cause uncontrolled growth and division of cells. It continues to be a major health problem and is the second leading cause of death in the United States.[1] The three most prevalent cancers in 2019 were prostate, colon, and rectum, and melanoma of the skin among males, and breast, uterine corpus, and colon and rectum among females.[2] Common side effects of cancer and its treatment are pain, fatigue, and emotional distress,[3,4] all of which can affect functional status. Pain can be problematic at different phases of cancer treatment. Van den Beuken-van Everdingen et al.[5] reported pain prevalence rates of 39% after curative treatment; 55% during anticancer treatment; 66% in advanced, metastatic, or terminal disease; and 51% in all cancer stages. There was a prevalence rate of 38% of moderate to severe pain in studies reporting pain intensity. Hematologic patients also have high prevalence rates of pain at diagnosis, during therapy, and in the last month of life.[6] Despite the availability of opioids and other treatment strategies, undertreatment of cancer pain remains problematic,[7,8] with some authors estimating that one in three patients does not receive an analgesic prescription to match the reported level of pain.[9] Despite increased attention to cancer pain, pain prevalence in cancer patients has not significantly changed over the last decade compared to the prior four decades.[10] This continues into survivorship, where the prevalence of pain also is high.[11] At initial diagnosis, oncology patients face a continuum of care that may progress from disease-oriented, curative, life-prolonging treatment through symptom-oriented, supportive, and palliative care extending to terminal-phase hospice care (Fig. 33.1).

Treatments are usually multifaceted and often include surgery, radiation therapy, and systemic treatment, which includes the use of chemotherapeutic cytostatic drugs, targeted therapy with small molecule inhibitors, monoclonal antibodies that involved targeted immunotherapy, and inhibition of tumor-associated angiogenesis or immune regulation by checkpoint inhibitors (Fig. 33.2, Table 33.1).

Once treatment is completed, patients frequently require an extended interval of surveillance, resulting in additional treatments for recurrences or the appearance of new diseases or problems. Advances in cancer prevention and treatment with an improved understanding of the biology of cancer have resulted in improved patient survival and quality of life.[12] Cancer survival has improved since the mid-1970s for all of the most common cancers except uterine cervix and uterine corpus,[13] and there has been an overall drop of 29% in the mortality rate since 1991.[1] Even after completion of care, pain can be a persistent problem, and the ability to address this is an increasing issue because of advances in cancer treatment with a record number of survivors in the United States.[12] Pain management should be an integral component of the cancer care continuum. For oncology patients, the ultimate goal is to cure disease and pain, often an undesirable consequence of disease or treatment. Although pain management should be integrated into oncology care, it should not be the focus of care in contrast to many chronic pain models. Interdisciplinary collaboration is essential for the comprehensive care of cancer patients with pain. Aggressive therapy of both cancer and pain is mutually beneficial and is best done by skilled, interdisciplinary teams that understand and respond to the changing demands of oncology care that include pain management.

The most successful strategy for managing tumor-related pain is identifying the source and directing appropriate anti-tumor measures (which may include all care options in oncology) toward the source. Symptomatic management of the pain may be appropriate while implementing these measures. However, such measures may not be appropriate for patients with pre-existing chronic non-cancer-related pain who present for oncology care. These issues can usually be differentiated by a comprehensive pain assessment with a clear understanding of the current tumor location(s) and correlation with the patient's pain complaint. The goal of any pain management strategy is to manage pain that allows for the optimization of function and enable an acceptable quality of life. Although a reduction in pain intensity is ideal, the guiding principle for pain management should be an improvement in function. Adequate management of cancer pain depends on making an accurate diagnosis of the underlying cause(s) of pain and contributing factors. In every situation, this requires a comprehensive assessment of these issues. The diagnosis will include a reason for the pain complaint, a summary of the current disease status, the appropriateness and efficacy of the current pain medication regimen, and an assessment of functional and social status. It is important to recognize that the source of pain in the cancer patient is usually not a single entity but often has multiple sources that may result from different issues such as tumor staging, treatment phase, preexisting conditions causing chronic pain, and posttreatment complications. Tumor-related pain may be classified according to the tissue source as nociceptive (somatic or visceral) or neuropathic. Once a treatment plan is implemented,

• **Figure 33.1** Cancer Care Continuum.



• **Figure 33.2** Major modalities of cancer therapy.

assessment and re-assessment at regular intervals are key to ensuring that treatment is appropriate and safe, as well as minimizing and addressing side effects related to treatment throughout care. The concurrent use of adjunctive, specialized, or complementary therapies should be considered, and referral for specialized surgical, anesthetic, or psychological intervention benefits selective patients. However, most patients can attain adequate management of pain (and improvement in function) using appropriate oral pharmacotherapy. Cancer (tumor-related) pain management guidelines typically incorporate pharmacologic, anesthetic, neurosurgical, and behavioral approaches. The mainstay of cancer pain therapy is pharmacologic, but radiotherapeutic, anesthetic, neurosurgical, psychological, physiotherapeutic, spiritual, and social interventions all play roles in adequate cancer pain management (Table 33.2). The basic principles of tumor-directed pain control include modifying the source of pain by treating cancer, altering the central perception of pain (for example, by the use of analgesics, anti-depressants, anxiolytics, and psychotherapy), and, when appropriate, interfering with nociceptive transmission outside of and within the central nervous system, for example, with anesthetic techniques (e.g. neurolytic celiac plexus block, neuraxial analgesia, and spinal neurolysis), or neurosurgery procedures (e.g. cordotomy, dorsal root entry zone lesioning). Options for disease modification should always be foremost.

World Health Organization Analgesic Ladder

In 1986, the World Health Organization (WHO) developed a simple model for the introduction and upward titration of analgesics, which became known as the WHO analgesic ladder.[14] In 2018, WHO updated its guidelines for pharmacologic and radiotherapeutic management of cancer pain (WHO 2018). Pharmacologic options should be used by following the WHO analgesic ladder (Fig. 33.3).

Implementation of the three-step ladder, in combination with appropriate dosage guidelines, should result in adequate pain relief for 70%–90% of patients.[15–17] Successful implementation of the ladder requires adherence to basic principles of medication use (Table 33.3).

The ladder advocates for the use of analgesics (non-opioids including automatic positive airway pressure [APAP] and non-steroidal anti-inflammatory drugs [NSAIDs], adjuvant analgesics such as anti-depressants and anticonvulsants, and opioids) should be used incrementally according to pain intensity with the focus on the use of opioids for moderate to severe intensity pain. Opioids are commonly used to treat moderate or severe cancer pain, and the most commonly used opioid drugs are buprenorphine, codeine, fentanyl, hydrocodone, hydromorphone, methadone, morphine, oxycodone, tramadol, and tapentadol.[18] For initiation and maintenance of pain relief, NSAIDs, APAP, and opioids either alone or in combination may be used with a strength appropriate for patient-reported pain severity. The use of steroids for the shortest time possible is recommended if deemed appropriate for care, but evidence for the efficacy of steroids in cancer pain is weak, and the side effect profile of prolonged use needs to be defined.[19] Optimal dosing of steroids likely depends on location and type of pain, presence of or risk of infection, stage of illness, presence of diabetes mellitus, and goals of care. In patients with pain related to bone metastases, bisphosphonates or monoclonal antibodies (denosumab) should be considered to prevent and treat bone pain. Regarding the use of anti-depressants and

TABLE 33.1 Types of Cancer Treatment

Surgery	Open versus minimally invasive Primary tumor resection Resection of metastases Cytoreduction Palliative Reconstructive
Radiation Therapy	External beam (photon, proton, neutron)* Internal radiation therapy (brachytherapy) Systemic radiation therapy (radioactive iodine, radium, radiostrontium)
Chemotherapy	Cytotoxic (oral, IV, injection, intrathecal, intraperitoneal, intra-arterial)
Immunotherapy	Immune checkpoint inhibitors Cellular immunotherapy (CAR T-cell, TIL) Monoclonal antibodies (rituximab) Cancer treatment vaccines Immune system modulators (cytokines – interferons, interleukins; BCG; immunomodulatory drugs – thalidomide, lenalidomide, pomalidomide, which are also angiogenesis inhibitors)
Targeted Therapy	Tyrosine kinase inhibitors (e.g. erlotinib for EGFR, venetoclax for BCL2, imatinib for BCR-ABL mutations in CML, ibrutinib in CLL) Monoclonal antibody-drug conjugate (e.g. brentuximab-vedotin for lymphoma, obinutuzumab-ozogamicin for ALL) Angiogenesis inhibitors primarily target VEGF (e.g. bevacizumab, everolimus) Hormone therapy Gene therapy
Hormone Therapy	Oral Injection Surgery (oophorectomy, orchiectomy)
Stem Cell Transplant	Autologous Allogenic Syngeneic
Precision Medicine	Certain tumors, including melanoma, some leukemias, and breast, lung, colon, and rectal cancers, may be tested for certain genetic changes

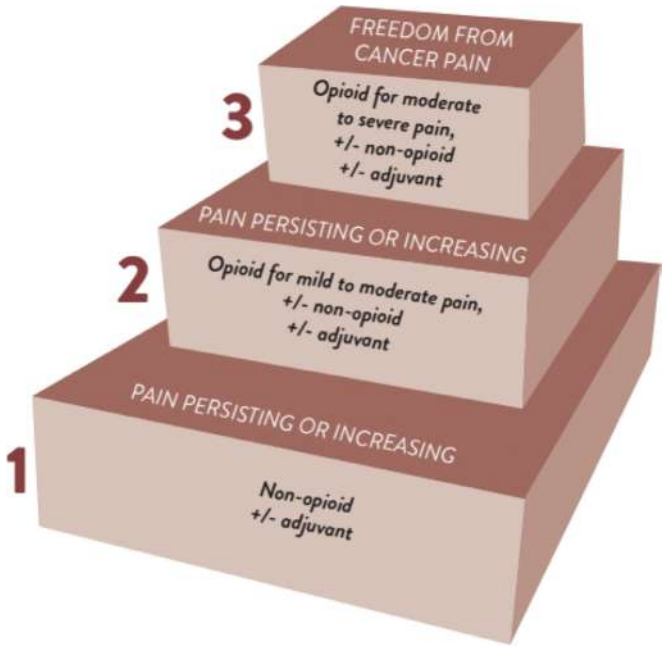
*Types of external beam radiation therapy include 3-D conformal therapy, intensity-modulated radiation therapy (IMRT), image-guided radiation therapy (IGRT), stereotactic radiosurgery, and stereotactic body radiation therapy.

ALL, Acute lymphoblastic leukemia; *BCG*, Bacillus Calmette- Guérin; *BCL2*, B-cell lymphoma 2; *BCR-ABL*, Breakpoint cluster region protein. The symbol ABL1 is derived from Abelson, the name of a leukemia virus. A fusion gene is created by juxtaposing the ABL1 gene on chromosome 9 (region q34) to a part of the BCR gene on chromosome 22 (region q11); *CAR-T*, chimeric antigen receptor; *CLL*, chronic lymphocytic leukemia; *CML*, chronic myeloid leukemia; *EGFR*, epidermal growth factor receptor; *IV*, intravenous; *TIL*, tumor-infiltrating lymphocytes; *VEGF*, vascular endothelial growth factor.

TABLE 33.2 Approaches to Oncology Pain Management

Drugs	Analgesics (opioids, NSAIDs, APAP) Adjuvant analgesics (anti-depressants, anti-convulsants) Steroids
Psychosocial	Cognitive behavioral Stress management, including biofeedback Social support
Integrative medicine	Acupuncture Massage Hypnotherapy
Physical therapy and Rehabilitation	Flexibility, strength, endurance, aerobic conditioning Lymphedema control
Modification of pathologic process	Radiation therapy Chemotherapy Surgery
Interruption of pain pathways	Local anesthetics Neurolytics (alcohol, phenol) Thermal ablation (radiofrequency, cryoablation) Neurosurgery (cordotomy, DREZ, anterior cingulotomy)

APAP, Automatic positive airway pressure; *DREZ*,**; *NSAIDs*, nonsteroidal anti-inflammatory drugs.



• **Figure 33.3** World Health Organization analgesic ladder (2018).

TABLE 33.3 Principles of Analgesic Use

Principle	Comment
By mouth	Oral intake is preferred. Transdermal/transmucosal can also be considered.
By the clock	Give medications regularly. Anticipate pain problems, particularly breakthrough pain. For opioid use, schedule ATC opioids and use BTP opioids as needed.
For the individual	Patient responses vary by patient and by medication. Variations in drug metabolism may cause unpredictable pharmacokinetics.
With attention to detail	Regular assessment of response to a regimen is essential. Assume patients may not follow a new regimen accurately or as prescribed.

ATC, Around the clock; *BTP*, breakthrough pain.

anti-convulsants for cancer pain management, the WHO report did not make a recommendation for these classes of medications for the treatment of cancer-related neuropathic pain. Adequate data from clinical trials regarding the use of anti-depressants and anti-convulsants in oncology pain was not available. In the absence of clear evidence in favor of use, practitioners may consider an individual trial of therapy and prescribe for those patients without adequate pain relief or have severe/unmanageable side effects to standard analgesic regimens. Drugs or drug classes recommended for the management of neuropathic pain are listed in Table 33.4.

Acetaminophen

N-acetyl-p-aminophenol (APAP) is an antipyretic/analgesic drug that is discussed extensively in Chapter 49. Hepatotoxicity is the most well-known severe adverse effect of APAP. Particularly in cases of overdose, APAP characteristically shows direct hepatocellular injury.[20] Hepatocellular injury may result in elevated aspartate aminotransferase (AST) and alanine aminotransferase (ALT) blood levels, usually 24–48 h after ingestion. Elevated ALT level greater than three times the upper limit of normal was seen in 33%–44% of normal volunteers who were administered 4 g of APAP daily for 14 days.[21] The maximum daily therapeutic dose of 3900–4000 mg was established in separate actions in 1977 and 1988, respectively, via the Food and Drug Administration (FDA) monograph process for nonprescription medications. The 3900 mg maximum daily dose, as recommended originally, was deemed to be safe and is five to seven times lower than the estimated median lethal dose (LD50) of 400 mg/kg.[22] Some studies have indicated that daily APAP doses of 4000 mg for 6 to 12 months demonstrated that no patient exceeded liver function tests beyond two times the upper limit of normal.[23] The FDA has conducted multiple advisory committee meetings to evaluate acetaminophen and its safety profile and has suggested (but not mandated) a reduction in the maximum daily dosage from 3900–4000 mg to 3000–3250 mg, which appears based on the potential of an overdose occurring if a patient was not using acetaminophen properly or if, unknowingly, a patient was using multiple acetaminophen-containing products. The concern was not with therapeutic dosing (≤4000 mg/24 h) but with excessive dosing when two or more products containing acetaminophen are taken inadvertently and the potential for hepatotoxicity with chronic use at excessive doses. In a Cochrane review, there was no high quality evidence to support or refute the use of APAP alone or in

TABLE 33.4 Drugs or Drug Classes With Strong or Weak Recommendations for the Management of Neuropathic Pain[192]

	Total Daily Dose and Dose Regimen	Recommendations
Strong Recommendations for Use		
Gabapentin	1200–3600 mg, in three divided doses	First line
Gabapentin extended release or enacarbil	1200–3600 mg, in two divided doses	First line
Pregabalin	300–600 mg, in two divided doses	First line
Serotonin noradrenaline reuptake inhibitors duloxetine or venlafaxine[a]	60–120 mg, once a day (duloxetine); 150–225 mg, once a day (venlafaxine extended release)	First line
Tricyclic anti-depressants	25–150 mg, once a day or in two divided doses	First line[b]
Weak Recommendations for Use		
Capsaicin 8% patches	One to four patches to the painful area for 30–60 min every three months	Second line (peripheral neuropathic pain)[c]
Lidocaine patches	One to three patches to the region of pain once a day for up to 12 h	Second line (peripheral neuropathic pain)

[a]Duloxetine is the most studied, and therefore recommended, of the serotonin noradrenaline reuptake inhibitors.

[b]Tricyclic anti-depressants generally have similar efficacy; tertiary amine tricyclic anti-depressants (amitriptyline, imipramine, and clomipramine) are not recommended at doses greater than 75 mg/day in adults aged 65 years and older because of major anticholinergic and sedative side effects and potential risk of falls; an increased risk of sudden cardiac death has been reported with tricyclic anti-depressants at doses greater than 100 mg daily.

[c]The long-term safety of repeated applications of high-concentration capsaicin patches in patients has not been clearly established, particularly with respect to degeneration of epidermal nerve fibers, which might be a cause for concern in progressive neuropathy.

combination with opioids for the first two steps of the three-step WHO cancer pain ladder.[24] It was not clear whether any additional analgesic benefit of acetaminophen could be detected in the available studies. In an era of concern for opioid prescribing, there is a tendency to prescribe regular and higher doses of APAP (up to 4 G/day) in cancer patients. Toxicity from high daily doses of APAP is of concern. Unintentional fever suppression in patients receiving chemotherapy is also an issue. APAP should be used cautiously and not for extended periods in oncology patients receiving active treatment.

Nonsteroidal Anti-inflammatory Medications

NSAIDs exhibit their action by inhibiting the cyclooxygenase (COX) enzyme, which consists of two isoforms named as COX-1 and COX-2. Most NSAIDs are nonselective and inhibit both COX-1 and COX-2. Celecoxib is the only marketed drug belonging to the class of selective COX-2 inhibitors approved by the FDA. COX-2 overexpression is demonstrated throughout various steps of tumorigenesis to metastasis, and COX-2 expression directly co-related with increased prostaglandin levels in neoplastic tissues, particularly in the gastrointestinal tract,[25] and possibly breast.[26] Long-term use of (low dose) aspirin and non-selective NSAIDs are potential candidates for chemoprevention of gastrointestinal cancer.[27] The anti-inflammatory activity of NSAIDs in descending order is indomethacin > diclofenac > piroxicam > ketoprofen > lornoxicam > ibuprofen > ketorolac > acetylsalicylic acid. The greater the degree of COX-1 block, the greater the tendency to cause gastrointestinal (GI) ulceration and the promotion of bleeding. From the first day of use, all NSAIDs increase the risk of GI bleeding, myocardial infarction, and stroke. The risk of bleeding is low for patients using NSAIDs intermittently. NSAIDs increase the risk of GI bleeding by inhibiting platelet aggregation, causing gastric mucosa lesions, ulceration, overt bleeding, enteropathy, and occult bleeding associated with a decrease in hemoglobin. Upper GI ulcers, gross bleeding, or perforation caused by NSAIDs occur in approximately 1% of patients treated for three to six months and in about 2%–4% of patients treated for one year. Even short-term (zero to three days) treatment with NSAIDs was associated with increased risk of bleeding compared with no NSAID use in patients receiving antithrombotic therapy.[28] Non-selective NSAIDs increase the risk of a GI bleed four fold, whereas COX-2 inhibitors increase this risk three fold. Co-prescription of NSAIDs with corticosteroids increases bleeding risk 12-fold, spironolactone 11-fold, and SSRIs 7-fold.[29] Monotherapy with non-selective NSAIDs increased the risk of upper GI bleeding by an incidence rate ratio (IRR) of 4.3 to a greater extent than monotherapy with COX-2 inhibitors (IRR, 2.9) or low-dose aspirin (IRR, 3.1). Combination therapy generally increased the risk of GI bleeding; concomitant NSAID and corticosteroid therapies increased the IRR to the greatest extent (12.8) and produced the greatest excess risk relative excess risk because of an interaction (RERI of 5.5. Concomitant use of NSAIDs and aldosterone antagonists produced an IRR for upper GI bleeding of 11.0 (RERI 4.5). The excess risk from the concomitant use of NSAIDs with selective serotonin reuptake inhibitors (SSRIs) was 1.6, whereas that from the use of COX-2 inhibitors with SSRIs was 1.9, and that for the use of low-dose aspirin with SSRIs was 0.5. Excess risk of concomitant use of NSAIDs with anticoagulants was 2.4, of COX-2 inhibitors with anticoagulants was 0.1, and of low-dose aspirin with anticoagulants was 1.9.[29] Concomitant use of non-selective NSAIDs or low dose aspirin, but not COX-2 inhibitors, with corticosteroids, aldosterone antagonists, or anticoagulants produces a significant excess risk of upper GI bleeding. Castellsague et al. pooled relative risks (RRs) of upper GI complications associated with individual NSAID use.[30] Agents such as celecoxib and ibuprofen have a low RR (1.5 and 1.8, respectively), while piroxicam and ketorolac have a higher RR (7.4 and 11.5, respectively).

Approximately 10% of the total drug-induced hepatotoxicity is NSAID-related.[31] Sulindac and diclofenac are the NSAIDs most associated with hepatotoxicity, but virtually all NSAIDs have been linked to at least rare cases of clinically apparent drug-induced liver injury. The most common adverse effects affect the gastric mucosa, renal system, cardiovascular system, hepatic system, and hematologic system. The mechanism of injury to the liver is usually hepatocellular, but cholestatic injury can also occur.[32] COX-2 selective inhibitors and non-selective NSAIDs are associated with an increased risk of acute cardiovascular events.[33] Even one week of NSAID use is associated with an elevated risk of myocardial infarction (MI), and this phenomenon may apply to those with no prior history of MI. While the risk increases with increasing dosage, the risk appears to plateau after a one-month duration of use.[34] In older patients with arthritis and established coronary artery disease or risk factors who used chronic NSAID therapy (celecoxib 100–200 mg twice daily, ibuprofen 600–800 mg thrice daily, or naproxen 375–500 mg twice daily), naproxen and ibuprofen at moderate doses were associated with more cardiovascular events that with celecoxib.[35] The vascular risks of high-dose diclofenac (150 mg/day) and possibly ibuprofen (2400 mg/day) are comparable to coxibs. In contrast, high-dose naproxen (1000 mg/day) is associated with less vascular risk than other NSAIDs.[36] NSAIDs can cause serious renal adverse effects, which include sodium and water retention with edema, worsening of heart failure, hypertension, hyponatremia, hyperkalemia, acute kidney injury, renal papillary necrosis, and acute interstitial nephritis. Acute forms of kidney injuries are transient and often reversible upon drug withdrawal. Approximately 1%–8% of patients taking NSAIDs develop renal adverse effects such as a reduction in glomerular filtration rate, acute renal failure, renal papillary necrosis, nephrotic syndrome, acute interstitial nephritis, and chronic renal failure.[37] NSAIDs, unlike aspirin, bind reversibly at the active site of COX-1, usually depressing platelet thromboxane formation to the degree that platelet function is impaired for only a portion of the dosing interval. Platelet function normalizes within 24 h of the last dose of ibuprofen in healthy volunteers who took 600 mg q 8 h for one week.[38]

Studies on the use of NSAIDs in cancer (including both aspirin and non-aspirin NSAIDs) show inconsistent and contradictory findings in terms of the role of these drugs in cancer, with some reporting an increased risk in certain types of cancer and others showing a reduction in cancer risk.[39] Although many NSAIDs are available to treat various painful conditions, it is unclear which agent is most clinically efficacious for relieving cancer-related pain and if there are clinical differences between these agents that justify their cost differences. In a Cochrane review of the use of NSAIDs either alone or in combination with opioids, the quality of evidence supporting the use of NSAIDs was poor and suggested that moderate to severe cancer pain was reduced to no worse than mild pain after one to two weeks in approximately 1:3 patients. One in four patients stopped taking NSAIDs because the drug did not work, and 1:20 stopped because of side effects.[40] In effect, there is no evidence to support or refute the use of NSAIDs alone

or in combination with opioids for cancer pain.[40,41] The long-term use of NSAIDs for pain management is not advisable in patients with cancer, particularly because of the additional bleeding risks in cancer patients undergoing active treatment with myelosuppressive regimens and the probability that a patient with cancer may be on a broad regimen of medications, some of which may increase NSAID-related toxicity (myocardial infarction, gastrointestinal bleeding, and renal failure).

Antiepileptic Drugs

The pharmacologic mechanism of action responsible for therapeutic effects in pain management is unclear (Table 33.5) and may involve enhancement of GABAergic inhibition, decreased glutamatergic excitation, modulation of voltage-gated sodium and calcium channels, and effects on intracellular signaling pathways.[42]

Antiepileptic drugs (AEDs) are often administered as polytherapy or combined with other treatments. The pharmacokinetics of carbamazepine is nonlinear because of autoinduction that completes within three weeks and can result in a threefold increase in elimination. It is extensively metabolized in the liver, primarily by CYP3A4. Because of this, it is readily inducible and potently inhibited. Therefore it is subject to many pharmacokinetic drug-drug interactions. As well as being an enzyme-inducing drug, carbamazepine is affected by the autoinduction of CYP3A4-mediated metabolism. This mainly occurs at the beginning of treatment when clearance can increase up to three times during the first two to three weeks. Carbamazepine, oxcarbazepine, phenobarbital, and phenytoin may reduce the levels of cyclosporin, tacrolimus, and corticosteroids, delaying the immunosuppressant effect by up to ten days.[43] Gabapentin, lacosamide, levetiracetam, pregabalin, and vigabatrin are essentially not associated with clinically significant pharmacokinetic interactions.[44]

Gabapentinoids include gabapentin and pregabalin. The α2δ-1, commonly known as a voltage-activated Ca2+ channel subunit, is a binding site of gabapentinoids.[45] Gabapentinoids commonly

TABLE 33.5 Antiepileptic Drugs

Medication	Mechanism of Action	Indication	IR	ER	Comment
Valproate	Influences GABAergic neurotransmission. It is also thought to block sodium and calcium channels.	Epilepsy, acute mania/ bipolar disorder, and migraine prophylaxis.	Yes	DR and ER tablets	ER formulation has lower bioavailability. Doses need to be increased by 12% (8%–20%) compared to the standard formulation. Effective for migraine prevention. Risk of fetal malformation. Adverse benefits include liver function test abnormalities, dizziness, drowsiness, and nausea. Maximum dose is 60 mg/kg/day.
Carbamazepine	Blocks voltage-gated sodium channels.	Epilepsy (especially partial seizures), bipolar disorder, and trigeminal neuralgia.	Yes	Carbatrol or Tegretol-XR	Side effects include hyponatremia, leukocytosis, thrombocytopenia, dizziness, drowsiness, ataxia, nausea/vomiting, and blurred vision. Dosing starts at 100–200 mg twice a day and is titrated up by 200 mg/day every three to five days until pain relief is achieved. The maximum dose is 1200 mg/day.
Phenytoin		Partial and generalized seizures; monotherapy for trigeminal neuralgia.	Yes	ER	Non-linear pharmacokinetics.
Oxcarbazepine	Blocks voltage-gated sodium channels.	Focal seizures with or without secondary generalization.	Yes	ER	ER peak concentrations are 19% lower than with OXC IR. It can be started at 300 mg twice a day and titrated up by 300 mg/day every three days for therapeutic effect. The maximum dose is 2400 mg/day.
Lamotrigine	Blocks Na+ channels, neuronal α-4-β2-nicotinic acetylcholine receptors may be a target.	Partial seizures, the generalized seizures of Lennox-Gastaut syndrome, primary generalized tonic-clonic seizures. Mood stabilizer in bipolar.	Yes	XR	Risk of Stevens-Johnson. Start at low doses (25 mg/day) with weekly titration to target dose. Syndrome, blood dyscrasia.

TABLE 33.5 Antiepileptic Drugs—cont'd

Medication	Mechanism of Action	Indication	IR	ER	Comment
Lacosamide	Selectively enhances the slow inactivation of voltage-gated sodium channels and interacts with the collapsin-response mediator protein-2.	Primary generalized tonic-clonic seizures, partial onset seizures.			Dosing starts at 50 mg twice daily and can be increased to 400 mg/day. Abrupt discontinuation can precipitate seizures. No convincing evidence of efficacy in neuropathic pain and fibromyalgia at doses of 200–400 mg daily.
Gabapentin	Binds to calcium channels and modulating calcium influx. Exert analgesic effect through high affinity binding and modulation of the calcium channel α2-δ proteins in the dorsal root ganglion.	Partial seizures, postherpetic neuralgia.	Yes	ER	Compared with other anti-convulsant drugs, the α2-δ ligands do not have significant drug interactions, predominantly because of their lack of hepatic metabolism or their modulation of cytochrome P450 activity. Nonlinear pharmacokinetics (absorbed in the proximal small bowel by the L-amino acid transporter, which is a saturable mechanism).
Pregabalin	Binds to calcium channels and modulating calcium influx. Exert analgesic effect through high affinity binding and modulation of the calcium channel α2-δ proteins in the dorsal root ganglion.	Painful diabetic peripheral neuropathy, postherpetic neuralgia, partial onset seizures, fibromyalgia, neuropathic pain associated with spinal cord injury.	Yes	ER	Compared with other anti-convulsant drugs, the α2-δ ligands do not have significant drug interactions, predominantly because of their lack of hepatic metabolism or their modulation of cytochrome P450 activity. Unlike gabapentin, it has linear pharmacokinetics over its recommended dose ranges. Start at low doses (50 mg daily), adding 50 mg each week on a twice a day basis to a max of 600 mg per day.
Topiramate	Blocks activity-dependent, voltage-gated sodium channels; enhance the action of GABA receptors; inhibit L-type voltage-gated calcium channels; presynaptically reduce glutamate release, and postsynaptically block kainate/α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors.	Generalized tonic-clonic seizures, partial seizures, migraine.	Yes	ER	Dosing starts at 50 mg/day and can be titrated up to 400 mg/day. No convincing evidence of efficacy in neuropathic pain. Serious adverse events thought to be related to topiramate included convulsion and bradycardia plus syncope. Additional adverse effects include sedation, nausea, diarrhea, and metabolic acidosis.

IR = Immediate release.
ER/XR = Extended release.
DR = Delayed release.

cause adverse effects such as sedation, confusion, dizziness, ataxia, visual disturbances, and altered cognition. Combined with opioids, this side effect profile can be potentiated. For first-time pregabalin users, dizziness and somnolence were reported by 25% and 14% of patients, respectively.[45] Gabapentinoids have the potential to be abused with an estimated prevalence of 1.6% in the general population with ranges from 3% to 68% among opioid abusers,[46] and are associated with euphoria, sedation, and dissociation. Gabapentin was misused primarily for recreational purposes, self-medication, or intentional self-harm and was misused alone or combined with other substances, especially opioids, benzodiazepines, and/or alcohol.[47] Risk factors for abuse include a history of substance abuse, particularly opioids, and psychiatric comorbidities. Sedation and dizziness are relatively common, and some patients experience cognitive difficulties while taking these drugs.[48] In 2008, the FDA issued a warning on all AEDs that these drugs have an increased risk of suicidal thoughts and behaviors. The relative risk was higher in the epilepsy patient group when compared to the groups of patients receiving AEDs for psychiatric and other conditions. However, patients and clinicians should not avoid the use of AEDs because of the risk of suicidality.[49] However, the high prevalence of comorbid behavioral health issues in patients treated with AEDs suggests that the association is confounded by indication, preexisting mental health conditions, and medications received. In a cohort analysis,

Patorno et al.[50] found an increased risk for these events in new users of gabapentin, lamotrigine, oxcarbazepine, and tiagabine compared with topiramate. A secondary analysis confirmed the increased risk and identified an excess of 5.6 cases of attempted or completed suicide per 1000 person-years among new users of gabapentin, 10.0 cases per 1000 person-years among new users of oxcarbazepine, and 14.1 cases per 1000 person-years among new users of tiagabine compared with topiramate. The risk remained increased for gabapentin in subgroups of younger and older patients, patients with a mood disorder, and patients with epilepsy or seizure disorders.

Gabapentinoids are indicated for the treatment of epilepsy, peripheral and neuropathic pain, fibromyalgia, and generalized anxiety disorder in adults. Recommendations for use and doses in neuropathic pain are listed in Table 33.4. For gabapentin, the only pain related indication approved by the FDA is postherpetic neuralgia. For pregabalin, FDA-approved indications related to pain are limited to postherpetic neuralgia, neuropathic pain associated with diabetic neuropathy or spinal cord injury, and fibromyalgia. Despite these limited indications, gabapentin and pregabalin are widely prescribed off-label for multiple different pain complaints.[51] A common mistaken perception is that an effective drug for one type of neuropathic pain is beneficial for all neuropathic pain, regardless of underlying etiology or mechanism. Recommendations across guidelines consistently endorse gabapentinoids as first line agents for general neuropathic pain complaints but that the overall quality of these guidelines is poor.[52] Similarly, the evidence does not support gabapentinoid therapy for low back pain or radiculopathy, suggesting that pregabalin was ineffective.[53] A Cochrane review showed that some patients with neuropathic pain would benefit substantially from pregabalin, while more are having moderate benefit, and many are without any benefit.[54] Gabapentin can provide good levels of pain relief to some people with postherpetic neuralgia and peripheral diabetic neuropathy, but evidence for other types of neuropathic pain is very limited.[55,56] Similarly, there is little evidence to support the effectiveness of oxcarbazepine in painful diabetic neuropathy, neuropathic pain from radiculopathy, and a mixture of neuropathies.[56] Overall, there is low quality evidence that gabapentinoids are effective in reducing pain intensity in patients with cancer pain.[57]

Anti-depressants

Anti-depressants can be classified into different classes based on their mechanisms of action (Table 33.6).

The two classic mechanisms are demonstrated by tricyclic antidepressants and monoamine oxidase inhibitors. The nonclassical anti-depressants, the most widely prescribed agents, are SSRIs and dual serotonin norepinephrine reuptake inhibition (SNRI). Anti-depressants have virtually no antinociceptive effects but are prescribed for neuropathic pain. Tricyclic anti-depressants and serotonin noradrenaline reuptake inhibitors are used to treat chronic pain, such as neuropathic pain and fibromyalgia. SSRIs are generally the first line anti-depressants for the treatment of depression in cancer patients because of their tolerability profile. SSRIs, which are frequently used to treat depression, are not effective against chronic pain.[58] The inhibitory effects of anti-depressants for neuropathic pain manifest more quickly than their anti-depressant effects, suggesting different modes of action. The analgesic effect on chronic pain may manifest in as little as a few days to one week, whereas the anti-depressant effects may take two to four weeks.[59] Anti-depressants that inhibit the reuptake of both noradrenaline and 5-HT have stronger analgesic effects than a drug that selectively inhibits the reuptake of only one of these neurotransmitters, and norepinephrine plays a greater role than 5-HT in the analgesic action. Anti-depressants have several other actions in addition to increasing monoamines that may contribute to the inhibition of neuropathic pain, such as sodium channel blockers, *N*-methyl-D-aspartate (NMDA) receptor antagonists, effects on α-1 receptors, calcium channel blockers, potassium channel activators, modulation of the adenosine system, and activation of GABA-B receptors.[59] Serotonin and dopamine may reinforce the noradrenergic effects to inhibit neuropathic pain. Increasing norepinephrine in the spinal cord by reuptake inhibition directly inhibits neuropathic pain through α2-adrenergic receptors. Also, increasing norepinephrine acts on the locus coeruleus and is an essential element of both the ascending and descending pain modulator systems regulated by these anti-depressants.[60] TCAs (amitriptyline, nortriptyline, and desipramine) have been the first line treatment for neuropathic pain for many years, but only a minority of people will achieve satisfactory pain relief.[61–63] Finnerup et al.[58] reviewed the pharmacotherapy for neuropathic pain in adults. Outcomes were generally modest even for effective drugs: in particular, NNTs were 3.6 (95% confidence interval [CI] 3.0-4.4) for TCAs and 6.4 (95% CI 5.2-8.4) for the SNRI anti-depressants duloxetine and venlafaxine. There was no evidence for a dose-response effect for amitriptyline. Combined NNH was 13.4 (9.3-24.4) for TCAs and 11.8 (9.5-15.2) for SNRIs. Low-dose amitriptyline (25 mg/day) for chronic low back pain did not improve outcomes at six months with no improvement in pain intensity, but there was a reduction in disability at three months.[64] When anti-depressants are used for chronic pain, the most prevalent adverse effects from anti-depressants were dry mouth, dizziness, nausea, headache, and constipation.[65] Risk for withdrawal because of adverse effects was highest for desipramine followed by venlafaxine and duloxetine. TCAs are associated with increased mortality in cases of intentional or accidental overdose, and their side effects profile and tolerability require careful dose titration and frequent monitoring, which substantially limits their wide use.[66] Minor side effects are common and more common with duloxetine 60 mg and particularly with 120 mg daily than 20 mg daily, but serious side effects are rare.

Chemotherapy-induced peripheral neuropathy (CIPN) is common among cancer patients who undergo chemotherapy with platinum analogs, taxanes, vinca alkaloids, epothilone, bortezomib, and thalidomide. Chemotherapeutic agents can damage nervous system structures and, depending on the individual compound, can cause various neuropathies that affect different structures, including large and small fibers and autonomic function.[67] The effects of chemotherapy on the nervous system vary among the different classes of drugs, depending on the specific physical and chemical properties of the drug used and its single or cumulative doses. The mechanism by which chemotherapeutics damages nervous system structures and causes CIPN is multifactorial and involves microtubule disruption, oxidative stress and mitochondrial damage, altered ion channel activity, myelin sheath damage, DNA damage, immunologic processes, and neuroinflammation.[68] The mechanisms of injury are complex and interested readers are referred to the review by Carozzi et al.[69] When patients experience drug-induced chronic neurotoxicity that necessitates intervention beyond dose reduction or discontinuation, the strongest evidence supports the use of duloxetine.[70] However, other anti-depressants have not shown a similar benefit. Furthermore, the best available data support a moderate recommendation for

TABLE 33.6 Classification of Anti-depressants

Drug Type	Example	Comment
Norepinephrine-dopamine reuptake inhibitors (NDRI)	Bupropion	Acts selectively to inhibit the noradrenergic and dopaminergic reuptake transporter pump systems. Side effects include anxiety, insomnia or sedation, weight loss, and may be excessively activating for some patients. Seizures may occur at dosages above 450 mg/day.
Serotonin noradrenaline reuptake inhibitors (SNRIs)		Mixed action on both NE and serotonin. Used in the treatment of pain disorders, including neuropathies and fibromyalgia. SNRIs are also used in the treatment of generalized anxiety disorder, stress urinary incontinence, and vasomotor symptoms of menopause. Pharmacologic properties are dose dependent. At low doses, behave essentially like an SSRI; while at medium doses, additional NE reuptake inhibition occurs, and at high-to-very high doses, weakly inhibit the reuptake of dopamine.
	Duloxetine	Side effects include nausea, dry mouth, constipation, dizziness, and insomnia.
	Venlafaxine	Serotonin reuptake inhibition in dosages below 150 mg/day; mixed serotonin and noradrenergic reuptake inhibition in dosages above 150 mg/day Side effects may include headache, nausea, sweating, sedation, hypertension, and seizures.
	Desvenlafaxine	Major active metabolite of venlafaxine. X10 times more potent inhibiting serotonin than norepinephrine uptake.
Selective serotonin reuptake inhibitors (SSRIs)		Proven efficacy in panic disorder, generalized anxiety disorders, obsessive-compulsive disorder, and bulimia, with encouraging findings in social phobia, post-traumatic stress disorder. Side effects of SSRIs may include nausea, sedation, decreased libido, sexual dysfunction, headache, and weight gain.
	Citalopram	QT prolongation.
	Escitalopram	(S)-enantiomer of citalopram.
	Fluoxetine	Can cause activation (take during daytime). Because of a long half-life and active metabolites, rare symptoms of discontinuation or withdrawal symptoms if abruptly stopped.
	Paroxetine	Can be sedating and thus taken at bedtime. Its anticholinergic side effects can affect cognition, especially in the elderly. Discontinuation/ withdrawal symptoms could develop if abruptly discontinued.
	Sertraline	
Serotonin receptors antagonist with serotonin reuptake inhibition (SARI)	Trazodone	Moderate-to-strong serotonin receptor(s) antagonism with a weak serotonin reuptake transporter inhibition. Side effects include sedation and drowsiness, tachycardia, and priapism (rarely).
Tricyclic anti-depressants (TCAs)		"Gold standard" anti-depressants. Among the best studied and most commonly used are the first-generation TCAs, which are mixed reuptake inhibitors with both NE and serotonergic 5-HT effects such as amitriptyline, imipramine, and doxepin.
	Amitriptyline	Most potent anticholinergic; cautious use in elderly.
	Clomipramine	
	Desipramine	As secondary amine, fewer anticholinergic effects.
	Doxepin	Most potent antihistamine effects.
	Imipramine	
	Nortriptyline	Acts by inhibiting the reuptake of NE and serotonin 5-HT and possesses central anticholinergic activities. As secondary amine, fewer anticholinergic effects.
	Desipramine	
Noradrenergic α2-receptor antagonist with specific serotonergic receptors-2 and -3 antagonism (NASSA)	Mirtazapine	Enhances release of NE and 5-HT1A-mediated serotonergic transmission. Side effects include drowsiness, dizziness, anxiety, confusion, increased appetite, and weight gain.

treatment with duloxetine.[71] CIPN trials were also inconclusive regarding tricyclic anti-depressants (such as nortriptyline) and a compounded topical gel containing baclofen, amitriptyline HCL, and ketamine.[71] Anti-convulsants, such as gabapentinoids, have not been proven effective for patients with CIPN.[70] Duloxetine, when used for diabetic peripheral neuropathy and fibromyalgia, has efficacy for pain associated with diabetic neuropathy at doses >60 mg/day (not at lower doses).[72] The effect in fibromyalgia was likely achieved through a greater improvement in mental symptoms than in somatic physical pain.

Opioids

Opioids are extensively discussed in Chapter 48. Although some suggest that opioids are relatively ineffective for the management of neuropathic in chronic pain,[58,73] this has not been our experience and of others in cancer pain.[74–76] Clinical pathways have emerged as one of the key approaches to minimize unwarranted variation in care and improve both the quality and efficiency of care. When appropriately designed and implemented, oncology pathways are detailed with evidence-based treatment protocols for delivering quality cancer care for particular patient presentations that include the type and stage of disease.[77] Extrapolation from opioid prescribing recommendations, including the guideline for prescribing opioids for chronic pain from the Centers for Disease Control and Prevention,[78] and applying these to the cancer population is problematic as most of the recommendations have not included opioid outcomes in this particular population. Consequently, some professional oncology organizations and societies have issued policy and position statements on opioid therapy emphasizing continued access for cancer-related pain.[79–81] Continued use of opioids in oncology requires risk evaluation and strategies for continued monitoring in all patients, including those considered at high risk for opioid misuse or abuse or illicit substance use (Table 33.7).

Opioids have been classified as weak and strong opioids, based upon their affinity for the μ-receptor.[82,15] Distinct opioids may elicit very different intracellular responses and may ultimately have very different outcomes on behavior, including analgesic ability, addiction liability, and the risk for acute negative side effects such as respiratory depression.[83] The wide-ranging drug-specific differences among opioids in their pharmacokinetics and pharmacodynamics include opioid receptor biases and ligand biases at the opioid receptors, as well as differential interactions with the non-opioid system. These result in differential coupling and activation of intracellular signaling and likely accounts for diverse interactions with various biologic systems, such as the immune

TABLE 33.7 Risk Evaluation and Monitoring for Continued Opioid (All Doses) Therapy in Oncology Patients

All Patients	
Risk stratification	Screening tool such as ORT Personal history of substance abuse including prescription opioids, psychoactive medications, illicit substances, alcohol Family history of substance abuse including prescription opioids, psychoactive medications, illicit substances, alcohol Presence of adequate support system (family, friends, social)
Education on opioid use and safety	Risk versus benefit Informed consent for opioid therapy Safe medication keeping Adherence to prescription instructions Naloxone use
Regular ongoing screening and monitoring	Regular follow-up with pill counts/opioid reconciliation (telephone/telemedicine/clinic) or office visit Prescription monitoring program review at each refill Current opioid misuse measure at each clinic/office visit Review for the presence of aberrant drug behaviors Urine toxicology screening (to include alcohol, illicit drug, comprehensive panel for opioids) at minimum yearly or sooner as clinically indicated
Regular concomitant psychoactive medication review	Elimination of other psychoactive medications when possible Avoidance of concurrent long term use of benzodiazepines or Z drugs
High Risk Patients	
No evidence of current substance use	Regular review of medical indication for continued opioid use Referral for addiction specialist assessment (as indicated) Frequent (at least four times per year) random urine drug screening (to include alcohol, illicit drug, comprehensive panel for opioids) Consequences for unsanctioned substance/non-prescribed medication use, including alcohol
Evidence of current substance use	No initiation of controlled substance prescriptions with ongoing illicit substance use, including alcohol Referral for addiction assessment and management Frequent (at least four times per year or more frequently as clinically indicated) urine drug screening (to include alcohol, illicit drug, comprehensive panel for opioids) Elimination of other psychoactive medications when possible Consequences for unsanctioned substance/non-prescribed medication use, including alcohol

The use of an opioid contract is not considered mandatory in oncology care. High risk patients include patients with an opioid risk tool (ORT) score of ≥ eight; history of chemical coping or issues with prescription adherence; active problematic alcohol use, illicit drug or prescription drug abuse. Aberrant drug-related behavior is a behavior suggestive of a substance abuse and/or substance use disorder.

system and the dopaminergic reward system.[84] Three distinct opioid receptors have been cloned, mu (MOR), kappa (KOR), and delta (DOR), with different selectivity for individual endogenous peptides and the various opioids. The three opioid signaling systems have unique and counterbalancing roles as they relate to their regulation of pain, stress, and affect. Though the MOR is the main target for opioid analgesics, the DOR and KOR also regulate pain, and analgesia and the relative affinities of opioid analgesics for these receptors confer their unique properties. MOR agonists produce euphoria and promote stress coping. KOR agonists produce dysphoria and are associated with stress and negative affect. DOR is on the opposite end of the continuum describing mood, and DOR agonists have anxiolytic and anti-depressant activity.[85] Opioids mimic endogenous opioids and act by binding to the opioid receptors, thereby activating them with individual differences in receptor binding and signal transduction.[86] Additionally, G protein signaling can be selectively targeted.[87]

Opioids are the mainstay of pharmacotherapy for patients with moderate or more intense pain resulting from virtually any cancer-related etiology. The specific pathogenic mechanism that underlies a patient's cancer pain should not be a factor in deciding which opioid to use, as the mechanism of pain does not reliably predict the response to opioid therapy. This particularly applies to situations in which tumor-associated neuropathic mechanisms dominate the pain complaint. Opioids should be used as first line therapy in such situations, particularly if the pain is considered moderate to severe in intensity. In oncology, opioids have demonstrable benefits for neuropathic pain.[88–90] Factors influencing the selection of a particular opioid are listed in Table 33.8.

All clinicians who prescribe opioids for the treatment of cancer pain should be familiar with at least three different agents appropriate for the management of moderate to severe pain.[91] The regimen for opioid medications should generally provide around the clock analgesia with provision for rescue doses for the management of exacerbations of the pain not covered by the regular dosage. Predicting the effectiveness of extended release opioids requires knowledge of associated pharmacokinetics. The onset time and time to maximal concentration (Tmax) are particularly helpful. For the extended release opioids, the elimination half-life is not particularly useful because of altered absorption characteristics into the central compartment.

Opioids are effective after peripheral (topical, intra-articular), neuraxial (intrathecal, epidural, intracerebroventricular), or systemic (intravenous, oral, subcutaneous, sublingual, intranasal, transdermal) administration, although the final effects are highly dependent on the particular pharmacokinetic and pharmacodynamic features of each drug.[84]

TABLE 33.8 Factors Influencing the Selection of Opioid Therapy

Risk assessment for problematic opioid use

TABLE 33.9 Opioid-Related Side Effects

	Transient Side Effects
Nausea/ vomiting	Direct effect on CTZ Sensitivity of vestibular apparatus (activation of MROs in vestibular epithelium) Delayed gastric emptying (central and peripheral)
Pruritus	? agonism at MOR
Sedation	Disordered level of consciousness in which both arousal mechanisms and content processing are functional but attenuated Symptoms include feeling drowsy, sleepy, groggy, dizzy, dreamy, cloudy, mentally foggy, or lethargic Signs may include cognitive impairment, lack of coordination, slowed reaction time, and performance deficits
Respiratory depression	Consider synergistic effects from concomitant other centrally acting drugs Rule out other contributors (e.g. pneumonia, sleep apnea)
Urinary retention	Spinal cord opioid receptor activation ® bladder wall relaxation Increased parasympathetic activity to detrusor muscle
Persistent Side Effects	
Opioid-induced constipation	Enteral activation of opioid receptors resulting in gastric emptying, sphincter tone, and peristalsis Consider peripherally acting MOR antagonist (PAMORA) agents
Endocrine effects	? direct effect on opioid receptors within hypothalamus, pituitary, and testes Hypothalamic effect, gonadotropin-releasing hormone

CTZ = Chemoreceptor trigger zone.
MOR = Mu opioid receptor.

All clinicians involved in the treatment of cancer patients should be familiar with the most common types and dosages of opioids, as well as the management of the most common side effects (Table 33.9).[18]

Selected Opioids

Tramadol

Tramadol is a synthetic analog of morphine and codeine and was approved by the FDA to treat moderate to severe pain in adults. Formulations include immediate-release tablets, sustained-release tablets, and extended release capsules. It has a unique mechanism of action and pharmacologic effects that differ from those of other opioid drugs. It has opioidergic, noradrenergic, and serotonergic actions and also has modulatory effects on several mediators involved in pain signaling. Tramadol's active metabolite (M1) contributes significantly to its analgesic effect. Cmax is achieved approximately 2 h after oral administration, t1/2 is 5–6 h, and bioavailability of 68%–84%. The kidneys are responsible for 90%

excretion of tramadol and its metabolites; the remaining 10% is excreted through feces. Because of its hepatic metabolism and renal clearance, impairment in these systems may require dose modifications.

Serotonin syndrome may occur with concomitant administration of serotonergic psychotropic agents within recommended dosing parameters for fluoxetine, paroxetine, sertraline, venlafaxine, mirtazapine, citalopram, bupropion, and olanzapine. Certain serotonergic anti-depressants (i.e. paroxetine, fluoxetine) inhibit cytochrome P-450 2D6, elevating plasma concentrations of tramadol and further increasing the risk for serotonin syndrome. Importantly, tramadol is specifically contraindicated with monoamine oxidase inhibitors or within 14 days of discontinuing a monoamine oxidase inhibitor.[92] Tramadol side effects are varied. However, the most common events are nausea, followed by vertigo, dizziness, vomiting, tiredness, constipation, sweating, dry mouth, and sedation. The causes of seizures after tramadol exposure are unclear. There is limited, very low quality evidence from randomized controlled trials that tramadol produced pain relief in some adults with pain because of cancer.[93]

Tapentadol

Tapentadol, a centrally acting analgesic, has been proposed as the first agent in a new class of drugs (MOR-NRI) combining the two mechanisms of action μ-opioid receptor (MOR) agonism and noradrenaline reuptake inhibition (NRI) in one molecule.[94] Because of its limited protein binding capacity, the absence of active metabolites, and significant microsomal enzyme induction or inhibition, tapentadol has a limited potential for drug-drug interactions.[95] Bioavailability is approximately 32% with t½ of 4 h for immediate-release formulations and 5–6 h for extended release. It shows moderate MOR agonist activity, pronounced NA reuptake inhibition, and minimal 5-HT effect. Clinical trials for chronic severe pain suggested that tapentadol provided equivalent or superior levels of pain relief for acute and chronic pain similar to oxycodone, hydromorphone, fentanyl, oxymorphone, and morphine and significantly less frequent gastrointestinal adverse events (nausea, vomiting, constipation) compared with fentanyl, morphine, hydromorphone, and oxymorphone.[96] From the limited data available for oncology pain, pain relief, and adverse events were comparable to morphine and oxycodone, with the most common adverse events being gastrointestinal (nausea, vomiting, constipation).[96]

Hydrocodone

Hydrocodone is a full opioid agonist with relative selectivity for the μ-opioid receptor, although it can interact with other opioid receptors (δ and κ) at higher doses.[97] Human PK studies indicate that the conversion of hydrocodone to its primary metabolite, norhydrocodone, and lesser metabolite, hydromorphone, is mediated by the cytochrome P450 enzyme system. Some authors suggest that hydrocodone is a pro-drug and requires metabolism to hydromorphone for therapeutic benefit and that pain relief correlates with plasma hydromorphone concentrations rather than hydrocodone.[98] Immediate-release hydrocodone is available as a combination product (acetaminophen, ibuprofen), and single entity hydrocodone only available as extended-release formulations. Hydrocodone is also an antitussive and indicated for cough in adults. The analgesic efficacy can be highly variable and devoid of therapeutic effect in some patients, likely because of CYP2D6 polymorphisms.[99] Data regarding the use of hydrocodone in oncology is limited. When low-dose hydrocodone (25 mg/day) was compared to tramadol (200 mg/day) in patients with chronic cancer pain, hydrocodone was not superior in terms of analgesic efficacy, and tramadol produced more mild side effects than hydrocodone.[100]

Methadone

Methadone is available as a racemic mixture of two stereoisomers – L-methadone (pharmacologically active isomer) and D-methadone. L-methadone is eight to 50 times more potent than D-methadone in humans and is believed to be almost entirely responsible for its analgesic properties. Because of its large volume of distribution and its long half-life, methadone tends to accumulate in adipose tissues, especially after repeated doses. It is 60%–90% bound to plasma proteins, and its bioavailability after oral administration is 70%–90%. Tmax averages 2.5–4.4 h following oral administration. On average, the half-life of methadone is around 24 h, but it may vary as much as from 8 to 120 h depending on an individual patient's adipose tissue composition. Because of its long, biphasic elimination half-life, it may take up to ten days to reach steady-state serum levels. Dosage adjustment is not required in renal or hepatic insufficiency or hemodialysis. Methadone is primarily metabolized by N-demethylation to an inactive metabolite. Cytochrome P450 enzymes are responsible for the conversion of methadone to EDDP and other inactive metabolites, which are excreted mainly in the urine. One of the enzymes, CYP3A4, is also involved in the metabolism of other drugs: benzodiazepines, calcium antagonists, macrolide antibiotics, and anti-convulsants (carbamazepine). Its activity is strongly inhibited by ketoconazole, fluoxetine, and grapefruit juice (large amounts). Because CYP3A4 is inducible, it can result in drug interactions with other drugs that are also dependent on that enzyme for metabolism. This may directly affect plasma concentrations of methadone with CYP3A4 inducers decreasing plasma levels and inhibitors increasing blood levels (Table 33.10).

Managing the Cardiac Effects of Methadone

The contribution of NMDA receptor antagonism to methadone's efficacy is unknown. While the ability of methadone to block the NMDA receptor has been demonstrated in animal models,[101] it is unclear if this has clinical relevance at normal doses. Studies for this indication are limited with very low quality evidence of efficacy and safety.[102] In cancer pain, the analgesic benefits of methadone appear similar to morphine.[103] Our experience is that this is an excellent opioid for pain management but should be avoided in situations of rapidly changing pain complaints where frequent changes in opioid dosing are anticipated (e.g. uncontrolled tumor pain). Further, many drugs used in oncology (e.g. tyrosine kinase inhibitors, 5-HT inhibitor antiemetics, monoclonal antibodies) can also prolong QTc.

Buprenorphine

Buprenorphine is a semi-synthetic high affinity partial agonist at μ-opioid receptors and an antagonist at κ receptors with a ceiling effect on sedation and respiratory depression without a clinically relevant ceiling on pain relief.[104] The high receptor affinity results in a slow dissociation from the receptor and prolonged activity. Precipitated withdrawal can result if buprenorphine is introduced in the presence of other opiates with lesser binding affinities. Unlike other opioids, buprenorphine exhibits a ceiling effect for respiratory depression (acts as a partial agonist) but not for pain relief.[105] Data in opioid-naive volunteers indicate that buprenorphine

causes dose-dependent respiratory depression that levels off at greater buprenorphine doses.[106] Also, in contrast to other opioids, buprenorphine has a pronounced antihyperalgesic effect, which may be because of its κ-receptor antagonism.[105] It is extensively metabolized through 14-N-dealkylation by the hepatic CYP3A4 (primary pathway) to norbuprenorphine with 50%–70% eliminated fecally. Routes of administration are typically oral, sublingual, buccal, and transdermal. It is often formulated with naloxone to deter diversion. Administration of buprenorphine via the sublingual route can quickly reach effective plasma concentrations (onset of effect is 30–60 min with Tmax at about 90–100 min). Oral formulations of buprenorphine have low bioavailability with only 10% of the intravenous route if swallowed and only between 30% and 50% bioavailability with the sublingual administration. The bioavailability of buccal buprenorphine is 46%–65%. In low doses, buprenorphine can only partially activate the μ-opioid receptor. In moderate doses, the buprenorphine's opioid agonist effect reaches a plateau (ceiling) such that any further dose increase is unlikely to enhance analgesia. In high doses, buprenorphine functions as an opioid antagonist to further limit its analgesic effect.[107] The role of buprenorphine in the management of chronic pain is questionable, with few high quality, unbiased studies performed in this area.[108] Two buprenorphine formulations are approved by the FDA for the management of pain—buprenorphine buccal film (Belbuca^{R}) and buprenorphine transdermal (Butrans^{R}). The transdermal is intended for use for patients requiring a MED <80 mg/day and the buccal for patients up to 160 mg/day.

The amount and quality of data on the use of buprenorphine for cancer pain are low.[109,110] Potential advantages in oncology pain management include alternate routes of administration, a presumed reduced risk of opioid-induced respiratory depression, and lack of QTc prolongation (compared to methadone). However, the use of buprenorphine potentially complicates acute pain management issues in oncology (post-surgical patients, severe mucositis) as the use of concomitant full μ-opioid agonists may be problematic. The perioperative management of patients using buprenorphine has not been definitively answered and for which there is no widespread consensus.[111] While a theoretical ceiling effect may exist for buprenorphine and respiratory depression, it can still cause significant adverse effects on respiratory function. One review suggests that there was no difference in respiratory depression or sedation in an acute pain setting compared with morphine.[112] Deaths have also resulted from buprenorphine intravenous misuse or concomitant sedative drug ingestion, such as benzodiazepines. In these situations of abuse, misuse, or association with elevated doses of psychotropic drugs, buprenorphine may cause severe respiratory depression.[113] Furthermore, the unique pharmacodynamics of buprenorphine as a semisynthetic opioid with a significant affinity for μ receptors leads to further complexities associated with naloxone reversal.

Use of Psychoactive Drugs in Oncology

The WHO has defined psychoactive substances as substances that affect mental processes such as cognition and comprise both legal and illegal substances.[114] A psychoactive medication may result in stimulation or depression of the central nervous system, potentially resulting in changes to motor function, thinking, behavior, perception, awareness, or mood. Table 33.11 lists examples of different categories of psychoactive medications commonly used in oncology.

Negative outcomes associated with polypharmacy may occur in patients taking as few as four drugs at any time[115] and are associated with older patients with comorbidities, including cancer.[116,117] Polypharmacy increases the risk of drug-drug interactions, drug-disease interactions, and adverse drug reactions. The risk of drug-drug interactions is high in oncology because of the large number of concomitant medication use,[118,115] and is associated with older patients with comorbid illnesses, including cancer.[116,117] Patients treated systemically for cancer are particularly at risk for drug-drug interactions. Typically, patients with cancer receive a high number of drugs concomitantly, including cytotoxic agents, hormonal

TABLE 33.11 Categories of Psychoactive Medication Use

Medication Class	Example
Non-opioid Analgesics	Tizanidine
Anti-depressants	Amitriptyline, nortriptyline, trazodone
Anti-convulsants	Gabapentinoids,
Anxiolytic/Sedative/ Hypnotics	Benzodiazepines
Sleep Aids	Z drugs (zolpidem, zaleplon, eszopiclone)
Muscle Relaxers	Carisoprodol, methocarbamol, tizanidine, cyclobenzaprine
Stimulants	Dextroamphetamine, lisdexamfetamine, methylphenidate, dextroamphetamine,
Neuroleptics	Olanzapine, haloperidol

agents, targeted agents, and supportive care agents, among medications prescribed to treat comorbidities. Drug-drug interactions from the combination of opioids with other drugs may result in sedation/respiratory depression, other CNS symptoms, impairment of pain control and/or opioid withdrawal, and other issues.[119] Morphine may also indirectly be affected by renal failure caused by other agents or diseases. Additionally, other drugs with sedative effects can cause pharmacodynamic interactions with an opioid. A typical observation is the combination of an opioid and a benzodiazepine, both contributing to sedation. Concurrent use of benzodiazepines in opioid users has also been associated with death from drug overdose,[120] and concurrent use of prescription opioids and sedative-hypnotics, even at low to moderate opioid doses, increases opioid mortality risk.[121] CNS symptoms (other than sedation and respiratory depression) associated with opioids include hyperactive or hypoactive delirium with or without hallucinations, serotonin toxicity, myoclonus, hyperalgesia, extrapyramidal symptoms, catatonia, and neuroleptic malignant syndrome. Because of the increased risk of osteoporosis and the extensive use of CNS-depressant drugs, cancer patients are particularly at risk for fractures.[122] Prescribed CNS-depressant drugs can result in an up to 47% increased risk of falls.[123] The prescription of combinations of CNS-depressant drugs may even further increase this risk.[124] Because of the increased risk of osteoporosis and the extensive use of CNS-depressant drugs, cancer patients are particularly at risk for fractures.[122] Prescribed CNS-depressant drugs can result in an up to 47% increased risk of falls.[123] The prescription of combinations of CNS-depressant drugs may even further increase this risk.[124]

Adjustment disorder, major depressive disorder, and anxiety disorder are the most common psychiatric comorbidities in cancer patients, with the persistence of these issues into survivorship.[125] Mild neurocognitive disorders can be secondary to chemotherapy or chemotherapy-associated with radiation therapy, which can cause impairment of memory, attention, concentration, learning functions, calculation, and visual-spatial perception.[126] A 2012 study from the Netherlands indicated that all classes of psychotropic drugs were more frequently prescribed to cancer patients than controls.[127] Furthermore, psychoactive medications may be used for many nonpsychiatric complaints in cancer patients, such as in the treatment of fatigue, insomnia, and pain. Psychoactive medications can affect neurocognitive functioning. Both TCAs[128,129] and SSRIs[130] impair sustained attention and memory in non-depressed adults. Anti-convulsants have negative effects on cognition in patients with epilepsy and may also produce untoward cognitive effects on attention, memory, and psychomotor speed in healthy adults.[131] These effects may emerge in a dose dependent fashion,[132] suggestive of a direct effect of these medications on specific neurocognitive processes. Anti-depressants, anti-convulsants, CNS stimulants, and neuroleptic medications were associated with reports of impaired functioning across multiple domains of neurocognition in adult survivors of childhood cancer.[133] Among all medications, central nervous system stimulants showed the largest associations with impaired task efficiency, organization, and memory.[133] Sedation, mental confusion, and delirium are common with all antipsychotic medications. Benzodiazepines and Z drugs (drugs taken for insomnia - zolpidem and zopiclone) are commonly used in patients with cancer for the management of symptoms such as sleep disturbance, anxiety, agitation, and dyspnea. Side effects of benzodiazepines include confusion, drowsiness, amnesia, and ataxia. The impact of the use of anti-depressants on depression in patients with cancer is unclear, and use in oncology should be considered on an individual basis and the choice of agent prescribed based on the data on anti-depressant efficacy in the general population of individuals with major depression considering that data on medically ill patients suggest a positive safety profile for the SSRIs.[134,133]

For some oncology groups, there is a general trend for medication use to markedly increase from precancer baseline to active care, followed by a decrease in first year survivorship, although not returning to baseline levels.[135] Polypharmacy is also prevalent in advanced cancer, with a reported mean and median number of prescribed drugs ranging from three to nine.[136] Older patients with cancer (aged 65 years and older) more often had polypharmacy than younger patients. In a study of 5,950 veterans with metastatic cancer, patients with extensive opioid use, 64% also received anti-depressants, and 38% received three or more classes of psychotropic medications.[137] Polypharmacy could be even more important in older oncology patients receiving chemotherapy, who tend to be more vulnerable to the adverse effects of medications than older adults without cancer.[138] The American Geriatrics Society Beers criteria are a tool for evaluating the appropriateness of medication use for older adults and endorsed by the American Geriatrics Society.[139] These comprise a list of potentially inappropriate medications that are typically best avoided by older adults in most circumstances or under specific situations, such as in certain diseases or conditions. They are intended for use in adults 65 years and older in all ambulatory, acute, and institutionalized settings of care, except for the hospice and palliative care settings. The criteria are composed of five primary tables of guidelines: medications that are potentially inappropriate in most older adults; medications that are potentially inappropriate in patients with certain conditions; medications that should be used with caution; potentially clinically important drug-drug interactions that should be avoided; and medications that should be avoided or have their dosages reduced with varying levels of kidney function. Drugs mentioned in these criteria relevant to oncology pain management include TCAs (avoid use), antipsychotics (avoid except for short-term use as antiemetic during chemotherapy), barbiturates (avoid), benzodiazepines (avoid), Z drugs (avoid), Gi – metoclopramide (avoid, unless for gastroparesis with a duration of use not to exceed 12 weeks except in rare cases), NSAIDs (avoid chronic use, unless other alternatives are not effective and

the patient can take gastroprotective agent), and skeletal muscle relaxants (avoid). To avoid drug-drug interactions, avoid the use of opioids concurrently with benzodiazepines and avoid the use of opioids concurrently with gabapentinoids (except when transitioning from the former to the latter). The concurrent use of any combination of three or more CNS agents (anti-depressants, antipsychotics, benzodiazepines, nonbenzodiazepine benzodiazepine receptor agonist hypnotics, antiepileptics, and opioids) have an increased risk of falls (all), and fracture (benzodiazepines and nonbenzodiazepine, benzodiazepine receptor agonist hypnotics) should be avoided with an attempt to minimize the number of CNS-active drugs. SNRIs should be avoided in patients with a history of falls or fractures. Of note, substantial harms can occur when opioids are used concurrently with benzodiazepines or gabapentinoids.

Oncology patients are frequently exposed to benzodiazepines to help manage common sequelae of cancer and its treatment, including anxiety and chemotherapy-related nausea. Long term cancer survivors (>10 years) in Norway with persistent or high-dose opioid use may also be prescribed benzodiazepines or benzodiazepine-like hypnotics.[140] The use of benzodiazepines may be particularly problematic with concurrent opioid use. Co-prescribing was associated may be associated with a significantly higher risk of death,[120] emergency room (ER) visits, or inpatient admission[141] than with the use of opioids alone. The FDA released a black box caution warning patients and providers about the potential risks of combined use.

The Opioid Epidemic and Cancer Pain

The opioid epidemic is discussed in Chapters 50 and 51. The widespread abuse of prescription opioids and a dramatic increase in the availability of illicit opioids have contributed to this problem.[142] Over and inappropriate medical prescribing, diversion and misuse of prescription opioids, a resurgence in heroin use, an increase in the abuse of illicit, and the availability of illicitly manufactured high-potency synthetic opioids such as fentanyl are likely major contributors to this problem. Overdose deaths related to opioids have dramatically increased. Identifiable characteristics associated with an elevated risk of opioid overdose include a history of overdose, a history of addiction to any substance (but particularly alcohol, benzodiazepines, or opioids), and health problems associated with respiratory depression or concurrent prescription of any medication that has a depressive effect on the respiratory system, such as benzodiazepines and sedative-hypnotics.[143] Abuse of opioids is a complex issue that is not solely related to the opioid used. Mental health disorders, genetic, environmental, and lifestyle factors are important contributors. Opioid abuse and misuse also occur for various reasons, including self-medication, use for reward, compulsive use because of addiction, and diversion for profit.[144] In a meta-analysis of 568,640 patients who had not used opioids in the six months prior and with a new diagnosis of any type of chronic non-cancer pain, the odds ratio for developing an opioid use disorder (OUD) was 14.9 for patients on chronic (> three months of use) low-dose (1–36 mg MED) opioids and 122.45 for patients on chronic high-dose (120 mg + MED) opioids, respectively, with the duration of opioid therapy more important than the daily dose in developing OUD.[145] Policy changes, including recommendations contained in Pain Management Best Practices Inter-Agency report,[146] and CDC guidelines[78] inform prescribers on best practices for using opioids in chronic pain. For chronic non-cancer pain, most recommendations caution against the use of opioids for chronic pain complaints.

Public and healthcare information has emphasized that addiction in the context of cancer pain and the use of opioids is rare or non-existent. The prevalence of opioid abuse in patients with cancer on opioid therapy is unknown, and most of the published data relate to non-cancer pain issues. Data about substance abuse in cancer patients and those seen in palliative care clinics have been scarce. Barclay et al.[147] found that more than 40% of cancer patients seen were moderate to high risk for opioid abuse as measured by the opioid risk tool; 62% of these at risk patients with a urine drug screen ordered had at least one abnormal result. However, most hospice and palliative care programs do not have substance abuse and diversion policies or report screening all patients.[148] In the complex milieu of complications of cancer and metastasis, including heterogeneous cancer biology, multiple drugs being used, pain, opioid analgesic use, and psychosocial factors, delineating the specific contribution of individual factors on survival is challenging. It is important to recognize that cancer patients are not immune to developing aberrant opioid and drug use behaviors. Patients who have ongoing anxiety, financial distress, and a prior history of alcoholism/illicit drug abuse are at increased risk.[149] Solutions for the opioid epidemic are complex and appear to have largely been focused on physician prescribing habits and regulating patient access to opioids.[150] Although well-intentioned, these regulations could inadvertently create an atmosphere that inhibits access to opioid pain treatment for cancer patients and cancer survivors. Withholding opioids from patients with advanced cancer pain has significant ethical implications. Clinicians should be concerned about problematic opioid use even in patients with advanced disease. Without screening or testing for opioid misuse or abuse, it is impossible to address and manage these issues. Standard precautions should include a risk assessment of opioid abuse in all patients, considering whether there is a risk of diversion or abuse, monitoring of adherence, the management of any known psychological or psychiatric conditions, and the monitoring of drug-related behaviors.[151] If problems are identified, these should be managed appropriately according to standard clinical guidelines with accommodation for continued oncologic care. The dynamic and frequently changing nature of oncology pain makes this particularly challenging.[149]

Prevention of Opioid Overdose

The opioid overdose epidemic in the United States has been closely associated with a parallel increase in opioid prescribing and with widespread misuse of these medications.[152] Long-term opioid therapy carries clinically significant risks, including motor vehicle collisions, sleep-disordered breathing, and accidental overdose.[153] All patients treated with opioids are at risk for overdose. Factors increasing that risk include end-organ (liver, kidney) dysfunction resulting in impaired clearance, pulmonary disease, sleep-disordered breathing, and concomitant use of psychoactive medications. Strategies to improve patient safety include patient screening and risk stratification, patient and community education and outreach concerning appropriate pain management, medication reviews/medication therapy management, education on safe storage and disposal, and distribution of naloxone/opioid rescue kits and training on their proper use. Prescription monitoring programs (PMPs) allow the assessment of a patient's prescription history (scheduled II and III medications). However, not all psychoactive medications are included in this monitoring program. Also, the program does not identify the prescription of

methadone for substance use disorder. PMPs can identify doctor shopping, concomitant benzodiazepine prescriptions, and evidence of undisclosed opioid prescriptions from other providers. Medication disposal boxes and community-based drug take-back events offer alternatives to storing unused opioids (or other controlled substances) at home. Hallmarks of OUD include emotional volatility and signs of problematic medication use, such as taking more medication than prescribed, using opioids for reasons other than pain, and frequent loss of medication or early refills. Several instruments are used clinically to screen for problematic opioid use (see Chapter 51).

Prescribers must carefully weigh potential benefits against the risks of opioid-related adverse events and overdose for all encounters involving prescription opioids, and if patients are to be continued on long-term opioids, informed consent should be obtained. Patients with or who are subsequently identified as having an OUD require specialized treatment with professional addiction care. With ongoing oncology care issues, a co-management model for pain and substance use disorder is likely ideal. Ideally, a carefully planned structure of care should be in place for patients receiving chronic opioid therapy. Opioids should be primarily prescribed for improvement of function (defined on an individual basis) and not for reductions in pain intensity scores. Opioid dose escalation among patients with chronic pain is not associated with improvements in Numeric Rating Scale pain scores.[154] Before medication refills, an assessment of pain, functional status, safety, and other pertinent information should be conducted. Patients should provide pill counts and are given specific use dates for each prescription. PMP should be routinely checked along with the utilization of mass spectrometry urine drug tests based on opioid morphine milligram equivalent per day. This comprehensive based structure is labor-intensive and understandably may not be easily replicable in every practice. However, we consider this approach as it is essential for the continued and safe prescribing of opioid doses in this patient population who may benefit from continued use.

Intravenous Infusions for Cancer Pain

Lidocaine, an amide local anesthetic, inhibits voltage-gated sodium channels resulting in a reversible block of action potential propagation, but its exact analgesic mechanism is unknown. Preclinical and clinical evidence, particularly for acute and chronic pain, indicates that IV lidocaine has antihyperalgesic effects and by infusion for chronic neuropathic pain may reduce spontaneous pain, allodynia, and hyperalgesia.[155] Most studies advocate an initial bolus of 1–2 mg/kg followed by continuous infusion of 2–4 mg/kg/h, resulting in plasma concentrations of 1–3 mcg/mL.[156] Lidocaine and oral analogs (mexiletine, tocainide) were considered safe and better than placebo in clinical trials for non-cancer neuropathic pain.[157] Evidence for cancer-related pain is more limited, and there is wide variation in recommendations for use. Sharma et al.[158] demonstrated in 50 opioid-refractory cancer patients that a 2 mg/kg bolus and 2 mg/kg infusion over 1 h resulted in pain relief lasting a mean of 9.34 ± 2.58 days after the single infusion. Side effects observed were tinnitus, perioral numbness, sedation, lightheadedness, and headache. These were self-limited and did not require any intervention except for one patient. However, the role of systemic lidocaine in the management of tumor-associated pain is not defined. For cancer-related pain, the frequency of administration needed for the benefit and sustainability of analgesic efficacy is unknown.

Ketamine, an NMDA receptor antagonist, at subanesthetic doses may alleviate various chronic and neuropathic pain complaints.[159] A Cochrane review in 2017 concluded that there was insufficient evidence for the use of ketamine (administered intrathecally, by intravenous bolus, and subcutaneously) as an opioid adjunct in cancer pain.[160] In this review, the study using intravenous bolus administration, ketamine caused hallucinations in four of ten participants. In the rapid dose escalation/high-dose (500 mg) subcutaneous ketamine study, there was almost twice the incidence of adverse events in the ketamine group. Adverse events are most commonly somnolence, feelings of insobriety, nausea/vomiting, hallucinations, depersonalization/derealization, and drowsiness.[161] In a randomized, double-blind study of subcutaneous ketamine (at three dose levels of 100 mg/24 h, 300 mg/24 h, 500 mg/24 h for a five day schedule) for cancer pain, Hardy et al.[162] reported that the number needed to treat was 20 and the number needed to harm was six, suggesting no clinical benefit from ketamine as an adjunct. To date, subcutaneous or intravenously administered ketamine has not been shown to be effective in cancer pain.[163]

Intrathecal Therapies for Cancer Pain

Intrathecal therapies are discussed in Chapter 72. Intrathecal therapy involves the administration of drugs directly into CSF and to CNS receptor sites. Therapy may be delivered by bolus injection or by infusion. Options for drug delivery include an externalized catheter system (percutaneous or tunneled), a fully implanted pump (subcutaneous electronic pump with a tunneled catheter into the intrathecal space), or into the intraventricular system via an intracerebroventricular (ICV) device such as Ommaya reservoir. Administration of drugs via an Ommaya reservoir is typically for anti-neoplastic therapy, and most of the experience of ICV infusion of morphine has been from the 1980s and 1990s.[164] This route is not commonly used for oncology pain management. Drugs most commonly infused for spinal administration include opioids and bupivacaine. Compared to epidural administration, intrathecal drug delivery has higher analgesic efficacy and lower rates of treatment failure.[165] Although implanted drug delivery systems have been advocated for the management of cancer pain,[166] we advise against such systems in the management of patients undergoing active oncologic care. The complexity of programming, organizational challenges related to dose changes and pump refills, and potential safety issues in immunocompromised patients with low platelet counts are problematic. The use of tunneled externalized infusions systems such as those advocated by Nitescu, Sjoberg, et al. has potential for the management of intractable pain that require the administration of intrathecal bupivacaine.[167–173] Such systems allow for easy adjustment and titration of intrathecal bupivacaine doses. However, the administration of bupivacaine in such systems is usually significantly functionally limiting and again is not usually indicated in patients with active oncologic treatment.

Vertebral Augmentation (Vertebroplasty, Kyphoplasty)

Metastatic tumors to the spine or primary diseases such as multiple myeloma can cause painful vertebral compression fractures. Pain associated with these processes may require surgical treatment or anti-neoplastic therapy such as radiation treatment. Patients with

intractable pain who are not responsive to conservative therapy, including analgesics, or who are not surgical or radiation therapy candidates, may benefit from vertebral augmentation techniques assuming no other contraindications to this technique. In an extensive review involving 3,391 citations, of which 111 clinical reports (4,235 patients) evaluated the effectiveness of vertebroplasty (78 reports, 2,545 patients) or kyphoplasty (33 reports, 1,690 patients) for patients with mixed primary spinal metastatic cancers, multiple myeloma, or hemangiomas, the authors concluded that vertebral augmentation could significantly reduce pain intensity, decrease opioid needs, and improve functional disabilities.[174] In oncology, the procedure is most often considered for fractures related to multiple myeloma or those induced by steroid therapy. A consensus statement from the International Myeloma Working group recommended that myeloma patients with significant pain at a fracture site and without neurologic compromise should be offered augmentation, and the procedure should be performed within four to eight weeks unless there are medical contraindications. As patients with myeloma are susceptible to multilevel fractures, the total number of fractures should be limited to three at a time.[175] Long term (>six months) steroid use may cause osteoporosis which is associated with an increased fracture (vertebral and non-vertebral) risk.[176] There is also an increased fracture risk in patients exposed to intermittent high-dose oral steroid therapy.[177] The role of vertebral augmentation in treating acute or subacute osteoporotic vertebral fractures in routine practice is controversial and has not been validated consistently.[178,179]

Neurolytic Autonomic Plexus Blocks

These blocks typically include neurolysis of the celiac plexus and superior hypogastric plexus. The role of neurolytic celiac plexus blocks versus systemic analgesic therapy alone in the management of intractable tumor-associated intra-abdominal visceral pain is well established, particularly for the management of pain associated with pancreatic cancer.[180,181] Different techniques have been described to denervate the celiac plexus. Extensive tumor involvement of the celiac axis may not result in adequate denervation of the plexus with approaches specifically targeting the celiac plexus because of tumor infiltration of the plexus.[182] In this situation, our preferred denervation technique is bilateral retrocrural neurolysis of the thoracic splanchnic nerves.[183–185] Plancarte[186] introduced the option of superior hypogastric plexus block for the management of chronic cancer-related pelvic visceral pain. Although the block is considered relatively safe for pelvic associated pain, there is a need for large prospective studies to determine efficacy in cancer pain management.[187,188] It is important to remember that both of these blocks modify only nociceptive visceral pain and will not affect other potential sources of pain that are somatic or neuropathic in origin. For example, patients with pelvic disease that extends to the pelvic side wall (somatic) or involve neural plexuses (sacral) will not benefit from a superior hypogastric plexus block.

Summary

The optimal method of managing cancer-related pain is to diagnose the factor(s) contributing to the pain complaint. This disease-based (in contrast to symptom management) model of pain management focuses on the source of pain, and in patients with tumor-associated pain, therapy (not exclusively pharmacologic) should be directed to modify the source of that pain. These options typically include surgical, chemotherapeutic, and radiation oncologic options. Management of pain in cancer survivors is also complex, and models for the management of chronic non-cancer pain do not apply. Inadequate treatment of cancer pain continues to be an issue over the last three decades.[9,189,190] The humanitarian impact of cancer pain management should not be forgotten. Cancer pain profoundly impacts a patient's quality of life with physical, psychological, and social consequences. It is incumbent on healthcare professionals involved in the care of cancer patients to educate themselves on the complexities of pain and methods of management that focus on improving function and overall quality of life. Commonly cited barriers to effective cancer pain management among healthcare providers were fear of drug addiction, tolerance of medication, and side effects of opioids continue to be an issue.[191] These issues are even more problematic in an era of concerns for opioid overprescribing. The overall approach for oncology pain management should focus on a disease-based model of pain that focuses on routine pain assessments, uses both pharmacologic and nonpharmacologic interventions, and requires ongoing reevaluation of the patient and the effectiveness of the treatment strategy. The emergence of new pain problems must be assessed, and the treatment plan modified appropriately. Oncology healthcare systems require a supportive pain management infrastructure to allow for longitudinal care of the course of a patient's treatment.

Key Points

- Undertreatment of cancer pain remains problematic, with the prevalence of pain remaining high in survivorship.
- The guiding principle for pain management should be focused on improvement in function with a reduction in pain intensity as an ideal.
- Adequate management of cancer pain depends on identifying the source and making an accurate diagnosis of the underlying cause(s) of pain and contributing factors.
- Pharmacologic therapy is the primary treatment for cancer pain, but radiotherapeutic, anesthetic, neurosurgical, psychological, physiotherapeutic, spiritual, and social interventions all play roles in adequate cancer pain management.
- Opioids are commonly used to treat moderate or severe cancer pain, but there is substantial interpatient variability in opioid responsiveness. Therefore clinicians should be familiar with different opioid options for the appropriate management of cancer-related pain.
- Multiple psychoactive medications can be hazardous. Frequent efforts should be made to eliminate all unnecessary or ineffective medications that detract from the primary goal of opioid use and improved function.
- Responsible opioid prescribing practices are paramount in managing oncology pain.

Evaluation and Treatment of Neuropathic Pain Syndromes

CHRISTOPHER M. LAM, ANDREA L. CHADWICK, ROBERT W. HURLEY

Introduction

Neuropathic pain comprises a wide range of heterogeneous conditions. Various types of neuropathic pain may have distinct pathophysiologic causes and different clinical signs and symptoms. Despite the diversity of conditions classified as "neuropathic pain," many potentially share common underlying mechanisms of nociception, including neuronal hyperexcitability, but others may not. This may, in part, explain why certain analgesic agents are relatively effective for a wide range of neuropathic pain states but why notable exceptions exist that appear to be resistant to conventional "neuropathic" pain therapy. A group has been assembled to address the inconclusive research on "neuropathic" pain and to operationalize and specify definitions and criteria for conditions to be referred to as neuropathic pain (Box 34.1).[1] This work should lead to a more reductionist approach to the study of neuropathic pain and effective therapies for specific disease processes.

This chapter focuses on some of the more common states of "neuropathic" pain as defined by the sensitive but non-specific definition of the International Association for the Study of Pain (IASP). These conditions include postherpetic neuralgia (PHN), painful diabetic peripheral neuropathy (DPN), human immunodeficiency virus (HIV) painful sensory neuropathy, and chemotherapy induced peripheral neuropathy (CIPN). While complex regional pain syndrome (CRPS) is considered nocicplastic in nature, it is also discussed in this chapter.

Complex Regional Pain Syndrome

The term *CRPS*, which denotes both types one and two, originated from a history of different names appointed by individuals who made particular observations. In 1864 Silas Weir Mitchell made an important observation of Civil War soldiers when he noticed that they suffered from burning pain and muscle atrophy at the sites of their injuries caused by gunshot wounds.[2] He called this "causalgia," which is derived from the Greek words *kausis* (burning) and *algos* (pain). In 1900 at a lecture in Germany, Paul Sudeck stated that this syndrome could not only extend from the initial insult but also had an inflammatory component.[2] The name Sudeck's dystrophy was applied in his honor. Half a century passed before the discovery that invasive procedures that block the sympathetic nervous system provide further relief of pain symptoms. Because of the success of these methods, Evans renamed the syndrome "reflex sympathetic dystrophy."[3] Over the years, cases arose in which patients lacked a trophic component, sympathetic involvement was absent, or there was no evidence of reflex involvement. These exceptions led to a meeting in 1993 by the IASP at which the term "*complex regional pain syndrome*" was formulated and subsequently published the following year.[4] The most commonly used clinical diagnostic criteria for CRPS types one and two are low in specificity but high in sensitivity, which has led to overdiagnosis of the pain syndrome.[5] This has made it difficult to obtain accurate epidemiologic data for CRPS or to perform rigorous studies of the pathologic state. In 2007, research criteria (also known as the Budapest criteria) were published that included objective signs of pathology characteristic of patients with CRPS (Box 34.2).[6] These criteria had good specificity and sensitivity. Although they were initially intended for research use, this was later revised to include both a clinical and research set of criteria commonly used for diagnosis.

• BOX 34.1 Updated Definition of Neuropathic Pain

IASP Definition:[323] 2017

"Pain caused by a lesion or disease of the somatosensory nervous system"

Revised Research and Clinical Definition:[1] 2007

"Pain arising as a direct consequence of a lesion or disease affecting the somatosensory system"

IASP, International Association for the Study of Pain.

Pathophysiology

There are two types of CRPS, known as type one and type two (Box 34.3). They differ because type two has evident nerve injury, whereas type one assumes an injury to the nerve or nerves. A consistent finding in both types of CRPS is the discrepancy between the severity of the symptoms and the severity of the inciting injury. In addition, symptoms have the propensity to spread in the affected limb in a pattern not restricted to the specific nerve's area of innervation. CRPS is characterized by intense burning pain with resultant hyperalgesia or allodynia. It may be associated with local edema and autonomic involvement, such as changes in skin color and sweating and increased or decreased skin temperature in the affected area. There may also be trophic changes in the skin, hair, and nails in the affected site (see Box 34.3). Although many

• BOX 34.2 Difference Between the IASP Criteria and the Budapest Criteria for the Diagnosis of CRPS

IASP Criteria for the Diagnosis of CRPS*

1. Presence of an initiating noxious event or reason for immobilization
2. Disproportional pain, allodynia, or hyperalgesia from a known inciting event
3. Sign or symptom of any evidence showing edema, skin changes, blood flow, or abnormal sudomotor activity in the region of the pain
4. No other condition that would otherwise explain the degree of pain or dysfunction

Budapest Criteria for Diagnosis of CRPS

1. Presence of continued disproportional pain from the known inciting event
2. Must report at least one symptom in three of these four categories:
   - Sensory: hyperesthesia, allodynia
   - Vasomotor: temperature asymmetry, changes in skin color
   - Sudomotor/edema: edema, changes in sweating, sweating asymmetry
   - Motor/trophic: decreased range of motion, motor dysfunction (tremor, weakness, dystonia), trophic changes (hair, nail, skin)
3. Must report at least one sign in two or more of these categories at the time of evaluation:
   - Sensory: hyperalgesia to pinprick, allodynia to touch, or joint movement
   - Vasomotor: temperature asymmetry, color asymmetry
   - Sudomotor/edema: edema, asymmetric sweating, sweating changes
   - Motor/trophic: decreased range of motion, motor dysfunction, trophic changes
4. No other condition that would otherwise explain the degree of pain or dysfunction

Budapest Clinical Criteria[6,42]

At least one symptom in three or four symptom categories
At least one sign in two or more sign categories

Budapest Research Criteria

At least one symptom in all four symptom categories
At least one sign in two or more sign categories

*If seen without any major nerve damage, the diagnosis is CRPS type one; if seen with evidence of nerve damage, the diagnosis is CRPS type two.
CRPS, Complex regional pain syndrome; *IASP*, International Association for the Study of Pain.

• BOX 34.3 Difference Between CRPS Type One and Two

CRPS Type One (Reflex Sympathetic Dystrophy)*

1. The presence of an initiating noxious event or a cause of immobilization
2. Continuing pain, allodynia, or hyperalgesia with which the pain is disproportionate to any inciting event
3. Evidence at some time of edema, changes in skin blood flow, or abnormal sudomotor activity in the region of the pain
4. This diagnosis is excluded by conditions that would otherwise account for the degree of pain and dysfunction

CRPS Type Two (Causalgia)†

1. The presence of continuing pain, allodynia, or hyperalgesia after a nerve injury, not necessarily limited to the distribution of the injured nerve
2. Evidence at some time of edema, changes in skin blood flow, or abnormal sudomotor activity in the region of the pain
3. This diagnosis is excluded by the existence of conditions that would otherwise account for the degree of pain and dysfunction

CRPS, Complex regional pain syndrome.
*Criteria two to four must be satisfied.
†All three criteria must be satisfied.

questions about the pathophysiology of this syndrome are still unanswered, three main principles remain at the core of CRPS: abnormalities in both somatosensory and sensory pathways and sympathetic nervous system involvement.

Somatosensory Abnormalities

Inciting injury to either the upper or lower extremity is an important trigger of CRPS. Studies have shown that changes in cutaneous innervation of the injured extremities occur even when no nerve injury is found. Albrecht et al. performed a study where skin biopsy samples were obtained from the affected limbs of patients with CRPS type one. A lower density of C and A fibers were found in the affected limbs than in the unaffected limbs, which led to sensory deficits in the affected limbs.[7] Brain plasticity is another important factor found to be associated with somatosensory abnormalities. Data suggest that patients with CRPS have decreased activity in the somatosensory cortex of the affected side.[8] These patients also tend to have tactile mislocation because of somatotopic reorganization, which was found to be directly correlated with hyperalgesia.[9] Changes occurring within the primary somato-

sensory (SI) cortex are dependent on pain and have been shown to be reversible after recovery from the pain.[10] Recently, a study published by Azqueta-Gavaldon et al. where 20 patients with sensory and motor deficits attributed to chronic CRPS (> six months of pain) underwent a battery of tests including functional magnetic resonance imaging, showed that patients with sensory and motor deficits had bilateral decreases in gray matter in the putamen. They theorize that putamen alterations may explain the pain and motor impairment seen in patients with chronic CRPS.[11]

Sensory Pathways (Central Nervous System Sensitization, Peripheral Sensitization)

Central sensitization occurs when pain perception increases because of the constant firing of painful stimuli to the central nervous system. Neuropeptides such as substance P and bradykinin are released in response to nociceptive stimuli and activate *N*-methyl-D-aspartate (NMDA) receptors, leading to hyperalgesia and allodynia.[12] Chronic exposure to these neuropeptides may influence and remodel normal neuroanatomy. Glial cells (namely microglia and astrocytes) are immunocompetent CNS cells that are activated after tissue injury. In a cadaveric study of an individual with CRPS comparing spinal cord anatomy to four control cadavers, significant posterior horn cell loss along with microglial and astrocyte activation was found at the level of the original injury and entire spinal cord.[13]

Peripheral sensitization is the counterpart of central sensitization. When a nerve injury occurs, multiple pro-inflammatory factors such as glial cell activation, substance P, bradykinin, tumor necrosis factor-α (TNFα), interleukin-1β (IL-1β), prostaglandin E_2, and nerve growth factor are activated, which results in increased nociceptive sensitivity and a decreased threshold for the firing of nociceptive stimuli.[14] A study where immunoglobulin G (IgG) from patients with chronic CRPS was injected into mice showed increased edema and paw hyperalgesia with concomitant sustained microglial and astrocyte activation in the spinal cord dorsal horn and pain-related regions of the brain. Furthermore, this was found to be IL-1β mediated as IL-1 receptor antagonists, and IL-1β floxed mice prevented these changes when exposed to IgG of CRPS patients.[15]

Together, central and peripheral sensitization results in the allodynia and hyperesthesia seen in patients with CRPS. There are other important factors in the inflammatory pathway, such as the role of nuclear factor kappa B (NFκB) upstream in the pro-inflammatory pathway observed in animal studies.[16] To date, anatomic, biomolecular, and immunohistologic studies such as those mentioned above illustrated the multifactorial influences in the development of central and peripheral sensitization of this disease along with their effect on neuroanatomy.

Neuroinflammation

An emerging hypothesis for the mechanism for CRPS development is neurogenic inflammation. As mentioned previously, many pro-inflammatory factors are released during nerve injury, evidenced in patients and animal models. This early stage of CRPS ("warm phase") results in vascular symptoms, trophic changes, and pain mediated by neuropeptides with resultant production of high levels of cytokines, nerve growth factors, and mast cells.[17] Studies on IL-6 and TNFα levels in patients with CRPS have shown elevated levels in blisters and skin that decrease once the patient's condition has become chronic.[18–20] Dendritic cells whose roles include activating helper T cells have been hypothesized as the primary mediator for neuroinflammation. [21] A study by Russo et al. utilizing mass cytometry immunophenotyping found that in 14 patients with Budapest criteria supported clinically diagnosed CRPS showed an increased level of central memory CD4 and CD8 T cells implicating a possible role of antigen mediated T-lymphocyte response in the development of CRPS.[22] Although further studies are needed to further validate this pathway, it is possible that neuroinflammation itself plays a role in the evolution of this condition.

Altered Sympathetic Nervous System Function

Involvement of the sympathetic nervous system is thought to be responsible for the limbs in patients with CRPS becoming cool, blue, and painful secondary to vasoconstriction because of excessive outflow from the sympathetic nervous system. In an animal study, rats with chronic post ischemic pain that had norepinephrine injected into their hind paws experienced increased nociceptive firing, supporting the notion that pain can be sympathetically maintained.[23] Interestingly, norepinephrine levels were found to be lower in the affected extremity than the normal contralateral extremity in patients with chronic CRPS. Several studies evaluating the effect of adrenergic receptor stimulation on the vasculature in patients with CRPS have indicated an increased response to an adrenergic stimulus.[24] However, this provides little evidence in support of sympathetic maintenance of CRPS pain.

Coupling of sympathetic neurons may occur not only to nociceptive afferents but also to non-nociceptive mechanosensitive or cold-sensitive neurons. Sympathetic afferent coupling, considered the cause of sympathetically maintained pain, occurs in cutaneous and deep somatic tissues, but during the acute event of CRPS, the deep somatic tissues are of greater importance.[25] Although coupling occurs in some patients with CRPS, a subset of patients with clinically identical CRPS have sympathetically independent pain. These patients exhibit little to no response to sympathetic blockade either pharmacologically with phentolamine or via interventional blockade of the sympathetic ganglia.

Epidemiology

Multiple studies of CRPS type one have shown that the male-to-female ratio ranges between 1:2 and 1:4, thus suggesting that females are at higher risk for the development of the syndrome.[26,27] However, the male-to-female ratio for most other pain syndromes is similar. A retrospective, cross-sectional analysis study showed that the male-to-female ratio was 1:4 and that the most common initiating events were bone fractures, sprains, and trauma.[27] In a prospective study, it was found that CRPS incidence four months after a wrist fracture was 3.8%. This group generated a prediction rule to identify high risk patients based on a 25 min assessment evaluating pain, response time, dysynchiria, and swelling one week after wrist fracture. This study found that a pain score of ≥ five within the first week of injury was nearly as accurate as performing the 25 min assessment in identifying wrist fracture patients at high risk for developing CRPS.[28]

Outcomes of the disease tended to be worse in patients with upper extremity injuries than in those with lower extremity injuries, injuries other than fractures, and "cold" (commonly chronic) CRPS rather than "warm" (acute) CRPS.[16] Other risk factors that contribute to the development of CRPS are age, workplace, concomitant use of angiotensin-converting enzyme (ACE) inhibitors, history of migraines, history of asthma, and type of injury.[29] The average age of patients ranges between 16 and 79 (median range, 41.6), with a higher incidence in the older population. Patients with motor nerve damage were found to be at higher risk for CRPS

than those with sensory nerve damage. Fracture has been reported to be the most common initiating injury.[30] The incidence of job-related injuries leading to CRPS was as high as 76%,[31] which may indicate a psychosocial or secondary gain component in reporting of this pain. Studies report that CRPS develops in patients with a family history of CRPS at a higher incidence and younger age, suggesting that CRPS may have a genetic component.[32] Another study showed that siblings of patients in whom CRPS developed before 50 years of age had a three-fold increased risk for development of the syndrome.[33] Psychological factors such as depression, personality disorders, and anxiety have no correlation with CRPS patients, suggesting no specific type of CRPS personality.[34]

Clinical Features

The pain must be greater in proportion to the inciting event. There must be at least one symptom in three of the following four categories: sensory (hyperesthesia/allodynia), vasomotor (changes in temperature or sweating in the affected limb than the normal limb), sudomotor/edema, and motor/trophic (demonstration of weakness, decreased range of motion, or trophic changes in hair, nails, or skin). At least one sign must be present at the time of evaluation in two or more of these four categories: sensory, vasomotor, sudomotor/edema, and motor/trophic. There must be no other diagnosis that better explains the patient's signs and symptoms.[29] This differs from the criteria proposed in 1993 by the IASP (see Box 34.3). A recent study in which the validity of CRPS was evaluated by comparing the Budapest criteria in patients with CRPS and those with neuropathy showed that the IASP criteria had a sensitivity of 1.0 and a specificity of 0.4, and the Budapest criteria had a clinical sensitivity of 0.99 and a specificity of 0.68.[35] The newly revised criteria are also divided into clinical and research. The research criteria contain more inclusions, which allows a specificity of 0.96.[36]

The current IASP taxonomy also divides CRPS into CRPS one (formerly known as reflex sympathetic dystrophy) and CRPS two (formerly known as causalgia).[29] The distinction between CRPS one and two is the presence of a definable nerve lesion in patients with CRPS two.[37] The signs and symptoms for both conditions are clinically indistinguishable and include sensory changes (allodynia, hyperalgesia, and hypoalgesia), edema, temperature abnormalities, and changes in sweating (see Box 34.3). Pain is the principal feature in both CRPS one and CRPS two. In patients with CRPS, the associated clinical signs are typically out of proportion to the inciting injury. Patients describe a burning, deep-seated ache that may be shooting in nature and associated with allodynia or hyperalgesia.[38] Pain occurs in 81.1% of patients meeting the CRPS criteria.[5] Patients also frequently complain of sensory abnormalities such as hyperesthesia in response to the typical mechanical stimuli encountered in day-to-day activities (such as dressing) involving the affected limb.

In CRPS two (i.e. CRPS with associated major nerve injury), patients often report hyperesthesia around the injured nerve in addition to electric shock-like sensations, shooting pain, and allodynia. Symptoms indicative of vasomotor autonomic abnormalities (including color changes) occurred in 86.9% of patients; temperature instability occurred in 78.7%. Sudomotor symptoms of hyperhidrosis and hypohidrosis were reported in 52.9%. Trophic changes in skin, nail, or hair patterns were reported in 24.4%, 21.1%, and 18%, respectively. Edema was reported in 79.7%, with decreased range of motion in 80.3% and motor weakness in 74.6%.[5]

Over time, symptom severity changes reflecting stability or progression of disease. In 2010 Harden et al. developed a CRPS symptom severity score (CSS) to help categorize the degree of CRPS for aiding in clinical decision making, which was validated by an international prospective multi-site study.[35,39] In the study, they found that changes in CSS correlated with greater changes in fatigue, pain intensity, social functioning, ability to take physical roles, and overall wellbeing, indicating the possible role of this score in clinical monitoring and research.[39] Eventually, approximately three-quarters of all CRPS cases resolve even without treatment, with the resolution of microvascular signs and symptoms resolving before resolution of pain.[40]

Diagnosis

There is currently no "gold standard" test for the diagnosis of CRPS. A very thorough history and physical examination are essential for evaluation and diagnosis. Patients with this condition will have the signs and symptoms mentioned. Many clinicians utilize the Budapest criteria (Box 34.2) to help diagnose this condition. In 2018, a European Pain Federation Task Force developed standards for diagnosis and treatment of CRPS where they recommended the utilization of the Budapest criteria as the main tool to diagnosis the condition with further diagnostic tests only to exclude other diagnoses.[41]

A physical examination must be performed to establish the sensory, motor, trophic, sudomotor/edema, and autonomic changes. Sensory changes such as allodynia may be evaluated by light touch and the application of warm/cold temperature to the affected area. Autonomic dysfunction may be confirmed by the presence of asymmetry in temperature and color. Trophic changes may be manifested as changes in skin, nails, and hair in the affected limb. Motor activity may be evaluated by examining motor strength and range of motion. Sudomotor/edema changes may be assessed by dragging a smooth object over the affected and unaffected limb, with the wetter limb allowing a smoother drag than the drier limb.[42] Common diagnostic tools used for diagnosis, characterizing, and monitoring of CRPS include quantitative sensory testing, tests of autonomic function, and imaging for trophic changes.

Quantitative Sensory Testing (QST)

QST is a noninvasive means to evaluate sensory and pain perception to classify pain but cannot be used as the sole method to diagnose a particular pain pathology. There is variability in the ability to reproduce results, and as such, the precision and accuracy of this modality are still up for debate.[43] Such testing includes the use of standardized psychophysical tests of the sensory and motor systems, thermal sensation, thermal pain, and vibratory thresholds to assess the function of myelinated small fiber and unmyelinated small fiber afferents. Patients with CRPS may have impaired paradoxical heat sensations, mechanical detection thresholds, mechanical pain thresholds to pinprick stimuli and blunt pressure, allodynia, and pain summation with the use of continuous pinprick stimuli.[44] There is currently no definitive diagnostic sensory pattern in patients with CRPS, but this test can aid in distinguishing other neuropathies from CRPS.[45,46]

Tests of Autonomic Function

Thermoregulation and sudomotor regulation are the main systems tested in patients with CRPS for disorders in autonomic function. Thermoregulation is tested by using the thermoregulatory sweat test (TST) and infrared thermography or thermometry. The TST

assesses calorimetric precipitation from a specific region of the body by adding a solution that changes color when enough heat is generated to produce sweat.[47] Infrared thermography is direct visualization of the change in temperature of the affected site, and in infrared thermometry, a device is used to measure temperature through the detection of infrared energy. Changes in temperature in patients with CRPS versus those with other types of pain had a sensitivity of 76% and a specificity of 94%.[48] Sudomotor regulation is tested by using the quantitative sudomotor axon reflex test (QSART), which measures sweat output from various regions of the skin. However, a recent retrospective review of patients who underwent QSART was found to have a sensitivity of 67.6% and specificity of 40.6%, with a not statistically significant odds ratio of 1.43.[49]

Trophic Changes

Three-phase bone scintigraphy (TPBS) is a very valuable test for the detection of CRPS. Although joint and bone alterations are not part of the IASP inclusion criteria, they are very important in the outcome of the syndrome.[25] TPBS detects alterations in periarticular bone metabolism, particularly increased bone metabolism, by detecting increase uptake of a periarticular tracer, which occurs predominantly within the first year. TPBS is low in sensitivity but high in specificity.[50] Furthermore, TPBS may have a role in monitoring treatment effectiveness for CRPS as well, possibly predicting disease response to ketamine treatment.[51,52] Magnetic resonance imaging of the affected limb has also been used for detection of CRPS but has high sensitivity (97%) and low specificity (17%).[53]

Treatment

Management of CRPS has been complicated by scant knowledge of the cause of the disease, which has resulted in few targeted therapies. Most of the medications initiated as first line therapy have been investigated for other non-CRPS neuropathic pain conditions and then applied to the treatment of CRPS, with mixed success. The historical approach to therapy for CRPS remains a multimodal, multi-disciplinary methodology. The predominant therapeutic modalities for the care of CRPS patients include physical therapy, pharmacologic agents, and interventional procedures.

Physical and Occupational Therapy

Physical and occupational therapy for restoration of function and improvement of limbs affected by CRPS has been studied widely. Physical exercises such as isometric strengthening, active range of motion, myofascial release, and stress loading are all tools that aid in restoring the functional capacity of the affected limb.[54] A 2019 multi-disciplinary study utilizing physical therapy modalities (graded motor imagery and physiotherapy exercises) along with psychological treatment, memantine, and morphine treatment was successful in reducing some of the CRPS symptoms.[55]

Other methods of therapy are currently under study. In a large controlled study in which tactile acuity and pain on the application of a tactile stimulus were measured in patients with CRPS, and mirror images were used to show the reflection of the unaffected limb during the stimulus, a decreased two-point discrimination threshold and decreased pain acuity were observed.[56] This suggests that therapies that improve functional restoration of the affected limb (including mirror therapy) may improve the outcome of CRPS.[57] However, evidence for other forms of physiotherapy for the management of CRPS I and II is unclear.[58] Despite ongoing studies and modeling, an optimal clinical physiotherapy algorithm to treat this condition has yet to be validated.[59]

Pharmacologic Therapy

Membrane Stabilizers

Medications such as gabapentin and pregabalin have been shown to be effective in relieving neuropathic pain.[60,61] CRPS is considered neuropathic pain, and gabapentin is presumed to be effective in treating it, yet there are very limited studies showing its specific efficacy for CRPS. In a randomized, double blind, placebo controlled crossover study in which patients were treated for two three week periods with two weeks in between, gabapentin had minimal effect on pain, but it significantly reduced patients' sensory deficits.[62] In a case report of a 15-year-old female with left arm CRPS one, pregabalin was successful in the management of her pain after she failed treatment with gabapentin, selective serotonin anti-depressants, and stellate ganglion block.[63] Although there is no clear evidence of efficacy for gabapentin, these neuroleptic medications are the first line therapy for neuropathic pain and are thus considered first line therapy for CRPS.

Corticosteroids

A large part of the pathophysiology in CRPS is the acute inflammatory process that occurs after an inciting event (see "Pathophysiology"). Because of this inflammatory course, corticosteroids have been used for treatment. In a 2006 randomized controlled trial comparing prednisolone with piroxicam, patients were given either medication for one month, and their shoulder-hand syndrome scores (measuring pain, distal edema, passive humeral abduction, and external rotation) were determined. In the prednisolone group, 83.3% showed improvement, and in the piroxicam group, only 16.7% improved. The shoulder-hand syndrome score in the steroid group was significantly lower than that in the piroxicam group.[64] Other studies have shown that continuation of prednisolone treatment (two months) after an initial one month high-dose (40 mg) taper was successful in reducing post stroke CRPS one patients.[65] Short term steroid use was further found to normalize microcirculation in response to remote ischemic conditioning (RIC, a non-damaging method to induce ischemia to an extremity) in CRPS patients (typically RIC causes an increased O_2 extraction and decreased blood flow) implicating the anti-inflammatory role of steroids in CRPS.[66]

Anti-depressants

These drugs have not been studied for use specifically with CRPS, but they have been widely studied for the control of neuropathic pain, and because CRPS is considered neuropathic pain, they are used in pain management. Anti-depressants such as tricyclic anti-depressants (TCAs) and selective serotonin-norepinephrine reuptake inhibitors (SSNRIs) have been used to control neuropathic pain effectively. In a recent Cochrane review, TCAs were found to be effective in treating neuropathy, with a number needed to treat (NNT) of 3.6 and a relative risk (RR) of 2.1. Venlafaxine, an SSNRI, was also found to be effective, with an NNT of 3.1 and RR of 2.2.[67] Further studies to investigate the drugs' ability to specifically target CRPS are warranted. A recent study showed that the combination of gabapentin and nortriptyline was a more effective therapy than either medication alone for neuropathic pain (including CRPS).[68] In children with CRPS, a randomized controlled trial comparing amitriptyline to gabapentin revealed no statistical difference between the efficacy of both medications in successfully decreasing pain intensity scores.[69]

Opioids

Studies on the effects of opioids directly on CRPS are lacking, although some have shown opioids to improve neuropathic pain when used in high doses.[70] However, a double blind, placebo controlled trial studying the efficacy of sustained-release morphine in CRPS patients for a total treatment of eight days showed that it was ineffective in decreasing pain, but the study had many limitations.[71] In 2016, a Cochrane review evaluating fentanyl use for the treatment of neuropathic pain including CRPS and PHN showed that there was insufficient evidence to support or refute the use of the medication in those conditions.[72] Substantial challenges to using opioid therapy for nonmalignant pain include nausea, constipation, cognitive impairment, tolerance, and hyperalgesia.[73,74] Therefore it should be used only until other therapies can be initiated. Studies of these medications in the CRPS population are lacking, and more is needed to demonstrate the efficacy of opioids.

Ketamine

Ketamine is an NMDA receptor antagonist. The NMDA receptor is a major part of the central sensitization that occurs in patients with CRPS (see "Pathophysiology"). Ketamine can be administered topically, orally, intranasally, or parentally in subanesthetic (analgesic) doses or in high doses to produce ketamine coma. Its role in medicine has expanded from anesthetic uses to include treatment of pain (acute and chronic), headaches, seizures, and depression.[75] A double blind, randomized, placebo controlled, parallel-group trial studying the effects of subanesthetic intravenous dosing of ketamine for four days in CRPS patients showed decreased pain levels, but the pain progressively increased from the first week after infusion to the 12th week. In patients undergoing ketamine infusion, minor and rare side effects such as nausea, vomiting, and psychomimetic effects developed.[76] In another nonrandomized open-label trial in which chronic CRPS patients refractory to standard therapies were treated with anesthetic doses of ketamine for five days, the pain improved significantly for six months, but 79.3% relapsed back to baseline after the six months.[77] A 2018 meta-analysis of 15 studies where ketamine was used for the treatment of CRPS included 15 randomized controlled or cohort studies revealing an immediate pain relief rate of 69% with a 58% pain relief rate at one to three months follow up.[78] The topical form of ketamine has also been shown to decrease allodynia and hyperalgesia in response to pinprick stimuli,[79] but this has not been well validated.

Bisphosphonates

Bone resorption at the site of inflammation in the affected limb contributes to the pain in CRPS. The use of bisphosphonates to decrease osteoclast overactivity has shown promise in its pain-reducing effects. In an eight week randomized, double blind, placebo controlled study, alendronate was used in patients with posttraumatic CRPS type one. This drug improved spontaneous pain, tolerance to pressure, and extremity range of motion.[80] However, other trials have shown no reduction in CRPS-related pain.

A 2013 Cochrane review evaluating interventions for pain treatment of CRPS patients from six Cochrane reviews and 13 non-Cochrane reviews showed low quality evidence that bisphosphonates may be beneficial for pain management.[81] A later review in 2018 of four moderate to good quality trials were analyzed, which revealed significantly lower short term (30–40 days) and medium term (two to three months) visual analog scale (VAS) reduction in patients on bisphosphonates for the treatment of CRPS one.[82] However, a higher percentage (35.5% vs. 16.4%) of adverse events occurred compared to placebo with a RR of 2.1, and the number needed to harm of 4.6 was reported, although no serious side effects were observed.[83] Because of the success of bisphosphonates in the management of acute phase CRPS type one, it was theorized that bone tissue involvement (through the release of inflammatory cytokines and effects on microvascular remodeling) plays an integral role in the early stages of CRPS one development.[84]

Interventional Treatment

Sympathetic Nerve Block

The most common sympathetic nerve blocks are the stellate ganglion and lumbar sympathetic blocks for the treatment of CRPS of the upper and lower extremities, respectively. Multiple modalities have been studied for their ability to disrupt the sympathetic pathway through these nerve plexuses, including local anesthetics, chemical neurolysis, and radiofrequency ablation. In a study in which both stellate ganglion and lumbar sympathetic blocks were performed with local anesthetic and normal saline on each subject, it was observed that the decreased pain that each experienced was almost identical, but the duration of decreased pain was longer when patients received the local anesthetic block.[85] In a small randomized study in which radiofrequency neurolysis was compared to chemical neurolysis, the pain decreased from baseline, but no significant difference was seen between the two methods.[86] A retrospective review of 287 stellate ganglion blocks for upper extremity CRPS treatment showed an average reduction of > three numeric rating scale from baseline or provoked pain.[87]

Although sympathetic blocks may provide a significant reduction in pain by blocking the sympathetic pathway of the pathophysiologic stages in CRPS, their greatest limitation is that they provide only short term relief in the vast majority of treated patients. This means that patients must continue to frequently undergo sympathetic blocks, which most often places them on maintenance therapy. A 32 question survey evaluating the use of sympathetic blocks for CRPS treatment was distributed nationally with a response from 248 pain physicians. In this group, 44% of providers schedule a sympathetic block at the first clinic visit, with 73% of providers performing one to three consecutive blocks with over 50% of respondents performing repeat injections for patients with at least 50% response from the prior injection.[88] This form of therapy should be performed to provide enough pain relief so that patients are able to perform physical therapy exercises for functional restoration and multi-disciplinary therapy, but not as a sole therapeutic modality.

Neuromodulation

Neuromodulation has implemented itself in the treatment algorithm of patients with chronic pain, including CRPS, utilizing percutaneous or surgically placed leads in the epidural space implementing electrical dosing via an implantable pulse generator (IPG). Currently, modalities for the treatment of CRPS include dorsal column neuromodulation and dorsal root ganglion (DRG) neuromodulation. In a randomized trial, patients with CRPS were separated into two groups: spinal cord stimulation (SCS) with physical therapy and physical therapy only.[89] This study showed that SCS provided significant improvement in pain for the first two years.[90] Unfortunately, there was no amelioration in quality of life or functionality in the group undergoing SCS with physical therapy, although this study was seriously flawed because of excessive patient dropout.[91] Several studies since have been performed evaluating the efficacy of these techniques in managing CRPS. A systematic review of 19 manuscripts evaluating SCS in

the treatment of CRPS revealed improvement of perceived pain, pain score, and quality of life in patients. However, the results from this review were inconclusive for the role of SCS in improving functional status, psychological status, sleep hygiene, or resolution of the signs of CRPS.[92]

DRG neuromodulation was first evaluated in a multicenter prospective trial for management of chronic pain, including nine patients with CRPS of the lower extremity. Six months after implant, participants had an overall reduction of 58% from baseline.[93] The ACCURATE study was a prospective multicenter randomized controlled trial evaluating the efficacy and safety of DRG neuromodulation in the treatment of CRPS of the lower extremities than tonic dorsal column neuromodulation. The 152 patient study showed that there was a greater percentage (81.2% vs. 55.7%) of patients with >50% pain relief at three months post implant without difference in the incidence of device related or serious adverse events.[94] This finding was further emphasized by the Neuromodulation Appropriateness Consensus Committee (NACC) guidelines for DRG best practices.[95] Though the role of neuromodulation for management of upper extremity CRPS requires further investigation, neuromodulation may be an effective therapy of management of lower extremity CRPS.

Intrathecal Treatments

Baclofen and ziconotide administered intrathecally have been examined for the treatment of CRPS. Baclofen is a γ-aminobutyric acid receptor agonist. It is used as a muscle relaxant and has been indicated for muscle spasticity and dystonia. A single-blind, placebo run-in, dose escalation study of CRPS patients with dystonia showed that intrathecal baclofen was very effective in decreasing dystonia and pain, as well as in improving quality of life, as indicated in a 12-month follow up.[96] Ziconotide is a very potent drug made from the toxin of sea snail venom and works by blocking chemicals that transmit pain signals. Intrathecal administration of this drug has great potential in reducing edema, trophic changes, and pain in these patients.[97] However, it is associated with a nearly 100% side effect profile. Incidentally, a four-year retrospective evaluation of 26 patients with intrathecal pumps for CRPS management revealed that intrathecal narcotics did not reduce the dose of oral narcotics while intrathecal ziconotide may.[98] Other medications trialed with success include clonidine[99] and morphine with bupivacaine.[100] The majority of the literature surrounding the use of intrathecal treatments for CRPS are case reports, and formalized trials are needed to verify the efficacy of these modalities.

Postherpetic Neuralgia

Postherpetic neuralgia is neuropathic pain that arises from herpes zoster (HZ- shingles) in a dermatome distribution. This form of pain is very debilitating and leads to poor quality of life and poor functional status at home and in society. Control of pain is difficult, with multiple interventions being required. There are multiple risk factors for the development of HZ and subsequent PHN. It is essential to understand the risk factors, pathophysiology, and diagnostic approach to PHN to delve into the various pharmacologic and interventional treatments available.

Epidemiology and Risk Factors

Varicella is a viral infection that may lead to varicella zoster (chicken pox) on first exposure and remains in a latent phase for the majority of lifetimes. HZ develops secondary to the reactivation of the varicella virus from its latent state. Varicella virus is kept in a latent state by the body's cell-mediated immunity. When there is a decrease in cell-mediated immunity, the risk for reactivation and subsequent HZ increases. Cell-mediated immunity may decrease with age, HIV infection, cancer, and immunosuppressive therapy as used for transplant patients.[101] The annual incidence of acute herpes zoster is estimated to be 3.4 cases per 1,000 patients with significant increases after the age of 50 years, with an approximate incidence of 11 cases per 1,000 patients by the age of 90 years.[102] A separate study found the incidence as 3.6 cases per 1,000 person-years that was low for patients between age 20–29 years old but increased to 7.1 cases per 1,000 person-years by seventy and 12.0 cases per 1,000 person-years by eight years old.[102]

PHN pain is pain that persists three months after the acute phase of the disease. It is seen in approximately 10%–20% of patients infected with HZ.[103] The incidence of PHN developing from HZ also increases with age, with 80% of cases occurring in patients 50 years or older.[103] Patients older than 70 years with HZ have a 50% risk for the development of PHN; approximately 13% of all patients over 50 years old will develop this condition.[104] PHN rarely develops in patients younger than 40 years. There are many risk factors for the development of PHN, and among them are increased age, greater severity of the rash during the acute phase, female gender, and greater acute pain severity.[105] In an epidemiologic study of patients with PHN in the Ferrara University Dermatology Unit, Italy, from 2000–2008, males had an earlier age at onset than females did, and 72% of the patients were older than 45 years. The most commonly observed sites were ophthalmic in 32%, thoracic in 16.5%, and facial in 16%.[106] The correlation of PHN developing after the first episode of HZ was reviewed in a prospective study in which patients were monitored for 12 months. It was concluded that three months after the appearance of the HZ rash, the risk for the development of PHN was 1.8%. In patients older than 60 years, the risk for the development of PHN and the severity of the pain was higher.[107]

In recent years, the administration of the varicella vaccine has become very popular as PHN cannot be prevented once a patient has developed HZ.[108] Some data suggest that these vaccines may lead to an increase in the incidence of HZ secondary to a reduced opportunity for subclinical boosting, which results in an extreme reduction in the incidence of varicella from the immunizations.[109] However, the administration of the zoster vaccine has been proven to decrease the incidence of HZ and PHN. In a randomized, double blind, placebo controlled trial of the zoster vaccine, the incidence of PHN decreased by 66.5% ($P < 0.001$), and the incidence of HZ decreased by 51.3% ($P < 0.001$).[110] In a population-based database review of post-vaccination incidence of HZ after starting a varicella vaccination program in Ontario the rate of HZ increased, incidence decreased by 29% in children, and hospitalization visits decreased because of HZ by 53%.[111]

Original versions of the vaccine contained live attenuated varicella zoster virus. The efficacy waned over time (six to eight years), but an immune boost can be provided with revaccination ten years after the initial vaccination. In 2017, a new recombinant glycoprotein E adjuvant vaccine was approved and available for use in the United States with increased efficacy and less decline over time than the live attenuated virus.[108] The recombinant vaccine was found to be significantly more efficacious in reducing HZ and PHN incidence in adults ≥60 years old than the live attenuated vaccine.[112]

Pathophysiology

Varicella zoster is the primary infection that leads to chicken pox. After the primary infection, the virus remains dormant within one of the sensory nerve ganglia, the most common of which are the trigeminal and thoracic ganglia; these are also the sites where most of the cutaneous dermatomes are involved. The cell-mediated immune system keeps the virus dormant in the latent phase. Progression from the latent phase to reactivation of the virus leads to the development of HZ and subsequently PHN in some patients.[113] During the reactivation phase of varicella zoster virus (VZV), destruction of neurons and satellite cells occurs because this is the site of replication for the virus.[114] VZV traveling along the affected sensory nerves leads to evasion of the host immune system and spreads from cell to cell until its characteristic unilateral dermatome rash is produced. The spread of the virus and its destruction of neurons occurs before the development of the rash.[115] Studies in postmortem patients have led to the conclusion that reactivation and replication of VZV result in inflammatory changes within the sensory neurons that it disturbs, which causes pain. This mechanism may help explain the findings of loss of cells, myelin, and axons, fibrosis of the affected ganglion, and atrophy of the dorsal horn in postmortem patients.[116]

The previously mentioned mechanism contributes to the two primary pathophysiologic mechanisms of PHN pain: sensitization (hyperexcitability) and deafferentation.[117] These mechanisms describe not only peripheral nerve pain but also central nerve pain.[118] Following nerve injury, nociceptive receptors in the peripheral and central nervous systems become sensitized, so the threshold for the firing of action potentials after a certain stimulus is lowered. This causes the nerve to become hyperexcitable and leads to allodynia without sensory loss.[117] Deafferentation pain arises from the neuronal destruction and loss of afferent neurons that occur after the virus reactivates and subsequently produces the inflammatory response within the affected nerve. The loss of afferent neurons leads to spontaneous activity centrally, which results in pain in areas where there is sensory loss. Neural sprouting is initiated in an attempt to reconnect the former C-fiber receptors, a process that leads to hyperalgesia with allodynia.[117] The sympathetic nervous system is also thought to play a role in PHN by stimulating a vasoconstrictive response during the inflammatory process that results in decreased intraneural blood flow, hypoxia, and endoneurial edema.[119] Typically, patients will report three types of pain, including constant pain without stimulus, intermittent pain without stimulus, and pain with a stimulus that is disproportionate to the stimulus.[118]

Diagnosis

Postherpetic neuropathy is principally a clinical diagnosis. The typical clinical scenario involves a patient complaining of persistent pain that is within a certain dermatome and affects the region that the dermatome innervates in a unilateral fashion.[120] The acute phase of HZ is characterized as a maculopapular vesicular rash that crusts over after one to two weeks and results in a burning sensation, hyperesthesia, itching, and severe pain. Prodromal symptoms that may occur one to five days before the rash include headache, fever, malaise, abnormal skin sensation, and photophobia. PHN may occur two weeks after the presence of HZ and is the chronic form of the disease. This is a very debilitating pain that consists of burning, dysesthesia, pruritus, and allodynia or paresthesia of the affected dermatomal region. The pain usually decreases or resolves within six months after exposure, but in some cases, it may last years.[121]

A detailed physical exam is often helpful in the diagnosis as patients will have sensory abnormalities in the area involved, including allodynia, hyperalgesia, or dysesthesia to touch. Furthermore, thermal stimulus and vibrational stimulus may elicit these sensory abnormalities as well.[118] Furthermore, QST may be a useful tool in helping further assess the functional status of the somatosensory system.[122]

Treatment

Therapy for HZ can be separated into the acute phase (shingles) and the chronic phase (PHN). In the acute phase of the disease process, the first line medications that have proved to significantly decrease the length of disease are antiviral medications such as famciclovir and valacyclovir. Three randomized controlled trials that measured the efficacy of these agents when initiated within the first 72 hours of disease onset concluded that they were all effective in increasing the rate of healing and decreasing pain.[123–125] Another study showed that valacyclovir resulted in faster complete resolution than acyclovir did (44 vs. 51 days, respectively).[126] In addition, a study comparing famciclovir with valacyclovir showed no statistically significant difference.[123] A Cochrane review of antivirals in the prevention of PHN showed high quality evidence that oral acyclovir does not reduce the incidence of PHN significantly. Unfortunately, data on the administration of antiviral medications aside from acyclovir for the prevention of PHN are inconsistent.[127] When deciding which agent to use, it is important to consider the amount of administration and cost (Table 34.1).

Other medications that may be used to control the pain of acute HZ are acetaminophen, nonsteroidal anti-inflammatory agents, tramadol, and opioids.[101] Studies and randomized trials comparing

TABLE 34.1 Antiviral Medications for Acute Herpes Zoster

Medications	Recommended Dosages	Side Effects	Prices
Acyclovir	800 mg five times a day for seven to ten days	Nausea, vomiting, diarrhea, constipation, decreased appetite, headache, joint pain	$24.95 for 30 400-mg tablets
Valacyclovir	1000 mg three times a day for seven days	Nausea, vomiting, diarrhea, constipation, abdominal pain and cramping, headache, tremors	$173.92 for 30 1-g tablets
Famciclovir	500 mg three times a day for seven days	Headache, nausea, vomiting, fatigue, pruritus	$166.38 for 21 500-mg tablets

opioids, TCAs, and membrane stabilizers for treatment of acute pain from HZ are lacking, but they are still recommended as adjunctive therapy for refractory severe pain.[101] The addition of corticosteroids with antiviral medications has proved effective in relieving the intensity of the pain of shingles, but not the duration of the disease process.[128] Furthermore, corticosteroid administration did not aid in preventing the development of PHN, as shown in a Cochrane review study.[129]

Interventional therapy for the treatment of acute HZ has proved effective in relieving the pain but not consistent in preventing the development of PHN. A randomized trial in which patients older than 50 years with HZ were given standard therapy versus standard therapy and one epidural injection of methylprednisolone, 80 mg, with bupivacaine, 10 mg, showed that in one month, patients in the epidural injection group experienced a significant reduction in pain.[130] A randomized prospective study was performed comparing interlaminar and transforaminal steroid injections for management of acute phase HZ found similar VAS, Short Form (36) Health Survey Physical Component Summary (SF 36 PCS), and Short Form (36) Health Survey Mental Component Summary (SF 36 MCS) scores with no difference in analgesic effects one or three months between the two groups.[131] An alternative method for acute HZ treatment with subcutaneous injection of triamcinolone with lidocaine was reported with improvement in pain at three months post infection than standard antiviral therapy with analgesics.[132] Further studies are needed to validate this modality of acute HZ treatment.

Analgesic Therapy

PHN is a neuropathic pain historically refractory to many forms of therapy. PHN therapies have been separated into analgesic medications (e.g. topical, membrane stabilizers, opioids), interventional procedures (such as sympathetic blocks, intrathecal injections, or surgical interventions), and preventative therapy with the zoster vaccine. Nontraditional PHN therapies such as cognitive and physical therapy have also proved beneficial. As with most other chronic pain disorders, a multimodal therapeutic plan leads to an optimal chance of success.

Medications such as gabapentin, pregabalin, tramadol, and topical lidocaine are considered first line treatments because they have been shown to be most well tolerated by the (commonly elderly) patient population. Other medications shown to help patients with PHN are TCAs and SSNRIs, opioids, and topical capsaicin cream (Table 34.2). The therapeutic modality chosen is patient specific and depends on a thorough history and physical examination.

Topical Medication

A 5% lidocaine patch and 4%–10% lidocaine cream are widely used topical forms. A randomized, two-treatment period, vehicle-controlled, crossover study showed that a lidocaine patch is effective in controlling PHN pain from allodynia. At the end of the study, 78.1% of subjects enjoyed the lidocaine patch treatment phase, and only 9% liked the placebo patch treatment phase.[133,134] The lidocaine patch is also very safe because of minimal systemic absorption. It is also used safely with other medications based on studies showing no significant drug-drug interaction. The most common side effect reported has been mild skin irritation.[135] The NNT has been quoted as 2.0 with 95% confidence intervals (CI) 1.4–3.3.[136]

Topical capsaicin in cream or high-concentration patch form has shown promise in treating PHN pain. The first application of the cream leads to exacerbation of the burning sensation, but with time, application leads to desensitization of the nerve root endings and decreases the hyperalgesia. In a four week, double blind study, patients were randomized to receive a high-concentration topical capsaicin patch or placebo. The study showed that the high-strength capsaicin patch relieved pain in 64% of patients at the six week mark than 25% taking placebo.[137] The NNT has been quoted as 3.3 with 95% CI 2.3–5.8 for the cream and NNT 11.0 with 95% CI 6.1–62.0 for the patch.[136]

Anti-convulsants

Gabapentin has been used widely as a first line therapeutic agent for PHN. A quantitative systematic review of randomized controlled trials indicated that the pooled NNT for gabapentin was approximately 4.4.[138] Another study, a randomized, double blind, parallel-group trial of nine weeks' duration, showed that gabapentin was

TABLE 34.2 Efficacy and Side Effects of Analgesic Medications for Post-herpetic Neuropathy

Medications	Number Needed to Treat (NNT)	Side Effects
Anti-convulsants		
Gabapentin	4.3	Diarrhea, dizziness, drowsiness, dry mouth, tiredness, somnolence
Pregabalin	4.9	Blurred vision, changes in sexual function, constipation, dizziness, drowsiness, dry mouth
Topical		
Lidocaine	2	Mild skin irritation
Capsaicin	3.6	Major skin irritation and burning
Tricyclic anti-depressants	2.64	Dizziness, drowsiness, dry mouth, headache, impotence, nausea, nightmares, pupil dilation, sensitivity to sunlight, sweating, tiredness
Opioids		
Tramadol	4.76	Constipation, dependence, dizziness, drowsiness, increased sweating, loss of appetite, nausea
Oxycodone	2.64	Constipation, dependence, dizziness, drowsiness, increased sweating, loss of appetite, nausea
Morphine	2.64	Constipation, dependence, dizziness, drowsiness, increased sweating, loss of appetite, nausea

just as effective as nortriptyline but was tolerated better. After nine weeks of gabapentin treatment, the pain score declined by 43%, and sleeping improved by 52%.[139] The dosage may be titrated up to effect to 1800 mg/day to a maximum of 3600 mg/day.[140] Pregabalin has an identical site of action as gabapentin and is as efficacious in the treatment of PHN. It has the drawback of being on patent (and therefore more expensive) but can be better tolerated by patients because of its greater bioavailability, which results in twice a day dosing compared to the three times daily dosing required for gabapentin.[141] Pregabalin has a similar NNT of 4.2 with 95% CI 3.4–5.4 with a similar side effect profile as gabapentin, including sedation, dizziness, and peripheral edema.[136]

Anti-depressants

TCA medications have been the first line therapy for neuropathic pain. In a 2006 randomized, double blind, parallel-group trial of nine weeks' duration, patients with PHN who received nortriptyline had a 47.6% reduction in pain with sleeping scores improved from baseline.[139] A quantitative systematic review of analgesic therapy for PHN noted a significant analgesic benefit with TCAs for the treatment of PHN pain, with the pooled data showing an NNT of 2.6 (95% CI 2.1–3.5).[138] The efficacy of amitriptyline in providing relief of pain in patients with PHN was studied by comparing nortriptyline with amitriptyline. The results showed that both these drugs provided adequate pain relief in 67% of patients. Although they are both equally effective, patients tolerated nortriptyline better because of its fewer side effects.[142]

Venlafaxine is another anti-depressant medication with the potential for the management of neuropathic pain, including PHN. It is classified as an SSNRI and provides relief of neuropathic pain by increasing the amount of serotonin and norepinephrine and inhibiting their reuptake. This drug has been shown to have fewer side effects than TCAs.[143] Venlafaxine must be used in doses exceeding a total daily dose of 200 mg/day to inhibit norepinephrine reuptake; doses below this level will only inhibit serotonin reuptake and have no analgesic benefit. A 2015 Cochrane review evaluated six double-blinded randomized controlled trials that revealed little compelling evidence to support the use of venlafaxine for neuropathic pain. However, there was some lower quality studies that implicated benefit, and the authors of the review do not recommend revising prescribing guidelines to promote venlafaxine use, given the number of effective medications available to treat neuropathic pain.[144] This may be because of venlafaxine's side effects, including hypertension, exacerbation of seizures, and mania.

Opioid Medications

Although opioids are considered effective in overall pain management, their efficacy in controlling neuropathic pain is still controversial. In a double blind, crossover, four week study of sustained-release oxycodone, 20–60 mg, for moderate to severe pain in patients with PHN, the response rate for pain relief was 58% versus 18% for placebo.[145] Another study reported that the administration of 10 mg oxycodone to a patient already taking pregabalin did not enhance the pain relief obtained,[145] demonstrating that oxycodone at low doses is not as effective as the administration at higher doses. Morphine was also found to be beneficial in managing the pain of PHN. It was shown that a combination of morphine and gabapentin improved neuropathic pain in patients with PHN more than did either of them alone.[146] These data suggest that opioids at high doses are of therapeutic value in relieving pain in patients with PHN. The NNT for morphine was quoted as 2.8 with 95% CI 2.0–4.6, while the NNT for oxycodone was 2.5 with 95% CI 1.7–4.4.[136]

Tramadol

Tramadol is a weak μ-receptor agonist medication with properties that increase the release of serotonin and inhibition of norepinephrine reuptake. This medication has been effective in treating neuropathic pain with an NNT of 4.8.[147] In a multicenter, randomized, double blind, parallel-group study involving 127 outpatients treated with tramadol or placebo for six weeks, the tramadol group showed significantly reduced pain than the placebo group. Quality of life in the tramadol group was also improved.[147]

Combination Therapy

Many studies have combined medications to achieve the greatest efficacy with the least dosage and increased tolerability of the medications. In a double blind, double-dummy, crossover trial in which patients with neuropathic pain took gabapentin or nortriptyline as monotherapy or combination therapy, combination therapy was shown to be better than monotherapy. However, each medication was effective in relieving neuropathic pain.[68] The combination of gabapentin and morphine has also been widely researched. Gabapentin combined with morphine was more effective than either medication alone.[146]

Interventional Therapy

Interventional therapy for the pain of PHN includes nerve blocks, intrathecal injections, and SCS. Interventional therapies are not considered a first line choice, but they should be considered in a multimodal management approach for PHN treatment.

Sympathetic Nerve Blocks

The role of sympathetic nerve blocks is to provide relief of pain during the development of HZ, provide relief of PHN pain, and prevent the development of PHN from HZ. Unfortunately, most of the data attempting to prove the efficacy of sympathetic nerve blocks in these three main roles come from retrospective studies and are limited. Thus the use of sympathetic nerve blocks remains controversial. In a small, randomized study based on retrospective data in which bupivacaine was compared to the saline solution, there was evidence of the reduced duration of acute HZ pain in patients with sympathetic nerve blocks.[119] Another retrospective study concluded that sympathetic nerve blocks provided temporary short term pain relief in 41%–50% of patients with PHN.[148] A study comparing sympathetic nerve blocks and lidocaine patches for the treatment of PHN revealed similar rates of failure (18.9% vs. 27.1%, respectively) with similar average Numerical Rating Scale (NRS) change (5.88 vs. 5.01) but a significant proportion of patients remaining pain free eight weeks after treatment in those treated with sympathetic blocks than those with lidocaine patches (34.4% vs. 13.5%).[149]

Neuraxial Blocks

Epidural injections, paravertebral injections, and intrathecal steroid injections have all been used for temporary relief of pain from PHN, with successful short term results. Epidural steroid injections have been proved to effectively reduce pain in the acute phase of PHN, but most research has focused on its effects in preventing the progression of HZ to PHN. In a study performed in Italy, 600 patients older than 55 years with HZ were administered bupivacaine and methylprednisolone through an epidural catheter versus intravenous administration of prednisolone and

acyclovir until they were pain free. After one year, the incidence of PHN was 22% in patients receiving intravenous prednisolone and acyclovir instead of 1.6% in those receiving bupivacaine and methylprednisolone through an epidural catheter.[150] A retrospective review of PHN patients receiving epidural steroid injections to determine variables to predict the efficacy of injection revealed no demographic characteristics, concurrent medication use, or type of epidural steroid injection were associated with efficacy at two or 12 weeks after the injection.[151]

The efficacy of paravertebral blocks in preventing PHN was assessed in a single-center randomized study of patients with HZ given either the standard therapy of oral antivirals and pain medications or a series of four paravertebral injections with bupivacaine and methylprednisolone besides standard therapy. The study concluded that after 12 months, the incidence of PHN with standard therapy alone was 16% compared to 2% in the paravertebral block group. Although it seems that paravertebral blocks are effective in preventing PHN, larger multicenter trials are still required.[152]

Another promising procedure for the relief of PHN pain is intrathecal methylprednisolone. A study in which 279 patients with intractable PHN pain for more than one year were given either intrathecal methylprednisolone with lidocaine, lidocaine alone, or no therapy concluded that the group receiving methylprednisolone with lidocaine experienced a significant reduction in pain than the groups receiving lidocaine alone or no therapy.[153] Unfortunately, these data have never been replicated, and clinical experience has not corresponded to the positive results that the authors obtained. Further, a planned randomized study was terminated prematurely after the six patients who had intrathecal methylprednisolone had increased pain and four of the six patients had the area of allodynia increased.[154] Although this method of management of intractable PHN may have been effective in this single study, its association with adhesive arachnoiditis has and should limit its application.

In a systematic review interventional treatments of PHN including transcutaneous electrical nerve stimulation (TENS), botulinum toxin A local injection, cobalamin injection, triamcinolone injection, stellate ganglion block, DRG destruction, pulsed radiofrequency ablation, and intrathecal methylprednisolone and midazolam injection were evaluated. All interventions to treat PHN except for intrathecal methylprednisolone injection was deemed level 2 evidence, substantiating a grade B recommendations. Subcutaneous injections of botulinum toxin A, subcutaneous injections of triamcinolone, TENS, stellate ganglion block, and peripheral nerve stimulation were recommended as treatments to try first given the invasiveness, price, and safety of these techniques. If pain persists, these authors recommended paravertebral blocks or pulsed radiofrequency therapy. With patients in refractory pain, SCS was recommended for consideration while DRG destruction and intrathecal methylprednisolone was reserved for select scenarios requiring comprehensive discussion given the risks associated.[155]

Neuromodulation

With the increase in evidence with concurrent development of neuromodulation technologies, neuromodulation has expanded its role in pain management to addressing PHN as well. The 2014 NACC guidelines reviewed the literature for PHN management with dorsal column SCS and peripheral nerve stimulation (PNS).[156] Since then, several retrospective studies evaluating the role of neuromodulation were performed. In one retrospective study evaluating short term (7–14 days) dorsal column SCS in 46 patients with acute HZ that failed conventional therapies, 69.6% of patients achieved minimally clinically important difference, with 39.1% reporting complete pain relief. The study was limited as no comparative group was available.[157] Another retrospective study of 99 patients with various stages of HZ (acute, subacute) along with PHN who received short term dorsal column SCS treatment were evaluated at one, three, five, and 12 months follow up. The study showed that 97.5% of acute HZ and 84% of subacute HZ patients had pain expressed as VAS scores of two or less at 12 months than 37.5% in patients with PHN. Although no control group was available for comparison, the authors implied that short term dorsal column SCS might decrease the incidence of PHN after an HZ infection.[158]

PNS is another potential modality for the management of PHN. Though most of the literature on this technique are case reports or nestled within a larger neuromodulation cohort, several reviews of this technique discuss the applicability of this procedure in treating PHN. In a case report of two patients with a ten month and 2.5 year follow up, PNS provided an average pain relief of 90%. A review of various neurosurgical techniques for the management of PHN included a review of three PNS studies encompassing ten patients. The procedure was performed after six months of HZ onset with a successful trial before PNS implant. Patients were evaluated at followed up with a mean follow up time of >20 months after IPG implant, where 80% of patients reported satisfactory reduction (>50%) of their pre-procedural pain.[159] Further well controlled trials are needed to validate PNS in the treatment of PHN. However, it may be a promising technique to help patients in the future.

Diabetic Neuropathy

Epidemiology and Risk Factors

The definition of diabetic neuropathy as proposed by the San Antonio Consensus Statement is "demonstrable disorder, either clinically evident or subclinical in the setting of diabetes without other causes of peripheral neuropathy."[160] The diabetic neuropathies are collectively considered a diverse, complex disease that affects many components of the nervous system and exhibits varied clinical manifestations. The condition is a unique neurodegenerative process that preferentially targets sensory axons, autonomic axons, and eventually motor axons to a lesser extent.[161] They can be classified into two main categories: generalized neuropathies versus focal or multifocal neuropathies. Generalized neuropathies include acute sensory neuropathy, chronic sensorimotor distal polyneuropathy, and autonomic neuropathy. Focal and multifocal neuropathies include cranial, truncal, focal limb, and proximal motor neuropathy (amyotrophy), as well as chronic inflammatory demyelinating polyneuropathy.[162]

The prevalence and incidence of DPN have been very difficult to verify given the inconsistencies in clinical diagnostic criteria, variability in patient populations, and wide range of physiologic techniques. The World Health Organization estimated that 150 million people had diabetes in the year 2000, and this number was expected to increase to 366 million by the year 2030.[163] It has been estimated that approximately 56% of patients with DPN will complain of pain that affects their quality of life.[164]

In earlier studies, the prevalence of lower limb pain ranged from 6% to 27%, and DPN affected men and women equally.[165] A study conducted in the United Kingdom involved 356 diabetic patients, most of whom had type two diabetes mellitus (T2DM),

and included a structured questionnaire with a physical examination. Chronic sensorineural DPN (CSDPN) was diagnosed in almost half the patients, but only a third of them complained of pain that had been present for at least one year. The prevalence rate for DPN in this study was 16% compared to 5% for chronic neuropathic pain in a similar population without diabetes. It is also important to note that in this study, 12.5% of patients with DPN did not report symptoms to their physicians, and the 39% who reported pain did not obtain treatment of their pain, which suggests that DPN is undertreated.[166]

A cross-sectional descriptive study reported the prevalence of DPN in patients with diabetes mellitus type two to be 26%. The prevalence of diabetic patients suffering from CSDPN was found to be 44%.[167] A 2009 multicenter study conducted in Belgium included 1111 diabetic patients, types 1 and 2, and estimated the prevalence of CSDPN and DPN.[168] The study was performed with the NeuroPEN device, which tests for pain and monofilament perception and, based on studies, is able to identify CSDPN with confidence.[169] The duration of diabetes in this population was greater in patients with type one than in those with type two, 16 versus 11 years, respectively. The study concluded that the prevalence of CSDPN was 43% and was higher with type two (51%) than with type one (26%) diabetes. The prevalence of lower limb neuropathic pain was 14%, again higher with type two (18%) than with type one (6%).[168]

The prevalence of peripheral neuropathy in type one diabetic patients was quoted as 34% in the Pittsburgh Epidemiology of Diabetes Complications Study, while the SEARCH for Diabetes in Youth Study quoted the prevalence of DPN in youths (average age 15.7) with type one diabetes mellitus (T1DM) as 8.2%.[170,171] In the SEARCH study, the prevalence of DPN was quoted as 26% while the Action to Control Cardiovascular Risk in Diabetes (ACCORD) trial found that 42% of adults with type two diabetes had peripheral neuropathy.[171,172]

The prevalence of diabetic neuropathy increases with increased T2DM duration as the prevalence increased from 8% to 42% when T2DM were monitored over ten years in a 1995 Finnish study.[173] Similar findings were seen in the 2013 Bypass Angioplasty Revascularization Investigation Two Diabetes trial where patients with advanced T2DM in the cohort with 50% confirmed diabetic neuropathy at baseline had a four year cumulative incidence of diabetic neuropathy of 66%–72% in patients who had no neuropathy at baseline.[174] According to these and other studies, the incidence of diabetic neuropathy in patients with T2DM is approximately 6,100 per 100,000 person-years, while it is 2,800 per 100,000 person-years in those with T1DM. The prevalence of diabetic neuropathy in patients with T2DM may be 8%–51%, while the prevalence in patients with T1DM may be 11%–50%.[161]

Risk factors for DPN have been widely studied to prevent its development. The most commonly reported risk factors are age, duration of diabetes, and hemoglobin A_{1C} levels.[161,175] Other risk factors associated with DPN are arterial hypertension,[165] impaired glucose tolerance (IGT),[176] smoking history, alcohol abuse history, and increased height.[177] In a study examining patients with neuropathy of unknown origin, 36% of patients had IGT, 77% of whom had painful neuropathy.[178] Other risk factors shown to have a relationship with the presence of DPN are obesity with low high-density lipoprotein cholesterol and high plasma triglyceride levels.[168] Genetic factors are also considered risk factors based on a study by Galer and colleagues;[164] 56% of patients with DPN also had first- or second-degree relatives suffering from DPN. Specific genes have also been implicated with this condition, including the *ACE* and *MTHFR* polymorphisms.[161]

Pathophysiology

Diabetic neuropathy is theorized to occur by three mechanisms: the polyol pathway, microvascular damage, and glycosylation end-product theories. These three models most likely act simultaneously, but there may also be some overlap between them.[179] Neurotrophic factors, neuronal membrane ion channel dysfunction, mitochondrial dysfunction, and lipid toxicity may likewise play a role in DPN.[180]

The polyol pathway theory proposes that increased blood glucose leads to elevated glucose concentrations within nerve endings. Through a series of reactions, the glucose is converted into sorbitol via the polyol pathway involving aldose reductase and elevation of the fructose level. The high sorbitol and fructose levels subsequently lead to a decrease in sodium-potassium adenosine triphosphatase (Na+, K+-ATPase) activity. Activation of the aldose reductase-depleting cofactor NADPH (reduced nicotinamide adenine dinucleotide phosphate) leads to decreased nitric oxide and glutathione, which inhibits the buffer against oxidative injury and vasodilation and results in chronic ischemia.[179]

In the microvascular damage theory, thickening of the capillary basement membrane along with endothelial cell hyperplasia leads to neuronal ischemia and infarction.[179] The glycosylation end-product theory proposes that interference in axonal transport results in decreased nerve conduction velocity because of chronic hyperglycemia, which results in the deposition of advanced glycosylation end products around peripheral nerves. These end products may also produce NADPH (which activates NADPH oxidase) and contribute to the formation of hydrogen peroxide and increased oxidative stress. These reactive species may have an increased effect in the face of mitochondrial dysfunction resulting in further nerve injury.[180]

Regardless of the mechanism, diabetic neuropathy ultimately develops when the peripheral terminal sensory axons are retracted with the preservation of perikarya (cell bodies). Ultimately the entire neuron, including the perikarya, is affected by diabetes. Schwann cells are targeted by chronic hyperglycemia resulting in damage furthering axonal dysfunction.[161] This progressive axonal damage results in loss of mRNA expressing needed for neurofilament production, promoting oxidative damage and loss of peripheral nerve function.[161]

Nerve growth factors are important in the repair of nerve structure and function after an injury. Low levels of these neurotrophic factors correlate with diabetic neuropathy in animal models. Other factors associated with diabetic neuropathy are abnormal calcium channel activity contributing to cellular injury and death and sodium channel dysfunction playing a role in the genesis of painful neuropathy.[181]

Clinical Features

Acute sensorimotor neuropathy often occurs in association with periods of poor metabolic control, such as uncontrolled glycemic levels or the development of ketoacidosis. This form of neuropathy is very rare.[162] The most common form of peripheral neuropathy is CSDPN, as seen in over 80% of patients with DPN. Patients with CSDPN typically complain of distal, symmetric burning pain that usually involves the feet initially and gradually moves upward in a symmetric fashion. This is because of damage to longer nerves, a

phenomenon known as length-dependent diabetic polyneuropathy.[182]

DPN causes neuropathic pain because of the involvement of small nerve fibers,[183] and diagnosis is achieved through a diligent history and physical examination. One study showed that clinical neurologic examination, including questionnaires, was 23% sensitive and 93% specific in diagnosing DPN.[184] A 2007 study concluded that the development of the DN4 questionnaire has improved diagnostic performance, with a sensitivity of 83% and specificity of 90% in patients with a neuropathic pain score greater than four out of 10.[185] However, such assessment tools, including the Michigan Neuropathy Screening Instrument, the Toronto Clinical Neuropathy Score, and the United Kingdom Screening test, are subjective and rely on examiner familiarity to interpret the results.[186] The initial symptoms in up to 50% of patients with DPN are highly nociceptive and include burning pain, electric or stabbing sensations, paresthesia, hyperesthesia, and deep aching pain, which are typically worse at night. Upper extremity involvement is rare.[187]

Physical examination of the lower limbs typically shows sensory loss of vibration, pressure, pain, temperature perception, and absent ankle reflexes. Loss of touch and pin sensation typically occurs before a loss of proprioception and vibration and is caused by the involvement of large-diameter fibers.[182] This is evaluated with 10 gauge monofilament and tuning fork tests.[169] Gait ataxia may occur with severe neuropathy. In addition, signs of peripheral autonomic dysfunction can be observed, including a warm or cold foot, distended dorsal foot veins, dry skin, and calluses under pressure-bearing areas.[162]

It is important to note that the diagnosis of DPN is a diagnosis of exclusion and that multiple pathologies may mimic this form of neuropathy. The gold standard for diagnosing DPN is with nerve conduction studies that may aid in verifying small and/or large fiber disease and ruling out other mimicking conditions.[186] The differential diagnosis should include peripheral vascular disease, restless legs syndrome, Morton's neuroma, vitamin B12 deficiency, hypothyroidism, and uremia.[162,182]

Several devices may be helpful in diagnosing DPN. DPN-Check, a handheld point of care device that performs a sural nerve conduction test that may serve as a proxy for a full nerve conduction test. It has a reported 95% sensitivity and 71% specificity compared against a reference standard nerve conduction test.[188,189] Neuropad is a device that measures plantar foot sweat production with relatively high sensitivity for detection of small fiber neuropathy. Compared to other tests for detecting DPN, it has a higher sensitivity than the 10 g monofilament test or the biothesiometer test.[190] Sudoscan is a device that quantifies electrochemical reaction between electrodes and chloride ions when sweat glands are stimulated with a sensitivity of 87.5% and specificity of 76.2% in classifying DPN.[191] Although primarily in the validation stage, these instruments may potentially allow for bedside use for confirming the diagnosis of DPN.

Autonomic neuropathy is a common pathology that may occur in patients with chronic diabetes types 1 and 2. This form of neuropathy may be present at any stage of the disease, but it most often affects patients who have had the disease for over 20 years.[192] The parasympathetic, sympathetic, and enteric nerves are affected, and myelinated and unmyelinated nerves are affected and damaged. The condition is considered irreversible, but cardiac sympathetic dysinnervation has been shown to revert with tight glucose control.[193] It affects multiple organ systems, including the cardiovascular, genitourinary, sudomotor, gastrointestinal, and endocrine systems. Some clinical manifestations include resting tachycardia, orthostatic hypotension, distal anhidrosis, bladder dysfunction, erectile dysfunction, female sexual dysfunction, severe constipation, diarrhea, and dysmotility syndrome.[194] In addition, because of the loss of sympathetic tone, vasodilation occurs and leads to the pooling of blood in the lower extremities. This has been proposed to cause osteopenia and is related to the development of Charcot's neuroarthropathy.[195]

Multifocal neuropathies comprise a wide spectrum of neuropathies, including diabetic amyotrophy, truncal neuropathies, cranial neuropathies, and mononeuropathies. Diabetic amyotrophy most often occurs in type two diabetics and is characterized by subacute pain and asymmetrical weakness and atrophy of the proximal lower limb muscles. There may also be involvement of the upper limb muscles and distal end of the lower extremity, but this is rare.[196] Mononeuropathies most commonly involve the ulnar, median, and common peroneal nerves secondary to nerve ischemia because these nerves are more susceptible to injury from compression. Cranial nerve involvement may be present but is extremely rare.[196]

Treatment Options

Treatment of DPN has been widely studied and includes the use of TCAs and SSNRIs, anti-convulsants, opioids, and other modalities. Treatment options can be viewed as approaches to prevent the development of DPN or alleviate its symptoms. As is true for all chronic pain syndromes, a multimodal approach is the most effective therapy for DPN, with the primary aim often focusing on protecting the lower limbs from damage caused by sensory loss or on relieving pain to enhance the quality of life and functionality of each patient.

Lifestyle Modification

Hyperglycemia and insulin deficiency are associated with the pathogenesis of DPN. It appears that glycemic control is one of the most effective treatments to slow the progression of the disease and delay its onset.[1] In a study conducted by the Diabetes Control and Complications Trial Research Group, a total of 1441 patients with insulin-dependent diabetes mellitus (726 of whom had no retinopathy and 715 had mild retinopathy) were monitored for 6.5 years after random assignment to intensive external insulin pump therapy or three or more daily insulin injections. The study concluded that in the group without retinopathy, intensive therapy reduced the risk for development of DPN by 76% compared to conventional therapy. In the retinopathy group, intensive therapy decreased progression by 54%. The study also showed that the progression of microalbuminuria in both groups was reduced by 39%, albuminuria by 54%, and clinical neuropathy by 60% with intensive insulin therapy.[197] Thus tight glycemic control contributes to a delayed onset and slowed progression of DPN.

Recent focus has also emphasized the role of dyslipidemia in the development of DPN. Obesity has been associated as a comorbid risk factor for the development of DPN, and having elevated lipids and triglycerides may contribute to the nerve injury seen in DPN. Non-esterified fatty acids from elevated triglycerides undergo β-oxidation in the cytosol of all peripheral nervous system cells. The byproduct of this process is acetyl Co-A, which is converted into acylcarnitine when accumulated, leading to worsening nerve injury.[198] Reactive oxygen species are also byproducts of β-oxidation, which may stress the endoplasmic reticulum, produce mitochondrial dysfunction, impair axonal transport, and

decrease available ATP.[199] Although dyslipidemia may be associated with the development of DPN, initiation of statins for dyslipidemia has had mixed results. In many mouse models, statins were able to reduce neuropathic pain from oxidative, physical, and chemotherapeutic induced neuropathies.[200,201]

Interestingly, statins were once thought of as a medication class capable of causing neuropathy. A small study in 2002 has implicated statins in causing peripheral neuropathy. However, reanalysis of this study by the same investigators found no association between the two.[202] Further well-controlled studies in humans are needed to establish statins as a preventative means of managing DPN. Regardless, exercise has benefits for lipid and glucose control that may have a role in preventing DPN.[161,203]

Anti-convulsants

Gabapentin has been used as first line therapy for neuropathic pain and has been shown to provide mild relief of pain in patients with DPN. In a randomized, double blind, placebo controlled, eight week trial comparing gabapentin and placebo, it was concluded that daily pain in the gabapentin-treated patients decreased from 6.4 to 3.9 versus a decrease in the placebo group from 6.5 to 5.1. Patients in the gabapentin treatment group also had improved sleep.[204] Another trial comparing the efficacy of gabapentin for DPN used three different forms of recording pain, including the VAS, present pain intensity, and McGill pain questionnaire (MPQ) completed before and after therapy. Only the MPQ showed statistical improvement in pain with gabapentin treatment versus placebo.[205] A 2019 prospective double blind randomized controlled study evaluated the effectiveness of duloxetine and gabapentin in treating DPN over eight weeks. The study found that both medications were effective in lowering VAS scores (64–39 for gabapentin and 62–36 for duloxetine) and improved sleep in both groups. Furthermore, gabapentin was found to be more effective earlier in treatment, while duloxetine had better medication compliance because of fewer side effects.[206]

A clinical synopsis of updated findings from the Cochrane review found that patients on gabapentin with DPN had a higher substantial benefit (38% vs. 21%) and moderate benefit (52% vs. 37%) than placebo.[207] Gabapentin has an NNT of three for overall neuropathic pain. The use of gabapentin for DPN had no effect on the quality of life, but it did yield improvements in sleep and mental health.[205] A systematic review of the literature on the treatment of DPN from 1960 to 2008 recommended that pregabalin be used if medically appropriate before gabapentin. Gabapentin and valproic acid should be considered as alternative therapies for DPN.[208]

A randomized controlled trial comparing pregabalin with placebo in patients with DPN for one to five years showed that 46% of the patients taking a dosage of 300 mg/day, 48% taking 600 mg/day, and 18% taking placebo had greater than a 50% reduction in pain.[209] In a 12 week randomized, double blind, multicenter, placebo controlled trial using a fixed dose of 100 mg/day for one week and 600 mg/day for 11 weeks in one group and flexible doses of 150, 300, 450, and 600 mg/day in the other group concluded that both treatments were superior in reducing neuropathic pain than the group receiving placebo.[210] A 2019 Cochrane review evaluated the efficacy of pregabalin in treating neuropathic pain across 22 studies found the number needed to benefit (NNTB) for 300 mg of pregabalin was 14 while the NNTB for 600 mg pregabalin was 6.1. Meanwhile, the patient global impression of change NNTB was 4.9 for 300 mg pregabalin and 3.7 for 600 mg pregabalin.[211] Thus pregabalin has been shown to be effective in providing relief of neuropathic pain in patients with DPN.

Anti-depressants

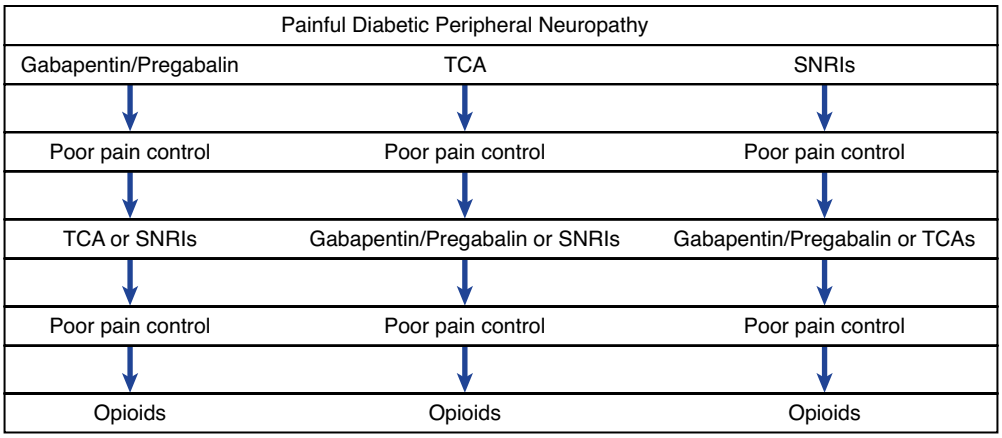
Multiple anti-depressant medications, including TCAs and SSNRIs, have been used for general neuropathic pain with positive results. In one study in which nortriptyline and fluphenazine were given in combination and compared with placebo, the group receiving combination therapy had 63% more patients with greater than a 50% reduction in VAS scores for pain.[212] The NNT for TCAs in patients with DPN was 1.3, as recorded by five randomized trials that established its effectiveness in treating neuropathic pain in those with DPN.[67] In addition, combination therapy with gabapentin has increased the effectiveness of treating PHN and DPN pain.[68] In a multicenter, double blind, randomized, placebo controlled study in which patients were treated with venlafaxine, those patients taking low dose venlafaxine (75 mg) had a 32% reduction from their baseline VAS scores after six weeks, and those taking high dose venlafaxine (150–225 mg) had 50% reduction after six weeks with an NNT of 4.5.[213]

Duloxetine is another SSNRI that has shown promise in relieving neuropathic pain from DPN. Multiple studies have demonstrated duloxetine to be more effective than placebo.[214,206,215] In a randomized, double blind, crossover clinical trial comparing duloxetine with amitriptyline after a six-week treatment concluded that both were effective in treating DPN. The duloxetine group had a 59% reduction in VAS scores with good pain relief, a 21% reduction with moderate pain relief, and a 9% reduction with mild pain relief. Duloxetine was also better tolerated than amitriptyline.[216] When utilizing TCA's and gabapentinoids for management of DPN, care should be taken when prescribing to geriatric populations as both medication classes were associated with increased risk of fall but not necessarily fracture risk.[217]

Opioids and Tramadol

Many studies have shown that opioid medications decrease pain in patients with DPN. The fear of dependency on and addiction to these drugs warrants close observation; opioid medication should be administered only if the patient's condition is unresponsive to non-opioid therapy (Fig. 34.1). Of these agents, tramadol, morphine sulfate, and oxycodone consistently decrease pain from DPN. An open, randomized comparative study of gabapentin versus tramadol and acetaminophen showed that the combination of tramadol and acetaminophen was just as effective in relieving DPN pain as gabapentin.[218] In a randomized, double blind, placebo controlled crossover study using tramadol, the group receiving tramadol experienced relief from polyneuropathy symptoms such as pain, allodynia, and paresthesia (NNT 4.3).[219] However, a 2017 Cochrane review of six randomized controlled trials of tramadol use in neuropathic pain including DPN, PHN, and CIPN showed substantial bias in the studies reviewed, implying the data behind the medication was not a reliable indication of its likely effect.[220]

Oxycodone has also been shown to be effective in treating neuropathic pain in patients with DPN. In a multicenter, randomized, double blind, placebo controlled study comparing controlled-release oxycodone with placebo, it was concluded that pain scores in the groups receiving oxycodone and placebo were 4.1 and 5.3, respectively.[221] This suggests that oxycodone is mildly effective in relieving neuropathic pain in patients with DPN. Another study that added oxycodone to the regimen of diabetic patients already taking gabapentin for neuropathic pain concluded that the use of the combination of these drugs relieved pain more than when gabapentin was used alone.[222] A 2016 Cochrane review of



• **Figure 34.1** Treatment algorithm for painful diabetic peripheral neuropathy. *SNRI*, Serotonin-norepinephrine reuptake inhibitor; *TCA*, tricyclic anti-depressant.

oxycodone use for neuropathic pain showed low quality evidence that oxycodone may have value in treating PHN and DPN but no other neuropathic pain conditions.[223] There are limited data on the use of morphine monotherapy in diabetic patients with neuropathy. A crossover study investigating morphine and gabapentin used as either monotherapy or combination therapy showed that the addition of morphine to gabapentin was more effective with lower doses of each medication.[146] Furthermore, Cochrane reviews of morphine and hydromorphone utilization for treatment of chronic neuropathic pain, including DPN, showed there was insufficient evidence for the use of either medication for chronic neuropathic pain.[224,225]

NMDA Receptor Antagonists

The NMDA receptor plays an important role in processing nociceptive and chronic pain. Thus antagonizing its actions may reduce neuropathic pain. One of the most common NMDA receptor antagonists is dextromethorphan. This drug has been examined in past studies, and it was shown to be efficacious in providing relief of pain in diabetic patients suffering from neuropathy. One study demonstrated that the pain in DPN patients had been reduced by 33% and that 68% of patients receiving dextromethorphan had more than moderate pain relief.[226] A study comparing dextromethorphan with placebo showed a 27% reduction in neuropathic pain in diabetic patients, with higher efficacy achieved with increased doses.[227] Also, it is worth noting that both these studies showed the efficacy of dextromethorphan for DPN but not for PHN.

Despite certain studies demonstrating the efficacy of dextromethorphan in addressing DPN, other studies reported varying results because of the variability of response to a wide range of doses. Furthermore, because of the amount of metabolism that it undergoes, it was argued that it would not have sufficient bioavailability to treat DPN as a monotherapy agent.[228] However, other formulations of dextromethorphan exist in conjunction with subtherapeutic (for cardiac use) dosing of quinidine to inhibit CYP 2D6 activity allows for dextromethorphan to be used as a single agent. A 13-week phase three randomized controlled trial evaluating the efficacy of dextromethorphan-quinidine (45 mg/30 mg or 30 mg/30 mg) in the treatment of DPN was successful at reducing patient reported pain and pain intensity while increasing sleep quality and activity.[228]

Topicals

Topical anesthetics have been deemed safe to use because of their lack of drug interactions, decreased side effects, and lack of titration required. Capsaicin cream (0.075%) has been shown to decrease neuropathic pain with an NNT of 6.6.[229] In addition, 5% lidocaine-medicated plaster has been demonstrated to be as effective as capsaicin, amitriptyline, gabapentin, and pregabalin, as shown in a systemic review study comparing the efficacy of each of these drugs in patients with DPN.[230]

Complementary and Alternative Medicine

Because oxidative stress may play an important role in the pathogenic mechanisms of diabetic neuropathy, the use of antioxidants such as α-lipoic acid may have some beneficial effect in the treatment of diabetic neuropathy. A meta-analysis showed that treatment with α-lipoic acid, 600 mg intravenously for a three-week course, provided effective relief of neuropathic pain and improved neuropathic deficits.[231] A more current study reported significant improvement in neuropathic pain with a 600 mg daily intravenous dose for five weeks (NTT 2.7).[232] Other treatment forms have been suggested for DPN based on its pathophysiology, such as glycation inhibitors, aldose reductase inhibitors, and growth factors, but further research in these areas is necessary.[233]

Acupuncture has been trialed for the management of DPN. In a randomized controlled trial involving 45 patients with DPN, where patients were assigned to either real or sham acupuncture, a 15 point drop in VAS was observed in patients receiving acupuncture.[234] A 2017 meta-analysis of four randomized controlled trials where acupuncture or electroacupuncture was used to treat patients with DPN showed that either form of acupuncture was successful in treating DPN. However, the majority of the studies had methodologic problems, and further well-controlled trials were needed.[235]

Neuromodulation

Growing interest has developed in utilizing neuromodulation for the treatment of DPN. Several studies in mice have shown that SCS may alleviate or attenuate mechanical hypersensitivity in DPN models utilizing various wave forms.[236–238] A case series have been published implicating a possible role for certain waveforms in the successful management of DPN.[239] Traditional targets of dorsal column and DRG neuromodulation are being investigated.

A study investigating the role of high-frequency dorsal column SCS in the management of painful DPN has recently been published on a cohort of 216 randomized patients in the SENZA-PDN study for a 6 month period.[240] Patients with greater than a 1 year history of PDN refractory to 2 analgesics including a gabapentinoid with a VAS for lower extremity pain of 5 or more, a BMI of 45 or less, oral morphine equivalents less than 120 mg a day, and a hemoglobbin A1c of 10 or less were eligible for enrollment in the study. These patients were trialed and, if found to have improved pain, implanted with the study device. Results of the study showed that patients treated with SCS had a statistically significant improvement of pain superior to conservative medical management (CMM) with a mean decrease in VAS of 5.9 compared to a mean decrease of 0.1 at 6 months. Further, SCS patients were noted have an improved sensory exam at 6 months compared to patients managed with CMM. Additional studies are needed to evaluate and verify the durable efficacy of this modality and other wave forms in managing DPN.

HIV-Related Pain Syndromes

Epidemiology

It is estimated that there are roughly 37.9 million people living with Human Immunodeficiency Virus (HIV)/acquired immunodeficiency syndrome (AIDS) worldwide as of 2018.[241] With the development and widespread use of highly active antiretroviral therapy (HAART) and the resultant decrease in opportunistic infections of the central nervous system, polyneuropathy has become the most prevalent neurologic complication associated with HIV infection.[242] This disease affects the patient's immune and nervous systems. As the patient progresses through different stages of the disease, a variety of neurologic complications arise that are directly or indirectly related to HIV infection.[243]

Although symptomatic neuropathy occurs in 10%–35% of individuals seropositive for HIV, pathologic abnormalities exist in almost all those with end-stage AIDS.[244] A systematic review in which multiple studies were compiled in the hope of determining the incidence and prevalence of neuropathy in HIV-infected patients found a high level of variation across all the studies. The prevalence of neuropathy ranged from 1.2% to 69.4%. The rate of development of neuropathy per 100 person-years in HIV patients ranged from 0.7 to 39.7, with a greater risk for neuropathy in older patients and those with more advanced disease.[245]

Multiple neurologic deficits occur with HIV infection, but the two most common forms of HIV-related sensory neuropathy (HIV-SN) are distal sensory polyneuropathy (DSP) and antiretroviral toxic neuropathy (ATN). DSP is because of the viral infection itself, whereas ATN is because of medical treatment of the viral disease.[242] The more common of the two disorders is DSP. The most common risk factors for the development of HIV-SN before the introduction of HAART were older age and advanced disease states (such as high plasma viral load and low CD4+ cell count).[246] After initiation of HAART, risk factors for the development of neuropathy became more ambiguous and included older age, CD4+ count lower than 50 cells/mm, nutritional deficit, use of dideoxynucleoside reverse transcriptase inhibitors, and exposure to protease and alcohol.[247] Medications associated with causing ATN include stavudine (d4T), didanosine (ddI), and zalcitabine (ddC), collectively known as dideoxynucleoside reverse transcriptase inhibitors or "D-drugs."[242]

Clinical Features

Although these HIV-SN disorders may represent two distinct entities,[248] the clinical syndrome and pathophysiologic manifestation of the two disorders are almost indistinguishable. In the case of ATN, the time course of the illness and the temporal relationship to commencement of antiretroviral therapy represent the primary differentiating characteristic. The onset of DSP can occur in either the subacute or chronic phase or following the development of an AIDS-defining illness. The clinical manifestations of ATN can appear within the first week to six months after the initiation of antiretroviral therapy and may subside after its cessation.

The clinical features of HIV-SN are dominated by painful dysesthesia, allodynia, and hyperalgesia. Its onset is often gradual, and it most commonly begins with bilateral lower extremity involvement. The neuropathy progresses in a length-dependent fashion with a worsening gradient of disease from distal structures to those more proximal. The dysesthesia commonly involves the soles of the feet first and progresses proximally; when the symptoms encompass the dermatomes of the knee, the patient will frequently report finger involvement. Though patients with DSP may be asymptomatic, most present with neurologic deficits. A 2014 study found that neuropathy was detected in 35% of participates 3.5 months after initial HIV transmission.[249]

The first symptoms noted are often numbness or burning sensations following a diurnal cycle, with the pain being worse at night. Shortly after that, patients will report allodynia (a stimulus previously not found to be noxious is perceived as painful) and hyperalgesia (a lower pain threshold) of the involved structures. Therefore wearing shoes and walking become painful, and the patient's gait becomes antalgic. There is minimal subjective or objective motor involvement, and pain is typically limited to the intrinsic muscles of the foot. Besides the sensory findings, physical examination reveals a diminution or loss of ankle reflexes.[250]

Diagnostic Studies

There is currently no gold standard for the diagnosis of DSP. In addition, the optimal combination of diagnostic studies has yet to be defined. The disease process remains primarily a clinical diagnosis.[251] The neuropathy may be secondary to many other physiologic processes for which blood work must be obtained for exclusion, such as vitamin B12 deficiency, diabetes mellitus, hypothyroidism, IGT, and syphilis.[250] In a nonrandomized, cross-sectional study, HIV patients with axonal peripheral neuropathy who were taking neurotoxic nucleoside analogs had their acetylcarnitine serum levels measured. Patients suffering from neuropathy while taking nucleoside analog medications had a deficiency in acetylcarnitine and were nutritionally deficient.[252] Although the level of acetylcarnitine may be used for the diagnosis of ATN, more studies are necessary.

Nerve conduction studies are not necessary for the diagnosis of DSP and will show an axonal, length-dependent, sensory polyneuropathy. Needle electromyograms are of no significant benefit because the findings are usually normal, but they may show chronic denervation and reinnervation.[253] Punch skin biopsy specimens from the distal end of the calf and proximal part of the thigh may be used to detect small fiber neuropathy by measuring intraepidermal nerve fiber density.[248] The lower the intraepidermal density, the greater the likelihood of DSP symptoms developing

and the greater the neuropathic pain level. Epidermal nerve fiber density may be used as a quantitative marker in clinical trials of neurodegenerative agents and predict the likelihood of symptoms developing in an asymptomatic patient.[254] DRG neuronal loss has been reported, although the reduction is more modest than distal axon loss.[255]

Pathophysiology

DSP and ATN are clinically similar but have distinct pathophysiology. The exact mechanism of the disease process is not fully understood, but it is hypothesized that there are multiple mechanisms at work that eventually cause axonal injury. The peripheral and central nerve toxicity related to HIV infection may be because of cytokine-mediated effects because HIV does not infect axons or Schwann cells. The gp120 protein is an HIV-associated protein thought to play a key role in pathogenesis through the ligation of chemokine receptors located on glial cells and neurons.[256] It may also play a role on chemokine receptors related to Schwann cell-to-neuron interaction.[257] Damage to axons occurs secondary to the inflammatory reaction in the nerve and surrounding tissues, which eventually leads to the characteristic pain seen in DSP. This hypothesis has been supported by animal studies in which gp120 was found to produce pain in rats when administered epineurally into the sciatic nerve[258] and intradermally into the paw.[259] The indirect causes of DSP pain are thought to be mediated by inflammatory injury. They can be divided into peripheral and central mechanisms. The peripheral hypothesis proposes that the pain results from the spontaneous activity of uninjured pain-transmitting or C fibers after injury to adjacent fibers. Inflammatory mediators released by macrophages may further sensitize these fibers. The central hypothesis involves an alteration in ion channels in the DRG combined with changes in the spinal cord dorsal horn that result in "central sensitization."[260]

ATN primarily occurs because of the use of nucleoside reverse transcriptase inhibitors and typically ensues within a year of beginning treatment or in patients with preexisting peripheral neuropathy.[261] The mechanism for ATN is currently unknown, but mitochondrial dysfunction as a result of abnormal mitochondria in Schwann cells and axons has been shown to play a role.[262]

Data have also shown that the depletion of mitochondrial Deoxyribonucleic Acid (DNA) seen in AIDS patients treated with Nucleoside/Nucleotide Reverse Transcriptase Inhibitors (NRTIs) leads to increased serum lactate levels and increased cell death.[263] In recent years, some of the protease inhibitor medications, more specifically, indinavir, ritonavir, and saquinavir, have led to an increased risk for mitochondrial toxicity that is partly because of their enhanced ability to penetrate within the neural compartments.[264]

Treatment

No medication is currently approved by the Food and Drug Administration for the treatment of HIV-SN. Most of the therapeutic modalities available have been tested and approved for other neuropathic pain (PHN and DPN). The therapeutic approach for HIV-SN first involves removing or reducing the dosage of the antiretroviral medication whenever possible.[265] Also, the patient's metabolic and nutritional status must be optimized to exclude alternative explanations for the neurologic symptoms (see "Diagnostic Studies") before initiating any other forms of therapy. Greater placebo response was attributed to the difficulty in evaluating analgesic efficacy in treating patients with HIV-SN. However, a systematic meta-analysis comparing placebo responses between HIV-SN and DPN found no statistical difference.[265,266]

Many different medications have been studied for the treatment of this form of neuropathic pain with no great success. Intranasal peptide T did not show any effectiveness in a randomized, double blind multicenter study in which patients with HIV-SN received either placebo or 6 mg/day of peptide T.[267] One medication that has been proved to be effective in relieving pain is recombinant human nerve growth factor, but it does not provide any evidence of neuroregeneration.[268]

Acetyl-L-carnitine (ALCAR) increases neurotrophic support of sensory neurons, as demonstrated in a double blind, parallel-group, placebo controlled, multicenter study. The groups were divided into those receiving placebo and those receiving ALCAR intramuscularly for 14 days, followed by ALCAR orally for 42 days. The group receiving ALCAR had significant improvement in pain.[269] Erythropoietin, a hematopoietic growth factor, was shown to prevent axonal degeneration in cells that had been exposed to HIV gp120 protein, but further studies are needed.[270] Amitriptyline and mexiletine have proved effective in relieving neuropathic pain in patients with DPN and PHN. Unfortunately, they did not prove to be more beneficial for HIV-SN than placebo in a randomized, double blind study.[271] Other medications such as duloxetine and venlafaxine, both SSNRIs, have been approved for the treatment of DPN, but further research is required to demonstrate their efficacy in relieving pain in patients with HIV-SN. Acetaminophen and nonsteroidal anti-inflammatory drugs have limited efficacy in the management of DSP. In cases of severe/refractory cases, opioids may be considered as an additive agent.[250]

Gabapentin has been shown to be effective in treating all types of neuropathy, including HIV-SN pain. In a placebo controlled trial in which patients were treated with gabapentin (1200 to 3600 mg/day) or placebo for four weeks and then an open trial for two weeks, the group receiving gabapentin experienced improvement in pain by 44% and improvement in sleep by 49% when compared with the placebo group, with the most statistically significant side effect being somnolence.[272]

Pregabalin is also very effective in relieving neuropathic pain. A recent randomized, double blind, placebo controlled, 14-week parallel-group trial testing the efficacy of pregabalin showed that there was no benefit in taking pregabalin over placebo.[273] Lamotrigine, 300 mg/day, was found to significantly reduce pain in patients with DSP and ATN in a randomized controlled trial.[274] Topical medication has also been studied for HIV-SN, including 5% lidocaine and high dose capsaicin cream. In a randomized controlled trial, 5% lidocaine cream was shown to be ineffective in treating HIV-SN pain.[275] A double blind, multicenter, randomized trial using high dose capsaicin cream demonstrated pain relief in patients with HIV-SN.[276]

Cannabis may have a role in treating HIV-SN. A randomized placebo controlled trial evaluated the use of cannabis (3.56% tetrahydrocannabinol [THC]) to placebo cigarettes in 50 patients with HIV-SN. Patients using cannabis reported a 34% reduction in daily pain than placebo (17%). A phase II, double blind placebo controlled crossover study of 28 patients with HIV-SN who failed two prior analgesic agents was performed comparing 1%-8% THC use to placebo in the management of their HIV-SN. Forty-six percent of patients who used cannabis reported >30% pain relief than the placebo group (18%). However, the

duration of treatment and primary end point of both studies was only five days.[277,278] Further studies are needed to verify long term outcomes.

Chemotherapy Induced Peripheral Neuropathy

In 2018 the World Health Organization attributed one in six deaths to cancer. The incidence of cancer in 2018 was estimated to be 18.1 million new cases with a cumulative lifetime risk of one in eight for men and one in ten for women.[279] Chemotherapy and surgery are the mainstays for the management of cancer. As cancer treatment algorithms evolve with increased efficacy, the number of cancer survivors are increasing. The five-year survival rate of cancer has increased dramatically since the 1960s from 39% to 70% among white and 27% to 63% among black patients.[280] Chemotherapy induced peripheral neuropathy (CIPN) is a neuropathic pain condition that results from chemotherapy exposure. Many cancer patients develop CIPN that continues long after their disease is in remission, and CIPN is developing into one of the most burdensome long term side effects from cancer.[281]

Epidemiology

Early studies have reported that CIPN occurred in roughly 90% of all patients who received neurotoxic chemotherapy.[282] Subsequent studies have found that CIPN more accurately had a prevalence of 68.1% within the first month of chemotherapy, 60.0% at three months, and 30.0% at six months or more.[283] Overall, it seems that the prevalence was found to be between 36% and 58% in patients actively on cancer treatment and patients 12 years after treatment.[284–286] CIPN presents a unique scenario as dose reductions of chemotherapy may help address the pain and concurrently increase the risk of morbidity and mortality from undertreatment of cancer. With increased survivorship from cancer diagnosis, CIPN has long-lasting consequences as it often continues beyond the period of treatment and once the cancer is in remission. Agents that may cause CIPN include platinum containing compounds (cisplatin, carboplatin, oxaliplatin), taxanes (paclitaxel and docetaxel), vinca alkaloids (vincristine and vinblastine), proteasome inhibitors (bortezomib), epothilones (ixabepilone), immune checkpoint inhibitors, antibody drug conjugates, and other chemotherapeutics (eribulin, thalidomide, lenalidomide).[287]

The main risk factors for CIPN include cancer type (because of the chemotherapeutics required to treat specific cancers) and the cumulative dose of the chemotherapeutic agent. Solid tumors (colorectal, breast, gynecologic, testicular, lung) and hematologic cancers are the most common cancers requiring neurotoxic chemotherapy.[287] Other risk factors include baseline neuropathy, age, concurrent chemotherapy treatment, smoking, early cancer diagnosis, and cancer treatment protocols utilizing drugs that can cause CIPN.[287,288]

Genetic markers have been implicated to be associated with CIPN. A Genome Wide Association Study (GWAS) on patients with multiple myeloma found 13 single nucleotide peptide polymorphisms associated with CIPN development.[289] A similar approach was performed in breast cancer patients with CIPN from taxane exposure where the GWAS revealed an association with an allele gene variant that may decrease the risk of developing CIPN when exposed to taxane.[290] However, current efforts have been unsuccessful in identifying genes that serve to reliably predict susceptibility to this condition.[291]

Clinical Features

Similar to DPN, CIPN manifests in a glove and stocking distribution with a proximal spread in more severe cases. Though largely a sensory neuropathy, patients may develop autonomic dysfunction, fine motor dysfunction, and decreased proprioception.[292] Patients can report either negative (impaired touch, pinprick vibration perception, imbalance) or positive (paresthesia, dysesthesia, neuropathic pain) symptoms in a distal to proximal fashion. Unique to exposure to platinum containing compounds, patients may report worsening symptoms months after cessation of chemotherapy, presenting the "coasting" phenomenon.[281]

Aside from pain and sensory loss, CIPN also negatively impacts the functionality and quality of life of afflicted patients. In a comparative cross-sectional descriptive study comparing cancer patients with all cause neuropathic pain to those without neuropathic pain on hospice found that 40% of all patients had neuropathic symptoms, of which 76.7% reported pain.[286] These patients are noted to be at high risk for falls, and the majority have decreased sleep quality.[293] In a prospective study evaluating SPADE symptoms in a cohort of 65 cancer patients with CIPN, 69.5% of patients reported sleep impairment.[294]

Diagnostic Studies

The diagnosis of CIPN is largely a clinical diagnosis. Care to obtain a detailed history and physical focusing on the natural history of other causes for neuropathy, including alcohol use, diabetes, nutritional deficiencies, and other exposures, should be exercised to rule out other causes of peripheral neuropathy. Although no gold standard exists for diagnosing CIPN, clinical tools including MPQ, brief pain inventory, Leeds assessment of neuropathic symptoms and signs, and Douleur neuropathique 4 may be helpful to characterize and trend the patient's pain. Specific tools for assessment of CIPN exist, including the Ajani scale, the functional assessment of cancer therapy-taxane, CIPN20, and the NCI common toxicity criteria, but may not truly reflect the incidence of neuropathy and suffer from inter-observer variations.[288,292]

Pathophysiology

Several theories regard the mechanism by which CIPN develops, as varying classifications of chemotherapeutics have different mechanisms of action and end targets. Overall, these theories fall within three main categories, including mitochondrial dysfunction with oxidative stress, neuroinflammation, and ion channel dysfunction although each associated chemotherapeutic has a target that is most likely affected.[288]

Many chemotherapeutics target nuclear DNA. However, mitochondrial DNA may be affected as well. Unlike nuclear DNA, mitochondrial DNA does not have a robust repair mechanism, and damage may result in mitochondrial dysfunction. Studies in rats exposed to paclitaxel producing painful peripheral neuropathy revealed intact myelin and DRG structure but swollen, atypical mitochondria in myelinated and unmyelinated neurons that correlated with the pain behavior displayed by the rats.[295] Another rat study with cisplatin induced peripheral neuropathy showed that DRG cell cultures from affected rats displayed dysfunctional mitochondrial transport that was reversible over time.[296] Among

the many roles of mitochondria, regulation of reactive oxygen species (ROS) plays a particularly important role, especially in light of chemotherapeutics, which inherently increases the amount of ROS. In a study of breast cancer patients, blood was evaluated in those with and without CIPN (from paclitaxel), which showed mitochondrial dysfunction pathways including those related to oxidative stress in patients with CIPN but not those without.[297]

Neuroinflammation plays a role in the development of chronic pain states. Certain cell types, including glial cells, are activated and play a role in inflammation and injury in chronic pain. In recent studies, the focus has shifted to astrocyte activation from chemotherapeutics as playing a role in maintaining the chronic pain state from CIPN. In rat models with oxaliplatin and bortezomib induced peripheral neuropathy, astrocyte but not microglial activation correlated to chemotherapeutic treatment.[298] These astrocytes contain adenosine kinase, which removes extracellular adenosine, a neuroprotective agent released to counter neuropathologic changes. A study in rodents with overexpression of adenosine kinase resulted in pro-inflammatory IL1ß expression indicating a possible mechanism by which dysfunctional astrocytes may result in CIPN.[299] Chemotherapies have also been associated with increased pro-inflammatory chemokine release, including TNF-α, bradykinin, and nerve growth factors, while downregulating anti-inflammatory chemokines.[300] Further studies are needed to elucidate the cellular mechanisms by which CIPN occurs.

It has been noted that certain chemotherapeutics (namely taxanes, platinum containing compounds, and vinca alkaloids) may modulate primary afferent neuron ion channel expression.[301] Channels reportedly affected include sodium channels, potassium channels, and to some extent, calcium channels. Sodium channel and potassium channel dysfunction have been found in acute oxaliplatin toxicity resulting in cold hypersensitivity by causing delayed sodium channel inactivation and decreased potassium receptor expression, respectively.[302,303] Studies in rats exposed to paclitaxel have shown an increase in calcium channel currents in the DRG by increased channel expression.[304] Despite these findings, targeting specific ion channels has had mixed results.

Treatment

Prevention and Physical Therapy

There is great emphasis on prevention in the management of CIPN, as many neuropathic treatments are ineffective for this condition. A 2014 review of 48 randomized clinical trials by the American Society of Clinical Oncology to provide guidance for the prevention of CIPN revealed that no agent is recommended given the lack of high quality evidence.[305] Similarly, a 2014 Cochrane review for agents to prevent CIPN from platinum containing chemotherapeutics concluded that there was insufficient evidence to recommend chemoprotective agents.[306] As such, a careful balance between chemotherapeutic dose reduction to achieve efficacious cancer treatment while minimizing the risk or severity of CIPN development needs to be weighed by oncologists.

Aside from neuropathic pain and numbness, patients consequently have difficulties with gait, balance, and falls. Although physical therapy has not been successful in reducing pain, work with physical therapists has been effective in addressing functional deficits as a result of CIPN. In a prospective study, 29 cancer survivors with CIPN underwent an eight-week exercise intervention under the guidance of physical therapists. There was a statistically significant improvement in objective and patient reported measures of dynamic balance, standing balance, mobility, and quality of life compared to pre-exercise intervention.[307]

Anti-convulsants

Gabapentin and pregabalin are effective in managing many neuropathic pain conditions. However, their use has not been as effective in managing patients with CIPN. In a study evaluating 61 ovarian cancer patients who developed CIPN, eligible patients were trialed on gabapentin with observed improvement in pain and neurologic deficits, but no improvement in quality of life was observed.[308] Gabapentin was further evaluated in a randomized, double blind placebo controlled crossover controlled trial of 115 patients with CIPN that revealed statistically similarly symptom severity despite the use of gabapentin.[309]

Comparatively, pregabalin may be more effective than gabapentin for symptom improvement. In a study of 120 cancer patients with CIPN, patients were trialed on either amitriptyline, gabapentin, pregabalin, or placebo with oral morphine for breakthrough pain for four weeks.[310] At the end of the trial, there was a statistically significant difference in morphine sparing pain score improvement in the pregabalin group than gabapentin and amitriptyline. One study evaluated the concurrent use of oxycodone/naloxone with either gabapentin or pregabalin in 72 patients with CIPN who had previously had inadequate symptom control alone with gabapentinoids. Over the course of four weeks, patients reported an NRS reduction of 1.29.[311]

Anti-depressants

Of the various classes of anti-depressants, the class of norepinephrine and serotonin reuptake inhibitors have shown the most promise in treating CIPN. In particular, duloxetine has been shown to be most effective in treating CIPN. A multicenter, randomized, double blinded, placebo controlled, crossover study of 231 patients with CIPN evaluated the efficacy of 60 mg daily duloxetine in pain management. The observed mean difference in pain score between duloxetine and placebo was 0.73, with 59% of patients on duloxetine reporting decreased pain than 38% of placebo.[312] Compared to venlafaxine in a randomized controlled trial with placebo, duloxetine was found to significantly reduce neuropathic pain grade by week two than venlafaxine or placebo. Reduction in cranial, motor, and sensory neuropathy was also found to be greater in patients treated with duloxetine than venlafaxine or placebo.[313]

Topicals

Useful adjuncts in treating other forms of neuropathic pain, there may be a role of topical anesthetics in this patient population. Like other neuropathic pain types, lidocaine patches have had anecdotal success, but evidence from studies to support their use is lacking.[314] Topical 1% menthol cream was utilized for the treatment of cancer associated neuropathic pain in a proof of concept study where 51 patients (35/51 with CIPN) were followed for four to six weeks. At the study conclusion, 82% of all patients reported an improvement in their Brief Pain Inventory (BPI) score, mood, catastrophizing, walking ability, and sensation.[315] Capsaicin (8%) has also been reported to provide pain relief and sensory improvement in patients with CIPN.[316] Other studies utilizing multi-component creams including baclofen, amitriptyline, and ketamine in pluronic lecithin organogel (BAK-PLO) were tried on patients with CIPN in a double blinded placebo controlled trial over four

weeks. Patients utilizing BAK-PLO experienced greater sensory and motor improvement than placebo.[317] However, further larger studies are needed to fully evaluate traditional and nontraditional topical analgesics for CIPN treatment.

Cannabinoids

Cannabinoids have been found to provide beneficial treatment for several other neuropathic pain conditions, but their use may be limited by the effects on the CNS.[318] Activation of the cannabinoid receptors (CB1 and CB2) have been found to have beneficial effects on CIPN in animals studies. A peripherally acting CB1 agonist (PrNMI) was found to successfully suppress allodynic effects in cisplatin induced CIPN rat models.[319] In a study in rats, a CB2 agonist was successful in suppressing mechanical and cold allodynia in cisplatin and paclitaxel induced CIPN models.[320] Further animal studies have shown that CB2 specific agonist MDA7 attenuated the behavior and molecular changes in rats associated with microglial dysregulation and CIPN. Despite these successes in animal models, large well-controlled studies are needed to verify use in humans for the management of CIPN.

Neuromodulation

Much of the literature on CIPN treatment with neuromodulation is limited to case reports of DRG or dorsal column stimulation.[321,322] There may be a role for neuromodulation in the treatment of CIPN, but randomized controlled trials are needed to fully assess their efficacy and role in this disease.

Summary

Despite the diversity of conditions and pathophysiology characterized by neuropathic pain, many of the underlying treatment options are comparable but not identical. Traditional systemic analgesic agents, such as anti-depressants, anti-convulsants, local anesthetics, and opioids, are typically the mainstay of treatment of neuropathic pain, although the efficacy of individual classes of agents varies with the specific type of neuropathic pain. Few high quality trials are available as interventional options for the treatment of neuropathic pain. Clinicians should be aware of the paucity and support the use of traditional interventional options in some cases.

Key Points

- The most commonly used clinical diagnostic criteria for CRPS types one and two have low specificity and high sensitivity, leading to overdiagnosis of this pain syndrome.
- In 2007, research criteria (also known as the Budapest criteria) were published that included objective signs of pathology characteristic of patients with CRPS[6] (see Box 34.2).
- Psychological factors such as depression, personality disorders, and anxiety have no correlation with CRPS patients, suggesting no specific type of CRPS personality.
- A double blind, randomized, placebo controlled, parallel-group trial studying the effects of subanesthetic intravenous dosing for four days in patients with CRPS showed decreased levels of pain but a progressive increase in pain from the first week after infusion to the 12th week. Minor and rare side effects such as nausea, vomiting, and psychomimetic effects developed in patients treated with ketamine infusion.
- In a randomized trial, patients with CRPS were separated into two groups: SCS with physical therapy and physical therapy only. This study showed that SCS provided significant improvement in pain for the first two years.
- The acute phase of herpes zoster is characterized by a maculopapular vesicular rash that crusts over after one to two weeks and leads to a burning sensation, hyperesthesia, itching, and severe pain. Prodromal symptoms that may occur one to five days before the rash include headache, fever, malaise, abnormal skin sensation, and photophobia. PHN may occur two weeks after the presence of herpes zoster and is the chronic form of the disease.
- Medications such as gabapentin, pregabalin, tramadol, and topical lidocaine are considered first line treatments because they have been shown to be most well tolerated by the (commonly elderly) patient population. Other medications shown to help in relieving the pain associated with PHN are tricyclic and serotonin-norepinephrine reuptake inhibitor anti-depressants, opioids, and topical capsaicin cream (see Table 34.2).
- The initial symptoms in up to 50% of patients with painful DPN are highly nociceptive and include burning pain, electric or stabbing sensations, paresthesia, hyperesthesia, and deep aching pain, which are typically worse at night. Upper extremity involvement is rare.[187]
- The rate of development of neuropathy per 100 person-years in patients infected with HIV ranged from 0.7 to 39.7, with a greater risk for neuropathy in older patients and those with more advanced disease.[245]
- Lamotrigine, gabapentin, and topical capsaicin are effective in the treatment of HIV-associated neuropathic pain, but amitriptyline, topical lidocaine, and pregabalin are ineffective.
- The current evidence for the management of CIPN is lacking. Emphasis should be placed on prevention by balancing the duration and dose of the chemotherapeutic. In situations where a patient has developed CIPN, pregabalin and duloxetine have shown the most promise for managing neuropathic symptoms.

Evaluation and Treatment of Complex Regional Pain Syndrome

FRANK J.P.M. HUYGEN

Introduction

As defined by the International Association for the Study of Pain (IASP), complex regional pain syndrome (CRPS) is a collection of locally painful conditions following trauma, usually manifesting distally and exceeding the clinical course of the original trauma in severity and duration, often resulting in a significant impairment of motor skills, and is characterized by a variable progression over time. CRPS can develop as a complication after surgery or trauma. The spontaneous occurrence has been described, but the question is whether there was no unnoticed trauma in these cases.[1] In the literature, the syndrome has been given more than 72 different names, including well-known names such as Sudeck dystrophy, posttraumatic dystrophy, and sympathetic reflex dystrophy.

At a meeting of the IASP in Orlando in 1992, it was agreed that only the term "complex regional pain syndrome" would henceforth be used. A distinction has been made between type 1 without and type 2 with demonstrable nerve damage.[2] Over time, it was proposed to add a third type, namely CRPS not otherwise specified, for conditions that meet the diagnostic criteria only to a limited extent but where no other diagnosis can be made. In clinical practice, "warm" CRPS (in which the skin is red, strongly perfused, and warm) is distinguished from "cold" CRPS (in which the skin is bluish, poorly perfused, and cold).[3]

CRPS has long been seen as a curious disease in which perception and behavior played a major role, which was self-limiting and did not last too long. Recent research has pointed out the opposite. CRPS is a complex condition based on an interaction between the immune system and the nervous system that severely damages various tissues and leads to severe limitations and ultimately disability. Genetic and immunologic factors can also play a role; the unraveling of pathophysiology has only just begun. The disease has serious consequences for functionality and quality of life and leads to high direct and indirect health costs.

This chapter will discuss the pathophysiology, epidemiology, clinical features, and treatment of CRPS. A review of the pharmacologic management will be brief since there is an expanded discussion of the topic in Chapter 34. Neuromodulatory treatments are also successful, as there is a detailed discussion of spinal cord stimulation, stimulation of the dorsal root ganglion (DRG), and peripheral nerve stimulation in Chapter 71.

Pathophysiology

During the last two decades, important discoveries have resulted in a better understanding of the pathophysiology.[4] Several mechanisms seem to play a role next to each other. A distinction can be made between afferent mechanisms, such as inflammation and endothelial dysfunction, efferent mechanisms, such as changes in the somatosensory and autonomic nervous system, and central mechanisms, including cortical reorganization and psychological factors.

Afferent Mechanisms

Some of the symptoms of CRPS are similar to those of inflammation, such as pain, redness, warmth, and swelling. Sudeck suggested more than 100 years ago that CRPS could be a form of bone inflammation, but this idea could not be confirmed because CRPS is not associated with fever, increased blood sedimentation rate, increased C-reactive protein (CRP), and leukocytosis.

However, over the past 20 years, several studies have shown that inflammation is an important mechanism in the development and maintenance of CRPS.[5] Increased levels of two neuropeptides, C-gene related peptide and substance-P, have been demonstrated in the serum of CRPS patients.

Levels of the pro-inflammatory cytokines, interleukin-6 (IL-6), and tumor necrosis factor (TNF)-α, measured in artificial blisters on the skin of CRPS patients, were found to be elevated in the affected extremity.[6] TNF-α and IL-6 levels in skin biopsies from fracture patients with and without CRPS were higher in patients with CRPS.[7] Serum levels of soluble TNF receptors, and the pro-inflammatory cytokines TNF-α, IL-1, and IL-8 are increased in patients with early CRPS. In contrast, the levels of anti-inflammatory cytokines such as IL- 4, IL-10, and transforming growth factor β-1 are reduced.[8]

Artificial blisters on the skin of CRPS patients have also been found to contain more tryptase in the affected extremity. Tryptase is a marker of mast cell activity. Therefore it seems likely that mast cells are involved in the release of pro-inflammatory cytokines in CRPS.

The involvement of T lymphocytes in CRPS has recently been demonstrated in a study in which levels of the soluble interleukin two receptor (sIL-2R) were higher in serum from CRPS patients. The level of sIl-2R is a biomarker of inflammatory activity. However,

it is important to realize that it is not a disease-specific biomarker; sIL-2R may also be increased in other syndromes. It is a specific measure of inflammatory activity. Signs and symptoms remain the cornerstone for the diagnosis of CRPS.[9]

In patients with CRPS, signs of hypoxia, such as increased lactate levels, muscle acidosis, and specific histopathologic features, have been found in local tissue. A decrease in the capillary oxygenation of the skin was observed with micro-light-guided spectroscopy.

In other studies, an imbalance between the vasodilating nitric oxide (NO) and the vasoconstricting endothelin-1 (ET-1) has been shown, in artificial blisters on the skin of patients with cold CRPS, the NO level is lower, and the ET-1 level is higher in the affected extremity.[10] This is probably a direct consequence of persistent inflammation.

Skin biopsies showed an increase in α receptors.[11] It was previously believed to be because of an autonomic nervous system disorder. Recent research has also shown a direct influence of persistent inflammation on the increase in α receptors. In the affected extremities of CRPS-1 patients, histopathologic examination of skin biopsies revealed a loss of C and Aδ fibers and abnormal branching nerve endings. In one study, axonal density was found to be 29% lower in CRPS patients.[12] This is probably the result of ongoing inflammation.

According to the IASP definition, CRPS-1 does not show nerve damage in classic neurophysiologic research. The fact that CRPS1 may have an unrecognized small fiber neuropathy makes the distinction between CRPS-1 and CRPS-2 somewhat artificial.[13]

Efferent Mechanisms

Chronic stimulation of nociceptors can lead to central sensitization, pain, and sensory disturbances. Previously, these signs and symptoms have been termed neuropathic. Today, we use the term nociplastic pain, which is a pain that arises from altered nociception despite the absence of clear evidence of actual or threatened tissue damage causing the activation of peripheral nociceptors or evidence of a disease or lesion of the somatosensory system causing pain.[14]

The sensory disturbances in CRPS are related not only to the pathology at the affected site but also to disturbances at the spinal or supraspinal level. Changes in the central nervous system, central sensitization, and neuroplasticity can lead to hypersensitivity to normal stimuli (allodynia) and painful stimuli (hyperalgesia). The exact mechanisms have not yet been fully elucidated. The action of neurotransmitters on postsynaptic receptors for N-methyl-D-aspartate, aminomethylphosphonic acid (AMPA), and neurokinin-1 (NK1) are involved. CRPS is also referred to as sympathetic reflex dystrophy because of the signs and symptoms of autonomic dysfunction. In the acute phase of CRPS, both phasic and tonic sympathetic reflexes in the affected extremity are disturbed.[15] Noradrenaline levels in the affected extremity are lower. Changes in the spinal cord or higher centers of the central nervous system are likely to play a role in the dysregulation of the autonomic nervous system. In the past, dysfunction of the sympathetic nervous system has been used to explain the increased blood flow in warm CRPS. With today's knowledge, it makes more sense to relate this increased blood flow to inflammation. Cold CRPS was thought to be caused by an increase in α-adrenergic receptors because of the depletion of local catecholamines. As previously described, the upregulation of α-adrenergic receptors can also be explained by continuing inflammation. The motor system may also be affected.[16] A decrease in the range of motion is common and cannot always be explained by pain alone but is also likely to be of spinal or supraspinal origin. Severe dystonia may occur, characterized by flexion of the fingers, wrist, elbow, and sometimes shoulder, and plantar flexion or extension of the foot. This is typical of a more chronic phase. Since dystonia responds to intrathecal administration of baclofen, spinal γ-aminobutyric acid (GABA) receptors are likely to play a role in its development.

Central Mechanisms

Functional MRI has shown that in CRPS patients, a reorganization can occur in the cerebral cortex.[17] Possibly altering blood flow to the thalamus plays a role, resulting in changes in activation patterns and sensory mapping.

It has been frequently suggested in the past that CRPS is an imaginary disease that typically occurs in women who somatize and have secondary gains because of chronic disabilities. In a systematic review of the literature, Beerthuizen et al. refuted this view and demonstrated that a link between psychological and/or psychiatric determinants and the development of CRPS could only be found in poorly conducted research and not in methodologically sound research.[18] A potentially important explanation for this misconception is that CRPS is regularly used as an embarrassment diagnosis. Another reason is that the natural course of a chronic pain syndrome such as CRPS easily gives rise to anxiety, depression, and catastrophizing. Therefore patients with chronic CRPS can also develop such symptoms. The cause and effect should not be confused.

Certain experiences and/or behaviors can influence the course of CRPS. Extreme fear of pain can lead to kinesiophobia and disuse. Therefore immobilization of the affected extremity takes longer than necessary, the blood flow decreases, and the final result is increased rigidity and muscle atrophy. This was confirmed in a study in which the forearm of healthy volunteers was immobilized with a plaster splint.[19] This immobilization has been shown to cause various symptoms of CRPS, such as temperature changes and changes in mechanical and thermal sensitivity. It is striking that the participants had no pain. The symptoms disappeared after the cast was removed. Several activation mobilization treatments have been developed for this mechanism that can play a role in CRPS, varying from regular physiotherapy to graded exposure.

Interactions Between the Different Mechanisms

CRPS appears to be the result of a complex cascade. The trigger is usually tissue or nerve damage. This leads to sterile inflammation, which is initially physiologic. For unclear reasons, this inflammation runs out of control and does not normally stop after healing. Continuing inflammation leads to spinal and supraspinal changes in sensory and motor skills. Continuing inflammation can also lead to endothelial dysfunction, an increase in α receptors, and small fiber neuropathy. In many patients, inflammatory symptoms are prominent in the early stages. Often, but not always, these symptoms disappear over time, and neuropathic/nociplastic, vasomotor, and/or motor dysregulation become more prominent. However, there are also patients in whom the affected extremity is cold from the start.

In this respect, patients with CRPS can be divided into subtypes, although this is difficult because there is a lot of overlap. Such a classification is relevant because it makes the treatment more mechanically oriented and better tailored to the individual patient. Bruehl distinguished several subtypes in a cluster analysis:[20]

- a relatively limited syndrome in which vasomotor symptoms are prominent
- a relatively limited syndrome in which neuropathic/nociplastic pain and/or sensory disturbances are prominent
- a profuse CRPS syndrome in accordance with the classic description

An important question remains as to why some develop and others do not get CRPS and, even more remarkably, how someone who has experienced major trauma does not advance to the pain syndrome while others progress into a thunderous CRPS after minor trauma. The process is likely determined by a combination of intrinsic factors, such as genetic susceptibility or an autoimmune disease that is acquired or not, extrinsic factors such as the type of trauma and treatment, and environmental factors.

Epidemiology

Various studies have reported different incidence rates for the general population in different studies. A North American study found an incidence of 5.5/100,000 person-years.[21] A Dutch study noted, depending on the diagnostic evaluation strategy used, an incidence of 20 to 26.2/100,000 person-years.[22] This discrepancy may result from differences in population characteristics (ethnicity, rural versus urban), in social, no-life, or health insurance, and in how the diagnosis is defined and classified. The Dutch data show that CRPS occurs more often in the upper extremity and that a fracture is the most common cause. There was no relationship between the severity of initiating trauma and the risk of developing CRPS. CRPS can develop at any age; the peak is between 50 and 70 years of age.

The incidence in women is 3.4 times higher than that in men. Several case reports have described the frequent co-occurrence of CRPS and chronic inflammatory diseases such as amyotrophic lateral sclerosis and Ehlers-Danlos disease. There is some evidence that autoimmunity plays a role in the pathophysiology of CRPS. Several case reports and small observational studies suggest an association between CRPS and previous exposure to certain viruses and bacteria, such as parvovirus B19.[23] About 35% of CRPS patients have autoantibodies against sympathetic neurons, mesenteric plexus neurons, and differentiated cholinergic neuroblastoma lines.

There are indications of a possible genetic predisposition to CRPS. Associations have been found with different polymorphisms of human leukocyte antigen (HLA) and with a TNF-α polymorphism.[24] The findings regarding the role of an ACE gene are contradictory. CRPS is more common in certain families. The prognosis of this condition remains unclear. In a Dutch study of patients with an average disease duration of 5.8 years, three-quarters of the participants still reported sensory and motor trophic disturbances, and some people still had vasomotor and sudomotor complaints.[25]

Clinical Features

The clinical presentation of CRPS is heterogeneous and may vary over time in the same patient.

Medical History

The condition often develops distally in one extremity. The affected area was often more extensive than the original damage. The complaints are characterized by a combination of pain, sensory, vasomotor, sudomotor, motor, and trophic symptoms. The pain is continuous.

TABLE 35.1 New IASP Criteria[26]

1. Continuous persistent pain that is disproportionate to the severity of an injury
2. From at least three of the following four categories, one symptom must be reported by the patient:
   - sensory: hyperesthesia and/or allodynia
   - vasomotor: temperature asymmetry, skin color changes, and/or skin color asymmetry
   - sudomotor/edema: edema and/or sweating changes and/or sweating asymmetry
   - motor/trophic: reduced range of motion and/or motor dysfunction (weakness, tremor, dystonia)
3. From at least two of the following categories, one symptom must be demonstrated at the time of evaluation:
   - sensory: evidence of hyperalgesia (pinprick) and/or allodynia (light touch and/or temperature sensation and/or deep somatic pressure and/or joint movement)
   - vasomotor: evidence of temperature asymmetry (>1°C) and/or skin color changes and/or skin color asymmetry
   - sudomotor/edema: evidence of edema and/or changes in perspiration and/or perspiration asymmetry
   - motor/trophic: evidence of a reduced range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nails, skin)
4. There is no other diagnosis that better explains the symptoms

The criteria in Table 35.1 apply for clinical purposes. For research purposes, the diagnostic decision rule is that it is anamnestic in each of the four at least one symptom is identified, and at the physical examination, at least one symptom in two or more categories.

The skin is hypersensitive to touch. Asymmetry can occur in temperature, color, edema, and/or sweating. Sometimes the range of motion is decreased, and sometimes there are motor impairments such as weakness, tremor, or dystonia. Changes in hair and/or nail growth may also occur. Often, the symptoms are not constant over time. CRPS can worsen with the exertion of the affected extremities.

The diagnosis of CRPS is based on these criteria. The criteria most commonly used today were originally initiated by Harden and Bruehl.[26] These were later called the Budapest criteria. After acceptance by the IASP, they are referred to as the new IASP criteria for CRPS. (See Table 35.1.)

Physical Examination

Vasomotor, sudomotor, and trophic signs may be present on inspection. There may be a difference in skin color, edema, hair, and nail growth between the affected and unaffected extremities. Sensory and vasomotor symptoms may be present on palpation. There may be allodynia, hyperalgesia, and skin temperature differences between the affected and contralateral extremities. Motor abnormalities such as loss of function, loss of strength, stiffness, and pain, involuntary movements, tremor, and dystonia may occur during motor function tests.

There are no specific clinical tests for the diagnosis of CRPS. Additional neurologic examination of sensitivity, strength, and reflexes did not reveal any other abnormalities besides the abnormalities previously mentioned.

Additional Research

Several additional studies are possible, but none are pathognomonic.[27] Sometimes supplemental testing is necessary to rule out other diagnoses. Several methods have been developed to classify

and quantify the clinical signs and symptoms of CRPS. These can be used in the context of research or to assess whether a patient meets the CRPS criteria. However, they have no additional value for clinical diagnosis. Examples are:

- infrared temperature measurements

Quantitative Sensory Tests

Volumetry and finger diameter in edema of the extremities

Differential Diagnosis

Many symptoms that can occur with CRPS also occur under other conditions. Therefore CRPS has an extensive differential diagnosis (see Table 35.2).[28] In addition to inflammation, neuropathic, myofascial pain syndromes, degenerative disorders, vascular disease, and psychogenic disorders can be distinguished.

TABLE 35.2 Differential Diagnosis of CRPS[4]

Neuropathic pain syndromes
Peripheral polyneuropathy
Nerve entrapment
Radiculopathy
Postherpetic neuralgia
Post-CVA deafferentation pain
Myofascial pain syndromes
Overload
CANS
Disuse
Fibromyalgia
Non-specific myofascial pain
Degenerative disorders
(Pseudo) osteoarthritis
Chronic tendinopathy
Malposition or pseudoarthrosis after fracture
Inflammation
Epicondylitis
Bursitis
Tendonitis
Erysipelas
Seronegative arthritis
Rheumatoid arthritis
Vascular disease
Thrombosis
Atherosclerosis
Acrocyanosis
Raynaud's phenomenon
Erythromelalgia
Charcot's disease
Psychogenic disorders
Somatoform disorder
Munchhausen syndrome

CANS, Complaints of arm, neck, and/or shoulder; *CVA*, cerebrovascular accident.

Treatment

Many different therapies are used in CRPS, but most have not been proven to be effective. One problem is that treatment targeting one of the mechanisms involved usually treats only part of the pathophysiology. Treatment outcomes can be improved if patients are divided into subgroups. The choice of therapy should be guided by the symptoms most prominent in a particular patient.

A common assumption is that the sooner the therapy starts, the better the result will be. This has never been demonstrated, but it seems likely that persistent inflammation will lead to damage: the sooner treatment starts, the less damage the disease can cause. Also widely accepted is the idea that CRPS patients, especially if they have had the disease for a long time, benefit most from multidisciplinary treatment combining pharmacotherapy, invasive techniques, physiotherapy, occupational therapy, and psychotherapy.

The individual treatments can be divided into anti-inflammatory, activation of mobilization, analgesic, vasodilating, spasmolytic, and psychological treatments. Generally, one will start with more conservative treatments and move to invasive treatments only after conservative treatment has failed.

Anti-Inflammatory Treatment

Dimethyl Sulfoxide and N-Acetyl-L-cysteine

Oxygen radical scavengers, such as dimethyl sulfoxide (DMSO) and N-acetyl-L-cysteine (NAC), appear to have a positive effect. Intravenous mannitol did not have any effect.

DMSO and NAC are excellent therapies in European countries, especially the Netherlands. However, the use of these drugs is much less in other parts of the world.[29]

Immune Modulating Drugs[21]

Corticosteroids

Corticosteroids have been shown to be effective in small studies, but their efficacy in practice remains limited. Side effects, in particular, require great restraint.[30]

TNF-α Inhibitors

TNF-α is a pro-inflammatory cytokine. Thus the effect of anti-TNF probably relies on the inhibition of the inflammatory cytokine cascade. The literature contains two case reports and one report of a prematurely terminated randomized control trial (RCT).[31–33] The case reports show a favorable effect. The provisionally terminated RCT did not provide a clear conclusion regarding the place of this therapy. Thalidomide inhibits monocyte TNF-α production thalidomide had a favorable outcome in two case reports and open-label studies.[34–36] Lenalidomide is a third-generation thalidomide. An RCT did not show any beneficial effects.[37] The adverse effects were serious.

Bisphosphonates

Bisphosphonates influence the production of pro- and anti-inflammatory cytokines. The literature contains four double-blind RCTs.[38–41] The RCTs examined the effects of oral or intravenous alendronate, clodronate, and pamidronate and found a significant reduction in pain.

Immunoglobulins

The mechanism of action of immunoglobulins is based on complex interference with the immune system. The literature contains a double-blind RCT, which compared intravenous immunoglobulin with placebo, the pain intensity in the treatment group decreased 1.55 units more on an 11 point numeric scale than in the placebo group.[42]

Activation and Mobilization

Fear of pain can lead to kinesiophobia (fear of physical movement and activity), disuse, prolonged immobilization of the affected extremity, and eventually rigidity and muscle atrophy.[43] Physiotherapy has a positive effect on the patient's activity level, reduces edema, improves blood flow, prevents muscle atrophy, contractures, and fear of movement, and promotes functional recovery. It is recommended to prescribe activation and mobilization therapy in all patients with CRPS.

Analgesia

Pain in CRPS can be the result of several underlying mechanisms. Inflammation causes nociceptive pain, and vasomotor disorder causes ischemic pain, which is mixed nociceptive and neuropathic; central sensitization causes nociplastic pain. Additionally, thin fiber neuropathy and, the underlying lesion of the somatosensory system in CRPS 2 will cause neuropathic pain. Dystonia and contractures cause nociceptive pain. Based on the underlying and predominant pain category (nociceptive, nociplastic, neuropathic), a choice can be made from one or a combination of painkillers.

The efficacy of individual analgesics in patients with CRPS has also been studied. Only a minor effect of gabapentin and S-ketamine has been demonstrated.[44,45] No effect has been shown for other drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs), opioids, other anti-epileptics, and anti-depressants. It is conceivable that there is a place for these drugs, but especially when prescribing NSAIDs and opioids, care must be taken with close monitoring for side effects and preferably only for the short term.

Vasodilation

There is evidence that local application of NO via an isosorbide dinitrate ointment 1% or 2% and/or a phosphodiesterase inhibitor is effective in patients with endothelial dysfunction with NO and endothelin-1 imbalance.[46]

Autonomic dysfunction and/or ongoing inflammation increase the number of α receptors. Calcium blockers, such as verapamil, can be effective.[47,48] Ketanserin intravenously appears to be effective.[49] Based on this, it is also prescribed orally, but the effectiveness of this route has not been proven.

Spasmolytic Therapy

Based on the observation that intrathecal baclofen can be effective in the treatment of dystonia in CRPS, the GABA system is believed to play a role. From the recommendation that we first start as conservatively as possible, oral antispasmodic therapy with benzodiazepines (diazepam or clonazepam) or baclofen is prescribed, but unlike the intrathecal administration of baclofen, there is insufficient evidence supporting the effectiveness of this route.[50] Although widely used, there is also no evidence of the efficacy of botulinum toxin A for the treatment of dystonia in CRPS patients.[51]

Psychological Counseling, Pain Management, and Rehabilitation Therapy

If components of perception or behavior perpetuate the clinical picture or cause much suffering, psychological treatment or a pain management program can be valuable. Disability in CRPS is the sum of the damage and disability.

Invasive Treatments

Several invasive treatments are available. In general, it is advisable to start with more conservative methods and start with more invasive therapies if the patients are refractory. The efficacy of invasive pain therapies has recently been summarized in an update of the evidence-based guidelines on invasive pain treatment.[52]

Sympathetic blocks

The application of sympathetic blocks is based on the idea that autonomic nervous system dysfunction and an increase in α receptors play a central role in CRPS. It is also believed that a pathologic connection may arise between the somatosensory system and the sympathetic system, causing sympathetic mediated pain.

Intravenous Block With Guanethidine

Intravenous sympathetic blockade with guanethidine has been widely used in the past, based on the idea that guanethidine depletes norepinephrine in nerve endings.

There is moderate evidence that intravenous regional blocks with guanethidine for the treatment of CRPS do not provide better pain relief than placebo at one, three, and six months.[53]

Blocks of the Sympathetic Chain

There are several ways to block the sympathetic ganglion: with a local anesthetic (repeated or not), with a neurolytic agent such as alcohol or phenol, botulinum toxin, or radiofrequency lesion. While it has been widely advocated and practiced in the past, the evidence is disappointing.

Sympathetic Blocks With Local Anesthetics

There is conflicting evidence that sympathetic blocks are effective. A Cochrane review showed moderate evidence that sympathetic blocks with a local anesthetic at the cervical and lumbar levels are ineffective for the treatment of complex regional pain.[54] However, there is low quality evidence showing that thoracic sympathetic blocks (T2-3) with ropivacaine and triamcinolone reduce pain significantly better in patients with upper extremity CRPS than a subcutaneous injection 12 months after treatment.[55] A more recent retrospective study showed very low quality evidence that sympathetic blocks with local anesthetics (with or without corticosteroids) to be effective (greater than 50% relief) in 61% of patients (155 of 255), with relief lasting one to four weeks or longer. In this study, the Budapest criteria were used, and the sympathetic blocks consisted of either stellate ganglion blocks, T1-T3 sympathetic blocks, or L2-L4 for lumbar sympathetic blocks.[56] They also noted that the effects of sympathetic blocks did not predict the success of spinal cord stimulation. There seems to be a place for sympathetic blockades, especially because of the minimal invasiveness of the treatment, the low cost, and the lack of more conservative alternatives. Further research is necessary, especially focusing on predictors of outcomes.

Neurostimulation

Neurostimulation is a direct clinical application of the gate-control. Primarily, it is used to treat neuropathic pain, but with stimulation of the spinal cord and stimulation of the DRG, there are additional effects on the vasomotor disturbance and possibly inflammation, as well as stimulation of the DRG on motor dysfunction. This is probably why spinal cord stimulation and spinal ganglion stimulation are among the most effective treatments for CRPS. Neurostimulation has simultaneous effects on the multiple mechanism which can play a role in the pathophysiology of CRPS.

Transcutaneous Electrical Nerve Stimulation (TENS)

TENS is widely used. However, there is no evidence to suggest that TENS is effective.

Spinal Cord Stimulation (SCS)

There is moderate evidence that SCS reduces pain in patients with complex regional pain syndrome.[57] A randomized placebo-controlled study with 29 CRPS patients was found to have a statistically and clinically significant effect on pain for different stimulation modes than a placebo after a two week test period.[58]

DRG Stimulation

A randomized controlled trial (ACCURATE study)[59] demonstrated the superiority of DRG stimulation over conventional SCS stimulation at three and 12 months of follow up in patients with lower extremity CRPS.

Peripheral Nerve Stimulation

There is evidence of very low quality that in CRPS, peripheral nerve stimulation effectively reduces pain during long term follow up and reduces pain-related disability.[60]

Intrathecal Baclofen

If conventional spasmolytic treatments are ineffective, baclofen can be considered intrathecally. It is a technically complex treatment with many potential side effects.[61]

Prophylaxis

In an RCT, it has been shown that vitamin C has a protective effect against the development of CRPS-1 after wrist fractures.[62] If a person with a history of CRPS has new trauma or requires surgery on an extremity, prophylactic therapy with vitamin C may be considered. Vitamin C can be administered during the perioperative period.

Summary

CRPS is a complication of tissue and/or nerve damage. Multiple pathophysiologic mechanisms, including autoinflammation, sensory, vasomotor and sudomotor, and motor/trophic disorders, may play a role simultaneously. Depending on the most prominent mechanism, different phenotypes can be distinguished. Treatment appears to be the most effective when it is mechanism oriented.

Key Points

- Several mechanisms contribute to the development of the CRPS. These include afferent mechanisms such as inflammation and endothelial dysfunction, efferent mechanisms such as changes in the somatosensory and autonomic nervous system, and central mechanisms, including cortical reorganization and psychological factors.
- Subtypes of CRPS include a relatively limited syndrome in which vasomotor symptoms are prominent, a relatively limited syndrome in which neuropathic/nociplastic pain and/or sensory disturbances are prominent, and a profuse CRPS syndrome in accordance with the classic description.
- The commonly used criteria for CRPS are the Budapest criteria, now referred to as the new IASP criteria for CRPS.
- Many therapies have been used in CRPS, but their effectiveness has not been proven. This is because the treatment targets one of the mechanisms involved, treating only a part of the pathophysiology. The choice of therapy should be guided by the symptoms most prominent in a particular patient.
- The individual treatments can be divided into anti-inflammatory, activation of mobilization, analgesic, vasodilating, spasmolytic, and psychological treatments.
- One usually starts with more conservative treatments and move to invasive treatments after conservative approaches have failed.
- Of the anti-inflammatory pharmacologic medications, biphosphonates appear to be effective.
- Physiotherapy has a positive effect on the patient's activity level, reduces edema, improves blood flow, prevents muscle atrophy, contractures, fear of movement, and promotes functional recovery.
- Oral antispasmodic therapy with benzodiazepines (diazepam or clonazepam) or baclofen was attempted. Unlike the intrathecal administration of baclofen, there is insufficient evidence regarding the effectiveness of the oral route. Intrathecal baclofen is technically complex and has many potential side effects.
- Sympathetic blocks with local anesthetics have not been uniformly effective.
- There is moderate evidence that SCS reduces pain in patients with CRPS.
- There is initial evidence of the superiority of DRG stimulation over conventional SCS in patients with lower extremity CRPS.
- There is very low quality evidence that peripheral nerve stimulation effectively reduces CRPS pain and diminishes pain-related disability.

Evaluation and Treatment of Pain in Selected Neurologic Disorders

AMIR HADANNY, ANNA BLANCHFIELD, OLGA KHAZEN, CHARLES E. ARGOFF, JULIE G. PILITSIS

Pain in Selected Neurologic Disorders

Although chronic pain may be the defining feature of certain neurologic disorders, physicians often focus on treatments aimed at addressing the primary neurologic condition. As most comorbidities may come from pain associated with the condition, it should be addressed early during treatment. Chronic pain is a three-dimensional process consisting of biologic, psychological, and social components. All three interact dynamically and affect the states of the others. Here, we provide a basic pathophysiologic explanation of pain that accompanies these conditions and treatment strategies to complement disease-based treatments and improve the quality of life of affected individuals. Although it is not possible to include every disorder in which pain is a feature, this chapter discusses the pertinent features of diseases that pain specialists are likely to encounter with some frequency (see the reference list for detailed reviews of each disorder in the literature, when available). We focused on the evaluation, diagnosis, and treatment of neuropathies due to peripheral nerve, spinal cord, and brain pathologies (Table 36.1). Chapter 34 discusses complex regional pain syndrome (CRPS); postherpetic neuralgia and diabetic peripheral neuropathy are addressed in Chapter 33. More details on neuroanatomy and pathophysiology can be found in Chapters 8 and 9.

Peripheral Neuropathies

Most instances of painful peripheral neuropathies are acquired and can be divided into metabolic, autoimmune, infectious, traumatic, iatrogenic, and idiopathic etiologies (Table 36.2). Evaluation begins with a medical history, physical and neurologic examinations, and laboratory tests. Nerve conduction studies (NCS), electromyography (EMG), autonomic function assessment, cerebrospinal fluid analysis (CSF), magnetic resonance imaging (MRI), and biopsy may be included.

The Workup

To differentiate among the different types of neuropathies, a detailed history must be obtained. Specifically, the time course, presence and characteristics of sensory, motor, and autonomic symptoms, the distribution of symptoms (proximal and/or distal, hands and/or feet, symmetric/asymmetric), and intensity must be assessed. Medical history, social history, family history, medications, and exposure to toxins must be considered. The duration of symptoms is important in categorizing neuropathy into acute (<4 weeks), subacute (4–12 weeks), and chronic (>12 weeks). Acute inflammatory demyelinating polyradiculoneuropathy (Guillain-Barre syndrome [GBS]) peaks at four weeks of onset, and progression beyond eight weeks suggests chronic inflammatory demyelinating polyradiculoneuropathy (CIDP). Based on their distribution, neuropathies can be categorized as mononeuropathy (single peripheral nerve involvement, usually due to trauma, compression, or entrapment), mononeuropathy multiplex (multiple, separate noncontiguous peripheral nerves either simultaneously or sequentially, commonly due to systemic vasculitis), and polyneuropathy (toes and soles are affected first and hands later, usually due to metabolic, toxic, or systemic disorders).

Sensory symptoms include positive (burning, pain, walking on cotton wool, band-like sensation on the feet or trunk, stumbling, tingling, pins and needles) and negative symptoms (numbness, loss of sensation) in the hands and feet. Motor symptoms include weakness and fine motor difficulties (e.g. unfastening a button and opening bottles). Autonomic symptoms, such as postural hypotension, impotence, sphincter disturbance, diarrhea, constipation, dryness, and excessive sweating, point to the involvement of small myelinated or unmyelinated nerve fibers.[1]

Medical history should look for systemic diseases that can be associated with neuropathy, such as diabetes, hypothyroidism, chronic infections, and/or autoimmune diseases. Aside from chemotherapeutic agents that may cause polyneuropathy, commonly used medications associated with polyneuropathy include pyridoxine (vitamin B6), phenytoin, linezolid, metronidazole, nitrofurantoin, isoniazid, chloramphenicol, dapsone, reverse transcriptase inhibitors, amiodarone, colchicine, and disulfiram.[1] Family history should include ethnic background, consanguinity, and details about parents and siblings, such as the presence of high-arched feet, flatfeet, hammertoes, gait dysfunction, bilateral carpal tunnel syndrome, and other signs of possible inherited neuropathies.[2] Social history includes the patient's country of origin, potential occupational exposure, potential exposure to people with transmittable illness, alcohol and drug use, and travel history.[3] Psychosocial assessment should be performed for depression, anxiety, personality disorders, substance use, and cognitive deficit comorbidities.[4]

Neurologic examination should include examination of cranial nerves, muscle power, tone, and reflexes, detailed evaluation

TABLE 36.1 Pain Syndromes in Neurologic Disorders

Primary Disorder	Pain Location	Pain Classification and Descriptors	Etiologies
Peripheral neuropathy	Stocking-glove distribution	**Neuropathic** Burning, tingling, stabbing, dysesthesias	• Metabolic (diabetes) • Autoimmune (vasculitis) • Idiopathic (trigeminal neuralgia, small fiber) • Infectious (postherpetic) • Trauma • Iatrogenic (chemotherapy) • Other
Spinal cord disorders	Radicular, transitional zone pain, deafferentation pain, musculoskeletal pain (shoulders), spasticity related pain (lower limbs), abdomen (visceral)	**Neuropathic** Constant burning, tingling, aching, evoked shooting pain **Nociceptive** Aching, dull **Visceral** Dull, cramping,dysreflexia, autonomic dysfunction	• Infectious • Trauma (SCI) • Tumor • Demyelination (MS) • Vascular (stroke, malformations) • Other
Brain and brainstem lesions	Contralateral extremities, ipsilateral face (brainstem)	**Neuropathic** Aching, burning, dysesthesias, sharp **Spasticity related** **Musculoskeletal**	• Vascular (stroke, malformations) • Neurodegenerative • Demyelination • Trauma (TBI) • Other

TABLE 36.2 Painful Peripheral Neuropathies

Classification by Cause	Examples
Metabolic disorders	Diabetes mellitus, vitamin deficiency (thiamine, vitamin B12), uremia
Toxins	Ethanol, heavy metals (arsenic, lead), industrial solvents
Drug induced	Chemotherapy, isoniazid, antiretroviral therapy
Trauma	Complex regional pain syndrome type 2, neuromas, postamputation pain, peripheral nerve trauma
Entrapment	Peroneal, ulnar, median (carpal tunnel syndrome), posterior tibial (tarsal tunnel syndrome)
Autoimmune	Connective tissue disorders, vasculitis, paraneoplastic disorders, Guillain-Barré syndrome, chronic inflammatory demyelinating polyneuropathy
Infectious	Lyme disease, spirochetal infection, herpes zoster, cytomegalovirus infection
Hereditary	Familial amyloid polyneuropathy, Fabry's disease

of all sensory modalities (pinprick, pain, temperature, vibration, and joint position), and an observation of the patient's gait and the ability to stand up from a chair. Specific findings include anosmia (as in B12 deficiency), impaired pupillary light reflex (diabetes, GBS), ophthalmoplegia (GBS), and widespread reflex loss, including muscles that are not particularly weak or wasted, favoring demyelinating neuropathy. In contrast, selective loss of ankle reflex in the presence of distal wasting and weakness is characteristic of axonopathy.[2] Meticulous general physical examination can identify several clues for diagnosis, nail changes (Mee's lines) in toxin poisoning (such as arsenic and thallium), musculoskeletal abnormalities, such as pes cavus, high-arched feet, and mutilation (usually hereditary neuropathy), skin changes, or nerve thickened nerves in rare diseases.

Following history and examination, chronic, distal, slowly progressive, symmetric, predominantly sensory polyneuropathy can be diagnosed clinically without further testing. If any atypical feature is noted in the initial or subsequent evaluation, including asymmetry, severe early sensory complaints such as ataxia and loss of proprioception, early or severe pain, the predominance of or early motor involvement, proximal symptoms, and fast progression, neurophysiologic testing should be pursued. Similarly, other than a classic presentation of acute GBS, all other acute neuropathies should be further evaluated.

The clinical evaluation includes evaluation of complete blood count (CBC), erythrocyte sedimentation rate (ESR), fasting glucose or glucose tolerance test, liver and renal function tests, serum vitamin B12 and folate levels, thyroid function tests, serum protein electrophoresis, and immunofixation electrophoresis. The vasculitis profile (antinuclear antibody, anti-neutrophil cytoplasmic antibody, rheumatoid factor, extractable nuclear antigen, anti-Ro, anti-La) is added when patients suffer from related complaints, such as joint pain or Sicca syndrome. Human immunodeficiency virus (HIV), hepatitis B and C, and Lyme tests should be added based on risk factors or previous exposure. In case of alcohol abuse, malnutrition, absorption abnormalities, or vitamin toxicity, methylmalonic acid (especially when borderline B12), homocysteine (especially when borderline B12), pyridoxine (vitamin B6), thiamine (vitamin B1), and vitamin E should be evaluated. Heavy metals, including copper and zinc, can also be checked for patients with an exposure history. Sarcoidosis can be evaluated using serum or CSF angiotensin-converting enzyme, although the specificity

is limited. Paraneoplastic markers, such as anti-Hu, can be added based on clinical suspicion and previous workup.

For acute neuropathy, laboratory work should mainly include infections (West Nile virus, Hepatitis B, C, Rabies, HIV, CMV, Lyme, ESR, and CRP), heavy metal levels (arsenic, thallium, and lead), inflammatory panel (antinuclear antibody, anti-neutrophil cytoplasmic antibody, rheumatoid factor, cryoglobulins), serum and urine paraproteins, urine porphobilinogen, and urine porphyrin excretion for porphyria evaluation.[5]

In many cases, NCS of sensory and motor nerves, late responses (F response and H reflex), and needle EMG are performed. These tests do not provide information regarding the cause of neuropathy but enable the determination of the type (demyelinating vs. axonal) and localize the lesion more precisely than on clinical examination alone. This is valuable mainly in acute neuropathies,[6] asymmetric neuropathies, and mononeuropathies. The classic demyelinating neuropathy findings include slowing of nerve conduction velocity, prolongation of terminal latency (F latencies), temporal dispersion, and prolonged compound muscle action potential (CMAP) or conduction block (decline in the compound muscle action potential exceeding 20% on proximal stimulation compared to that on distal stimulation). Axonal neuropathy usually shows mild slowing of nerve conduction (due to sparing of remaining axons), reduced CMAP amplitude, and fibrillations on EMG. Sensory nerve action potentials and sensory conduction velocities are reduced in both axonal and demyelinating neuropathies. However, sensory conduction studies evaluate only fast-conducting fibers, which may be normal in selective small fiber and autonomic neuropathies.[3] Thus NCS and EMG tests are mainly useful for large fiber peripheral neuropathies rather than small fiber neuropathies.

CSF analysis is indicated in acute neuropathies for GBS evaluation, and it is useful in chronic inflammatory demyelinating polyneuropathy and chronic immune-mediated axonal neuropathies where the levels of CSF protein are elevated. Significant pleocytosis can suggest other acute inflammatory neuropathies, such as Borrelia, sarcoidosis, and HIV. Nerve biopsy, usually taken from the sural nerve, remains the primary method of establishing vasculitis neuropathy when histology is unavailable elsewhere. Combined nerve and muscle biopsies are recommended to improve the diagnostic yield. The yield of biopsy in the diagnosis of chronic axonal neuropathies is very small and not justified when vasculitis is unlikely.[3] Skin biopsy allows for the quantification of somatic and autonomic small nerve fibers. Small fiber neuropathy is diagnosed when intraepidermal nerve fiber density falls below age- and sex-adjusted normative reference values.[7] Fine-needle aspiration biopsy of the abdominal fat pad with Congo red staining is a minimally invasive procedure used to demonstrate tissue deposits of amyloid in patients with neuropathy related to amyloidosis.

In the case of autonomic neuropathy, bedside autonomic tests include blood pressure response to standing or vertical tilt (normal fall, <20/10 mm Hg), heart rate response to standing (increase, 11–90 beats/min), heart rate variation with respiration (normal, ≥15 beats/min, inspiratory expiratory ratio 1.2), cold pressure test (after 1 min, increase in systolic blood pressure of 15–20 mm Hg, diastolic 10–15 mm Hg). Other tests may include quantitative sudomotor axon reflex sweat test (applying electrical stimulation to introduce acetylcholine into the skin, with subsequent measurement of the volume of sweat produced), pupillary tests, Schirmer's test, and sympathetic skin response. When hereditary etiology is suspected based on age, time course, and/or family history, genetic testing can be performed for Charcot-Marie-Tooth, amyloidosis, distal hereditary motor neuropathy, Friedrich's ataxia, and others.

The Differential Diagnosis

Autoimmune Causes

Autoimmune neuropathies may result from connective tissue diseases, vasculitis, and autoimmune disorders of the peripheral myelin. Neuropathic pain may precede diagnosis or occur during an established disease. Mononeuropathy multiplex is characterized by pain, numbness, and weakness in the distribution of peripheral nerves, most commonly the ulnar, median, and peroneal nerves. Dysfunction typically occurs at common sites of nerve entrapment. Another presentation is distal symmetrical polyneuropathy (DSP). DSP is characterized by numbness, tingling, and pain in a characteristic symmetric stocking-glove distribution. Symptoms typically begin in the feet and include burning, aching, and dysesthesia. Asymmetry of progression is a hallmark of the disease.

Acute inflammatory demyelinating polyneuropathy, known as Guillain-Barré syndrome, occurs at an annual incidence of approximately 1.11/100,000 person-years, with a 20% increase every decade after the first decade of life.[8] GBS may develop during the initial manifestation of HIV seroconversion. Paresthesia or dysesthesia typically precedes the development of weakness, which proceeds in an ascending pattern (distal to proximal). Clinical diagnostic criteria for GBS include relatively symmetrical weakness with decreased or absent tendon reflexes. Symptoms reach maximal intensity within four weeks of onset, and other possible causes must be excluded. A high level of protein in the CSF is suggestive.

Contemporary treatment strategies with intravenous immunoglobulins, plasmapheresis, and other agents have limited the disability associated with the disorder, but a small proportion of patients may have disability and chronic pain. Pain is often a prominent symptom during the acute phase of the illness. Deep aching and throbbing pain in the lower back region associated with radiation into the lower extremities is typically the most excruciating and disabling pain. A positive straight leg raise test may also be performed. Myofascial pain may coincide with the development of muscle spasms, cramps, and muscular tenderness. Stabbing, shock-like, or electric pain may be present in the extremities and face. Ectopic impulses caused by acute nerve root inflammation may be the pathologic mechanism associated with the acute neuropathic pain component in GBS. Chronic neuropathic pain may persist beyond treatment and recovery from paralytic disorders in a small proportion of patients.[9] The autonomic nervous system dysfunction present in GBS may lead to the development of headaches, cardiovascular instability, visceral pain secondary to ileus, and urinary retention.

Infectious. Peripheral neuropathic pain is a common accompaniment of HIV. It is estimated that 35% of patients infected with HIV experience symptomatic DSP.[10] Neuropathic pain may complicate any stage of the infection and result in disordered sleep and ambulation, disability, and psychosocial distress. Acute polyneuropathy associated with seroconversion typically resolves with mild, if any, residual sequelae of neuropathic pain. In the intermediate to late stages of the disease, chronic inflammatory polyneuropathy, distal symmetric HIV-induced sensory axonal polyneuropathy, and vasculitic mononeuropathy multiplex may appear. Chronic inflammatory polyneuropathy manifests as neuropathic pain associated with severe sensory loss, weakness, and gait disturbance. Distal symmetric HIV-induced sensory axonal polyneuropathy manifests as burning pain, numbness, allodynia, and evoked dysesthesia beginning in the lower extremities, with variable progression to the upper extremity. They often persist despite treatment of the primary disease.

Infections during the illness, especially if untreated or refractory to treatment, such as neurosyphilis, herpes simplex virus, and toxoplasmosis, may contribute to neurologic symptoms. Cytomegalovirus infection may give rise to progressive polyradiculopathy, mononeuropathy multiplex, or both. Polyradiculopathy is characterized by the development of pelvic and lower extremity radicular pain and urinary retention and may progress to cauda equina syndrome.[11]

Besides the neuropathies associated with primary HIV infection, antiretroviral agents may be neurotoxic. The dideoxynucleoside family of nucleoside analog reverse transcriptase inhibitors has been shown to have specific peripheral neurotoxic effects.[12] Antiretroviral-induced neuropathies are manifested by distal dysesthesias, burning, tingling, and shooting pains and are more rapidly progressive and more painful than HIV polyneuropathy. Antiretroviral polyneuropathy occurs in 26%–66% of patients, but the symptoms often improve with drug cessation or reduction.[10] The antiepileptic drug lamotrigine has been shown to be beneficial in refractory cases.[13]

Lyme disease is a multisystem disorder caused by several Borrelia subspecies bacteria that are transmitted by infected ticks. A history of a tick bite, especially when the patient has been in the northern, mid-Atlantic, and north-central regions of the United States, is common. Patients may also show a ring-like skin lesion at the site of the bite and flu-like symptoms.[14] Within days to weeks, a disseminated infection may affect the skin, nervous system (neuropathy, headaches, cognitive deficits, sleep disorder, fatigue), heart (conduction blocks), or joints. Diagnosis is confirmed by serology or polymerase chain reaction on suspected lesion skin biopsy. It is distinguished from other neurologic disorders as it is transferred focally, and there is no evidence of multiple sclerosis or demyelinating disease.[15]

Appropriate antibiotics are mandated. However, more than 16%–18% of antibiotic-treated Lyme patients continue to suffer from chronic pain years after diagnosis. Chronic neuropathic pain may be radicular and associated with sensory abnormalities, such as paresthesias.[16] Additionally, in 10% of patients with antibiotic-treated Lyme-arthritis, chronic arthritis develops and is unresponsive to additional antibiotic courses. Nonsteroidal medications are the mainstay of treatment.[17]

Metabolic. Nutritional deficiencies can cause peripheral neuropathies and chronic pain. Thiamine or vitamin B1, vitamin B12, and vitamin B9 (folate) are used for myelination of the central and peripheral nervous system and are necessary for function.[18] Thiamine is responsible for the use of glucose and energy in the central nervous system.[19] B12 and B9 work together to produce methionine from homocysteine. The deficiencies should not be considered independently of one another.[20] Deficiencies of these vitamins lead to demyelination of the spinal cord, cranial nerves, and peripheral nerves, and loss and swelling of the myelin sheath.[18] The prevalence of B12 deficiency varies by age group and affects 3% of young adults and up to 6% of the elderly,[21] whereas folic acid deficiency has been estimated to have a prevalence of 2%.[22] In elderly patients, B1 deficiency is about 5%.[23]

Although the symptoms are largely overlapping, there are more spinal cord and peripheral nerve disorders caused by B12 deficiency, more affective disorders caused by folate deficiency, and additional cardiovascular disorders caused by B1 deficiency.[19,24] Typical symptoms progress symmetrically, including pain, paresthesia, ataxia, spasticity, paraplegia, impaired sense of vibration and proprioception, and progressive weakness.[25,26] In addition, cognitive deficits, hearing loss, macular degeneration, and affective changes including depression can be prominent.[27]

The main source of B9 and B12 intake comes from the consumption of animal products, whereas that of B1 intake comes from meat, whole grain, and fish.[25] Therefore it is important to examine the patient's diet and any digestive issues they may have. Malnutrition, alcoholism, gastric surgery, anemia, malabsorption disorders, pernicious anemia, and gastric acid reduction therapy can all contribute to B12 and B9 deficiencies. Elderly patients are also at a higher risk of developing B12 deficiency.[26] Alcoholism, dialysis, chronic diarrhea, and high doses of diuretics are risk factors for B1 deficiency.

Initial laboratory assessments include CBC, which can show megaloblastic anemia and macrocytosis (mean cell volume greater than 100 femtoliters), serum/plasma folate levels, and B12. For folate deficiency, additional assessments include red cell folate concentrations, whereas B12 deficiency should be confirmed with elevated plasma methylmalonic acid levels. Total plasma homocysteine levels are also indicative of both folate and B12 deficiency.[20] Cervical and thoracic spinal cord MRI T2-weighted sequence may show bilateral posterior column hyperintensities indicating severe myelopathy.[18,28] B1 levels can be measured by thiamine diphosphate using chromatography.[19] Oral or injected administration of the missing factor is recommended as a treatment. Patients with anemia or digestive issues are recommended life-long therapy.[18]

Traumatic. Injuries from motor vehicle accidents, falls, sports, and medical procedures can stretch, crush, or compress nerves or detach them from the spinal cord. Furthermore, less severe traumas, such as broken or dislocated bones, can also cause serious nerve damage. Prolonged pressure on a nerve (such as a cast) or repetitive, forceful activities can cause ligaments or tendons to swell, which narrows the slender nerve pathways. The incidence of traumatic peripheral nerve injury varies from 2.8% to 5% in the population.[29] Chronic postsurgical pain is experienced by 10%–50% of individuals, depending on the type of surgery and surgical technique. It is experienced by 50%–85% of patients after limb amputation, 30%–50% of patients after thoracotomy, and 20%–50% of patients after mastectomy.[30] Medical history, trauma details, and physical examination are usually enough for clinical diagnosis. In cases of peripheral neuroma formation following trauma, classic surgeries including neuroma resection, neurorrhaphy, and nerve stump repositioning can be considered.[31] Peripheral nerve stimulation or spinal cord neurostimulation (SCS) may be options in cases with severe pain or when drug adverse events prevent the continuity of pharmacologic therapies.[32]

Iatrogenic. Neurotoxic cancer treatments, such as platinum compounds, taxanes, vinca alkaloids, thalidomide, and bortezomib, can damage the organization of microtubules in neuronal axons and sensory axons, resulting in neuropathic pain.[33-35] Moreover, 30%–40% of patients treated with neurotoxic chemotherapy develop neuropathic pain.[35] Most chemotherapy-induced neuropathic pain is dose-dependent, and neuropathy develops about two months after the start of treatment.[35] However, with some medications, neuropathy can worsen even with the cessation of chemotherapy. In one study, 30% of 114 lymphoma patients continued to present new symptoms after discontinuation of vincristine administration.[34] Patients developed paresthesia, burning sensations, numbness, autonomic dysfunction in the cardiovascular and digestive systems, and tactile hypersensitivities.[33,34] Some patients also experienced urinary retention, sexual dysfunction, and constipation.[34] Symptoms are typically symmetric and occur in the hands and feet in a stocking-glove distribution.[36]

Although chemotherapy-induced neuropathy is common in oncologic patients, it is important to rule out other causes of neuropathy. Direct neoplastic infiltration can mimic CIDP and can occur in leukemia, neurolymphomatosis, and carcinoma. Graft-versus-host disease from bone marrow transplantation can also cause neuropathy. Certain comorbidities can present a higher risk of chemotherapy-induced neuropathy, such as diabetes.[35] For diagnostic testing, NCS are the best as reduced compound sensory action potentials are associated with chemotherapy-induced neuropathy.

Small Fiber Neuropathy

Small fiber neuropathy results from dysfunction of small diameter peripheral nerve fibers, such as C fibers and Aδ fibers.[37] Worldwide, 53 out of 100,000 people suffer from small fiber neuropathy.[37,38] About 50% of all small fiber neuropathy cases are idiopathic. Symptoms of small fiber neuropathy include pain, paresthesia, allodynia, hyperesthesia, and autonomic and enteric dysfunction such as dry eyes, dry mouth, abnormal sweating, syncope, and gastrointestinal issues.[37,38] The pain is described as burning, shooting, and electric shock-like.[37,38] Patients often have multifocal and widespread pain. However, fibromyalgia patients tend to lack pinpoint tenderness on physical examinations.

Several conditions are associated with small fiber neuropathy, such as diabetes, HIV and hepatitis C infections, B12 deficiency, thyroid dysfunction, chronic inflammatory demyelinating polyneuropathy, Sjogren's syndrome, and GBS.[37,38] Recent studies also show that there may be a relationship between complex chronic pelvic pain, as 64% of patients with complex chronic pelvic pain from referral clinics also tested positive for small fiber neuropathy.[38] Exposure to toxins such as alcohol, thallium, neurotoxic antibiotics, and chemotherapy medications are also associated with the development of small fiber neuropathy.[33,37]

Diagnostic criteria include signs of small fiber damage (pinprick and thermal sensory loss and/or allodynia and/or hyperalgesia) and/or length-dependent symptoms along with low intraepidermal nerve fiber density on skin biopsy from the thigh or distal calf and/or abnormal quantitative sensory testing thermal thresholds in the ankle and foot.[39] Autonomic function tests, such as a quantitative sudomotor axon reflex test, can also be a helpful diagnostic test when combined with other tests. A sural nerve conduction study or electromyography may be used to reject large fiber neuropathy.[37]

Idiopathic Sensory Polyneuropathy

A significant number of patients exhibit symptoms of peripheral neuropathic pain in a characteristic stocking-glove distribution without a definable causative agent. This diagnosis is one of exclusion following a comprehensive evaluation, including history, physical and laboratory tests, NCS/EMG studies, and biopsy. The disorder is estimated to occur in approximately 25% of those aged 65 years and older and in as many as 50% of those aged 85 years and older. In many cases, the disorder is characterized by the loss of peripheral pain and temperature sensation. In a significant proportion of cases, complaints of burning, tingling, and symptoms of restless legs syndrome may be predominant. This syndrome may be associated with difficulty ambulating, falls, and a reduction in quality of life.[40] The symptoms are typically worse at night, leading to disrupted sleep, with therapy aimed at minimizing insomnia.

Pain in Neuromuscular Disorders

Neuromuscular disorders describe a heterogeneous group of neurologic conditions associated with diseases of the peripheral motor nerves, neuromuscular junction, muscles (muscular dystrophies, myopathies), and anterior horn cells. In a large series of patients with post-polio syndrome, a large proportion of patients (80%) reported muscular and joint pain.[41] The common feature in these conditions is the notable loss of muscle power and tone and the presence of muscular atrophy. Syndromes with slow progression over time are characterized by disorders of ambulation, which may lead to chronic disability and incapacitation. With disease progression, concomitant musculoskeletal pain may be associated with the loss of neuromuscular support of the axial spine, pelvic, and shoulder girdles. As is common in other chronic pain syndromes, pain may be associated with significant psychosocial distress, mood, and sleep disorders.

The Treatment of Peripheral Neuropathies

This section will focus on the treatment of pain related to peripheral neuropathies. Attention must be paid to treating the underlying causes. Infectious pathogens should be treated with antibiotics or antiviral agents, as appropriate for specific conditions. Nutritional deficiencies should also be addressed. Systemic autoimmune disorders and specific demyelinating disorders (such as GBS/CIDP) can be treated with steroids and other immunosuppressants, and in some instances, IVIG or plasmapheresis. Neuromodulatory medications may also be utilized. Gabapentinoids, serotonin-norepinephrine reuptake inhibitors (SNRIs), tricyclic anti-depressants (TCAs), and capsaicin are the most effective options.[42] Most of these first- and second-line options come with considerable potential for side effects. If the patient does not gain significant relief or has adverse effects from a medication, then dosing should be adjusted and/or alternative therapy may be used or added.[42] The treatment of autonomic neuropathies should not be overlooked. Most cases of orthostatic hypotension can be initially managed with non-pharmacologic treatments, including avoidance of triggers, a head-up tilt of the bed at night, and adequate hydration and compression stockings. Gastroparesis, which can be a significant pain generator, should be managed with supportive measures including small regular meals 4–5 times a day, low-fat and low-residue meals, avoidance of carbonation, alcohol, and tobacco, and optimization of liquid nutrition (Table 36.3).[4]

First Line Agents

Gabapentinoids are traditionally the first agents trialed and include gabapentin and pregabalin. They work by blocking presynaptic α-2-δ calcium channels in the dorsal horn, thereby inhibiting neurotransmitter release.[43] Gabapentin and pregabalin both have been shown to be effective with numbers needed to treat (NNT) of 50% pain reduction of 3.9 (3.3–4.7) in painful polyneuropathy, 4.6 (4.3–5.4) in postherpetic neuralgia, and 4.0 (3.6–5.4) in combined etiologies of peripheral neuropathy pain.[44] Gabapentanoids should be trialed for four to six weeks with two weeks at the maximum tolerated dose.[45] Effects are typically not seen in practice for three to four weeks.

The most commonly used anti-depressants for the treatment of chronic pain today are serotonin and norepinephrine reuptake inhibitors, such as duloxetine and venlafaxine. They facilitate descending inhibition by blocking serotonin and noradrenaline reuptake and have been shown to be effective in peripheral diabetic neuropathy, painful peripheral neuropathy, and

TABLE 36.3 Therapeutic Considerations

Neuropathic Pain		
	First line	• Gabapentinoids • SNRI anti-depressants • Caution with TCA • Carbamazepine and Oxcarbazepine in specific indications
	Second line	• Combination therapy • Tramadol • Tapentadol • Topical Lidocaine • Topical Capsaicin
	Third line	• Botulinum toxin A • Spinal cord stimulation • Intrathecal drug therapy
Nociceptive pain		
	First line	• Non-pharmacologic interventions • NSAIDs
	Second line	• Spinal cord stimulation
Spasticity related pain		
	First line	• Baclofen • Diazepam • Gabapentin • Tizanidine
	Second line	• Botulinum toxin A • Intrathecal drug therapy
Headaches		
	Acute measures	• Triptans
	Preventive measures	• Dihydroergotamine • CGRP inhibitors • Non-pharmacologic interventions

multiple sclerosis.[44,46] The NNT for 50% degree of pain relief in peripheral neuropathy is 5.1 (3.9–7.4).[44] The period of the trial should be limited to four to six weeks. Patients with comorbid depression may benefit from duloxetine, which can be used to treat both depression and neuropathic pain with similar higher dosing.[4,43]

TCAs, such as amitriptyline, nortriptyline, and desipramine, are less commonly used today because of their side effects. TCAs have multiple modes of action, with the most important pain-relieving effect likely due to the inhibition of serotonin and noradrenaline reuptake.[43,45] However, they also block histamine, adrenalin, acetylcholine, and sodium channels, accounting for their broad side effect profile. Their pain-relieving effect occurs in 20%–30% of the effective anti-depressant dose. Caution is required in the use of TCAs in the elderly and frail to avoid potential adverse effects, such as falls, cardiac arrhythmias, orthostasis, urinary retention, and dry mouth.[42] Based on a meta-analysis of randomized controlled trials, the NNT to obtain one patient with a 50% degree of pain relief is 2.8 (2.2–3.8) for painful polyneuropathy, 2.3 (2.1–2.7) for postherpetic neuralgia, 2.5 (1.4–11) for peripheral nerve injury, and 2.3 (2.1–2.7) for combined etiologies of peripheral neuropathy pain.[44] When trialing TCAs, it is recommended that it be done over four to eight weeks.[42]

Second Line Agents

Combination therapy is acknowledged as a significant part of the management. The combination of anti-depressants and pregabalin has shown efficacy in diabetic neuropathy. Combination therapy should be trialed for several weeks (determined by the specific added drug) and ceased if ineffective or if there are significant side effects.[47] Topical agents may also be employed.

Topical lidocaine works by decreasing ectopic firing of peripheral nerves, and both topical application and patch have shown efficacy for postherpetic neuralgia and mixed neuropathic pain with an NNT of 50% pain relief of 4.4 (2.5–17).[48] Topical lidocaine has been shown to be less effective in postsurgical neuropathic pain and diabetic peripheral neuropathy with allodynia or hyperalgesia.[44] The main advantage is the lack of significant side effects and safety profile in the elderly compared to the previous options.[47] Capsaicin is another topical choice. It binds to the TRPV1 receptor located on the Aδ and C-nerve fibers and results in the release of substance P and depolarization of the nerve.[42] Capsaicin has an NNT of 30%–50% pain relief of 11 (5.5–317) for painful polyneuropathy, 10–12 for postherpetic neuropathy, 6.5 (3.4–69) for peripheral nerve injury, and 11 for HIV-related peripheral neuropathy.[44] Despite their analgesic effect, the use of opioids is controversial, and they should be used as an adjunct second or third therapy, if at all. Several reviews have shown no evidence for using hydromorphone, fentanyl, morphine, or buprenorphine.[4,47,49,50] Combination therapy with gabapentin and opioids may provide better pain relief than gabapentin or opioids alone but is associated with higher rates of side effects.[47]

Tramadol has been shown to be effective in the treatment of painful polyneuropathy with an NNT of 3.5 (2.4–6.4) and in the treatment of postherpetic neuropathy with an NNT of 4.8 (2.6–27), with a combined etiologies NNT of 3.9 (2.7–6.7).[48,50,51] Tapentadol is a newer weak μ-receptor agonist and norepinephrine reuptake inhibitor. Its mechanism of action is slightly different from that of tramadol, with stronger noradrenaline reuptake inhibition and nearly no effect on serotonin reuptake. It is the first opioid that is FDA-approved for painful diabetic peripheral neuropathy. However, tapentadol efficacy remains inconclusive.[48] Anti-convulsants, such as lamotrigine, carbamazepine, topiramate, and sodium valproate, and N-Methyl-D-aspartate antagonists have been suggested. Nevertheless, no clear benefit was demonstrated, with a relatively higher number of side effects.[42]

Third Line Agents

More invasive options have been considered, including botulinum toxin type A, a neurotoxin that treats focal muscle hyperactivity with repeated administration locally over six months. Several small trials have studied its use in patients with postherpetic neuralgia, trigeminal neuralgia, and diabetic neuropathy and showed an NNT of 1.9.[52] Neurostimulation is another treatment option. Patients should have a successful trial of stimulation (>50% pain relief) before permanent implant,[53] which is difficult to treat with SCS. Dorsal root ganglion stimulation and intrathecal drug therapy (IDT) have shown higher efficacy.[54] IDT involves the delivery of medications directly to their site of action at the dorsal horn of the spinal cord, bypassing the first pass effect and the blood–brain

barrier. This significantly increases the potency of the medication, allowing much smaller doses to be used. For effective therapy, patient selection is crucial and should undergo a successful trial before implantation.

Pain Associated With Spinal Cord Disorders

The differential diagnosis of spinal cord disorders that result in pain can be divided into infectious, demyelinating, vascular, trauma, and neoplastic etiologies. The evaluation includes specific history, physical/neurologic examination, and MRI imaging in most cases. The causes and locations of spinal cord disorders typically determine the need for surgical or medical management of the primary condition. Pain may be a prominent element in the manifestation of certain spinal cord disorders (e.g. spinal cord injury) or may occur as a late effect of the disease or therapy (e.g. radiation treatment or tumor resection). The characteristics of the pain experience, variable findings, and secondary pain generators are common to all spinal cord disorders.

The Workup

To differentiate between the different types of spinal cord disorders, specific history should assess the speed of symptom onset (acute or chronic), disease course (monophasic, relapsing, progressive, complete or partial), additional clinical features (pain, visual symptoms in multiple sclerosis (MS), systemic symptoms in autoimmune disorders, and lung/eye/skin involvement in sarcoidosis. MRI can distinguish between lesions according to position, size, and enhancing pattern.[55]

Hyperacute onset (minutes to hours) includes vascular etiologies (spinal infarction and/or, more rarely, hemorrhage). Infarction phenotypes are classified according to the vascular supply involved. The most frequently encountered clinical presentation is symmetric motor dysfunction, bilateral spinothalamic sensory deficit below the level of the lesion, autonomic sphincter dysfunction, and flaccid weakness associated with areflexia. Weakness is due to anterior and lateral column dysfunction as a result of anterior spinal artery territory infarction. Posterior spinal artery infarcts are rare and involve proprioception and vibration loss below the level of the injury besides complete anesthesia at the level of the lesion.[56]

Acute/subacute onset (days to weeks) can suggest trauma, infectious, inflammatory, autoimmune, demyelinating, neoplastic, paraneoplastic, and metabolic etiologies.

Etiologies of chronic onset (months to years) may include infectious, neoplastic, paraneoplastic, autoimmune, metabolic, and vascular causes.[55] Tumors comprise a small percentage of cases. Here, the pain that slowly starts initially fluctuates prior to becoming more constant, gradually increases and worsens at night when the patient is recumbent, and eventually disturbs the patient even at rest and is considered the most typical sign for spinal tumors.

Additional information should include medical, surgical, family, and detailed social histories. If a suspected infectious etiology occurs, patients should be further asked about any recent infection, an immunocompromised or autoimmune condition, space-occupying lesion, travel, vaccination, trauma, sexual exposure, and/or animal/insect bites. The assessment of pain as the chief complaint begins with medical history concerning pain descriptors, including pain onset, time course, pain location, intensity, quality, quantity, alleviating and aggravating factors, clonus and/or spasticity, medications, and medications, previous evaluations, and treatments. Associated cord symptoms, including bladder and bowel control, weakness, and altered sensations, should be investigated. Functional capacity history, including both occupational and recreational history, should be obtained for functional impact as well as possible pain promoters (such as wheelchair, crutch, or cane use).[57] Psychosocial comorbidity assessment is required to assess depression, anxiety, personality disorders, substance use, personality disorders, and cognitive deficits.[58]

Physical examination should be broadly systemic and should focus on neurologic findings such as motor weakness, changes in sensation such as allodynia, hyperalgesia, and hyperpathia (pinprick, light touch, vibration, position sense, or temperature), tone, muscle stretch reflexes, coordination, muscle overactivity (clonus, spasticity, spasms), focal examination of specific pain regions, and bowel and bladder function. Local back tenderness may suggest trauma, osteoporotic fractures, or a tumor. Gait (if possible), how the walking aids are used, and functional capacity should all be observed.

Following the history and physical examination, either computed tomography (CT) (in case of bony lesions) or MRI (preferred in most cases) is required for diagnosis.[59] Short lesions (<three segments) suggest MS, sarcoidosis, or neoplasm (primary or metastatic). Long lesions may be due to infections, metabolic, neoplasms, vascular lesions, and sarcoidosis.[55] In cases of suspected vascular lesions, MR angiography or digital subtraction angiography is needed. NCS and electromyography are rarely helpful in primary spinal cord disorders but may rule out peripheral disease. Laboratory tests can assist in the investigation of systemic pathologies, such as multiple myeloma, malignancy, and spondylarthritis. In cases of suspected spinal cord infarction, inflammatory or infectious etiologies should include CBC, chemistry, metals, vitamin B12, vitamin D, viral and bacterial serologies, Lyme titers, vasculitis markers, hypercoagulable profile, and paraneoplastic autoantibodies.[60] CSF analysis may be considered for bacterial and viral infections (pleocytosis), inflammation/autoimmune causes, suspected demyelination (oligoclonal bands), and/or suspected sarcoidosis (ACE). Tissue biopsy is infrequently performed. For malignant lesions with specific treatment implications, a biopsy is necessary to confirm the diagnosis and histologic type.[55]

Following specific spinal cord disorder diagnosis, classifying patients with pain according to a mechanism-based approach may help choose the most appropriate treatment. Evaluation is based on medical history, investigating complex pain features, spasticity, disability, and psychological factors. Pain may be related to bowel, bladder, or kidney dysfunction or distention but may also represent a neuropathic type of pain. Below-level pain has typical neuropathic descriptors, including shock-like, sharp, shooting, squeezing, and burning. It is distributed in more than three dermatomes below the neurologic level of injury but may extend up to the level of injury. Pain may be triggered by sudden noises, vibration or physical jarring, urinary tract infection, constipation, or skin problems (spinal cord injury-induced pain: mechanisms and treatments). At-level pain has typical neuropathic features, such as below-level pain. Above-level pain generators are heterogeneous, such as those of "ergonomic" pathology secondary to overuse of the shoulders and arms causing myofascial pain in the shoulder joints from wheelchair use, or "crutch palsy" resulting from mechanical compression of nerves from orthotics. It is usually a musculoskeletal type of pain and is described as dull and aching. Postural anomalies may worsen this situation. Often, accompanying central pain are symptoms associated with

autonomic dysreflexia, including increased or decreased blood pressure, pulse, and headache.

The Differential Diagnosis

Traumatic Spinal Cord Injury

Pain is a frequent consequence of both complete and incomplete spinal cord lesions.[61] A recent systematic review estimated the prevalence of any type of pain after spinal cord injury (SCI) at 61%.[62] Among all types of SCIs, below-level pain is the most common (23%–52%) and the most difficult to treat. It has a mean onset time of 1.8 years. At-level and above-level pain also occur a year after SCI.[63] Visceral pain occurs later (mean of 4.2 years).[63]

Syringomyelia most commonly follows trauma but may also be congenital (associated with Arnold-Chiari malformation), postinfectious (associated with arachnoiditis), or associated with intramedullary spinal cord tumors. Post-trauma, this diagnosis should be considered if there is a worsening of motor/sensory/autonomic issues and/or spasticity. Atrophy and fasciculations indicate the involvement of the anterior horn cell columns by the syrinx. Patients with a cervical syrinx will have pain and numbness typically in a "cape" distribution. Extension into the upper cervical region may be associated with ipsilateral facial pain caused by the involvement of the descending trigeminal tract and nucleus. Thoracic syringomyelia manifests as neuropathic pain in the trunk or abdominal distribution, dissociated distal sensory loss, spasticity, and urinary retention. Lower thoracic syringomyelia will exhibit symptoms of dysfunction of the conus medullaris, with prominent sacral neuropathic pain and urinary retention.

Demyelinating Disease

MS is a relapsing, remitting, and chronic progressive autoimmune disorder involving central nervous system demyelination. Acute exacerbations are associated with acute inflammation of the central myelin in the optic nerves, periventricular white matter, the brainstem, and the spinal cord. Diagnostic criteria include MRI evidence of damage in at least two separate locations in either the brain or spine and evidence of damage that occurred at different times (either clinically and/or MRI). The prevalence of pain ranges between 26% and 86%. Although neuropathic, MS pain is multifactorial and can have neuropathic and nociceptive origins and may be strongly associated with multiple psychological comorbidities.[64] With the increasing burden of disease, it is likely that the intensity, location, and complexity of the pain in MS progress, along with neurologic disorders. Pain has a significant impact on psychosocial functioning, daily activities, mood, and sleep.[65,66]

MS-associated neuropathic pain syndromes include dysesthetic extremity pain, Lhermitte's phenomenon, secondary trigeminal neuralgia, and optic neuritis. Dysesthetic extremity pain is characterized by constant burning pain in the legs and feet, with nocturnal exacerbations. Lhermitte's phenomenon is a short electric shock-like sensation felt in the back of the neck and lower back, occurring mainly with MS flares, is usually provoked by neck flexion, and is limited in clinical course to a 4- to 6-month period.[57] Spasms and headaches are common in these patients.[67] Box 36.1 summarizes the pain conditions associated with MS.

Infectious

Transverse Myelitis. Transverse myelitis (TM) is a focal inflammation of one or more levels across the spinal cord in the absence of a compressive lesion. This inflammation can cause damage to the myelin, resulting in pain and neurologic dysfunction, including weakness of the lower limbs or of all four limbs, sensory level impairments, and bowel and bladder problems. Different bacterial, viral, fungal, and parasitic infections can cause TM in addition to several autoimmune diseases (MS, neuromyelitis optica). Pain is a common symptom in 33%–50% of patients and may be central or localized, aching or radicular in character.[68] Diagnosis is confirmed with MRI, which allows visualization of the lesion and rules out treatable causes, such as a tumor, abscess, and other lesions causing compressive myelopathy.[69] Labs should include blood counts and chemistry, tests for autoimmune conditions, and Lyme/viral titers. Pleocytosis and oligoclonal bands in the CSF support the diagnosis.[68] NCS may be helpful for disease monitoring.

Tabes Dorsalis. Neurosyphilitic involvement of the dorsal root entry zone is a classic neurologic pain disorder. The disorder is characterized by "lightning pain" involving the lower extremities. Similar pain may occur in the trunk, thorax, and abdomen. Tabetic pain may occur for brief periods (seconds or minutes) or last for several days. Occasionally, visceral involvement predominates, known as "visceral crises." These crises are characterized by epigastric or pelvic pain, accompanied by nausea or vomiting. Physical examination is remarkable for the loss of sensory modalities distally in the lower extremities. There may also be significant ataxia, hypotonia, and dysautonomia. CSF analysis demonstrating positive venereal disease research laboratory test (VDRL) or fluorescent treponemal antibody absorption (FTA-ABS) is diagnostic. The classic finding of Charcot's joints results from deep anesthesia caused by the disorder.

Osteomyelitis. Osteomyelitis may develop after trauma to the spine, postsurgery, or via hematogenous spread from an adjacent site. It is most often a single pathogen infection, and *Staphylococcus aureus* is the most common pathogen.[60] Back pain is the most common presenting symptom, with fever being present in only 35%–60% of cases. The most common site was the lumbar spine (58%), followed by the thoracic spine (30%) and cervical spine (11%). Physical examination may detect spine tenderness and neurologic deficits, including sensory loss, weakness, or radiculopathy, in 33% of cases.[60] Laboratory tests, including CBC, ESR, CRP, and blood cultures, may be used.[70] MRI is the modality of choice for diagnosis, demonstrating signal changes in the vertebral endplates, disc space, and epidural hematoma. Percutaneous aspiration or biopsy can isolate microorganisms when blood cultures are negative.[70]

• Box 36.1 Pain Conditions Associated With Multiple Sclerosis

Neuropathic Pain

Acute transverse myelitis
Acute radicular pain
Chronic myelopathy (deafferentation pain, transitional pain, radicular pain)
Focal peripheral neuropathies (secondary to disability)

Myofascial Pain

Spasticity secondary to myelopathy
Regional myofascial pain (overuse syndromes, posture and gait disorders)
Diffuse myofascial pain (chronic fatigue, sleep deprivation)

Musculoskeletal Pain

Overuse syndromes (wheelchair-bound patients)
Accelerated osteoporosis because of immobility

Vascular

Spinal cord infarction is relatively uncommon, estimated at 1%–2% of ischemic strokes, due to the extensive collateral vascular network. The risk of spinal cord stroke increases significantly during thoracoabdominal aortic surgery. Symptoms are usually abrupt in onset and progress rapidly from minutes to hours. Over 70% of spinal stroke patients suffer from back and/or limb pain.[71] Suspected patients are managed with hemodynamic support to maximize blood pressure and sometimes lumbar drainage to lower CSF pressure.[72] A long-term follow-up study found that spinal patients had higher rates of employment and lower mortality than cerebral stroke patients but higher rates of chronic pain and lower functional independence (modified Rankin scale).[71] The main component of pain is neuropathic and can be treated with neuromodulatory drugs.[73]

Spinal vascular malformations are another relevant vascular pathology that may include cavernomas, intradural arteriovenous malformations (AVM), dural arteriovenous fistulas (AVF), and perimedullary AVFs.[74] Presentation can range from an incidental radiologic finding, a slow-progressing myelopathy or polyradiculopathy (cavernomas, perimedullary AVF), and ischemic injury (dural AVF), which results in progressive myelopathy, subarachnoid hemorrhage with sharp back pain, and catastrophic neurologic injury (intradural AVM, perimedullary AVF).[74]

Typical patients are often younger.[74] Physical examination may be normal or detect different stages of myelopathy. Skin examination for cutaneous angiomata and examination of the extremities for limb hypertrophy may suggest genetic syndromes. MR angiography (CT angiography when MR is not available or contraindicated) or digital subtraction angiography is invaluable. Following hemorrhage or progressive neurologic deficit, most symptomatic malformations are treated either by surgery, radiosurgery, or endovascular intervention for complete or partial excision or embolization of the lesion. Chronic pain is one of the predominant symptoms induced by spinal AVMs or hemorrhage.[75] It has been reported to persist in up to 80% of cases post-treatment, significantly affecting patients' quality of life.[76] Neuropathic pain can be treated with medications. However, it is frequently refractory to pharmacologic modalities.

Tumor

Spinal tumors can be classified into three groups based on their location: extradural, intradural extramedullary, and intramedullary. Extradural tumors are the most common, as they occupy the vertebral body or structures outside the dura. They are the most commonly metastatic. Intradural extramedullary tumors are characterized by meningiomas or neurofibromas. The least common (2% to 5%) is intramedullary spinal cord tumors that arise from the spinal cord, leading to invasion and destruction of the gray and white matter. Ependymomas and astrocytomas are the most common intramedullary spinal cord tumors, followed by hemangioblastomas. Pain is the most common presenting symptom, and its distribution depends on tumor location. In addition, motor weakness, sensory changes, ataxia, and loss of bladder/bowel function can occur.[77] In patients with suspected spine tumors, CT can assist in extradural lesions and bony lesions, including fractures, osteolytic metastasis, and osteoblastic metastasis (prostate and breast). MRI is the preferred modality to characterize the lesion, size, location, length, extent of the surrounding edema, presence of the cord-tumor interface, and associated cysts or syringomyelia.[77]

Treatment

The first step includes specific treatments per etiology. Traumatic SCI and spinal infarction should be managed acutely with hemodynamic stabilization and prevention of secondary injury. Surgical intervention is indicated in cases of instability or spinal cord or nerve compression. Vascular lesions can be treated surgically or via endovascular intervention. MS should be treated with specific disease-modulating drugs.

For infectious etiologies, surgery for an epidural abscess in the face of neurologic deficit and long-term antibiotic treatments may be needed. TM treatment involves anti-inflammatory treatments, including corticosteroids, immunosuppressive agents, IVIG, and plasma exchange, along with intensive physical therapy and rehabilitation programs. Braces are used to provide stability and reduce pain in ambulation.[78] To treat syringomyelia, neurosurgical drainage of the syrinx, surgical resection of a spinal cord tumor (when present), or both can help ease symptoms. Syrinx drainage is primarily performed to limit neurologic progression. However, alleviation of central pain following drainage of the syrinx is not uncommon.[79]

In cases of extradural metastasis, spinal instability, vertebral collapse with or without any neurologic deficit, radiotherapy-resistant tumors, intolerable pain unresponsive to conventional therapy, and neurologic deficits before, during, or after radiotherapy are indications for surgery. Surgery is the best treatment option for pain and neurologic symptoms caused by spinal instability. Surgical resection should be performed as soon as possible following a diagnosis of intradural tumor, as outcomes correlate with the preoperative neurologic conditions, and observation can lead to further neurologic deficits, some of which are irreversible. Postoperative radiotherapy may be indicated, depending on the pathology.[80] Vertebroplasty and kyphoplasty may be considered for selected pathologic fractures.[81] Following the primary intervention, all factors involved in producing the associated residual pain must be identified and addressed separately. The realistic goal is to reduce the intensity of the pain to a tolerable level with interventions that have acceptable risks and costs.

Medical Management

Physiotherapy with targeted exercise programs can alleviate pain and spasticity. A regular exercise regimen or yoga may be beneficial for alleviating diffuse nociceptive pain symptoms. In addition, occupational therapy can address biomechanical abnormalities associated with mobility aids. Modification of orthotics, canes, walkers, crutches, and wheelchairs can potentially influence detrimental ergonomics. Concomitant sleep disorders and depression should be addressed and treated by non-pharmacologic means (e.g. sleep hygiene measures, cognitive behavior therapy [CBT] if required) and pharmacologic modalities when appropriate.

First line therapies for at-level and below-level neuropathic pain include gabapentinoids (pregabalin and gabapentin) with a combined NNT of 6.3–8.3 (for all neuropathic pain) and antidepressants.[48] Second line therapies include tramadol and anticonvulsant lamotrigine, which is a voltage-sensitive sodium channel inhibitor. Other sodium channel blockers, carbamazepine, and oxcarbazepine have been suggested for paroxysmal pain and Lhermitte's in MS.[82] Third line therapies in selected patients include combination therapy.

Intractable neuropathic pain may be treated with IDT.[83] Patients with impaired sensation after SCI are much less responsive to tonic

SCS than others. The efficacy of new SCS paradigms with paresthesia-free SCS for SCI pain requires further investigation.[78] SCS may benefit MS-related symptoms as shown in one study with follow up of 97 months, wherein 74.1% of patients retained significant pain improvement after implantation.[84]

Multiple non-drug related treatment strategies, including transcranial direct current stimulation, rTMS, cranial electrotherapy stimulation, acupuncture, self-hypnosis, TENS, and CBT, are not well established.[85]

Spasticity Related Pain

Muscle stretching is a common practice in the management of spasticity and related pain to reduce muscle tone, maintain or increase soft tissue extensibility, reduce pain, and improve function, but the available evidence on its efficacy is inconclusive. Spasticity can also be addressed with antispasticity medications, such as baclofen, diazepam, gabapentin, and tizanidine. Botulinum toxin A injections can be added to treat focal spasticity (adductors). Sodium channel blockers (carbamazepine and oxcarbazepine) have been suggested as the first line treatment for painful spasms.[86] Cannabinoids and gabapentin have been shown to have an antispasticity effect leading to improvement in spasticity related pain.

The use of intrathecal baclofen (ITB) for diffuse spasticity is recognized as an effective therapy for patients with an incomplete response to oral therapy. In non-ambulatory MS patients, ITB has been shown to provide relief of discomfort and pain related to spasticity, greater ease of care, improved posture, and improved ability to transfer.[84] Repeated MRIs remain possible.[87] Primary surgery is usually considered for selected patients with contractures. The goals of surgical treatment include improvement of function and autonomy, control of pain, and prevention of orthopedic disorders (Table 36.3).[88]

Central Pain Syndromes Due to Brain Pathology

Lesions in the brain may lead to chronic central pain. Etiologies can be divided into degenerative, demyelinated, traumatic, neoplastic, and vascular. Central pain presentation depends chiefly on the site of the lesion, not on the size of the lesion or the specific pathology. The neuroanatomic substrate for brain central neuropathic pain involves a lesion along the somatosensory pathways in the brainstem trigeminothalamic pathways, medial lemniscus, thalamus, thalamocortical projections, and somatosensory cerebral cortex.

The Workup

Differentiation between different brain pathologies requires a specific history, neurologic examination, brain imaging (preferably MRI), and specific tests per suspected diagnosis. History should assess the time course of onset (days, weeks, years) and progression of different symptoms (constant, attacks, progressive) and distribution of symptoms (hemibody/bilaterally, involving one or more limbs, involving the trunk, involving the face and head). Symptoms may include pain, facial and/or sensory body changes, facial and/or body motor weakness, visual deficits, speech difficulties, muscle spasms, spasticity, and bladder and bowel symptoms. Pain descriptors, including location, timing, intensity, quality, and alleviating and aggravating factors, should be explored. History should also include details of previous ischemic/hemorrhagic event/brain trauma, previous therapeutic interventions, previous and current functioning, social history, family history (including dementia, movement disorders, cancer, cardiovascular and psychiatric diseases), and psychological comorbidities including depression and anxiety.

Complete neurologic examination should be performed, including observation of facial expression, examination of cranial nerves, muscle power and tone, tendon and pathologic reflexes, sensory evaluation, gait, and function. Orientation, reasoning, and short memory are assessed when cognitive decline is suspected. Rigidity, muscular spasticity, paresis-related malposition, overuse, contractures, and decubitus ulcers should be carefully examined as other non-central pain generators. Brain MRI is required for lesion definition and ruling out secondary abnormalities (such as hydrocephalus post-stroke/trauma, new MS plaque) and the correspondence with current symptoms. In addition to anatomic sequences, in cases of suspected vascular lesions or trigeminal neuralgia, specific sequences and/or angiography (CT or MR based) may be required to visualize the cerebral blood vessels properly.

Differential Diagnosis

Vascular Etiology

The classic and most characteristic central neuropathic pain condition is central post-stroke pain, accounting for approximately 90% of central pain syndromes.[89] It is estimated to occur in approximately 10% of individuals after the first year following a stroke. The lesion may be in the thalamus (most common), medulla, spinothalamic tracts, operculum, or insular cortex and can cause chronic pain.[90] Post-stroke pain typically coexists with a concomitant contralateral sensory deficit. Pain most commonly begins one to three months after stroke, with most affected patients developing symptoms by six months.[91] Remarkably, there may be a very mild motor deficit compared to significant pain and hemi hypoesthesia.

Patients with brainstem infarctions, particularly lateral medullary infarcts (Wallenberg syndrome), may also be affected by central neuropathic pain. Ipsilateral neuropathic facial pain may coexist with contralateral sensory deficits.[92] Evaluation includes a history of ischemic/hemorrhagic events, previous functioning, and pain descriptors. In addition to neurologic examination and assessment of deficits, physical examination is important to rule out other pain generators. Other pains need to be distinguished from central pain, including spasticity, paresis-related malposition, overuse of the unaffected body site, painful shoulder-arm syndrome after subluxation of the scapulohumeral joint, or CRPS of the paretic arm that developed due to a peripheral trauma secondary to the stroke.[89] Brain imaging should be considered for evaluation of secondary lesions post-stroke.

Trigeminal Neuralgia

Severe pain is characterized by recurrent unilateral orofacial pain that is restricted to one or more branches of the trigeminal nerve. The incidence of trigeminal neuralgia (TN) is estimated to be 12 per 100,000 per year.[93] Pain is usually described as shooting, electric, shock-like, stabbing, or sharp attacks lasting several seconds to a few minutes. Facial movements classically trigger attacks during talking, eating, or mechanical stimulation, such as shaving. TN is classified as idiopathic TN, trigeminal neuropathic pain (unintentional injury), trigeminal deafferentation pain (intentional injury), symptomatic TN (associated with MS), postherpetic TN, and atypical facial pain (which is not considered TN). Idiopathic

TN is further divided into TN1 and TN2. TN1 is defined by the symptomatic description of a sharp, shooting electric shock-like episodic pain, whereas TN2 is described as aching, throbbing, and burning pain, which is constant over 50% of the time. Both TN types 1 and 2 may occur due to compression of the trigeminal nerve root entry zone. In cases of facial pain with the features of TN2, the likelihood of detecting a structural entity, such as a tumor or vascular malformation in the posterior fossa is higher.[94]

The diagnosis is based on typical pain descriptors and location, along with ruling out of other headache and facial pain generators, including oral cavity and salivary gland lesions, paranasal sinus disease, cluster headaches, and other types of trigeminal neuropathy.

Classic pain triggers include mastication, touch, tooth brushing, eating, talking, and cold winds on the face. Neurologic examination should rule out cranial nerve deficits that are usually absent in idiopathic TN. Next, brain MRI should follow to locate a possible trigeminal nerve compression by a blood vessel and rule out posterior fossa lesions such as tumors, stroke or MS plaque, and other causes of facial pain.[95] Treatment usually includes pharmacologic therapy with sodium channel blockers (carbamazepine, oxcarbazepine, or gabapentin). Botulinum toxin A injections[93] can also be used. However, refractory pain mandates different surgical interventions, including microvascular decompression, radiosurgery, and three types of trigeminal nerve rhizotomies (balloon compression, glycerol rhizotomy, and radiofrequency rhizotomy). The TN is discussed in Chapter 38.

Degenerative Disease

Parkinson's disease. Parkinson's disease (PD) is a slowly progressive movement disorder characterized by resting tremor, rigidity, and bradykinesia. It typically occurs in older individuals with variable progression patterns. With progression of the disease, patients typically have significant motor fluctuations with "on" periods of relative ease of movement interspersed with "off" periods of rigidity, bradykinesia, and tremor. Between 40% and 85% of patients with PD have chronic pain that frequently includes more than one type of pain.[96] The different pain subtypes associated with PD can be classified as musculoskeletal pain (most frequent), articular/arthritic pain, neuropathic pain, radicular pain, pain due to dystonia, pain due to rigor/bradykinesia, akathitic discomfort, restless legs syndrome, and central pain.[97] More than 50% of the patients report one type of pain, 24% report two, and 5% report three pain types. Of these, musculoskeletal pain was noted in 70%, dystonic pain in 40%, radicular-neuropathic pain in 20%, and central neuropathic pain in 10%.[98] Pain in PD correlates with age, disease duration, and severity, and, as with many pain conditions, female sex is a significant predictor of pain.[99]

Pain assessment in PD involves obtaining a careful history of whether the patients are appropriately medicated from a dopaminergic standpoint. A neurologic examination can help determine the relationship between the symptoms and medication dosing. That is, if pain occurs when medications are worn off, additional dopamine may be needed. Restless leg syndrome should be treated with low-dose dopamine agonists before nighttime. Botulinum toxin A can be used to treat dystonia-associated pain. Abdominal pain secondary to constipation can be treated using macrogol. Neuromodulatory medications may also be useful. Subthalamic nuclei and globus pallidal deep brain stimulation (DBS) performed mainly for motor symptom control have shown significant long-lasting pain relief effects in selected patients.[100–102]

Dystonia may occur outside the PD as an isolated disorder. It may be either primary or secondary. Primary dystonia is hereditary. Secondary dystonia is post-infectious, posttraumatic (usually following peripheral nerve trauma), and/or idiopathic forms. Dystonias are classified according to the extent of neuromuscular involvement: focal, segmental, multifocal, or generalized. There may be profound contractures that are painful. Dystonia-related pain treatment (including PD) includes dopaminergic agents, anticholinergic agents, muscle relaxants (e.g. baclofen), and benzodiazepines. In focal dystonias, especially idiopathic cervical dystonia, the use of locally injected botulinum toxin has resulted in significant symptomatic benefit and is the first line therapy.[103]

Alzheimer's Disease. Alzheimer's disease (AD) is a neurodegenerative disorder and the most common form of dementia. History should be obtained from both the patient and a close family member or friend. History should characterize the nature (language, word-finding, episodic memory), magnitude (severity and daily life function), and course of cognitive changes (speed of onset and pattern of progression). History should include comorbidities (hypertension, previous brain injury, or stroke), medications that may impair cognition (e.g. benzodiazepines), and family history (especially dementia). Neurologic examination should evaluate frontal disinhibition (hyperorality, hypersexuality), unusual behaviors, parkinsonism, or other focal neurologic signs. Cognitive assessment should be conducted using a screening tool (such as the Montreal cognitive assessment).[104] Formal neuropsychological evaluation should follow. The laboratory panel should include CBC, renal and liver function, thyroid function, and B12 and B1 levels. Brain imaging should be performed to rule out other etiologies and evaluate general atrophy and hippocampal atrophy.[105]

The reported prevalence of chronic pain in AD patients is 45.8%, based on a recent meta-analysis.[106] Pain processing may be altered in patients with dementia. Due to patients' diminished ability to report pain and/or side effects in connection with the pain treatment, pain evaluation/treatment is even more complex. The prevalence of undiagnosed and untreated pain is described as unacceptably high in the primary healthcare system, with a reported prevalence of up to 32% in home-dwelling people with dementia and about 60% in nursing home patients.[107] Development of a comprehensive treatment plan is essential in the population with dementia. Using an interdisciplinary approach is key to establishing a multimodal pain management plan.[108] The incorporation of non-pharmacologic interventions, including exercise and/or movement therapies, psychological interventions, massage, heat and relaxation therapies, and human interactions, has a significant effect on chronic pain.[109]

When pain cannot be relieved by either targeting the cause of pain and/or applying non-pharmacologic strategies alone, pharmacologic treatment of pain is necessary with neuromodulatory medications for neuropathic pain and nonsteroidal analgesics (nonsteroidal anti-inflammatory drugs) for nociceptive pain.

Demyelinating Disease

As noted earlier, MS is a relapsing, remitting, and chronic progressive disorder. Pain in MS may also result from brain lesions. Most commonly, this may include headaches (35%–61%), dysesthetic pain (18.1%), and TN (2%)[110] (see Box 36.1). The diagnosis of TN can precede the diagnosis of MS in up to 15% of the patients.[110]

Evaluation should include a history of the disease and headaches description including quality, intensity, location, timing, and associated aura and symptoms. Neurologic examination should assess the current status and rule out new deficits. MS patients can suffer from different types of headaches, including migraines, tension in addition to cranial neuralgias (trigeminal, occipital, and glossopharyngeal neuralgias), and disease-modifying drug related headaches (interferon-β, natalizumab, and others).[111] Depression, anxiety, and other psychiatric disorders, when combined with life stressors, have a negative impact on headaches.[112] Interventions that include anti-depressants and CBT have a favorable outcome.[113]

Trauma

Besides cognitive changes that occur in traumatic brain injury (TBI), motor deficits, and sensory abnormalities, accumulating evidence suggests that acute and chronic pain are also common after TBI. Chronic pain occurs in 43.8%–45.5% of these patients.[114] A recent analysis concluded that mild TBI was associated with a 75.3% rate of pain, while moderate to severe TBI was associated with a 32.1% rate of pain.[115] Chronic pain can occur independently of concomitant diagnoses of depression and post-traumatic stress disorder.[116] Naturally, headaches are the most common type of pain,[116] followed by neck, shoulder, back, and upper and lower limb pain. Some TBI patients develop a late-onset pain syndrome, six months or more after injury, with characteristics similar to post-stroke chronic pain.[117] Severe symptoms following severe TBI mandate either CT or MRI imaging to rule out posttraumatic complications, such as hydrocephalus, hemorrhages, strokes, and skull defects related and others.

Posttraumatic headaches may be similar to other types of headaches. Patients may also experience debilitating headache exacerbations in the absence of aggravating factors, resembling a state of dysesthesia commonly found in other neuropathic pain states.[118] The sensory profiles of patients with posttraumatic headaches have higher thermal thresholds and lower mechanical pain thresholds in the hands and face, suggestive of a central origin of pain.[118] Their scalps are often very sensitive to light touch. Early identification and intervention are key factors in the management of pain conditions and emotional distress related to TBI, both in the acute and chronic stages. Moreover, severe initial pain intensity has been identified as a risk factor for developing chronic pain post-TBI, which may be prevented if treated early.[119]

Comorbid cognitive impairments, including attentional and memory problems, should be assessed. Comorbid mood dysfunction, such as major depression or anxiety and suicidality, should be documented.

The Treatment

Initially, each central pain syndrome requires primary treatment for the disease. MS-specific drugs are prescribed or changed to reduce the frequency of attacks and/or disease progression. Neuromodulatory medications are used for TN, post-stroke pain, and post-TBI pain. Patients with PD and dystonia must be medically optimized.

In conjunction, neuromodulatory medications may be used, including those discussed above, for spinal and peripheral nerve pathology. TN medical management differs slightly as it begins with carbamazepine. Restless leg syndrome should be treated with low-dose dopamine agonists before nighttime, whereas gabapentin and pregabalin are second line therapies.

Several neuromodulation treatments have shown efficacy in cases of refractory pain, intolerance, or resistance to pharmacologic therapy. DBS has been shown to relieve central pain to various degrees, sometimes even allowing for complete discontinuation of pain medications. Meta-analysis of DBS implanted in the ventral posterolateral thalamus nuclei and periventricular/periaqueductal gray matter has shown that over 50%–80% of patients who underwent a stimulation trial elected a permanent device surgery with over 50% showing long-term pain relief.[120,121] Motor cortex stimulation (MCS), involving the implementation of electrodes epidurally over the motor cortex, has shown significant visual analog scale reduction in several cases in a series of patients with post-stroke pain.[122] In addition, MCS has shown promising results in chronic refractory cases; 72%–84% of trialed subjects pursue permanent implantation of the system, and over 80% of them have good pain control.[123]

With motor weakness, other pain can occur due to immobility of the hemiplegic limbs or contractures. Occupational therapy, physical therapy, stretching, or bracing may be used. Botulinum toxin A and ITB may be used for medical management failure. Functional electrical stimulation may serve as an adjunct.[124,125] Secondary pain complaints may be proactively managed by symptomatic treatment of arthralgia, management of concomitant osteoarthritis, and prevention of falls.

In patients with headaches, management depends on the type of headache. Migraine management includes triptans, which act as selective activators of the 5-HT receptors, dihydroergotamine, which is an agonist of serotonin and other receptors, and calcitonin gene-related peptide (CGRP) inhibitors.[119,126] Topiramate and erenumab, a CGRP inhibitor, have shown some efficacy in posttraumatic headaches.[127,128] Although behavioral therapeutic modalities, such as CBT, biofeedback, and relaxation, are well accepted for primary headache prevention, their applications and efficacy for posttraumatic headaches are unknown.[129] Regular aerobic exercise can improve post-concussion and MS symptoms and should be encouraged; patients should be informed that it does not cause symptom exacerbation and that this is an important method to improve post-concussion symptoms.[130]

Conclusion

Pain is a frequent component of a wide spectrum of neurologic disorders that results from a wide range of pathophysiologies. Following the diagnosis and management of the disease, evaluation should focus on identifying all factors and different types of pain generators. Therapy should be tailored for each type of pain in a stepwise manner, considering baseline disease and comorbidities.

Key Points

- Disorders of the peripheral nerves, spinal cord, and brain may result in chronic pain.
- Peripheral neuropathy evaluation includes history, examination, stepwise labs, and EMG. A skin biopsy may be indicated for small fiber neuropathies.
- Brain and spine disorder evaluation includes history, physical examination, laboratory tests, and MRI.
- The primary goal of pain evaluation in neurologic patients is the discernment of the type of the most disabling pain, its origin, and classification (neuropathic, nociceptive, visceral spasticity related). Most patients have more than one type of pain generator.
- Following primary disease management, therapy should be tailored to address each type of pain using a stepwise approach, including pharmacologic, non-pharmacologic, and neuromodulation interventions.
- Neuropathic pain is mainly treated with medications, including gabapentinoids and SNRIs. Neuromodulation (SCS, DRG) or intrathecal drug delivery can provide relief in refractory cases.
- Spasticity is a major source of myofascial pain in central disorders and is primarily treated with muscle relaxants or intrathecal drug delivery. Botulinum toxin A injections can be used to treat focal spasticity.
- All chronic pain is biopsychosocial, and it is critical to embrace psychosocial dysfunction pain because these features are often easier to treat than biomedical targets.

Chronic Widespread Pain

MEREDITH C.B. ADAMS, DANIEL J. CLAUW

Chronic widespread pain presents challenges to patients, clinicians, and researchers in diagnosing and treating its complex manifestations. Chronic widespread pain is a broad category of heterogeneous, centrally mediated pain conditions. While recent advances in understanding centrally mediated pain have improved its mechanistic understanding, consistently applying clinical diagnosis and treatment remains challenging. The unifying theme for these disorders is pain and sensory hyper-responsiveness, which can be identified using sensory testing and is associated with functional neuroimaging changes.[1] Although widespread pain conditions, including fibromyalgia (FM) conditions, have historically struggled for credibility, advances in our mechanistic understanding of these conditions have occurred so rapidly that we can now use this information to better diagnose and treat individuals with chronic pain. FM is a painful condition for a third new descriptor of pain, nociplastic pain, which has been recently adopted by the International Association for the Study of Pain.[2]

Longstanding negative perceptions and beliefs about centrally mediated pain states are likely to interfere with the adoption of standardized treatment protocols. However, some of the objective tests that can be used to identify pathology in these conditions, such as quantitative sensory testing and functional neuroimaging, are not generally available clinically. Despite this, clinicians can use various simple patient-reported outcomes to make inferences regarding underlying pain mechanisms. This chapter summarizes the current status of these chronic widespread pain conditions, focusing on fibromyalgia and its clinical features, epidemiology, pathogenesis, and management.

Fibromyalgia

Evolution of Diagnostic Criteria

One of the more recent developments in understanding fibromyalgia (FM) has been the paradigm shift in evaluating fibromyalgia as a continuum rather than a binary diagnosis. However, the move toward clinical diagnostic criteria and the use of tools such as the current 2011 FM survey criteria have taken a lengthy path to reach our current state. The first American College of Rheumatology (ACR) developed research criteria for the classification of FM syndrome based on the results of a multicenter research study in 1990 (Table 37.1). The scientific community quickly accepted these criteria with a broad application for epidemiologic, biologic, and therapeutic studies. The ACR research classification required only two components for diagnosis: a history of widespread pain (i.e. located in all four quadrants of the body and axial) for at least three months and allodynia in response to digital pressure (defined as pain with 4 kg of pressure) at 11 or more of the 18 anatomically defined tender points (Table 37.2). The research diagnostic criteria demonstrated moderate sensitivity (88.4%) and specificity (81.1%) for FM in control patients. The study design included pain-free individuals and patients with other painful conditions as the control group.

The tender points in FM are conceptually and anatomically different from the trigger points (TrPs) that define myofascial pain syndrome (MPS). FM tender points are symmetrically distributed throughout the body, whereas TrPs have a more random distribution. In contrast to MPS, these tender points are not limited to muscular locations but also include other soft tissue structures and do not radiate or refer pain to other locations.

The ACR's original research criteria provided a structure but did not extend to clinical applications. Researchers have developed these criteria to standardize the research identification of FM. The research classification identified 18 anatomically defined tender points (Table 37.2), where patients with FM have allodynia in response to digital pressure. Lacking alternative algorithms for diagnosis, clinicians have appropriated these criteria for clinical practice. Primary care physicians diagnose the majority of FM cases rather than subspecialists. Consequently, many physicians rigidly applied the research criteria or rejected their face validity. Accordingly, few providers consistently identified and applied 4 kg of pressure to all 18 designated areas. They used symptom-based diagnostic criteria that focused on fatigue, cognitive impairment, and somatic symptoms, which were excluded from the original research criteria. Moreover, an additional problem with the criteria is that patients with symptom improvement and examination findings no longer met the research classification.

Twenty years after the initial research classification was developed, the FM research community recognized the growing need for clinical diagnostic criteria that reflect the spectrum of FM and practical components of clinical diagnosis. The objective was to develop a screening tool with wide applicability that could be used to diagnose and assess the severity of FM symptoms. Researchers evaluated patients in whom FM was previously diagnosed using the widespread pain index (WPI) and categorical scales. The new criteria, developed in 2010 and revised in 2011 and 2016,[3–5] used these categorical scales to assess patients' cognitive symptoms, unrefreshing sleep, fatigue, and other somatic symptoms.

TABLE 37.1 American College of Rheumatology Criteria for Research Classification of Fibromyalgia

Criterion	Description
1. History	Chronic, widespread (four quadrants) soft tissue pain for three months.
2. Examination	Pain (1+ or greater in severity) induced by 4 kg of digital palpation pressure at 11 of 18 anatomically defined tender points (Table 37.2).
3. 1 and 2 are true	When 1 and 2 are true, sensitivity and specificity for FMS are >80%.

Adapted from Wolfe F, Smythe HA, Yunus MB, et al. The American College of Rheumatology 1990 criteria for the classification of fibromyalgia report of the multicenter criteria committee. *Arthritis Rheum.* 1990;33:160–172.

FMS, Fibromyalgia syndrome.

The ACR used these categorical scales to develop a severity scale. Finally, they combined the severity scale with the WPI to stratify disease severity in patients with FM (Box 37.1). The diagnostic criteria for fibromyalgia were initially designed by unblinded rheumatologists for research purposes. With the evolution of diagnostics to extend to clinical space, a large proportion of clinically diagnosed fibromyalgia does not meet the research diagnostic criteria.[6] A critical advance in our understanding of fibromyalgia is the evolution to symptom-based diagnosis and elimination of the tender point criteria, reflecting a shift in thinking about the spectrum of FM symptoms.[3]

Prevalence Estimates

FM has been found in all ethnic groups studied to date; it is not limited to affluent or industrialized nations. With prevalence estimates ranging from 2% to almost 12% in the general population, it must be viewed as a common medical condition.[7,8] Its prevalence increases with age, most dramatically in women, with a peak in the fifth to seventh decade (7.4% to 10%). Using the original 1990 criteria, including tender points, women were four to seven times more likely to be affected than men of similar age.[8] This was another unintended consequence of the 1990 ACR criteria, by using the same tenderness threshold in men and women, even though we now understand that women are substantially more tender than men, which overestimates the prevalence of FM in men. Using the newer criteria, the ratio was closer to a 2:1 female:male ratio. In contrast, the sex distribution of childhood FM is almost equal (until puberty, girls have similar levels of tenderness relative to boys). Many children outgrow their symptoms.[9] Fibromyalgia the incidence of fibromyalgia is poorly characterized, but risk factors for its development may include obesity, lack of physical activity, poor life/job satisfaction, physical trauma, a febrile illness, or a family history of FM; these factors may not be mutually exclusive.

Clinical Features

The proposed clinical flow would stratify these patients for improved management (Box 37.2). The clinical manifestations of FM typically involve much more than pain, and in fact, these non-pain symptoms are often the key to differentiating the nociplastic pain of FM from nociceptive or neuropathic pain.

TABLE 37.2 Eighteen Anatomically Defined Tender Points in Fibromyalgia Syndrome

Number	Official American College of Rheumatology Bilateral Tender Point Sites
1, 2	Occiput—suboccipital muscle insertions
3, 4	Low cervical—anterior aspects of the C5-7 intertransverse spaces
5, 6	Trapezius—midpoint of the upper border
7, 8	Supraspinatus—origins above the scapular spine, near the medial border
9, 10	Second rib—upper lateral surface of the second costochondral joint
11, 12	Lateral epicondyle—2 cm distal to the epicondyles
13, 14	Gluteal—upper outer aspect of the buttock, anterior fold of the muscle
15, 16	Greater trochanter—posterior to the trochanteric prominence
17, 18	Knees—medial fat pad, just proximal to the medial condyle

Adapted from Wolfe F, Smythe HA, Yunus MB, et al. The American College of Rheumatology 1990 criteria for the classification of fibromyalgia report of the multicenter criteria committee. *Arthritis Rheum.* 1990;33:160–172.

The most important manifestation in FM and nociplastic pain is that pain is more widespread and more severe than expected. In the new FM criteria, the widespread nature of pain is assessed by asking individuals if they have pain in 19 different bodily regions; this is scored from zero to 19 depending on how man sites are involved. The comorbid symptoms that are most commonly seen and thus are scored from zero (not present) to three (severe) within the Symptom Severity Index in the new FM criteria are difficulty with sleep, memory, and fatigue, and headaches, irritable bowel syndrome symptoms, and depression are also assessed in this measure and are given one point each toward the total score on this measure. Another set of symptoms that are becoming increasingly understood with a better understanding of the pathophysiology of these conditions is sensory hyper-responsiveness. Individuals with FM are just as sensitive to the loudness of noises or brightness of lights as they are to painful stimuli, and these symptoms of sensory hyper-responsiveness throughout the body (leading to symptoms such as urinary frequency, dry eyes) can be very helpful in identifying this type of pain.

Cognitive Dysfunction

Ranging from difficulty concentrating when reading a book to short-term memory deficits, people with FM frequently complain of diminished cognitive function. Research has suggested that FM patients perform poorly on a range of cognitive tasks[10] and exhibit premature cognitive aging, with the main evidence of abnormality being derived from distraction or multitasking experiments.

Insomnia

Most patients with FM experience chronic insomnia. Some have difficulty falling asleep (initial insomnia), but most awaken feeling distressingly alert after only a few hours of sleep (mid-insomnia)

• Box 37.1 American College of Rheumatology Preliminary Diagnostic Criteria for Fibromyalgia and Measurement of Symptom Severity

1. Criteria

A patient satisfies the diagnostic criteria for fibromyalgia if the following three conditions are met:

1. Widespread pain index (WPI) score >7 and symptom severity (SS) scale score >5 or WPI score of 3 to 6 and SS scale score >9.
2. Symptoms present at a similar level for at least three months.
3. No disorder present that would otherwise explain the pain.

2. Ascertainment

1. WPI: note the number of areas in which the patient experienced pain over the last week. In how many areas has the patient had pain? The score will be between zero and 19.
   Shoulder girdle, left hip (buttock, trochanter), left jaw, left upper part of the back
   Shoulder girdle, right hip (buttock, trochanter), right jaw, right lower part of the back
   Upper part of the arm, left upper part of the leg, left side of the chest, or neck
   Upper part of the arm, right upper part of the leg, right side of the abdomen
   Left lower part of the arm, left lower part of the leg
   Right lower part of the arm, right lower part of the leg
2. SS scale score:
   Fatigue
   Waking unrefreshed
   Cognitive symptoms
3. For each of the three symptoms above, indicate the level of severity over the past week according to the following scale:
   0= No problem
   1= Slight or mild problems, generally mild or intermittent
   2= Moderate: considerable problems, often present and/or at a moderate level
   3= Severe: pervasive, continuous, life-disturbing problems
4. Considering somatic symptoms in general, indicate whether the patient has the following*:
   0= No symptoms
   1= Few symptoms
   2= Moderate number of symptoms
   3= Great deal of symptoms

The SS scale score is the sum of the severity of the symptoms (fatigue, waking unrefreshed, cognitive symptoms) and the extent (severity) of somatic symptoms in general. The final score ranged from 0 to 12.

*Somatic symptoms that might be considered are muscle pain, irritable bowel syndrome, fatigue or tiredness, difficulty thinking or remembering, muscle weakness, headache, pain or cramps in the abdomen, numbness or tingling, dizziness, insomnia, depression, constipation, pain in the upper part of the abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhea, dry mouth, itching, wheezing, Raynaud's phenomenon, hives or welts, ringing in the ears, vomiting, heartburn, oral ulcers, loss of or change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulty, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms.

• Box 37.2 Proposed Plan for Screening and Comprehensive Care of Patients With Fibromyalgia

1. Phase 1: Pain Screening and Primary Care

Phase 1 involves a simple screening questionnaire in which the receptionist for a primary care health professional (primary care physician [PCP], chiropractor, nurse practitioner, physician assistant, general practitioner, general internist) would give every patient entering the waiting room until all the primary care professionals' regular patients had been assessed (Fig. 37.2). After that, it may be administered only to new patients. When the PCP reviews the form of a patient with pain (question 1 answered "yes"), a decision about the symptom's distribution would be made (localized pain, regional pain, widespread pain). A second decision would be to initiate care for the patient's symptoms or refer the patient for further care of this problem.

2. Phase 2: Comorbidity Screening and Secondary Care

Based on the findings on the screening material, a patient identified as having widespread pain would be examined by the PCP or referral physician to make the diagnosis (fibromyalgia [FM] if it applies). The next stage would be screening for comorbid conditions by a well informed and willing PCP or consultant (rheumatologist, neurologist, pain specialist, internist, physiatrist). The patient began an exercise program and counseling with a professional specifically trained to provide advanced care for FM. Problems found in counseling (e.g. marital, financial, and psychiatric) would spin off to an experienced specialist (e.g. counselor, psychologist, psychiatrist, disability advisor, financial counselor).

3. Phase 3: Comorbidity Screening and Tertiary Care

Based on the second line screening for comorbid conditions, care would begin for additional diagnoses. This phase may invoke referral to tertiary subspecialty care (e.g. cardiologists, gastroenterologists, neurologists, neurosurgeons, physical therapists, psychiatrists, physiatrists, obstetrician-gynecologists, urologists). This care should be integrated with follow up by primary care resources.

4. Phase 4: Long-Term Primary Care and Follow Up Assessment

Primary or secondary healthcare professionals will continue to monitor the patient over time and assess the status of care for pain and comorbid conditions. There would be monitoring for side effects to medications and new problems intruding on the continuity of the FM that might or might not be related to it. In this phase, it is important not to assume that every new symptom in a patient with FM is a component of FM. Healthcare providers need to know what is and is not expected with FM.

and are then unable to sleep soundly again until it is almost morning (terminal insomnia). People with FM typically awaken in the morning feel painfully stiff, cognitively sluggish, and unrefreshed by their sleep.[11]

Stiffness

The morning stiffness experienced by most FM patients is lengthy and severe compared with other mechanisms for morning stiffness. The typical stiffness of osteoarthritis usually lasts 5 to

15 min, whereas that of patients with inflammatory rheumatoid arthritis is 30 min to 2 h. By comparison, the stiffness of FM patients typically lasts from 45 min to 4 h. The best clinical correlate with morning stiffness in FM is pain; therefore patients have challenges distinguishing these constructs from their experiences.

Fatigue

Approximately 80% of FM patients complain of fatigue. Consequently, a large proportion of individuals who meet the criteria for FM also meet the criteria for chronic fatigue syndrome.[12] The differential diagnosis of fatigue is difficult because it must include various sleep disorders, chronic infections, autoimmune disorders, psychiatric comorbidities, and neoplasia. Fatigue may also result from residual levels of prescribed medication, such as tricyclic anti-depressant drugs or other neuropathic medications often used to treat insomnia associated with FM.

Constellations of Previously Diagnosed Comorbid Pain Conditions

There are two sets of comorbid conditions typically seen in association with FM or nociplastic pain: other Chronic Overlapping Pain Conditions (COPCs),[13] that are also predominantly nociplastic pain (e.g. irritable bowel syndrome or tension headache); and other pain conditions that have a different primary pain mechanism (nociceptive or neuropathic pain) wherein nociplastic pain is superimposed. The former category had previously been called primary FM, and the latter category secondary FM or central sensitization.

It may be very important to differentiate primary from secondary FM because, in secondary FM or central sensitization, ongoing nociceptive input or neuropathic damage may be partially driving or maintaining the central sensitization. In these individuals, more aggressively treating the underlying problem might help improve the FM or nociplastic pain, whereas that would not be expected in primary FM, which seems to be more of a top-down brain disorder that typically begins early in life.

Chronic Overlapping Pain Conditions

COPCs appear to be system-based expressions of central sensitization,[14,15] reflecting a range of severities and present on functional neuroimaging and quantitative sensory testing.[16,17] An alternate term previously used was sensory sensitivity symptoms. The spectrum of centrally mediated painful conditions includes headache, facial pain, temporomandibular disorders (TMD), irritable bowel syndrome, dyspepsia, interstitial cystitis, painful bladder syndrome, vulvodynia, endometriosis, and female urethral syndrome. These disorders may have specialist involvement of neurology, dentistry, gastroenterology, urology, or gynecology with a primary diagnosis of one of these centrally sensitizing spectrum conditions.

Neurologic/Dental Sensitization

People with coexisting headaches, facial pain, and TMD may cycle between specialist providers in neurology, dentistry, and pain, but the shared sensitization appears to be consistent across the diagnoses.[18–20] Headache demonstrates overlapping sensitization through shared pathways and treatment responses.[21,22]

Gastrointestinal Sensitization

Irritable bowel syndrome (IBS) and benign dyspepsia are common gastrointestinal conditions that occur in 30% to 50% of patients with FM. A feature common to both FM and IBS may be central sensitization and underlying neuroplastic alterations. These conditions may be synergistic with respect to patients' perceptions of their illness and have a modulating effect on clinical outcomes.

Gynecologic Sensitization

Pelvic pain syndromes may first present to gynecologists, including vulvodynia, dysmenorrhea, and endometriosis. Nevertheless, these disorders are associated with sensitization findings and have a complicated association with stress.[23–25]

Urological Sensitization

Approximately 60% of FM patients experience urinary urgency and nocturia regularly, and there is a high rate of bidirectional comorbidity between interstitial cystitis/painful bladder syndrome and FM. Up to 12% of FM patients also fulfill the diagnostic criteria for female urethral syndrome,[26] which is defined as the presence of urinary frequency, dysuria, suprapubic discomfort, and urethral pain despite sterile urine. Many patients are frequently treated with antibiotics for culture-negative urinary tract infections. Intensive investigations often fail to identify specific causes. Self-report questionnaire instruments were developed to facilitate screening for this condition in patients with FM (Fig. 37.1).[27]

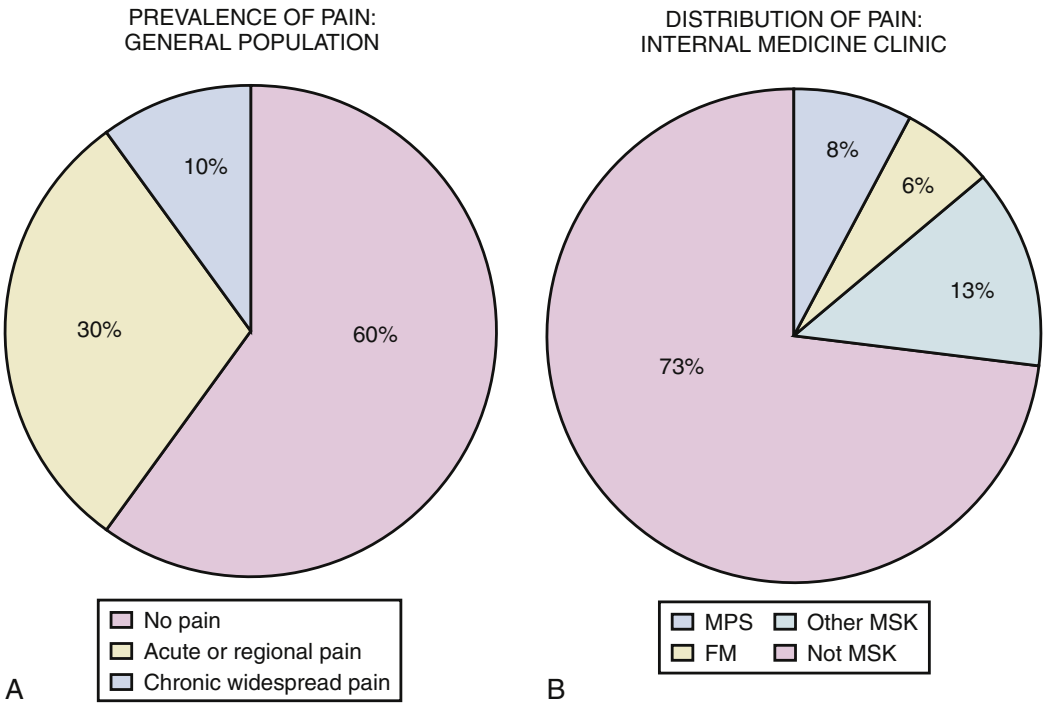
Secondary Fibromyalgia Diagnoses

Conversely, FM can develop in patients with other chronic diseases during the course of their symptoms. In the setting of another painful condition or inflammatory disorder, the FM condition has been referred to as secondary FM. This terminology is not intended to imply that the FM is always caused by the other condition, but the terminology is entrenched and serves a purpose. Secondary FM may not be clinically distinguishable from primary FM,[28] but increasingly, laboratory findings can be used to distinguish these FM subgroups.[29]

As examples of secondary FM, almost 30% of patients with rheumatoid arthritis, 40% of patients with systemic lupus erythematosus, and 50% of those with Sjögren's syndrome have concomitant FM. Patients with rheumatic disease and FM seem to experience articular pain disproportionate to synovitis. This must be considered when treating rheumatic conditions because increasing the dosage of antirheumatic medications in the absence of active inflammation may have little effect on the pain amplified by FM. The best results are obtained by treating each condition separately.

Patients with rheumatic disease and concomitant FM should be warned that a transient increase in FM symptoms may occur with each decrease in glucocorticoid dosage (steroid withdrawal FM). Therefore usual FM therapy may need to be increased transiently. This is a surprising phenomenon because glucocorticoids do not help treat primary FM. To avoid interference with a steroid taper by emergent FM, it is best to decrease the dosage of the glucocorticoid used to treat rheumatic disease in graduated steps at approximately two week intervals. The rate of tapering depends on the current dosage.

Infectious and inflammatory conditions that seem to be associated with FM include hepatitis C, tuberculosis, syphilis, and Lyme disease. The prevalence of overlap may depend on the prevalence of infectious diseases in the community. An academic practice in a Lyme-endemic area evaluated 788 patients with apparent infection for a mean of 2.5 years.[30] Of those with Lyme disease, 20% met the criteria for FM. The symptoms of FM developed one to four months after infection, often associated with Lyme arthritis. The signs of Lyme disease generally resolved with antibiotic



• **Figure 37.1** Prevalence of Pain in the General Population (**A**) and an Academic Internal Medicine Clinic (**B**). *FM*, Fibromyalgia; *MPS*, myopathic pain syndrome; *MSK*, musculoskeletal.

therapy, but FM symptoms often persisted. The largest subgroup of the 788 patients did not have Lyme disease, but they met the criteria for FM or chronic fatigue syndrome.

Pathogenesis

Patients with FM have a constellation of symptoms, but the most common symptom is pain. Before the advent of research techniques such as quantitative sensory testing and functional neuroimaging, many believed that FM and chronic widespread pain had primarily a psychosocial origin with little "organic" basis. However, patients with FM demonstrate reliably augmented sensory processing that was initially thought to be confined to the sensation of pain (i.e. hyperalgesia or allodynia) but is now known to include hypersensitivity to other sensory stimuli such as auditory stimulation.[31,32] Functional magnetic resonance imaging (fMRI) studies have corroborated this finding of hyperalgesia or allodynia in that multiple studies have now shown that FM patients display increased neuronal activation in comparison to controls when the same low-intensity stimulus is applied to both groups.[33] fMRI studies have demonstrated the impact of comorbid psychological factors influencing FM.[34] People with central sensitization conditions, such as FM, appear to have lower thresholds to generate pain responses than in normal controls.[35-37] These imaging studies also provide a theoretical basis for globally augmented sensory processing in FM since the area of the brain that most consistently exhibits increased activity in FM and most other chronic pain states is the insula, a region involved in polysensory integration.[38] Even though multiple mechanisms to assess alterations in pain perception are used, the pressure pain threshold (rather than heat or electrical stimuli) response has the closest relationship with the clinical features of FM and other chronic pain states.

Patients with FM have also been found to have altered levels of biomarkers associated with pain, specifically glutamate and substance P (SP).[39] Harris and colleagues' recent work using proton spectroscopy to evaluate insular glutamate elevations in patients with FM demonstrated higher mean levels than in controls.[40,41] Although such techniques do not allow simple patient testing, the findings support the distinct biologic identity of FM. Endogenous opioid levels are elevated relative to controls, thereby providing a potential mechanism for the lack of responsiveness to opioid therapy in patients with FM, laying the foundation for using low dose naltrexone as a treatment option.[42] Objectively, this has been demonstrated through positron emission tomography (PET)-derived μ-receptor occupancy.[43,44]

Abnormalities in neurochemical mediators of central nervous system (CNS) nociceptive function are present in ways consistent with the patterns of symptoms. The role of neurochemicals as neurotransmitters and modulators of the nociceptive process has been studied extensively in animals.[45] It is believed that these agents participate in the descending inhibition of nociception. This line of reasoning has led to the measurement of neurotransmitter levels in biological fluids obtained from patients with FM. Several major classes of biochemical participants in the nociceptive process are biogenic amines (e.g. serotonin, norepinephrine, and dopamine), excitatory amino acids (e.g. glutamic acid, glutamine, aspartic acid, asparagine, glycine, arginine), neurokinins (e.g. SP, calcitonin gene-related protein, arginine vasopressin, neuropeptide Y), nerve growth factor (NGF), and nitric oxide. Biogenic amines are generally considered antinociceptive, whereas the excitatory amino acids, SP, NGF, and perhaps even nitric oxide are more likely to be pronociceptive.

Another approach to understanding the cause of FM has been through genetic studies. While this is a promising approach to developing personalized treatment paradigms, this is an area of active research. Genetic studies have not yet identified reproducible and strong candidate polymorphisms or haplotypes despite familial associations in people with fibromyalgia. Candidate

Phase 1: Screening Questionnaire

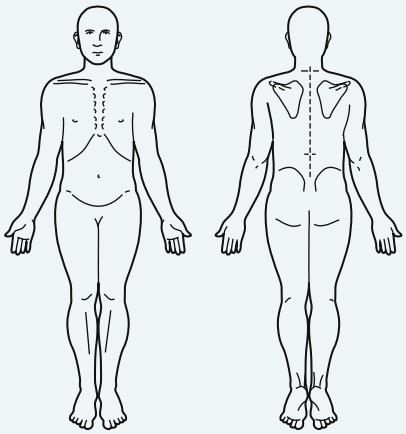
Instructions: Answer yes or no to each of the following questions. If you answer no to question 1, you are done. You do not need to read any of the other questions. When you are done, please return the completed questionnaire to the office clerk.

Yes	No	
☐	☐	1. Have you had body pain for at least three months?
☐	☐	2. Was your body pain one of your reasons for coming to the doctor today?

Instructions: If you answered Yes to question 1, mark a slanted line across the line below to indicate how severe your pain has been over the past two weeks.

No pain — Severe pain

Instructions: If you answered yes to question 1, use a pencil or pen to mark darkly on the body diagrams the locations of your pain during the last week.



Below this line is for office use only. Please do not mark below this line.

- Physician interpretation [check one]:
  ___ Localized ___ Regional ___ Widespread Soft Tissue Pain
- Optional examination findings [indicate values]:
  Total Tender Point Count_____ TPI_____ APT_____
- Referral: ____Yes ____No To _____

• **Figure 37.2** Screening Questionnaire for Chronic Widespread Pain as Seen in Fibromyalgia Syndrome (FM). The findings supportive of FM would be chronic pain from question 1, the relative severity of the pain from question 3, and widespread pain from question 4. Each question could also be applied to other categories of soft tissue pain, and patients with localized or regional musculoskeletal pain, if present, would be identified by the body pain diagram.
APT, Average pain threshold; *TPI*, tender point index.

polymorphisms for fibromyalgia have been inconsistent in studies, including serotonin 5-HT2A receptor polymorphism T/T phenotype, serotonin transporter, dopamine four receptor, and catecholamine *o*-methyl transferase (COMT).[46,47] Epigenetic theories are emerging in mechanistic fibromyalgia research because of their strong association with environmental factors such as stressful experiences.[48] Published studies have documented familial patterns. Some have predicted an autosomal dominant mode of inheritance for FM,[49,50] and evidence for this has increased. In a study by Yunus et al.[51] a linkage of FM with the histocompatibility locus was examined using the sibship method. A complete genome scan of families with two or more FM-affected members has been undertaken by using samples of DNA from a large number of multi-case FM families for comparison of clinical and laboratory genotypic features.[52] Meanwhile, several candidate genes have been proposed to directly explain the specific metabolic abnormalities that have been consistently observed in FM.[53] No evidence for linkage was found in the HTTLPR gene region. Families with an older age of onset were linked to the human leukocyte antigen (HLA) region (logarithm of the odds [LOD] = 3.02, $P = 0.00057$), thus suggesting an immune-mediated pathogenesis. Bioinformatics mining and further sequencing of genes in the HTR2A region will help identify specific polymorphisms for further clinical association testing.

Subsets of patients with FM exhibit functional abnormalities in the hypothalamic-pituitary-adrenal (HPA) axis, sympathoadrenal

(autonomic nervous) system, hypothalamic-pituitary-thyroid axis, hypothalamic-pituitary-gonadal axis, or hypothalamic-pituitary-growth hormone axis.[54] In FM patients, the HPA axis exhibits an exaggerated adrenocorticotropic hormone (ACTH) response to insulin-induced hypoglycemia or stressful exercise. Despite this dramatic rise in serum ACTH levels in FM, the level of cortisol did not increase commensurately. Mediators that regulate the HPA axis include corticotropin-releasing factor, serotonin, norepinephrine, SP, and interleukin (IL)-6.[55,56]

The reasons why these endocrinopathies are associated with chronic pain syndrome are not entirely clear.[54,56] It may be that CNS abnormalities in the availability of biogenic amines such as serotonin, norepinephrine, and/or dopamine are responsible for the abnormal regulation of the neuroendocrine system.[57] These systems interact and are interdependent, so in susceptible individuals, a partial failure of one system may lead to subtle malfunctions in others. Moreover, immune function abnormalities have been identified as early as the 1980s.[58] This foundation has been expanded to include additional markers. Research on fibromyalgia has spanned the search for serum antinuclear antibodies,[59-61] lymphocyte immune abnormalities,[58] and critically evaluating the role of cytokines such as IL-6 and IL-8.[55,62,63]

In summary, the pathogenesis of FM was shaped by the recognition of allodynia as a manifestation of abnormal central nociceptive processing. This has redirected the collective view of the FM. This revised perspective pointed out research on this condition in a new direction, specifically toward the study of central sensitization. Some abnormalities found in FM are logically consistent with the pain amplification syndrome. The extent to which these mechanisms are unique to FM is critical in determining the direction of future research.

Management Approaches

The objectives of FM treatment are to reduce pain, improve sleep, restore physical function, maintain social interaction, and re-establish emotional balance. A reasonable community objective might be to reduce the need for expensive healthcare resources. To achieve these goals, patients will need a combination of social support, education, physical modalities, and medication. A six-step outline of therapy has been developed; *ADEPT living* stands for attitude, diagnosis, education, physical modalities, treatment with medication, and living.

Attitude

Attitude refers to the preparation or frame of mind that each participant brings to the therapeutic interaction. For clinicians, viewing FM as a neuroinflammatory disorder that creates central sensitization provides a framework for understanding the tremendous impact on the patient's life. From the patient's perspective, it is important to realize that FM is a constellation of symptoms with treatments that require biopsychosocial efforts and participation by the patient. Recognizing and sharing updates and limitations in knowledge regarding FM can help set up a more positive treatment dynamic for clinicians and patients.

Diagnosis

The correct diagnosis should be made to identify FM and disclose any comorbid medical conditions. The management approach will also need to accommodate these other conditions if the patient has concomitant hypothyroidism, diabetes mellitus, or renal insufficiency. For example, when rheumatoid arthritis and FM are evident in the same patient, treatment is more successful when both conditions are treated as though the other is not present. Fibromyalgia is not a diagnosis of exclusion, and patients can have comorbid pain conditions that may benefit from tailored treatment (e.g. low back pain).

Education

Education is crucial for the management of FM. Understanding is crucial for playing an active role in therapeutic programs. Several studies have examined the effects of cognitive behavior therapy (CBT) on outcomes in FM and demonstrated positive effects on pain scores, pain coping, pain behavior, depression, and physical functioning.[64] Such gains are often maintained for several months after completion of the therapy, and periodic booster sessions may prolong the benefits. Joining a resource-oriented support group can help FM patients come to terms with a complicated illness.

Physical Modalities

A variety of physical modalities have been proposed as interventions for FM and can logically be segregated into two categories: those that patients can accomplish for themselves and those that require active participation by a trained therapist. At home, patients can pace their usual activities by setting a clock to time the necessary work activity and then balance the work time with an equal period of rest. Progressive exercise, heat applied as a shower or bath, and Jacobson relaxation techniques can all be used as self-directed therapies with minimal cost.[64]

Aerobic exercise was among the first nonpharmacologic strategies advocated for FM patients, with convincing evidence of benefit.[64] Its goals are to maintain function for everyday activities and to prolong life through cardiovascular fitness. Low-impact exercise, with an intensity sufficient to challenge aerobic capacity, can also reduce pain, improve sleep, balance mood, improve stamina, instill new perspectives, restore cognition, and facilitate a sense of wellbeing.[65] Patients who can exercise sustain a less negative impact of FM in their lives.[66,67] Other recent studies have shown benefits in terms of quality of life and pain in patients involved in exercise programs alone.[68] However, one should be aware that high levels of exertion can temporarily worsen the pain and result in fear of movement (kinesophobia), especially in this patient population. When FM is first diagnosed, the patient is usually deconditioned and has already learned to fear the pain induced by exercise. When prescribing exercise for FM patients, the clinician should begin with low-intensity exercise, such as walking in place in a swimming pool and minimize eccentric muscle contractions.[69] the continuation of the exercise program. Other physical therapies, including yoga,[70] pilates,[71] and tai chi,[72] have been found to be effective in reducing the pain associated with FM. However, other alternative and complementary methods, including Reiki, provided no benefits.[73]

Most patients report benefits from heat in the form of dry or moist heat. Many studies have found that a hot bath or shower can be more effective than analgesic medication for headaches, body pain, and stiffness. The application of heat can relax muscles, facilitate exercise, and improve the sense of wellbeing. Cold applications are preferred by some researchers. Light massage that gradually progresses to deep sedative palpation of large body surfaces can reduce muscle tension, but its influence on body pain usually lasts only one or two days.

Treatments

Cognitive Behavior Therapies

Numerous psychological therapies have been found to be beneficial for pain relief in patients with chronic widespread pain, including

FM. In a recent randomized controlled trial (RCT),[74] telephone-based CBT was found to be beneficial for healthcare related quality outcomes. In this study, 442 patients with chronic widespread pain were randomized to receive six months of telephone CBT, graded exercise, combined intervention, or treatment as usual. Patients receiving CBT with or without exercise performed better than those who underwent standard medical treatment. Those who combined CBT with exercise showed the greatest improvement. These improvements in quality of life were long lasting, and the interventions were cost-effective by using telephone instead of face-to-face CBT. Attention modification has also been very successful in altering the perception of pain in patients with chronic widespread pain. Attention bias refers to the phenomenon whereby patients identify with information that reinforces their focus on their painful condition. The goal of attention modification is to interrupt this negative and self-reinforcing cognitive cycle. In a recent RCT, the Attentional Modification Paradigm (AMP), in which patients completed two 15 min AMP sessions per week for four weeks, was used to facilitate such changes in attentional pain biases.[75] Those in the AMP program reported statistically significant and substantial reductions in several individual difference variables relative to those in the control condition, and a greater proportion experienced clinically significant reductions in pain.

Pharmacotherapies

Recent developments regarding FM therapy relate to new medications being developed and tested specifically for this condition. Three medications, including amine reuptake inhibitors duloxetine and milnacipran, and the membrane stabilizer pregabalin, are currently approved by the Food and Drug Administration (FDA) for the treatment of pain related to FM. Many medications have been used with varying success in an off-label fashion. The theoretical background relating these agents to FM has been based on various biochemical or physiologic abnormalities found in FM,[76-78] and is known to be an important contributor to the pathogenesis of pain. One approach to the therapeutic goals of pharmaceutical therapy would be to say that FM has three main domains (or symptoms) that represent targets for therapeutic intervention, which include pain, insomnia, and depression, but others could be substituted as well.

Nonsteroidal Anti-Inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are not effective as a monotherapy for this condition. Perhaps the more important role of such agents is to contribute to synergy with other medications because it is very likely that some of the central sensitization seen in conditions such as FM is probably driven by peripheral nociceptive input.

Local Anesthetics

Lidocaine infusions have not generally been found to provide supplemental benefit in addition to oral amitriptyline intake for pain outcomes.[79] However, a recent study of 68 FM patients with MPS and 56 FM patients with regional joint pain showed that peripheral TrP injections and hydroelectrophoresis ameliorated FM pain and increased pain thresholds at sites distant from the therapeutic interventions, thus providing further evidence that painful peripheral stimuli contribute to the perpetuation of central augmentation.[80]

Opioids

Although opioids are prescribed for the treatment of FM, clinical experience and empirical evidence indicate that they are not effective in ameliorating this condition.[81,82] Thus the risk of tolerance, opioid-induced hyperalgesia, addiction, and prescription drug diversion is not justified by the insignificant therapeutic benefit. Opioids can disrupt the sleep architecture of people with fibromyalgia, increasing lighter sleep and decreasing slow wave sleep. Sleep disruption can negatively impact symptoms associated with fibromyalgia. The higher the opioid dose, the greater is the sleep quality disruption.[83] The aim of opioids in severe cases and those refractory to all conservative medical and psychological therapies should not be merely pain relief but rather a clear improvement in physical function. If improvement in function is not achieved, these agents must be discontinued and not restarted. A therapeutic trial with a defined endpoint and defined target dose must be discussed with the patient before starting opioid-based therapy. If the physician and patient engage in opioid therapy, a clear behavioral contract needs to be signed by both parties.

Amine Reuptake Inhibitors

Tricyclic anti-depressant (TCA) drugs are effective at low doses (10–150 mg) and improve sleep and enhance the effects of analgesics. Two TCAs that have been extensively studied in FM are amitriptyline (typically administered in doses from 10 to 50 mg) and cyclobenzaprine (typically given in doses from 2.5 to 20 mg) administered at night to improve sleep.

Selective serotonin reuptake inhibitor (SSRI) drugs were developed for the treatment of depression. However, in the usual antidepressant dosages, these agents are effective as monotherapy for depression, and at higher dosages (fluoxetine, 40–50 mg/day), to relieve FM pain.[84] This analgesic effect may be non-serotonin selective at these high doses. The analgesic effects of the tricyclic drugs, not apparent with normal dosages of SSRIs, have suggested that the small contribution from inhibition of the norepinephrine transporter might be critical to their pain-relieving effect. In the tricyclic class, there is a large up to a 900-fold difference between norepinephrine reuptake inhibition activity and that of serotonin.

Another class of amine reuptake inhibitors includes serotonin-norepinephrine reuptake inhibitors (SNRIs), which have been developed to achieve a better balance between the inhibition of the reuptake of serotonin and norepinephrine. One class (exemplified by duloxetine) exhibits almost equivalent activity to SNRI, whereas the other class (norepinephrine selective reuptake inhibitor [NSRI] exemplified by milnacipran) exhibited potent inhibition of norepinephrine reuptake. At dosages of 60 to 120 mg once daily in the morning, duloxetine can be effective in controlling FM body pain, regardless of whether the patient is depressed.[85-87] It is well tolerated by most FM patients. Nausea, dry mouth, constipation, diarrhea, and anorexia are reported more frequently with active drugs than with placebo. The adverse effects can be lessened by starting the drug at a low dosage (30 mg in the morning) and gradually increasing it as tolerated, such as increasing the morning dosage by 30 mg every week. The most common target dose is 60 mg in the evening. However, some studies have noted efficacy at higher doses. Milnacipran is typically administered at doses of 100 to 200 mg daily.[88] Because it is more noradrenergic than duloxetine, it might be helpful in individuals with more prominent fatigue or memory problems, although many individuals have trouble tolerating noradrenergic side effects.

N-Methyl-D-Aspartate Antagonists

The pain amplification of central sensitization can be inhibited or attenuated by *N*-methyl-D-aspartate (NMDA) receptor antagonists. Several NMDA receptor antagonists, including ketamine,

memantine, and dextromethorphan, have been studied in patients with FM and have been shown to have some beneficial effects.[89,90] In the case of ketamine, about 50% of FM patients benefited from an open trial. The concept of FM subgroups was advanced by these findings because ketamine clearly identified responsive and unresponsive subjects from among otherwise comparable FM patients. The usefulness of ketamine as a therapeutic agent for FM has been limited by the fear of adverse effects, such as psychological disturbances (e.g. feelings of unreality, altered body image perception, modulation of hearing and vision), dizziness, anxiety, aggression, and nausea.[91] Furthermore, a more recent trial that examined the long-term analgesic benefit of intravenous ketamine infusions found no benefit of discontinuation of ketamine or at eight weeks following discontinuation.[92] Therefore the benefit of intravenous ketamine infusion may be restricted to its predictive value for dextromethorphan or oral ketamine therapy.[93]

$\alpha_2\delta$ Ligands

Some drugs initially developed as anti-convulsants can raise the threshold for pain fiber depolarization, as they do for central neurons to reduce seizure activity. Pregabalin and gabapentin are ligands for the $\alpha_2\delta$ subunit of voltage-gated calcium channels.[94,95] These compounds have been shown to have anti-hyperalgesic/anti-allodynic, anxiolytic, and anti-convulsant activities in animal models. They reduce the release of several neurochemicals, including glutamate, norepinephrine, and SP. Pregabalin was found to be effective in reducing the severity of body pain, improving quality of sleep, and reducing fatigue in FM patients.[96] Pregabalin is available in the United States but is scheduled as a controlled substance because of its mild anti-anxiolytic activity. At therapeutic dosages (300 to 600 mg/day in two or three divided doses), it was well tolerated. Adverse effects can include dose-related dizziness and somnolence, which resolve despite continuous therapy with the drug. This observation suggests that it is helpful to start at a low dosage and increase it gradually (perhaps weekly) to help the patient adapt. One approach is to start with 100 to 150 mg at bedtime and increase the nighttime dosage weekly to 300 to 450 mg before adding a smaller morning dosage to achieve 450 to 600 mg/day. Weight gain (5–10 lb) and peripheral edema occur in 6% to 12% of patients without any evidence of an effect on the heart or kidneys. Gabapentin has been shown to be effective in FM patients.[97]

Low Dose Naltrexone and Combination Therapies

Low dose naltrexone (LDN), an opioid antagonist, has emerged as a treatment option for fibromyalgia.[42] The mechanistic theory supporting the use of LDN reflects its role as a central anti-inflammatory agent. LDN is used in the range of 1–4.5 mg for these indications.[98,99] The use of specific combinations of newer therapeutic agents, or strategic polypharmacy, has been proposed for the management of FM.[100] It should be noted that there are no published data on the consequences of combining drugs that are effective as monotherapy. The critical principles of this concept for FM are that complementary medications should be from different drug classes, have different mechanisms of action, and not be synergistic for any serious adverse effects.

Procedural Interventions

Surgical interventions for FM pain are not indicated or recommended, and the search for a surgical panacea has resulted in unnecessary or potentially harmful surgical care for patients with chronic widespread pain, including FM. Other non-invasive procedures have been examined for their efficacy in populations with chronic widespread pain.

Other Comorbid Conditions

Dysfunctional Sleep and Fatigue

The bidirectional relationship between sleep and FM is a critical component in identifying strategies to improve pain and function. Focusing on sleep as a goal for improvement may be the first step in targeted therapy. People with fibromyalgia can demonstrate abnormal sleep rhythms, and abnormal sleep rhythms in people without fibromyalgia can cause symptoms that mimic tenderness, myalgia, and fatigue. Poor sleep quality can influence the development of chronic widespread pain states.[101] The management of insomnia in patients with FM remains non-specific and empirical. CBT for insomnia may provide benefits for sleep initiation, maintenance, and perceived quality.[102] The sedating of tricyclic biogenic amine reuptake drugs, such as amitriptyline and cyclobenzaprine, has been the most commonly prescribed medication for FM insomnia. They are not ideal for this role because they cause several adverse effects and are subject to tachyphylaxis, but a one month holiday from all biogenic amine reuptake inhibitors can restore effectiveness.[82] Because SSRIs, SNRIs, and NSRIs are sometimes so stimulatory that they can interfere with sleep, they should be taken in the morning. Two medications used for FM, pregabalin and oxybate, are effective for pain and sleep disturbances.[95,103,104] In addition, both correct the non-rapid eye movement sleep pattern abnormalities seen with FM. Fatigue in FM is probably a direct result of chronic insomnia. Exercise can be an important component in shifting the fatigue cycle.[67] Depression and comorbid conditions, such as sleep apnea, hypothyroidism, diabetes, chronic infection, or anemia, can also drain energy and should therefore be included in the differential diagnosis. Mild exercise can reduce fatigue in patients with FM.

Summary

Despite our evolving understanding of the disease process and increased therapeutic options, patients with chronic widespread pain continue to present diagnostic and management challenges. The disparate range of symptoms found in patients with chronic widespread pain and the multitude of associated comorbid conditions in the patient population contribute to the diagnostic difficulties in an increasingly overburdened healthcare system. Moreover, the most successful treatment modalities require significant personal changes in the behavior and lifestyle of patients, which creates a substantial barrier to implementation. Even the diagnostic criteria for FM are controversial, with researchers and clinicians working to develop a working definition to help identify these patients. The most recent collaboration has resulted in the development of preliminary diagnostic criteria that address symptom severity (Box 37.1).

The clinical manifestations of FM include cognitive dysfunction, affective distress, insomnia, stiffness, musculoskeletal pain, and fatigue. These non-specific symptoms contribute to both the diagnostic and therapeutic challenges of managing FM. Associated comorbid conditions include chronic fatigue syndrome, IBS, interstitial cystitis, rheumatoid arthritis, systemic lupus erythematosus, and Sjögren's syndrome. This diverse clinical

picture complicates both the diagnostic specification and burden of individual patient suffering.

The evolution of the pathogenesis of FM is being clarified through molecular studies, sensory testing, and other testing modalities, including functional MRI and PET. Abnormalities in neurochemical biomarkers are being recognized as being associated with FM. Immunologic changes have also been identified through work with ILs and cytokines. Genetic markers (COMT gene) and sex may also play a role in the development of these chronic widespread pain syndromes. The composite result of these novel investigative approaches is an emerging spectrum of identifiable biochemical and functional changes that contribute to chronic widespread pain.

Treatment modalities align with a multi-disciplinary paradigm that includes multiple recent drug developments, cognitive behavior modalities, physical therapy, and exercise programs. Recent changes in FDA-approved pharmacotherapies include the use of pregabalin, as well as the amine reuptake inhibitors duloxetine and milnacipran. The implementation of therapeutic agents is frequently tailored to the patient's symptoms and comorbid conditions (e.g. osteoarthritis vs. insomnia). Ultimately, the most successful treatment outcomes result from multimodal therapy, which relies heavily on patient involvement and investment (physical therapy, exercise regimens, CBT).

Key Points

- The objectives of treatment of fibromyalgia (FM) include reducing pain, improving sleep, restoring physical function, maintaining social interaction, and reestablishing emotional balance. To achieve these goals, patients will need a combination of social support, education, physical modalities, and medication.
- Patients with FM demonstrate reliably augmented sensory processing, which was initially thought to be confined to the sensation of pain (i.e. hyperalgesia and allodynia) but is now known to include hypersensitivity to other sensory stimuli.
- Patients with FM have also been found to have altered levels of biomarkers associated with pain, specifically glutamate and substance P.
- The FDA currently approves three medications for the treatment of pain related to FM: the amine reuptake inhibitors duloxetine and milnacipran, and the membrane stabilizer pregabalin.

Headache Management

STEPHEN D. SILBERSTEIN

Introduction

Headache has plagued humans since the beginning of recorded time. It is one of the most common medical complaints and accounts for more than 18 million outpatient visits per year in the United States. More than 1% of physician's office visits and emergency department visits are primarily for headaches.[1,2] In 1988 the International Headache Society (IHS) published a formal classification system for the diagnosis of headache disorders,[3] which has since been updated and improved (International Classification of Headache Disorders, third edition [ICHD-3]).[4] The IHS classification system (Box 38.1) continues to divide headaches into primary and secondary disorders. In a primary headache disorder, headache itself is the illness, and no other etiology is diagnosed. In a secondary headache disorder, headache is attributed to an identifiable structural or metabolic abnormality.

Instruments and Scales in Headache

Headaches can severely interfere with daily functioning and productivity.[5,6] Research has demonstrated that improvement in symptoms and quality of life (QOL) are not perfectly correlated: symptoms may improve, but function may not.[7] Consequently, it is important to embrace instruments that measure QOL. Instruments that assess migraine disability can improve headache care by facilitating physician-patient communication and guiding treatment decisions. Various headache scales are in use. The scales can be divided into two main groups: scales that measure the impact of a single migraine attack (with or without therapy) over a 24 h period and scales that measure the impact of migraine over a span of weeks or months. The first group of scales has been used in randomized, placebo-controlled trials; they are highly sensitive to acute treatment effects.[8] The second group of scales has been chosen to compare results in randomized trials.[9]

Scales that measure the impact of an acute attack include (1) QOL (Migraine-Specific Quality of Life Questionnaire [MQoLQ] and Quality of Life Questionnaire [MSQ Version 2.1]) and (2) headache impact and disability (Headache Needs Assessment [HANA] Survey). Scales that measure long-term impact are (1) QOL (Migraine-Specific Quality of Life [MSQOL] Scale), (2) headache impact (Headache Impact Test [HIT], Headache Impact Questionnaire [HimQ], and Henry Ford Hospital Disability Inventory [HDI]), and (3) migraine disability (Migraine Disability Assessment [MIDAS]).

Scales that Assess Quality of Life

QOL is influenced by environmental, economic, social health-related, spiritual, and political factors. The fundamental domains of instruments that measure QOL include physical, psychological, and social areas. Both generic and disease-specific measures have been used to measure QOL. The most commonly used generic scales are the Medical Outcomes Study (MOS) instrument, which includes the 20 item Short Form Health Survey (SF-20),[10] the SF-36, and the SF-12.[11] Other generic QOL scales used in headache studies include the Sickness Impact Profile,[12] the Nottingham Health Profile,[13] and the Psychological General Wellbeing Index.[14] The specific QOL scales for migraine fall into two broadly defined categories: those that measure QOL in a single migraine attack (MQoLQ and MSQ version 2.1) and those that measure the QOL over a period of weeks or months (MSQOL).

Migraine-Specific Quality-of-Life Questionnaire

The MQoLQ is a questionnaire that assesses the short-term decrements in QOL associated with acute migraine headache attacks.[15] This questionnaire evaluates QOL impairment in the 24 h period following the onset of a migraine headache. The questionnaire is self-administered and is completed quickly and easily. The MQoLQ consists of 15 items with five domains: (1) work functioning, (2) social functioning, (3) energy/vitality, (4) migraine headache symptoms, and (5) feelings and concerns. There are three items within each domain. The response option for each of the items is on a seven point scale, with one indicating maximum impairment of QOL and seven indicating no impairment. Each domain has a maximum score of 21 and a minimum score of three. The scores were compared between migraine-free and migraine periods. The construct validity of the questionnaire was established by showing that there are significant relationships between subjects' 24 h MQoLQ scores and other indices of clinical migraine headache such as headache severity, limitation of activity, number of associated migraine symptoms, global change in migraine symptoms, and migraine duration.[15] The ability of the MQoLQ to capture within-subject change in QOL was evaluated by comparing QOL scores during a "migraine-free" period with MQoLQ scores 24 h after migraine onset.[8] The MQoLQ should be applicable to all adults suffering from episodic migraine headaches. It was designed primarily for use in clinical trials to assess migraine management and to be responsive to subject changes in QOL in the 24 h following the onset of a migraine headache. The

• Box 38.1 International Headache Society Criteria (ICHD-3)

- Migraine
  - Migraine without aura
  - Migraine with aura
    - Migraine with typical aura
    - Migraine with brainstem aura
    - Hemiplegic migraine
    - Retinal migraine
  - Chronic migraine
  - Complications of migraine
- Status migrainosus
- Persistent aura without infarction
- Migrainous infarction
- Migraine aura triggered seizure
- Episodic syndromes that may be associated with migraine
- Tension-Type Headache
  - Infrequent episodic tension-type headache
  - Frequent episodic tension-type headache
  - Chronic tension-type headache
- Cluster Headache and Other Trigeminal Autonomic Cephalalgias
  - Cluster headache
  - Paroxysmal hemicrania
  - Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT)
  - Short-lasting unilateral neuralgiform headache attacks with cranial autonomic symptoms (SUNA)
  - Hemicrania continua
- Other Primary Headaches
  - Primary cough headache
  - Primary exercise headache
  - Primary headache associated with sexual activity
  - Primary thunderclap headache
  - Cold stimulus headache
  - External-pressure headache
  - Primary stabbing headache
  - Nummular headache
  - Hypnic headache
- New Daily Persistent Headache (NDPH)
- Secondary Headaches
  - Headache attributed to head and/or neck trauma
  - Headache attributed to cranial or cervical vascular disorders
  - Headache attributed to nonvascular intracranial disorders
  - Headache attributed to a substance or its withdrawal
  - Headache attributed to infection
  - Headache attributed to a disorder of homeostasis
  - Headache or facial pain attributed to a disorder of the cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structure
  - Headache attributed to a psychiatric disorder
  - Cranial neuralgias and central causes of facial pain

ICHD-3, International Classification of Headache Disorders, second edition.

MQoLQ assesses subjective wellbeing and daily ability to function, in addition to measuring the typical associated symptoms of migraine, such as nausea, photophobia/phonophobia, and head pain. The 24 h MQoLQ should not be used to measure global QOL between headache episodes.

Quality-of-Life Questionnaire (MSQ Version 2.1)

The MSQ is a disease-specific QOL instrument with three hypothesized scales; it has been developed, tested, and revised.[16] The MSQ (version 2.1) was structured similarly to older versions of the MSQ (versions 1.0 and 2.0). The revised 14 item MSQ (version 2.1) consists of seven items in the role-restrictive dimension that measure the degree to which performance of normal activities is limited by migraines, four items in the role-preventive dimension that measure the degree to which performance of normal activities is interrupted by migraines, and three items in the emotional function dimension that measure the emotional effects of migraine.[16] The MSQ dimensions had low to modest correlations with the two component scores of the SF-36 and were modestly to moderately correlated with migraine symptoms. The validation was structured in three separate analyses applied to 267 subjects.[17] The MSQ provides clinicians, researchers, and those who fund health care a measurement tool to assess health-related QOL. The questionnaire was designed to be completed quickly and easily in a self-administered form. This study suggested that the mean MSQ (version 2.1) scores six to 12 points higher (indicating better QOL).

Migraine-Specific Quality-of-Life Scale

The MSQOL is used to assess a migraine patient's QOL over a long period (average of three weeks). It is a valid and reliable self-administered measure and a useful tool in clinical migraine research.[18] The information that MSQOL provides can add important information about migraine's impact on QOL and the potential benefits of therapeutic interventions. This questionnaire has 25 items, with each question having four answers. The general format and scoring are one, very much; two, quite a lot; three, a little; and four, not at all. The total score is then transferred to a scale of zero to 100, with a higher number representing a better QOL. For the MSQOL, Cronbach's alpha was 0.92, suggesting that the items are tapping into a single concept. The MSQOL can provide valuable information on a migraineur's QOL and be a useful adjuvant measure when assessing long-term treatment outcomes.

Scales that Assess Headache Impact and Disability

Headache impairs physical, social, and emotional functioning, but a diagnosis cannot always be made despite the availability of helpful tools. One reason for this is poor patient-physician communication. If the impact that headaches are having on a person's life can be communicated adequately to the physician, the likelihood of appropriate management will increase.[19] Impact and disability instruments are scored differently and have different interpretations. Generally, the impact is scaled in a positive direction, with higher scores reflecting better QOL (i.e. lower impact). For disability measures, higher scores reflect a greater limitation of activity (i.e. higher impact). Measurement of headache-related disability, together with assessments of pain intensity, headache frequency, tiredness, alterations in mood, and cognition, can be used to assess the impact of migraine on sufferers' lives and on society.[20] The tools currently used for assessing headache impact are the HIT and HIT-6, HimQ, HANA Survey, and HDI or Henry Ford Hospital Questionnaire. These scales, when used properly, can improve communication between patients and physicians, assess migraine severity, and act as outcome measures to monitor treatment efficacy. Impact tools are also used, along with other clinical assessments, to produce an individualized treatment plan.[20] Disability measures assess impairment in role functioning (i.e. reduced ability to function in defined roles, such as

paid work).[6] The disability instruments used are the HDI and the MIDAS.

Headache Impact Test

The HIT is a tool that measures headache's impact on a person's ability to function on the job, at home, and in social situations. The HIT was developed by the psychometricians who developed the SF-36 health assessment. HIT was designed for greater accessibility (on the Internet at www.headachetest.com and www.amlhealthy.com and as a paper-based form known as HIT-6). HIT-6 is a practical test that consists of six questions. A patient can complete the test in less than 2 min. HIT-6 assesses disability over a four week period. The range of scores is 36 to 78. Higher scores signify the greater impact of disability. A score of 60 or higher indicates a severe impact (the headache stops family, work, school, or social activities), a score between 56 and 59 indicates a substantial impact, a score between 50 and 55 signifies some impact, and a score below 49 denotes no impact.[21] The availability of this test on the Internet, with feedback provided, makes it a useful tool to help headache sufferers understand the burden of their migraines and seek appropriate management.

Headache Impact Questionnaire

The HimQ measures pain and limitations in activity over a three month period. This instrument was the precursor to the MIDAS instrument (see disability scales). The HimQ score is derived from four frequency-based questions (i.e. number of headaches, missed days of work, missed days of chores, or missed days of non-work-related activity) and four summary measures of the average experience across headaches (i.e. average pain intensity and average reduced effectiveness when having a headache at work, during household chores, and in non-work-related activity).[22,23] This scale was validated after assessing the pain and limitations in activity in a population-based sample of 132 migraine headache sufferers enrolled in a 90 day daily-diary study who completed the HimQ at the end of the study. Previous studies of the validity of retrospective pain and disability reporting were mixed.[22,24–31] Study participants completed the HimQ in person and then completed daily diaries for 90 days. The HimQ was developed to identify headache sufferers who have the greatest need for medical care. Self-administered questionnaires can adequately capture information to rate pain severity.

Headache Needs Assessment Survey

The HANA questionnaire was designed to assess two dimensions (frequency and bothersomeness) of migraine's impact.[32] Seven issues related to living with migraine were used as ratings of frequency and bothersomeness. Validation studies were performed in a Web-based survey, a clinical trial responsiveness population, and a retest reliability population. Headache characteristics (e.g. frequency, severity, and treatment), demographic information, and the HDI were used for external validation. The HANA can be used in medical practice groups (e.g. headache centers, managed care groups) as a screening tool to detect potential problems. Scores from the scale are compared before and after treatment to determine the headache's impact. Primary care physicians could use the HANA to screen patients with a migraine for further evaluation. Once identified, those with severe migraines may be candidates for further evaluation and immediate treatment. The HANA has several advantages in that it can (1) select who should be treated, (2) increase productivity by adequately treating headaches, and (3) identify the need for aggressive treatment without the usual slow advancement through stepped-care algorithms. This brief, self-applied questionnaire may be a useful screening tool to evaluate migraine's impact. The two-dimensional approach to patient-reported QOL allows individuals to weigh the impact of both frequency and bothersomeness of chronic migraine (CM) on multiple aspects of daily life.

Henry Ford Hospital Disability Inventory

The HDI is useful in assessing the impact of headaches and its treatment on daily living.[33–36] It is a paper-and-pencil instrument that probes the functional and emotional effects of headaches on everyday life. The HDI is a 25 item headache disability inventory, with each item requiring a "yes" (four points), "sometimes" (two points), or "no" (zero points) response. Therefore a maximum score of 100 points reflects severe self-perceived headache disability. The scale is easy to complete and simple to score and interpret. The HDI has high internal consistency, reliability, and good content validity; the long-term (two month) test-retest stability of the HDI was robust.[33,34] The test-retest reliability for the beta-HDI was acceptable for the total score and functional and emotional subscale scores.[33] Scales of this nature help investigators understand headache's impact on everyday life. Therefore the HDI can be used to (1) assess the impact of headache on the patient's daily living, (2) monitor the effect of therapeutic intervention, and (3) plan for a global approach to coping with headache with the patient's involvement.

Migraine Disability Assessment Questionnaire

The MIDAS questionnaire (Fig. 38.1) was developed to measure headache-related disability and improve doctor–patient communication about the functional consequences of migraines. The questionnaire was based on five disability questions that focus on lost time in three domains: schoolwork or work for pay; household work or chores; and family, social, and leisure activities.[37] This scale can be used by physicians, nurses, pharmacists, and alternative practitioners. It is easy to complete and takes only a few minutes. The MIDAS questionnaire has demonstrated reliability,[38] as reported in two separate population-based studies, one in the United States and one in the United Kingdom, and validity by using a three month daily-diary study as the "gold standard."[39] Scores on the MIDAS are highly correlated with physician judgments about the severity of illness and the need for treatment.[40] This instrument is scored as follows: a score of 5–10 indicates little or no disability, 10–20 indicates moderate disability, and higher than 20 indicates severe disability. The MIDAS questionnaire is an important part of a package of educational, investigative, and therapeutic measures and could play a major role in improving the care of patients with migraines and other types of headaches.[20,41–48] A randomized, placebo-controlled trial showed that the MIDAS grade provides a basis for selecting initial treatment in stratified care.[49]

Migraine

Migraine is a chronic neurologic disease characterized by episodic attacks of headache and associated symptoms. "Migraine" is derived from the Greek word "hemicrania" (Galen ≈200 A.D).[50]

Instructions: Please answer the following questions about ALL your headaches you have had over the last three months. Write your answer in the box next to each question. Write zero if you did not do the activity in the last three months.

1 On how many days in the last three months did you miss work or school because of your headache? ☐☐

2 How many days in the last three months was your productivity at work or school reduced by half or more because of your headaches? (Do not include days you counted in question 1 where you missed work or school.) ☐☐

3 On how many days in the last three months did you not do household work or go to school because of your headache? ☐☐

4 How many days in the last three months was your productivity in household work reduced by half or more because of your headache? (Do not include days you counted in question three where you did not do household work.) ☐☐

5 On how many days in the last three months did you have a headache? (If a headache lasted more than 1 day, count each day.) ☐☐

Total days ☐☐

A On how many days in the last three months did you have a headache? (If a headache lasted more than one day, count each day.) ☐☐

B On a scale of 0-10, on average how painful were these headaches (where 0 = no pain at all and 10 = pain as bad as it can be). Once you have filled in the questionnaire, add up the total number of days from questions 1-5 (ignore A and B). ☐☐

Grading system for the MIDAS questionnaire:

Grade Definition	Score	
I	Little or no disability	0-5
II	Mild disability	6-10
III	Moderate disability	11-20
IV	Severe disability	21+

• **Figure 38.1** MIDAS questionnaire.[37]

The diagnosis is based on retrospective reporting of headache characteristics and associated symptoms.[51] The revised IHS diagnostic criteria for headache disorders[3] (ICHD-2) provide the criteria for a total of seven subtypes of migraine.[4]

Epidemiology

The prevalence of migraines is similar and stable in Western countries and the United States.[52] Three large-scale population-based studies have been conducted in the United States, one in 1989,[53,54] one in 1999,[55,56] and one in 2004.[57,58] The first American Migraine Study[53] found that the prevalence of migraine was 17.6% in women and 6% in men. Two follow-up studies, the American Migraine Study II and the American Migraine Prevalence and Prevention Study (AMPPS), provided results identical to the first, indicating that the prevalence of migraine has been stable in the United States, at least over the last 15 years.[58]

Before puberty, the prevalence of migraine is approximately 4%[58]; after puberty, it increases more rapidly in girls than in boys. It increases until approximately 40 years of age and then declines. Prevalence is lowest in Asian Americans, intermediate in African Americans, and highest in Caucasians.[6] In the United States, the prevalence of migraines decreases as household income increases.[6,53,56]

Migraines decrease the sufferers' QOL. The World Health Organization (WHO) ranks migraine among the world's most disabling medical illnesses.[59] Approximately 28 million Americans have severe, disabling migraine headaches.[55] Migraine's cost to employers is approximately $13 billion per year, and annual medical costs exceed $1 billion.[6] Instruments to quantify migraine disability include the MIDAS[39] and the HIT.[21]

Description of the Migraine Attack

The migraine attack can consist of premonitory, aura, headache, and resolution phases. Premonitory symptoms occur in 20% to 60% of migraineurs, hours to days before the onset of the headache. They may include psychological, neurologic, constitutional, or autonomic features, such as depression, cognitive dysfunction, and bouts of food craving.[60]

Aura

The migraine aura consists of focal neurologic symptoms that precede, accompany, or (rarely) follow an attack. Aura usually develops over a period of 5 to 20 min and lasts less than 60 min. The aura can be visual, sensory, or motor and may involve language or brainstem disturbances.[3] Headache usually follows within 60 min of the end of the aura. Patients can have multiple aura types: most patients with a sensory aura also have a visual aura.[61] Simple auras include scotomata (loss of vision), simple flashes (phosphenes), specks, geometric forms, and shimmering in the visual field. More complicated visual auras include teichopsia or fortification spectra (the characteristic aura of migraine), metamorphopsia, micropsia, macropsia, zoom vision, and mosaic vision. Paresthesias are often cheiro-aural: numbness starts in the hand, migrates up the arm, and jumps to involve the face, lips, and tongue.[51,62] Weakness is rare, occurs in association with sensory symptoms, and is unilateral.[63] Apraxia, aphasia, agnosia, states of altered consciousness associated with déjà vu or jamais vu, and elaborate dreamy, nightmarish, trance-like, or delirious states can occur.[60]

Headache Phase

The median migraine attack frequency is 1.5 per month.[53] The typical headache is unilateral, of gradual onset, throbbing (85%),[64] moderate to marked in severity, and aggravated by movement.[3] Pain may be bilateral (40%) or start on one side and become generalized. It lasts 4 to 72 h in adults and 2 to 48 h in children.[3]

Anorexia is common. Nausea occurs in almost 90% of patients, whereas vomiting occurs in about a third.[65] Sensory hypersensitivity results in patients seeking a dark, quiet room.[51,65] Blurry vision, nasal stuffiness, anorexia, hunger, tenesmus, diarrhea, abdominal cramps, polyuria, facial pallor, sensations of heat or cold, and sweating may occur. Depression, fatigue, anxiety, nervousness, irritability, and impairment of concentration are common. Symptom complexes may be generated by linked neuronal modules.[66]

Formal Diagnostic Criteria

The IHS subdivides migraine into migraine with aura (Box 38.2) and migraine without aura (Box 38.3).[4] To diagnose migraines without aura, five attacks are needed. No single feature is mandatory, but recurrent episodic attacks must be documented.[3] Migraine persisting for more than three days defines "status migrainosus."[3,4] Migraine occurring 15 or more days per month is called CM by the ICHD-3 (Box 38.4).[67]

• Box 38.2 Diagnostic Criteria for Migraine With Aura

A. At least two attacks fulfilling criteria B and C
B. One or more of the following fully reversible aura symptoms:
   1. visual
   2. sensory
   3. speech and/or language
   4. motor
   5. brainstem
   6. retinal
C. At least three of the following six characteristics:
   1. at least one aura symptom spreads gradually over ≥5 min
   2. two or more aura symptoms occur in succession
   3. each individual aura symptom lasts 5-60 min[1]
   4. at least one aura symptom is unilateral[2]
   5. at least one aura symptom is positive[3]
   6. the aura is accompanied, or followed within 60 min, by headache
D. Not better accounted for by another ICHD-3 diagnosis.

• Box 38.3 Diagnostic Criteria for Headache Without Aura

A. At least five attacks fulfilling criteria B to D
B. Headache attacks lasting 4 to 72 h and occurring less than 15 days/month (untreated or unsuccessfully treated)
C. Headache with at least two of the following characteristics:
   1. unilateral location
   2. pulsating quality
   3. moderate or severe intensity
   4. aggravated by or causing avoidance of routine physical activity (i.e. walking or climbing stairs)
D. During headaches, at least one of the following:
   1. nausea and/or vomiting
   2. photophobia and/or phonophobia
E. Not attributed to another disorder

• Box 38.4 Revised International Headache Society Criteria for Chronic Migraine

A. Headache on 15 or more days per month for at least three months and Fulfilling criteria B and C
B. Patient has had at least five attacks fulfilling criteria B to D for *migraine without aura* (see Box 38.3)
C. On eight or more days per month for at least three months, fulfilling any of the following:
   1. criteria C and D for 1.1 *Migraine without aura*
   2. criteria B and C for 1.2 *Migraine with aura*
   3. believed by the patient to be migraine at onset and relieved by a triptan or ergot derivative
D. Not better accounted for by another ICHD-3 diagnosis

Migraine with aura is subdivided into typical aura, prolonged aura, hemiplegic migraine, basilar-type migraine, and migraine with acute-onset aura. The IHS classification now allows the association of aura with other headache types. Prolonged aura lasts from 1 h to one week, and persistent aura lasts for more than one week (but resolves); if neuroimaging demonstrates a stroke, a migrainous infarction has occurred.

Migraine Variants

Basilar-type migraine aura is characterized by brainstem symptoms: ataxia, vertigo, tinnitus, diplopia, nausea and vomiting, nystagmus, dysarthria, bilateral paresthesia, or a change in the level of consciousness and cognition.[3] It should be considered when patients have paroxysmal brainstem disturbances. Some have suggested that hemiplegic migraines should be diagnosed if weakness is present.[63]

Ophthalmoplegic migraine is caused by idiopathic inflammatory neuritis.[68] There is an enhancement of the cisternal segment of the oculomotor nerve, followed by resolution over several weeks as the symptoms resolve.

Hemiplegic migraines can be sporadic or familial.[51] Attacks are frequently precipitated by a minor head injury.[63] Familial hemiplegic migraine (FHM) is an autosomal dominant, genetically heterogeneous disorder with variable penetration. FHM includes attacks of migraine without aura, migraine with typical aura, and episodes of prolonged aura, fever, meningismus, and impaired consciousness.[69] Headache may precede the hemiparesis or be absent. The onset of hemiparesis may be abrupt and simulate a stroke. In 20% of unselected FHM families, patients have cerebellar symptoms and signs (nystagmus, progressive ataxia). All have mutations in the *CACNA1A gene*.[70]

Treatment

Migraine varies widely in its frequency, severity, and impact on patients' QOL. A treatment plan should consider the patient's diagnosis, symptoms, and any coexistent or comorbid conditions, and the patient's expectations, needs, and goals.[71] Migraine treatment begins with making a diagnosis,[51] explaining it to the patient, and developing a treatment plan that considers any coincidental or comorbid conditions.[72] Comorbidity indicates an association between two disorders that is more than coincidental.[1]

Conditions that occur in migraineurs with a higher prevalence than would be expected include stroke, myocardial infarction, angina, patent foramen ovale (aura), epilepsy, Raynaud's syndrome, and affective disorders (depression, mania, anxiety, and panic disorder). Possible associations include essential tremor, mitral valve prolapse, and irritable bowel syndrome.

Pharmacologic treatment of migraine may be acute (abortive) or preventive (prophylactic), and patients with frequent, severe headaches often require both approaches. Acute treatment attempts to relieve or stop the progression of an attack or the pain and impairment once an attack has begun. It is appropriate for most attacks and should be used a maximum of two to three days per week. Preventive therapy is given, even in the absence of a headache, in an attempt to reduce the frequency, duration, or severity of attacks. Additional benefits include improving responsiveness to acute attack treatment, improving function, and reducing disability.

Treatment for Acute Migraine Headache

Acute treatment can be specific (ergots, triptans, gepants [small molecule calcitonin gene related peptide [CGRP] receptor antagonists], and lasmiditan [selective $5HT_{1F}$ selective agonist]) or nonspecific (analgesics and opioids). Non-specific medications control the pain of migraines and other pain disorders, whereas specific medications are effective for migraine (and certain other) headache attacks but are not useful for non-headache-related pain disorders. Specific treatments are effective for mild, moderate, and

severe migraine attacks.[73] Devices approved for acute migraine treatment include vagal nerve stimulation (VNS), Nerivio (conditioned pain modulation), and Cefaly (transcutaneous stimulation of the area above the nose).

The choice of treatment depends on attack severity and frequency, associated symptoms, coexistent disorders, previous treatment response, and the medication's efficacy and potential for overuse and adverse events (AEs). A non-oral route of administration and an antiemetic should be considered when severe nausea or vomiting is present.[74] Injections can provide rapid relief. Headaches can be stratified by severity and disability, using the MIDAS or the HIT. Analgesics are used for mild to moderate headaches.[74] Triptans, gepants, lasmiditan, and dihydroergotamine (DHE) are first-line drugs for severe attacks and less severe attacks that do not adequately respond to analgesics.[74] Patients with moderate or severe headaches and moderate or severe disability (based on the MIDAS) who were stratified to treatment with a triptan did better than patients given aspirin and metoclopramide.[75]

Early intervention prevents escalation and may increase efficacy.[76] Triptans can prevent the development of cutaneous allodynia, and the presence of cutaneous allodynia predicts triptans' effectiveness.[77] Before deciding that a drug is ineffective, at least two attacks should be treated with that modality. It may be necessary to add an adjuvant or change the dose, formulation, or route of administration. If the response is inadequate, the headache recurs, or AEs are bothersome, a change in medication may be needed. Limiting acute treatment to two to three days a week can prevent medication overuse headache (MOH). When headaches are very frequent, early intervention may not be appropriate.

All treatments occasionally fail. Therefore rescue medications (opioids, neuroleptics, and corticosteroids) are potentially needed. They provide reliable relief but often limit function because of sedation or other AEs.

Preventive Treatment

Preventive therapy is given in an attempt to reduce the frequency, duration, or severity of attacks. Additional benefits include improving responsiveness to acute attack treatment, improving function, and reducing disability. Preventive treatment may avert episodic migraine's progression to CM and result in reductions in healthcare costs. Silberstein and colleagues retrospectively analyzed resource utilization information in a large claims database. The addition of migraine preventive drug therapy to therapy that consisted of only an acute medication was effective in reducing resource consumption. When the six months after the initial preventive medication was compared with the six months preceding preventive therapy, office and other outpatient visits with a migraine diagnosis decreased by 51.1%, emergency department visits with a migraine diagnosis decreased by 81.8%, computed tomography (CT) scans with a migraine diagnosis decreased by 75.0%, magnetic resonance imaging (MRI) with a migraine diagnosis decreased by 88.2%, and other migraine medication dispensing decreased by 14.1%.[78]

Preventive medications reduce attack frequency, duration, and severity.[51,79] According to the United States Headache Consortium Guidelines,[80] as recently revised,[81] indications for preventive treatment include:

- recurring migraine that significantly interferes with the patient's QOL and daily routine despite acute treatment;
- failure of, contraindication to, or troublesome AEs from acute medications;
- acute medication overuse;
- very frequent headaches (>1/week) (risk for CM or medication overuse);
- patient preference; and
- special circumstances such as hemiplegic migraine; frequent, very long, or uncomfortable auras; or attacks with a risk for permanent neurologic injury.

Prevention is not being used to the extent that it should be. Results from the American Migraine Study I and II and the Philadelphia Phone Survey 2 demonstrated that migraine preventive therapy is underused: only 13% of all migraineurs currently use preventive therapy to control their attacks.[58] In the American Migraine Study II, 25% of all people with migraine, or more than seven million people, experienced more than three attacks per month, and 53% of those surveyed reported either having severe impairment because of their attacks or needing bed rest.[56] According to the AMPPS, 38.8% of patients with migraines should be considered for (13.1%) or offered (25.7%) migraine preventive therapy.[82]

Preventive medication groups include β-adrenergic blockers, anti-depressants, calcium channel antagonists, anti-convulsants, CGRP antagonists, and nonsteroidal anti-inflammatory drugs (NSAIDs). The choice is based on efficacy, AEs, and coexistent and comorbid conditions. The drug chosen is started at a low dose and increased slowly until therapeutic effects develop or the ceiling dose is reached. A full therapeutic trial may take two to six months. Acute headache medications should not be overused. Because of potential teratogenicity with some of these prophylactic medications, women of childbearing potential should be on adequate contraception.

Preventive treatment is often recommended for only six to nine months, but until now, no randomized, placebo-controlled trials have been performed to investigate migraine frequency after preventive treatment has been discontinued. Diener and associates[83] assessed 818 migraine patients who were treated with topiramate for six months to see the effects of discontinuation of topiramate. Patients received topiramate in a 26 week open-label phase. They were then randomly assigned to continue this dose or switch to a placebo for a 26 week, double-blind phase. The mean increase in the number of migraine days was greater in the placebo group (1.19 days in four weeks, 95% confidence interval [CI] = 0.71 to 1.66, $P < 0.0001$) than in the topiramate group (0.10, −0.36 to 0.56, $P = 0.57$). Patients in the placebo group had more days on acute medication than those in the topiramate group (mean difference between groups: −0.95, −1.49 to −0.41, $P = 0.0007$). Sustained benefit was reported after topiramate was discontinued, although the number of migraine days did increase. These findings suggest that patients should be treated for six months with the option to continue for 12 months. If headaches are well controlled, medication can be tapered and discontinued. Dose reduction may provide a better risk-to-benefit ratio.

Behavioral and psychological interventions used for prevention include relaxation training, thermal biofeedback combined with relaxation training, electromyography biofeedback, and cognitive behavior therapy.[84] Devices include gammaCore (non-invasive VNS), the Nerivio Migra device (non-invasive electronic device worn on the upper arm, which is operated through a mobile application and looks like a sports armband), and the Cefaly device (external trigeminal nerve stimulation device [e-TNS] placed on the forehead).

Coexistent diseases have important implications for treatment. In some instances, two or more conditions may be treated with a single drug. If individuals have more than one disease, certain categories of treatment may be relatively contraindicated.

The preventive medications with the best documented efficacy are divalproex, topiramate, and β-blockers, and the CGRP antagonists. The choice is based on a drug's proven efficacy, the physician's informed belief about medications not yet evaluated in controlled trials, the drug's AEs, the patient's preferences, the headache profile, and the presence or absence of coexisting disorders.[51] The drug chosen should have the best risk-to-benefit ratio for the individual patient and take advantage of the drug's side effect profile.[85,86] An underweight patient would be a candidate for one of the medications that commonly lead to weight gain, such as a tricyclic anti-depressant (TCA); in contrast, one would try to avoid these drugs and consider topiramate if the patient is overweight. Tertiary TCAs that have a sedating effect would be useful at bedtime for patients with insomnia. Older patients with cardiac disease or patients with significant hypotension may not be able to use TCAs, calcium channel blockers, or β-blockers but could use divalproex or topiramate. Athletic patients should use β-blockers with caution. Medications that can impair cognitive functioning should be avoided when patients are dependent on their faculties.[85,86]

Comorbid and coexistent diseases have important implications for treatment. The presence of a second illness provides therapeutic opportunities but also imposes certain therapeutic limitations. In some instances two or more conditions may be treated with a single drug. However, there are limitations to using a single medication to treat two illnesses. Giving a single medication may not treat two different conditions optimally: although one of the two conditions may be treated adequately, the second illness may require a higher or lower dose. Therefore the patient is at risk for the second illness not being treated adequately. Therapeutic independence may be needed should monotherapy fail. Avoiding drug interactions or increased AEs is a primary concern when using polypharmacy. For some patients, a single medication may adequately manage any comorbid conditions. However, this is likely to be the exception rather than the rule. Polytherapy may enable therapeutic adjustments based on the status of each illness. TCAs are often recommended for patients with migraines and depression.[87] However, appropriate management of depression often requires higher doses of TCAs, which may be associated with more AEs. A better approach might be to treat the depression with a selective serotonin reuptake inhibitor or selective serotonin-norepinephrine reuptake inhibitor and treat the migraine with an anti-convulsant. Migraine and epilepsy[88] may both be controlled with an antiepileptic drug, such as topiramate or divalproex sodium. Divalproex and topiramate are the drugs of choice for a patient with migraine and bipolar illness.[89,90] When individuals have more than one disease, certain categories of treatment may be relatively contraindicated. For example, β-blockers should be used with caution in a depressed migraineur, whereas TCAs or neuroleptics may lower the seizure threshold and should be used with caution in an epileptic migraineur.

Although monotherapy is preferred, it is sometimes necessary to combine preventive medications. Anti-depressants are often used with β-blockers or calcium channel blockers, and topiramate or divalproex sodium may be used in combination with any of these medications. Pascual and colleagues[91] found that combining a β-blocker and sodium valproate could lead to increased benefit in patients with migraines previously resistant to either drug alone. Fifty-two patients (43 women) with a history of episodic migraine with or without aura and previously unresponsive to β-blockers or sodium valproate monotherapy were treated with a combination of propranolol (or nadolol) and sodium valproate in an open-label fashion. Fifty-six percent had a greater than 50% reduction in migraine days. This open trial supports the practice of combination therapy. Controlled trials are needed to determine the true advantage of this combination treatment in patients with episodic migraine and CM.

With the advent of monoclonal antibodies against CGRP and its receptor, we have a class of medications with good safety tolerability and efficacy. The four anti-CGRP monoclonal antibodies (eptinezumab, erenumab, fremanezumab, and galcanezumab) are safe, effective, and approved to prevent episodic migraine, CM, and MOH.[92]

Summary

Migraine is an extremely common neurobiologic headache disorder that is caused by increased central nervous system excitability. It ranks among the world's most disabling medical illnesses. Diagnosis is based on the headache's characteristics and associated symptoms. The economic and societal impact of migraines is substantial. It affects the sufferers' QOL and impairs work, social activities, and family life. There are many acute and preventive migraine treatments in the market. Acute treatment is either specific (triptans and ergots) or non-specific (analgesics). Disabling migraines should be treated with triptans. Increased headache frequency is an indication for preventive treatment. Preventive treatment decreases migraine frequency and improves QOL. More treatments are being developed, which provides hope to the many sufferers whose migraines are still uncontrolled.

Chronic Daily Headache

Chronic daily headache (CDH) refers to headache disorders experienced very frequently (15 or more days per month), including those associated with medication overuse (MOH). CDH can be divided into primary and secondary varieties.[93] Primary CDH is not related to a structural or systemic illness. Population-based studies in the United States, Europe, and Asia suggest that 4% to 5% of the general population has primary CDH,[94–96] and that 0.5% has severe headaches daily.[97,98] In population samples, chronic tension-type headache (CTTH) is the leading cause of primary CDH.[99] CDH patients account for the greatest number of consultations in headache subspecialty practices.[100] They often overuse medication, which may play a role in initiating or sustaining the pattern of pain. Anxiety, depression, and other psychological disturbances may accompany the headaches.[100]

Once secondary headache (including MOH) has been excluded, frequent headache sufferers are subdivided into two groups based on headache duration. When the headache duration is less than 4 h, the differential diagnosis includes cluster headache, paroxysmal hemicrania, idiopathic stabbing headache, hypnic headache, and short-lasting unilateral neuralgiform headache with conjunctival injection and tearing (SUNCT syndrome). When headache duration is longer than 4 h, the major primary disorders to consider are CM (see Box 38.4), hemicrania continua (HC), CTTH (Box 38.5), and new daily persistent headache (NDPH).[100] CM, NDPH, and HC are primary CDH disorders that are now included in the second IHS classification.[4] Transformed migraine (TM) is similar to CM.[4]

CM (see Box 38.4) has been called TM.[101] Most patients with this disorder are women, 90% of whom have a history of migraines without aura. Patients often report a transformation process characterized by headaches that become more frequent

• Box 38.5 Diagnostic Criteria for Tension-Type Headache

Infrequent Episodic Tension-Type Headache (IHS Diagnostic Criteria)

A. At least 10 episodes of headache occurring on <1 day/month on average (<12 days/year) and fulfilling criteria B-D
B. Lasting from 30 min to seven days
C. At least two of the following four characteristics:
   1. bilateral location
   2. pressing or tightening (non-pulsating) quality
   3. mild or moderate intensity
   4. not aggravated by routine physical activity such as walking or climbing stairs
D. Both of the following:
   1. no nausea or vomiting
   2. no more than one of photophobia or phonophobia
E. Not better accounted for by another ICHD

Frequent Episodic Tension-Type Headache

A. At least 10 episodes of headache occurring on one to 14 days/month on average for >3 months (≥12 and <180 days/year) and fulfilling criteria B-D
B. Lasting from 30 min to seven days
C. At least two of the following four characteristics:
   1. bilateral location
   2. pressing or tightening (non-pulsating) quality
   3. mild or moderate intensity
   4. not aggravated by routine physical activity such as walking or climbing stairs
D. Both of the following:
   1. no nausea or vomiting
   2. no more than one of photophobia or phonophobia
E. Not better accounted for by another ICHD-3 diagnosis[1]

Chronic Tension-Type Headache (IHS Diagnostic Criteria)

A. Headache occurring on ≥15 days/month on average for >3 months (≥180 days/year), fulfilling criteria B-D
B. Lasting hours to days, or unremitting
C. At least two of the following four characteristics:
   1. bilateral location
   2. pressing or tightening (non-pulsating) quality
   3. mild or moderate intensity
   4. not aggravated by routine physical activity such as walking or climbing stairs
D. Both of the following:
   1. no more than one of photophobia, phonophobia, or mild nausea
   2. no moderate/severe nausea or vomiting
E. Not better accounted for by another ICHD-3 diagnosis

IHS, International Headache Society.

over months to years, with the associated symptoms of photophobia, phonophobia, and nausea becoming less severe and less frequent. A pattern of daily or nearly daily headaches often develops that phenomenologically resembles a mixture of tension-type headache (TTH) and migraine. That is, the pain is often mild to moderate and is not always associated with photophobia, phonophobia, or gastrointestinal features. Other characteristics of migraine, including aggravation by menstruation and other trigger factors, as well as unilaterality and gastrointestinal symptoms, may persist. Attacks of full-blown migraine superimposed on a background of less severe headaches occur in many patients. The term TM had been used to refer to this process. The term CM is now being used by the IHS, in part because a history of transformation is often missing.

Drug Overuse and Medication Overuse (Rebound) Headache (Box 38.6)

MOH was previously called rebound headache, drug-induced headache, and medication misuse headache. Patients with frequent headaches often overuse analgesics, opioids, ergotamine, and triptans. Although stopping the acute medication may result in the development of withdrawal symptoms and a period of increased headache, subsequent improvement in headache usually occurs.[102–106] Many primary CDH patients who were withdrawn from ergotamine and analgesics and given no further therapy no longer had daily headaches, although about 40% still had episodic migraine attacks.[96,107]

Definition and Classification of Medication Overuse Headache

In 1988 the IHS used the term "drug-induced headache" for MOH.[3] Overuse is now defined in terms of treatment days per month (see Box 38.6).

The epidemiology of MOH is uncertain. In European headache centers, 5% to 10% of patients have drug-induced headaches. One series of 3000 consecutive headache patients reported that 4.3% had drug-induced headaches.[108] Experience in the United Kingdom (P. Goadsby, personal communication) suggests that drug-associated headache is more common than the literature suggests. In American specialty headache clinics, as many as 80% of patients with primary CDH were reported to use analgesics on a daily or nearly daily basis.[96] Other headache clinics have reported a smaller percentage but a majority nonetheless.[109] In India, in contrast, medication overuse is less common.[110]

Diener and colleagues[111,112] summarized 29 studies that included 2612 patients with chronic MOH. Migraine was the primary headache in 65% of patients, TTH in 27%, and mixed or other headaches (i.e. cluster headache) in 8%. Women had more drug-induced headaches than men did (3.5:1; 1533 women, 442 men). This ratio is slightly higher than one would expect because of the usual gender differences in migraine frequency. The mean duration of primary headache was 20.4 years. The mean admitted time of frequent drug intake was 10.3 years in one study, and the mean duration of daily headache was 5.9 years. Results from headache diaries show that the number of tablets or suppositories taken daily averaged 4.9 (range, 0.25 to 25). Patients averaged 2.5 to 5.8 different pharmacologic components simultaneously (range, 1 to 14).[112]

• Box 38.6 Headache Attributed to Medication Overuse

A. Headache present on more than 15 days/month in a patient with a preexisting headache disorder
B. Regular overuse for more than three months of one or more acute or symptomatic treatment drugs as defined under subforms of 8.2.
   1. Ergotamine, triptans, opioids, *or* combination analgesic medications on 10 or more days/month regularly for more than three months
   2. Simple analgesics *or* any combination of ergotamine, triptans, analgesics, and opioids on 15 days/month or more regularly for more than three months without overuse of any single class alone
C. Not better accounted for by another ICHD-3 diagnosis

A prospective study of 98 patients investigated the pharmacologic features, such as the mean critical duration until the onset of MOH, mean critical monthly intake frequency, and mean critical monthly dosages, as well as the specific clinical features of MOH after the overuse of different acute headache drugs.[112] In this study, triptan overuse far outnumbered ergot overuse. This reflects the fact that despite the high cost, triptans have become widely used (and overused) and suggests that they are about to become the most important group causing MOH. Unlike patients who suffer from MOH following ergot or analgesic overuse, migraine patients (but not TTH patients) with triptan-induced headache did not describe the typical tension-type daily headache but rather a migraine-like daily headache (a unilateral, pulsating headache with autonomic disturbances) or a significant (and pure) increase in migraine attack frequency. Furthermore, the delay between frequent medication intake and the development of daily headache was the shortest with triptans (1.7 years), longer with ergots (2.7 years), and the longest with analgesics (4.8 years). Intake frequency (single dosages per month) was the lowest for triptans (18 single dosages per month), higher for ergots (37 single dosages per month), and the highest for analgesics (114 single dosages per month). Hence triptans cause a different spectrum of clinical features and result in MOH faster and with lower dosages than needed with other substance groups.[113]

In addition to exacerbating the headache disorder, drug overuse has other serious effects. Overuse of acute drugs may interfere with the effectiveness of preventive headache medications. Prolonged use of large amounts of medication may cause renal or hepatic toxicity in addition to tolerance, habituation, or dependence. Tolerance refers to decreased effectiveness of the same dose of an analgesic, which often leads to the use of higher doses to achieve the same degree of effectiveness. Habituation and dependence are, respectively, psychological and physical needs to repeatedly use drugs.

Epidemiology

In population-based surveys using the Silberstein-Lipton criteria, primary CDH was found to occur in 4.1% of Americans, 4.4% of Greeks, 3.9% of elderly Chinese, and 4.7% of Spaniards. Population-based estimates for the one year prevalence of CTTH are 1.7% in Ethiopia,[114] 3% in Denmark,[115] 2.2% in Spain,[116] 2.7% in China,[98] and 2.2% in the United States.[97]

Scher and coworkers,[97] using a validated computer-assisted telephone interview, ascertained the prevalence of CDH in 13,343 individuals aged 18 to 65 years in Baltimore County, Maryland. Those reporting 180 or more headaches per year were classified as having frequent headaches. Three mutually exclusive subtypes of frequent headache were identified: TM, CTTH, and unclassified frequent headache. The overall prevalence of CDH was 4.1% (5.0% in women, 2.8% in men; 1.8:1 female-to-male ratio). The prevalence was the highest in the lowest educational category for both men and women. More than half (52% of women, 56% of men) met the criteria for CTTH (2.2%), almost a third (33% of women, 25% of men) met the criteria for TM (1.3%), and the remainder (15% of women, 19% of men) were unclassified (0.6%). Overall, 30% of women and 25% of men who were frequent headache sufferers met the IHS criteria for migraine (with or without aura). Based on chance, migraine and CTTH would co-occur in 0.22% of the population; the fact that TM occurred in 1.3% of this population would suggest that their co-occurrence is more than random.

Castillo and associates[116] sampled 2252 subjects older than 14 years in Cantalucia, Spain. Overall, 4.7% had CDH. According to the criteria of Silberstein and colleagues,[100] none had HC, 0.1% had NDPH, 2.2% had CTTH, and 2.4% had TM. Nineteen percent of CTTH patients and 31.1% of TM patients had a history of acute medication overuse. Eight patients had a history of migraines without aura and now had primary CDH with the characteristics of TTH only. These headaches met the criteria for CM but could have been migraines and coincidental CTTH.

Wang and associates[98] looked at the characteristics of primary CDH in a population of elderly Chinese individuals (older than 65 years) in two townships in Kinmen Island. Seventy-seven percent of the eligible population (1533 of 2003) participated. Sixty patients (3.9%) had CDH. Significantly more women than men had primary CDH (5.6% and 1.8%, $P < 0.001$). Of the patients with primary CDH, 42 (70%) had CTTH (2.7%), 15 (25%) had CM (1%), and 3 (5%) had other CDH. Only 23% of patients had consulted a physician for headaches in the previous year.

Lu and colleagues[117] conducted a two-stage population-based headache survey of subjects 15 years or older in Taipei, Taiwan. Subjects who had experienced CDH in the past year were identified, interviewed, and followed up. CDH was defined as a headache frequency of greater than 15 days a month with a duration of more than 4 h per day. Of the 3377 participants, 108 (3.2%) fulfilled the criteria for CDH, with a higher prevalence in women (4.3%) than in men (1.9%). TM was the most common subtype (55%), followed by CTTH (44%). Thirty-four percent of the CDH subjects overused analgesics.

The gradual evolution of the definition of CM has resulted in varying conclusions drawn from prevalence studies. Two reviews that defined chronic headache as being present on 15 or more days per month estimated its global prevalence to be 3% to 4%.[118,119] A systematic review from 2010 focused on 12 worldwide, population-based incidence and prevalence studies that determined the rates of CM with either the Silberstein-Lipton criteria for TM[101,120,121] or the current ICHD-2R criteria for CM.[122] The prevalence of CM in these studies ranged from 0.0% to 5.1% (initial estimates of these rates were typically in the range of 1.4% to 2.2%) and varied by WHO-defined geographic regions, as well as by gender.[122] These estimates are imperfect because of the heterogeneity of definitions applied across studies and the lack of data from certain regions. Nevertheless, the target population is equally well defined by both the Silberstein-Lipton TM criteria and the ICHD-2R term CM; thus the data presented are likely to give a reasonably accurate global perspective. The prevalence of CM in this systematic review also suggests that this condition represents approximately half of all cases of chronic primary headache. In further population-based studies—HUNT 2 and HUNT 3, published in 2011—the age-adjusted prevalence of CM was consistently 0.5% throughout an 11 year follow-up period.[123]

Risk Factors (Box 38.7)

Wang and associates[98] ascertained that significant risk factors for CDH included analgesic overuse (odds ratio [OR] = 79), a history of migraine (OR = 6.6), and a Geriatric Depression Scale-Short Form score of eight or higher (OR = 2.6). At follow up, patients with persistent primary CDH had a significantly higher frequency of analgesic overuse (33% vs. 0%, $P = 0.03$) and major depression (38% vs. 0%, $P = 0.04$).

Granella and colleagues[124] found that risk factors associated with the evolution of migraine without aura into TM included head

• Box 38.7 Risk Factors for Chronic Daily Headache

High headache frequency
Female gender
Obesity (body mass index >30)
Snoring
Stressful life events
High caffeine consumption
Acute medication overuse
Depression
Head trauma
History of migraine
Less than a high school education

trauma (OR = 3.3), analgesic use with every attack (OR = 2.8), and long duration of oral contraceptive use.

Scher and coworkers[125] described factors that predict CDH onset and remission in an adult population. CDH was more common in women (OR = 1.65 [1.3 to 2.0]), those previously married (OR = 1.5 [1.2 to 1.9]), those with obesity (body mass index >30) (OR = 1.27 [1.0 to 1.7]), and those with less education. Obesity, high baseline headache frequency, high caffeine consumption, habitual daily snoring, and stressful life events were significantly associated with new-onset CDH.[126] Having less than a high school education was associated with a threefold increased risk for CDH (OR = 3.56 [2.3 to 5.6]).

Bigal and colleagues,[127] in a clinic-based study, looked for risk factors associated with CDH and its subtypes. TM without MOH (vs. episodic migraine) was associated with allergies, asthma, hypothyroidism, hypertension, and daily caffeine consumption.

Zwart and associates[128] examined the relationship between analgesic use at baseline and the subsequent risk for chronic pain (≥15 days/month) and analgesic overuse in a population-based study. In total, 32,067 adults reported the use of analgesics from 1984 to 1986 and at the follow up 11 years later (1995 to 1997). The risk ratios for chronic pain and analgesic overuse in the different diagnostic groups (i.e. migraine, nonmigrainous headache, and neck pain) were estimated in relation to analgesic consumption at baseline. Individuals who reported using analgesics daily or weekly at baseline had a significantly increased risk of having chronic pain at follow up. The risk was most evident for CM (relative risk [RR] = 13.3, 95% CI = 9.3 to 19.1), intermediate for chronic nonmigrainous headaches (RR = 6.2, 95% CI = 5.0 to 7.7), and lowest for chronic neck pain (RR = 2.4, 95% CI = 2.0 to 2.8). In subjects with chronic pain associated with analgesic overuse, the RR was 37.6 (95% CI = 21.3 to 66.4) for CM, 14.4 (95% CI = 10.4 to 19.9) for chronic nonmigrainous headaches, and 7.1 for chronic neck pain (95% CI = 5.5 to 9.2). The RR for chronic headache (migraine and nonmigrainous headache combined) associated with analgesic overuse was 19.6 (95% CI = 14.8 to 25.9) versus 3.1 (95% CI = 2.4 to 4.2) for those without overuse. Analgesic overuse strongly predicts chronic pain and chronic pain associated with analgesic overuse 11 years later, especially in those with CM.

Although data on the natural history of patients with CM are not available (because of the 10 to 15 year time scale that would be required for a population-based study of this condition), information from the American migraine prevalence and prevention (AMPP) on the clinical evolution of this condition was published in 2011.[129] Longitudinal data over a three year period were analyzed to determine rates of CM remission and to assess predictors of remission via logistic regression models. Three hundred and eighty-three individuals who had CM in 2005 were identified and evaluated in 2006 and 2007. Among individuals with CM at baseline, 52.7% continued to report this condition for at least one year of follow up. The study also found that 34% had persistent CM (defined as CM across all three years), whereas only 26% had remission of CM (defined as fewer than 10 headache days per month).[129] Over a two year period, the individuals with persistent CM demonstrated increased disability, whereas those with remission showed decreased disability. Predictors of remission included a lower baseline headache frequency (15 to 19 headache days per month vs. 25 to 31 headache days per month; OR = 0.29, 95% CI = 0.11 to 0.75) and the absence of allodynia (OR = 0.45, 95% CI = 0.23 to 0.89).

Treatment

Overview

Patients with CDH can be challenging to treat, especially when the disorder is complicated by medication overuse, comorbid psychiatric disease, low tolerance of frustration, and physical and emotional dependency.[95,130] We recommend the following steps. First, exclude secondary headache disorders. Second, diagnose the specific primary headache disorder (CM, CTTH, HC, or NDPH). Third, identify comorbid medical and psychiatric conditions and exacerbating factors, especially medication overuse. Limit acute medications (with the possible exception of long-acting NSAIDs). Patients should start taking preventive medication (to decrease reliance on acute medication), with the explicit understanding that the drugs may not become fully effective until medication overuse has been eliminated.[51] Some patients need to have their headache cycle terminated.[51] Patients need education and continuous support during this process. Outpatient detoxification options, including outpatient infusion in an ambulatory infusion unit, are available. If outpatient treatment proves difficult or is dangerous, hospitalization may be required.[93,131]

Two separate studies in Europe and the United States showed that topiramate at a dose of 100 mg daily was effective as preventive therapy for CM.[132,133] The key difference between the two studies was that patients were allowed to take acute rescue medication as usual in the European trial[132] but not in the United States trial.[133] Remarkably, the benefits of topiramate extended to the subgroup of patients who were overusing acute medications, as demonstrated by the significant reductions in mean monthly migraine days in this group versus the placebo group.

The Phase III Research Evaluating Migraine Prophylaxis Therapy (PREEMPT 1 and 2) multicenter randomized clinical trials were conducted to evaluate the efficacy and safety of botulinum toxin type A as prophylactic treatment in adults with CM. A total of 1384 patients with CM were enrolled across trials.[134–136] Patients were stratified into groups according to whether they were overusing acute headache medications at baseline and were randomly assigned in a 1:1 ratio to treatment with either botulinum toxin type A or placebo injections. A total dose of 155 units of botulinum toxin type A was administered to 31 sites in seven head and neck muscles.[134–136] The PREEMPT study results demonstrated significant improvement at the population level in multiple measures of headache symptoms and improvement in patients' functioning, vitality, psychological distress, and overall health-related QOL in response to treatment with botulinum toxin type A.

The four anti-CGRP monoclonal antibodies (eptinezumab, erenumab, fremanezumab, galcanezumab) are safe, effective, and

approved for the prevention of episodic migraine and CM even in the presence of MOH without acute medication withdrawal.

In some cases, CDH reverts to episodic headaches when preventive medication is initiated and acute medications are limited. In other cases, only moderate or no improvement may occur. Zeeberg and coworkers[137] described the treatment outcomes of patients withdrawn from medication overuse. They studied 337 outpatients in whom MOH was diagnosed and who were treated and discharged from the Danish Headache Centre in 2002 and 2003. A 46% decrease in headache frequency from the first visit to dismissal was noted ($P < 0.0001$). Patients with no improvement two months after complete drug withdrawal ($n = 88$) subsequently responded to pharmacologic or nonpharmacologic prophylaxis (or both) with a 26% decrease in headache frequency as measured from the end of withdrawal to dismissal. At dismissal, 47% of patients were being maintained on prophylaxis. In this population, about half of the MOH patients benefited from drug withdrawal alone.[137]

Prognosis

The AMPPS was published in 2011.[129] Among individuals with CM at baseline, 52.7% continued to report this condition for at least one year of follow up. The study also found that 34% had persistent CM (defined as CM across all three years), whereas only 26% had remission of CM (defined as fewer than 10 headache days per month).[138] Over two years, the individuals with persistent CM demonstrated increased disability, whereas those with remission showed decreased disability. Predictors of remission included a lower baseline headache frequency (15 to 19 headache days per month vs. 25 to 31 headache days per month; OR = 0.29, 95% CI = 0.11 to 0.75) and the absence of allodynia (OR = 0.45, 95% CI = 0.23 to 0.89). In addition, retrospective analysis suggests that there may be periods of stable drug consumption and periods of accelerated medication use. Patients treated aggressively generally improve. There are no literature reports of spontaneous improvement of rebound headache, although this may happen. We performed follow-up evaluations on 50 hospitalized primary CDH drug overuse patients who were treated with repetitive intravenous DHE and became headache free.[139] Once detoxified, treated, and discharged, most patients did not resume daily analgesic or ergotamine use. Seventy-two percent continued to show significant improvement at three months, and 87% continued to show significant improvement after two years. This would suggest at least 70% improvement at two years in the initial group (35 of 50) if allowance is made for patients lost to follow up.

Our two year success rate of 87% is consistent with the long-term success rates reported in the literature.[139] In a series of 22 papers published between 1975 and 1999, the success rate of withdrawal therapy (often accompanied by pharmacologic or behavioral intervention, or both) for patients overusing analgesics, ergotamine, or both was between 48% and 91%, with the rate being reported as 77% or higher in ten papers.[103,104,107,124,140–145]

Tension-Type Headache

Epidemiologic studies of the general population have shown that TTH is the most common type of headache, with a lifetime prevalence of 69% in men and 88% in women.[146] TTHs can begin at any age, but onset during adolescence or young adulthood is most common. The prognosis of patients with frequent episodic TTH (ETTH) and CTTH was favorable in a Danish follow up to a cross-sectional headache study that included 549 persons. Among 146 subjects with frequent ETTH and 15 with CTTH at baseline, 45% experienced infrequent or no TTH (remission), 39% had frequent ETTH, and 16% experienced CTTH (poor outcome) at follow up. A poor outcome was associated with baseline CTTH, coexisting migraine, sleeping problems, and single state.[147]

Clinical Features and Associated Disorders (see Box 38.5)

ETTH is now classified as either infrequent (<1 day/month or 12 days/year) or frequent (>1 but <15 days/month or >12 but <180 days/year). The IHS criteria for TTH require that patients experience at least 10 previous headaches, each lasting 30 min to seven days (median, 12 h) and with at least two of the following characteristics: a pressing or tightening (non-pulsating) quality, mild to moderate intensity, bilateral location, and no aggravation with physical activity. In addition, the patient should not have nausea or vomiting or a combination of photophobia and phonophobia. ETTH occurs less than 15 days per month, whereas CTTH occurs 15 or more days per month.[148] The pain is a dull, achy, nonpulsatile feeling of tightness, pressure, or constriction (vise-like or hatband-like), and it is usually mild to moderate, in contrast to the moderate to severe pain of migraine. The intensity increases with headache attack frequency.[149] Most patients have bilateral pain, but the location varies considerably within and between patients and can involve the frontal, temporal, occipital, or parietal regions, alone or in combination, and can change locations during an attack.[150] An occipital location is less common than a frontal or temporal location. Some patients have neck or jaw discomfort or have frank problems with their temporomandibular joint.[151,152]

The onset of TTH is gradual, often occurring after or during stress, and the pain is typically worse late in the day. There is no prodrome. The pain is usually a nagging, tight, or vise-like bilateral pressure that is located in the forehead, the temples, or the back of the head. It may radiate to the neck and shoulders. There are no associated autonomic or gastrointestinal symptoms except for occasional anorexia. The frequency of ETTH ranges from two to 12 days per month, with a median of six days per month. The headaches may be associated with menstruation.[148,153]

Twenty-five percent of TTH patients also have migraines.[154] What we call ETTH may be two distinct disorders. The first disorder may be a mild migraine. The second may be pure TTH that is not associated with other features of migraine (nausea, photophobia, or sensitivity to movement) or with attacks of severe migraine.[4] The fact that sumatriptan is effective for the TTH that migraineurs experience but not for the TTH that non-migraineurs experience supports this concept.[155]

Patients with ETTH are no different from controls in terms of stress, depression, anxiety, emotional conflicts, sleeping problems, and fatigue. Patients with CTTH are often depressed.[153]

Differential Diagnosis

Migraine is the headache disorder most frequently confused with TTH. Both can be bilateral, non-throbbing, and associated with anorexia. Migraine is more severe, often unilateral, and frequently associated with nausea. Idiopathic intracranial hypertension, brain tumor headache, chronic sphenoid sinusitis, and cervical, ocular, and temporomandibular disorders need to be considered.[148,153]

Evaluation

Most patients with a long history of unchanged ETTH do not require extensive evaluation if they have normal findings on neurologic examination and are otherwise healthy. Patients with CTTH should be evaluated with CT or MRI, even if the results of the general and neurologic examination are normal. A metabolic screen, complete blood count, electrolytes, and kidney and thyroid function studies are also appropriate.[153]

Management

TTH patients usually self-medicate with over-the-counter analgesics (aspirin, acetaminophen, NSAIDs), with or without caffeine. If these medications are not effective, prescription NSAIDs or combination analgesic preparations can be used. Narcotics and combination analgesics that contain sedatives or caffeine should be limited because overuse may cause dependence. Symptomatic medication overuse can cause ETTH to convert to CTTH. Patients with both migraine and TTH benefit from specific migraine medication, such as sumatriptan or DHE (see Boxes 38.5 and 38.6).[148,153]

Preventive therapy should be administered when a patient has frequent headaches that produce disability or may lead to symptomatic medication overuse. Medications used for the prevention of TTH include anti-depressants, β-blockers, and anti-convulsants. Anti-depressants, the medication of first choice, should be started at a low dose and increased slowly every three to seven days. An adequate trial period of at least one to two months must be allowed. The addition of biofeedback therapy or β-blocking agents may improve its therapeutic benefit.[148,153]

Prognosis and Future Perspectives

ETTH is a benign recurrent condition that usually improves with time. However, some patients progress to CTTH, especially when analgesic overuse is present. The prognosis of patients with CTTH is controversial because many studies include patients with more severe headaches and coexisting conditions, such as migraine and psychiatric disorders.

Cluster Headache and Other Trigeminal Autonomic Cephalgia (Box 38.8)

The short-lasting primary headache syndromes may be conveniently divided into those that exhibit marked autonomic activation and those without autonomic activation. This group includes cluster headache (episodic or chronic), paroxysmal hemicrania (episodic or chronic), and SUNCT syndrome.

Pathogenesis and Pathophysiology

The pathogenesis of cluster headache involves the trigeminovascular system, as demonstrated by a marked increase in the level of CGRP in the cranial venous circulation during attacks.[156] Activation of the parasympathetic system has been corroborated by the finding of dramatically elevated levels of vasoactive intestinal polypeptide during attacks[156] with robust ipsilateral autonomic features. Cluster events are probably related to alterations in the circadian pacemaker, which may be because of hypothalamic dysfunction. Attacks increase following the beginning and end of daylight saving time, and there is a loss of the circadian rhythm for blood pressure, temperature, and hormones, including prolactin, melatonin, cortisol, and β-endorphins. Evidence for the role of the hypothalamus in the pathogenesis of cluster headaches has come from functional and morphometric neuroimaging. May and colleagues demonstrated marked activation in the ipsilateral ventral hypothalamic gray matter during nitroglycerin-induced acute cluster headache attacks using positron emission tomography.[157] Neurogenic inflammation, dysfunction of the carotid body chemoreceptor, an imbalance in central parasympathetic and

• Box 38.8 Cluster Headache

A. At least five attacks fulfilling criteria B to D
B. Severe or very severe unilateral orbital, supraorbital, and/or temporal pain lasting 15 to 180 min f untreated
C. Either or both of the following:
   1. at least one of the following symptoms or signs, ipsilateral to the headache:
      a) conjunctival injection and/or lacrimation
      b) nasal congestion and/or rhinorrhea
      c) eyelid edema
      d) forehead and facial sweating
      e) miosis and/or ptosis
   2. a sense of restlessness or agitation
D. Occurring with a frequency between one every other day and 8 per day
E. Not better accounted for by another ICHD-3 diagnosis

Episodic Cluster Headache

A. Attacks fulfilling the above criteria A to E for *Cluster Headache*
B. At least two cluster periods lasting seven to 365 days and separated by pain-free remission periods of three months or longer

Chronic Cluster Headache

A. Attacks fulfilling criteria A to E for *Cluster Headache*
B. Attacks recurring longer than one year without remission periods or with remission periods lasting less than three months for at least one year

Paroxysmal Hemicrania

A. At least 20 attacks fulfilling criteria B to F
B. Attacks of severe unilateral orbital, supraorbital, or temporal pain lasting 2 to 30 min
C. Either or both of the following:
   1. at least one of the following symptoms or signs, ipsilateral to the headache:
      a) conjunctival injection and/or lacrimation
      b) nasal congestion and/or rhinorrhea
      c) eyelid edema
      d) forehead and facial sweating
      e) miosis and/or ptosis
   2. a sense of restlessness or agitation
D. Occurring with a frequency of >5 per day[1]
E. Prevented absolutely by therapeutic doses of indomethacin[2]
F. Not better accounted for by another ICHD-3 diagnosis.

Episodic Paroxysmal Hemicrania

A. Attacks fulfilling criteria A to F for *Paroxysmal Hemicrania*
B. At least two attack periods lasting seven to 365 days and separated by pain-free remission periods of three months or longer

Chronic Paroxysmal Hemicrania

A. Attacks fulfilling criteria A to F for *Paroxysmal Hemicrania*
B. Attacks recurring more than one year without remission periods or with remission periods lasting less than three months

sympathetic tone, and increased responsiveness to histamine have been proposed as the cause of cluster headache.[158]

Epidemiology and Risk Factors

With an incidence of 0.01% to 1.5% in various populations, the prevalence of cluster headaches is lower than that of migraine or TTH. Men have a higher prevalence than women, and African American patients have a higher prevalence than Caucasian patients. Recent evidence suggests a progressively decreasing male preponderance: the male-to-female ratio based on the year of onset in Manzoni's study[159] decreased from 6.2:1 in the 1960s to 2.1:1 in the 1990s.[160] A family history of cluster headache is rare. The most common form of cluster headache is an episodic cluster. The rarest form is chronic cluster headache without remissions, with only about 1% of patients suffering from this variety of cluster. Cluster headaches can begin at any age but generally commence in the late twenties. Cluster headaches rarely begin in childhood and develop in only about 10% of patients when they are in their sixties.[158,161]

Clinical Features and Associated Disorders

A. Severe or very severe unilateral orbital, supraorbital, and/or temporal pain lasting 15 to 180 min if untreated
B. Either or both of the following:

Patients with cluster headaches have multiple episodes of short-lived but severe, unilateral orbital, supraorbital, or temporal pain lasting 15 to 180 min if untreated, with either or both of the following: 1) at least one of the following symptoms or signs, ipsilateral to the headache: conjunctival injection and/or lacrimation; nasal congestion and/or rhinorrhea; eyelid edema; forehead and facial sweating; miosis and/or ptosis or 2) a sense of restlessness or agitation.

An episodic cluster consists of headache periods of one week to one year, with remission periods lasting at least 14 days, whereas a chronic cluster headache has either no remission periods or remissions that last less than 14 days.[158,161]

The pain of a cluster attack increases to excruciating levels rapidly (within 15 min). The attacks often occur at the same time each day and frequently awaken patients from sleep. If the condition is left untreated, the attacks usually last from 30 to 90 min, but they may last as long as 180 min. The pain is deep, constant, boring, piercing, or burning in nature and located in, behind, or around the eye. It may radiate to the forehead, temples, jaws, nostrils, ears, neck, or shoulders. During an attack, patients often feel agitated or restless and feel a need to isolate themselves and move around. Gastrointestinal symptoms are uncommon. A small subset of patients experience a typical migraine aura before a cluster headache attack.[162] Attack frequency varies from one every other day to eight per day, with cluster periods lasting a week to a year. Remissions between cluster periods generally last from six months to two years. Most patients have one or two cluster periods per year that last two to three months, with one to two attacks per day.[158]

Peptic ulcer disease is the only known associated medical disorder. Secondary cluster-like headaches may be because of structural lesions near the cavernous sinuses.[158,161]

Differential Diagnosis

The differential diagnosis of cluster headache includes chronic paroxysmal hemicrania, migraine, trigeminal neuralgia, temporal arteritis, pheochromocytoma, Raeder's paratrigeminal syndrome, Tolosa-Hunt syndrome, sinusitis, and glaucoma.[158] Raeder's syndrome has characteristics similar to cluster headaches. It may be associated with severe pain, unilateral and supraorbital distribution, and an associated partial Horner syndrome. It is distinct from cluster headache in that there are no distinct attacks, and the pain is constant.

Evaluation

No studies have addressed the need for testing in patients with cluster-like headaches. In most cases, a careful history is all that is needed to make the diagnosis. MRI of the head is justified only for atypical cases or those with abnormal findings on neurologic examination (except when the abnormality is Horner's syndrome).

Management

Patients with cluster headaches should avoid alcohol and nitroglycerin, but other dietary and drug restrictions have little effect. Pharmacologic treatment of cluster headaches is divided into acute and preventive therapy, and recommendations are based mainly on uncontrolled trials.[158,161] Because oral preparations are absorbed slowly, they are not recommended for acute attacks. Effective acute treatments that provide a rapid onset of action include oxygen, sumatriptan, DHE, and (perhaps) topical local anesthetics. Inhaled oxygen, 7 to 10 L/min for 10 min following the onset of the headache, is 70% effective and is often the first choice of treatment. Parenteral injections of sumatriptan or DHE provide significant relief to about 80% of patients. An intranasal local anesthetic provides relief for some patients.[158,161]

Most patients with cluster headaches require preventive treatment because each attack is too short in duration and too severe in intensity to treat with only acute medication. In addition, ergotamine, DHE, sumatriptan, and oxygen may just postpone rather than abort the attack. Preventive therapy for cluster headache includes ergotamine, calcium channel blockers, lithium, corticosteroids, divalproex, topiramate, melatonin, and galcanezumab for an episodic cluster. Occasionally, indomethacin is effective. If medical therapy fails, surgical intervention may be beneficial for psychologically stable patients with strictly unilateral chronic cluster headaches. The surgery consists of neuronal ablative procedures directed toward the sensory input of the trigeminal nerve and autonomic pathways and is effective in 75% of patients.[163] Gamma knife radiosurgery was reported to be effective in six medically recalcitrant cluster headache patients, but delayed radiation necrosis can occur.[164] Deep brain (hypothalamic) stimulation has been reported to be effective for intractable chronic cluster headaches.[165] Since cluster headache is a chronic headache disorder that may last a patient's lifetime, the prognosis is guarded. Drug therapy may help convert chronic headaches in some patients to episodic cluster headaches.[158]

Deep brain stimulation of the posterior hypothalamus (hDBS) and ONS along the greater occipital nerve have been introduced, and evidence is accumulating. Deep brain stimulation was developed based on findings of activation in the posterior part of the lateral portion of the hypothalamus.[166] Both hDBS and ONS have so far resulted in positive outcomes in patients with drug-resistant chronic cluster headache (about a 50% reduction in attacks), but long-term studies have revealed that a positive outcome, especially with ONS, may take a week to months of stimulation to be reached, thus pointing at long-term brain alterations in pain processing as a mechanism.[167–170] With both hDBS and ONS, the

pain and autonomic symptoms return to baseline levels when the stimulator is turned off.[167–170] So far, no predictors of treatment response have been found, and greater occipital nerve block does not predict ONS response.[171]

Sphenopalatine Ganglion Stimulation

In 2010 Ansarinia and coauthors described the acute effect of external electrical stimulation in eight patients with cluster headache, of whom four achieved complete freedom from pain, three achieved a reduction in pain, and one had no change.[172] More sophisticated systems have been developed, and an ongoing European multicenter study is now testing the effect of an electrode implanted directly in the sphenopalatine fossa very close to the sphenopalatine ganglion (SPG). The preliminary results are very promising; there appears to be a significant preventive effect in addition to an acute abortive effect. The side effects have been limited; therefore the therapy looks promising for severely affected chronic cluster headache patients. However, long-term studies are needed. Furthermore, important insight into the pathophysiology of cluster headaches and the mechanisms of SPG stimulation can be achieved.

Chronic Paroxysmal Hemicrania (see Box 38.8)

Chronic paroxysmal hemicrania resembles cluster headache in character but is distinguished by its dramatic responsiveness to indomethacin therapy. The pathophysiology of chronic paroxysmal hemicrania is unknown. The changes in intraocular pressure that occur during attacks suggest autonomic dysfunction, and the periodicity of this disorder suggests a central generator.[173] In contrast to cluster headache, chronic paroxysmal hemicrania is a rare disorder that affects women more than men (ratio of approximately 7:1). Its prevalence is approximately 2% that of cluster headache.[173]

Like patients with cluster headaches, those with chronic paroxysmal hemicrania have severe unilateral headaches associated with unilateral nasal stuffiness, lacrimation, conjunctival eye tearing, ptosis, and eyelid edema. Headaches average 13 min in duration and occur an average of 11 times per day. Occasionally, patients experience a continuous dull ache between attacks. Ten percent of patients can trigger attacks by flexing, rotating, or pressing the upper portion of the neck.[173] Typically, no remissions occur. Rarely, a patient has episodic paroxysmal hemicrania with remissions that last weeks or months. Patients may evolve from the episodic to the chronic form of the illness. By definition, chronic and episodic hemicranias are responsive to indomethacin. No other medical or psychiatric disorders have been associated with chronic paroxysmal hemicrania.[173]

Differential Diagnosis

The differential diagnosis of chronic paroxysmal hemicrania is similar to that for cluster headaches. In addition, patients with "jabs and jolts syndrome" occasionally resemble those with chronic paroxysmal hemicrania. A rare headache disorder called SUNCT syndrome should be considered, although these headaches are much shorter in duration (15 to 30 s) and occur much more frequently (many times per hour) than those of chronic paroxysmal hemicrania.

Evaluation

When evaluating a patient with chronic paroxysmal hemicrania, a trial of indomethacin is necessary to establish the diagnosis. Brain imaging with MRI or CT should be undertaken to exclude symptomatic causes of apparent chronic paroxysmal hemicrania. The treatment of choice is indomethacin (in a dose of up to 200 mg/day). Aspirin may also be beneficial, but it does not usually afford complete relief. Chronic paroxysmal hemicrania may last indefinitely, but the indomethacin requirement may be reduced over time. Temporary remissions and spontaneous cures have been described. Selective prostaglandin synthesis inhibitors, or indomethacin-like drugs without the gastrointestinal side effects of the current NSAIDs, are in development and may be beneficial.

Summary

Headache is a problem that has plagued humans since the beginning of recorded time. Headaches can severely interfere with daily functioning and productivity. Migraine is a chronic neurologic disease characterized by episodic attacks of headache and associated symptoms. The migraine attack can consist of premonitory, aura, headache, and resolution phases. The IHS subdivides migraine into migraine with aura and migraine without aura. Migraine varies widely in its frequency, severity, and impact on patients' QOL. Pharmacologic treatment of migraine may be acute (abortive) or preventive (prophylactic), and patients with frequent, severe headaches often require both approaches. CDH refers to headache disorders experienced very frequently (15 or more days per month), including headaches associated with medication overuse. The major primary disorders to consider are CM, HC, CTTH, and NDPH. MOH was previously called rebound headache, drug-induced headache, and medication misuse headache. Patients with frequent headaches often overuse analgesics, opioids, ergotamine, and triptans. Patients with CDH can be difficult to treat. First, secondary headache disorders should be excluded; second, the specific primary headache disorder should be diagnosed; and third, comorbid medical and psychiatric conditions should be identified. Acute medications should be limited. Patients should start taking preventive medication, with the explicit understanding that the drugs may not become fully effective until medication overuse has been eliminated. TTH is the most common type of headache, with a lifetime prevalence of 69% in men and 88% in women. ETTH is now classified as either infrequent (<1 day/month or 12 days/year) or frequent (>1 but <15 days/month or >12 but <180 days/year). Patients with TTH usually self-medicate with over-the-counter analgesics, with or without caffeine. Preventive therapy should be administered when a patient has frequent headaches that produce disability or may lead to symptomatic medication overuse. Cluster headache and other trigeminal cephalgias are short-lasting primary headache syndromes that may be conveniently divided into those that exhibit marked autonomic activation and those without autonomic activation. This group includes cluster headache, paroxysmal hemicrania, and SUNCT syndrome. Patients with cluster headaches have multiple short-lived but severe unilateral, orbital, supraorbital, or temporal pain episodes. Chronic paroxysmal hemicrania resembles cluster headache in character but is distinguished by its dramatic responsiveness to indomethacin therapy.

Key Points

- Headaches are one of the most common reasons patients see their doctors, and besides the pain involved, they can severely interfere with daily functioning, QOL, and productivity.
- WHO ranks migraine among the world's most disabling medical illnesses, and approximately 28 million Americans have severe, disabling migraine headaches.
- Migraine attacks can consist of premonitory, aura, headache, and resolution phases. Premonitory symptoms occur in 20% to 60% of migraineurs, hours to days before the onset of the headache. They may include psychological, neurologic, constitutional, or autonomic features, such as depression, cognitive dysfunction, and bouts of food craving.
- There are many acute and preventive migraine treatments in the market. Acute treatment is either specific (triptans and ergots) or non-specific (analgesics). Preventive treatment decreases migraine frequency and improves QOL.
- CDH refers to headache disorders experienced very frequently (15 or more days per month), including those associated with medication overuse (MOH).
- Patients with frequent headaches often overuse analgesics, opioids, ergotamine, and triptans. Although stopping the acute medication may result in the development of withdrawal symptoms and a period of increased headache, subsequent improvement in headache usually occurs.
- ETTH is a benign recurrent condition that usually improves with time. However, some patients progress to CTTH, especially when analgesic overuse is present.
- Patients with cluster headaches have multiple episodes of short-lived but severe, unilateral orbital, supraorbital, or temporal pain with conjunctival injection and/or lacrimation; nasal congestion and/or rhinorrhea; eyelid edema; forehead and facial sweating; miosis and/or ptosis; or a sense of restlessness or agitation.
- Most patients with cluster headaches require preventive treatment, which can include ergotamine, calcium channel blockers, lithium, corticosteroids, divalproex, topiramate, melatonin, and galcanezumab.
- If medical therapy fails completely for cluster headache, surgical intervention consisting of neuronal ablative procedures directed toward the sensory input of the trigeminal nerve and autonomic pathways may be considered and is effective in 75% of patients.

Cervicogenic Headache, Post-meningeal Puncture Headache, and Spontaneous Intracranial Hypotension

LORI-ANN EDWARDS, LOUISE HILLEN, DEEPTI AGARWAL, DOST KHAN, REDA TOLBA

CERVICOGENIC HEADACHE

Definition

The International Headache Society (IHS) defines cervicogenic headache as "Headache caused by a disorder of the cervical spine and its component bony, disc and/or soft tissue elements, usually but not invariably accompanied by neck pain."[1]

Epidemiology

The incidence of cervicogenic headache is 2% when using the IHS criteria[2] and up to 4% when using the Cervicogenic Headache International Study Group (CHISG) criteria.[3] Furthermore, in studies conducted using the CHISG criteria for diagnosis, cervicogenic headaches were 66% more common in women.[4] It encompasses 17.7% of all severe headaches. Epidemiologic studies are limited because of the wide variation in the diagnostic criteria. Cervicogenic headaches represent 25% of headache cases seen in pain management clinics.

Pathophysiology

The pathogenesis of cervicogenic headaches can be explained by the overlap between the first three cervical nerves, the trigeminal nucleus, and the cervical plexus. This is illustrated in Fig. 39.1. The first three cervical nerves supply other structures, such as the upper cervical synovial joints and muscles, the dura mater of the upper spinal cord and posterior cranial fossa, and the intervertebral discs.[5] The nociceptive afferents from the first three cervical nerves overlap with the second-order neurons that also receive afferents from the trigeminal nerve through the trigeminal nerve spinal tract. This overlap occurs in the trigeminocervical nucleus and allows for referral of cervical pain to the occipital and auricular regions as well as frontal, parietal, and orbital regions because of trigeminal afferents.[6] The trapezius, sternocleidomastoid, and splenius capitis are also innervated by the cervical nerves, and trigger points within these muscles can cause cervicogenic headaches.[7] This is because nociceptive afferents from these muscles also converge with the trigeminocervical nucleus.[4]

Summary of Cervical Nerve Anatomy[5]

First Cervical Nerve
Second Cervical Nerve
Third Cervical Nerve

Diagnostic Criteria

Cervicogenic headaches can be diagnosed based on clinical symptoms that meet the criteria or diagnostic block.

A. Clinical Diagnosis

Table 39.1 describes the clinical criteria put forth by the CHISG for the diagnosis of cervicogenic headache.[8] In Table 39.2, the IHS International Classification of Headache Disorders 3 diagnostic criteria are described.[9]

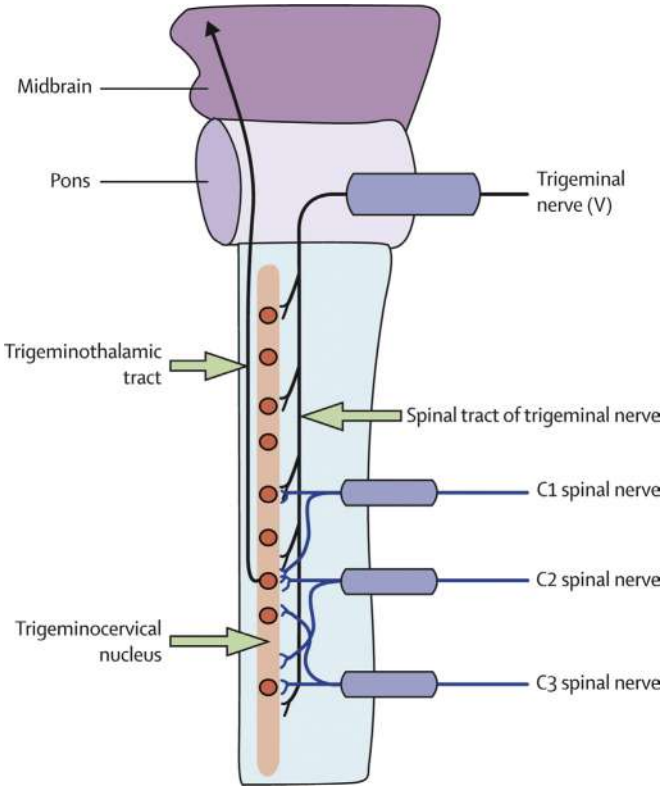
B. Diagnostic Block

While clinical diagnostic criteria help diagnose cervicogenic headaches, a true diagnostic block can completely relieve headaches. It can be used to confirm the diagnosis of cervicogenic headache, rather than relying on clinical diagnosis alone. The third occipital nerve block can be used to diagnose pain arising from C2–C3 zygapophysial joint disease and is performed under fluoroscopic guidance. Patients who obtain complete relief of their headache after controlled blocks of the third occipital nerve can be treated successfully by radiofrequency neurotomy of the nerve.[10]

Diagnostic medial branch block (MBB) of C3 and C4 can also be performed together with a third occipital nerve block to help with the associated component of neck pain. The techniques for C3 and C4 MBB and third occipital nerve block are described in detail under interventional management of cervicogenic headache.[10]

Differential Diagnosis

Serious conditions should be ruled out in the presence of alarming features or red flags. Red flags include fever and chills, age >50 years, history of cancer, night pain leading to awakening, and weight loss. Special attention should be paid to high-risk patients, such as immunocompromised individuals, as they are more susceptible to more serious conditions, such as infections. The differential diagnosis includes:



• **Figure 39.1** Nociceptive afferents of the trigeminal and upper three cervical spinal nerves converge onto second-order neurons in the trigeminocervical nucleus in the upper cervical spinal cord. This convergence mediates the referral of pain signals from the neck to regions of the head innervated by cervical nerves or the trigeminal nerve. (Reprinted with permission from Elsevier. Bogduk N, Govind J. Cervicogenic headache: an assessment of the evidence on clinical diagnosis, invasive tests, and treatment. *Lancet Neurol* 2009;8:959–968.)

Internal Carotid or Vertebral Artery Dissection

- The vertebral and internal carotid arteries are innervated by the cervical nerves, and dissection of these vessels can result in headaches.[7]
- May have stroke-like symptoms within one to three weeks.[6]
- Treatment with cervical manipulation can be fatal.[6]

Tumor in the Posterior Fossa, Arnold Chiari Formation

- The dura mater in the posterior cranial fossa is supplied by the sinuvertebral nerves C1–3[5].

Herniated Cervical Vertebral Disc

- The C3 vertebral branch supplies the intervertebral discs of C2/C3. Discogenic pain may be an underlying cause.

Spinal Nerve Compression or Tumor, Intramedullary or Extramedullary Spinal Tumor

- The dura mater of the upper cervical spinal cord is supplied by the sinuvertebral nerves C1–3[5].

Occipital Neuralgia

- Greater occipital nerve entrapment.
- The greater occipital nerve can be entrapped in its course between the obliquis capitis inferior and the semispinalis capitis. This is a commonly accepted cause of cervicogenic headaches resulting from occipital neuralgia.[7]

C2 Nerve Lesions

- Nerve-vessel compression on the C2 nerve root.
- This nerve runs across the capsule of the lateral atlantoaxial joint, and its roots are covered in the dura mater and a plexus of the epiradicular veins. Inflammatory lesions of the joint and lesions of the dura or surrounding vessels may result in compression of this nerve.[5] C2 neuralgia is characterized by intermittent and lancinating pain, unlike cervicogenic headache, because of C2/C3 facet disease, which is a constant and dull ache in nature.

Migraines and Tension-Type Headaches

- Cervicogenic headaches can be differentiated from migraine and tension-type headaches. These include:
  - Side-locked pain.

TABLE 39.1 Cervicogenic Headache International Study Group (CHISG) criteria

Major Symptoms	Pain Characteristics	Other Important Criteria	Minor Symptoms and Signs
Unilateral pain	Non-clustering episodes	Female sex	Autonomic symptoms and signs
Symptoms and signs of neck involvement*	Varying duration	Head or neck trauma	Dizziness
	Moderate, non-throbbing, non-excruciating	Pain abolished by C2 or major occipital nerve	Phonophobia and Photophobia
	Starting in the neck and spreading to the oculo-frontotemporal region		Difficulty swallowing

*a) Provocation of attacks
i) Pain triggered by neck movement; ii) pain elicited by external pressure over the ipsilateral upper, posterior neck, or occipital region.
b) Reduced range of motion of the cervical spine
c) Ipsilateral neck, shoulder, and arm pain of a rather vague, non-radicular nature
Both major criteria must be present for diagnosis: unilateral pain with at least one sign or symptom of neck involvement. Other important criteria strongly support this diagnosis.
Adapted from Sjaastad O, Fredriksen TA, Pfaffenrath V. Cervicogenic headache: diagnostic criteria. *Headache.* 1990;30(11):725–726.

TABLE 39.2 IHS International Classification of Headache Disorders 3 Diagnostic Criteria

A. Headache fulfilling criterion C.
B. Clinical and/or imaging evidence of a disorder or lesion within the cervical spine or soft tissues of the neck.
C. Evidence of causation demonstrated by at least two of the following:
   - Headache developed in a temporal relation to the onset of cervical disorder or appearance of the lesion
   - Headache significantly improved or resolved in parallel with improvement in or resolution of cervical disorders or lesions
   - Cervical range of motion is reduced
   - Headache is made significantly worse by provocative maneuvers
   - Headache was not explained by any other International Classification of Headache Disorders, 3rd edition (ICHD-3).
D. Headache abolished following diagnostic blockade of a cervical structure or its nerve supply

Adapted from the Headache Classification Committee of the International Headache Society. The international classification of headache disorders, third Edition. *Cephalalgia.* 2018;38(1):1–211.

- Can be elicited by digital pressure on neck muscles and by head movement.
- Radiation of pain in a posterior-to-anterior radiation fashion.
- Lesser degree of nausea, vomiting, photophobia, and phonophobia.[9,11]
- Not throbbing and no side shifts, unlike migraine headaches.
- Lack of response to ergotamine and triptans, unlike migraine headaches.

Investigations

A full history and physical examination are necessary for the diagnosis of cervicogenic headache. History should include:

- History of trauma (e.g. whiplash injury) or cervical disease.
- The presence of associated neurologic symptoms or stroke-like symptoms (may indicate more serious diagnoses).

Physical examination should include the range of motion of the neck and attempt to produce a typical headache with head movement or head positioning. There should be a reasonable suspicion of cervicogenic headache prior to imaging studies. Imaging modalities, such as ultrasound, computed tomography (CT), and magnetic resonance imaging, may be helpful. Ultrasound may detect entrapment of the occipital nerve in occipital neuralgia. However, user variability affects reliability. CT imaging can be used to identify the bony pathology of the cervical spine. MRI is the modality of choice because it can visualize the bony pathology, soft tissue, and nerves of the cervical spine. Overall, it is important to remember that the imaging findings were not diagnostic. There should be a temporal relationship between positive findings and headaches to prove causation.

Treatment

Non-pharmacologic Treatment

Although there have been no controlled studies proving the efficacy of non-pharmacologic methods in the treatment of cervicogenic headaches, the potential benefits should still be considered.[11]

- Massage
- Cold compress
- Physical therapy, including manual therapy
  - Exercises to improve posture
  - Cranio-cervical exercises
- Transcutaneous electrical nerve stimulation therapy
- Biofeedback/relaxation therapy
- Psychotherapy

Pharmacologic Treatment

- Tricyclic anti-depressants (TCAs)
- Antiepileptic drugs[12]
  - Gabapentin
  - Carbamazepine
  - Divalproex sodium
  - Topiramate
- Serotonin and norepinephrine re-uptake inhibitors (SNRIs)
  - Venlafaxine
  - Duloxetine
- Muscle relaxants
- Nonsteroidal anti-inflammatory drugs (can be topical or enteral)[12]
  - Non-selective cyclo-oxygenase inhibitors
  - Cyclo-oxygenase-2 selective inhibitors
- Topical local anesthetics

Interventional Minimally Invasive Procedures

Cervical Facet MBB and Radiofrequency Ablation (RFA)[12]

Pain mediated by cervical facet joints can be diagnosed using a cervical MBB. Local anesthetics, with or without steroids, can be used. Patients who experience relief from this block tend to respond favorably to RFA.

Once it has been proven that the headaches are relieved by diagnostic anesthetic blockade of a specific medial branch nerve, radiofrequency ablation can be performed to provide longer-lasting relief. This is primarily used to treat cervicogenic headaches arising from the C2–C3 zygapophysial joint, whose nerve supply is via the third occipital nerve.[5] RFA of C3 and C4 medial branches can also be performed in the same setting to help with concomitant neck pain.

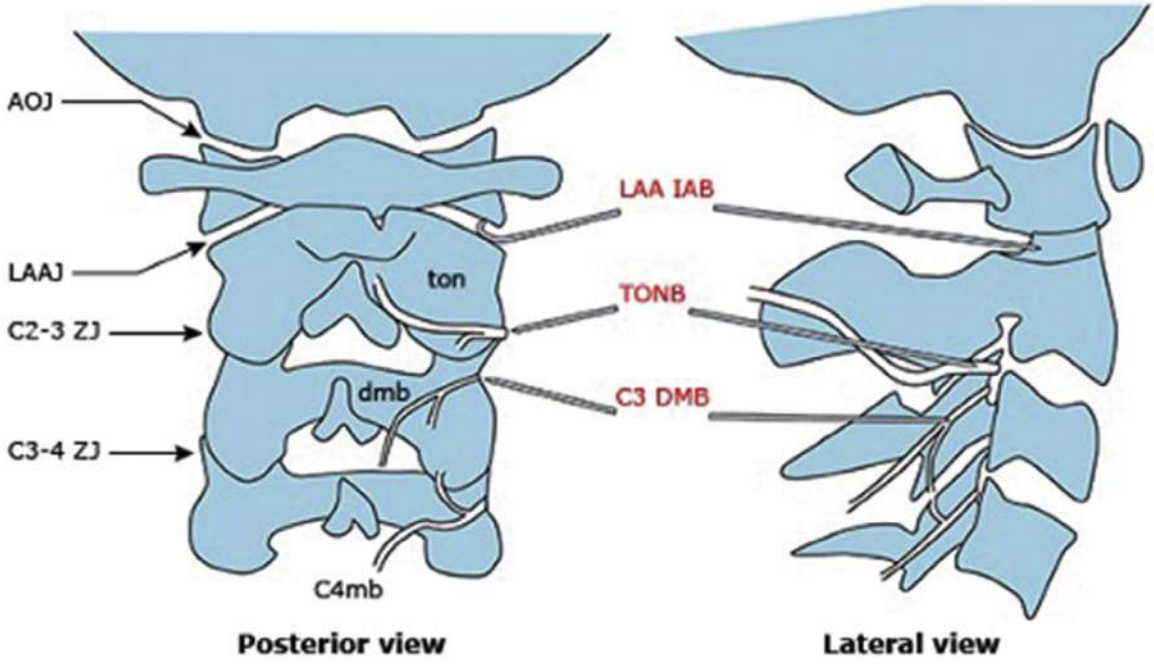
Technical Note for Cervical Facet MBB and RFA

In the posterior approach, the patient was placed in the prone position, and the facet column was identified using anterior and posterior pillar views. The needle was aimed at the "waist" of the articular pillars. A lateral view can confirm optimal positioning. The target is the middle of the articular pillars of the target vertebra.[13] The target for the third occipital nerve is the inferior aspect of C2–C3.[14] This is because the nerve usually travels along the C2–C3 joint just opposite to the center of the superior articular process of C3.[10] This is illustrated in Fig. 39.2, and the fluoroscopic images in Figs 39.3 and 39.4 highlight the needle placement targets.

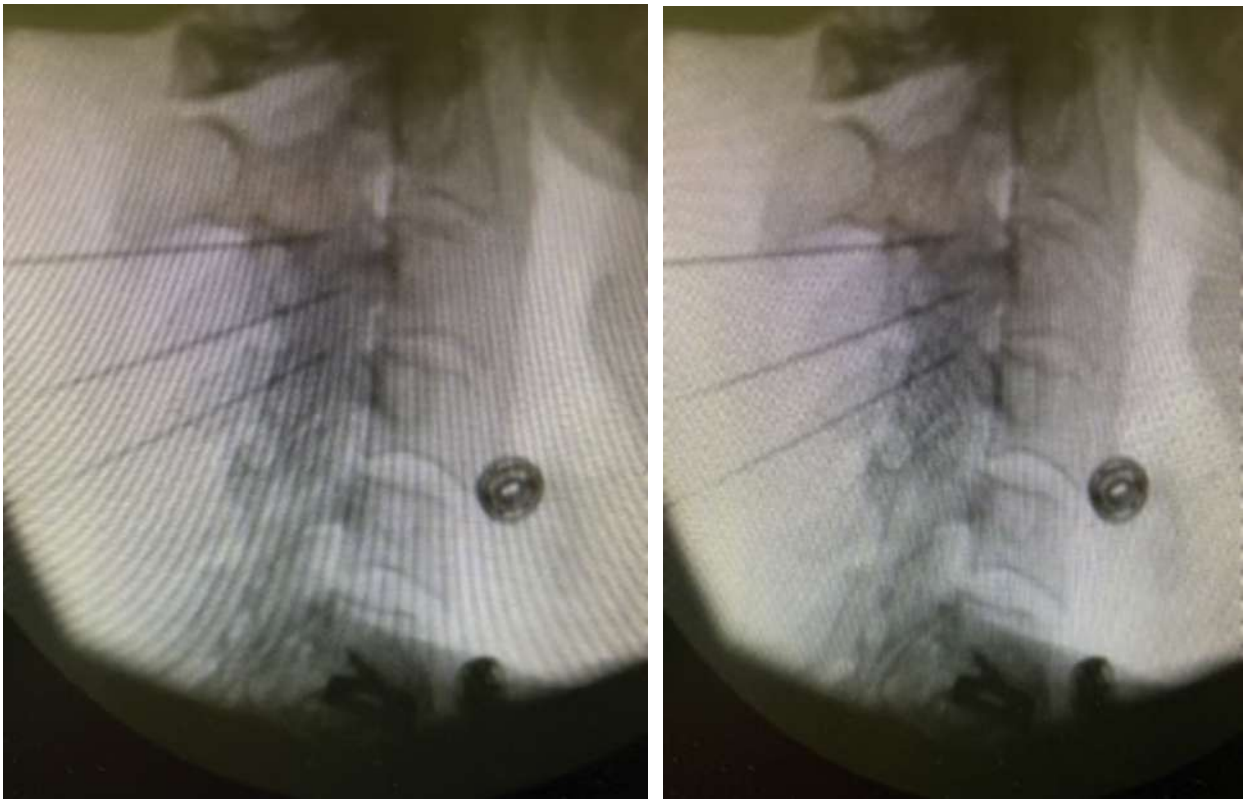
This procedure can also be performed when the patient is in a lateral position. Special precautions should be taken to ensure that the articular pillars are well superimposed, and fluoroscopy shows a true lateral image. This helps avoid faulty needle placement, which can result in spinal cord injury.

Other Interventions

- Trigger point injections (TPIs)



• **Figure 39.2** "Posterior and lateral views of the upper cervical spine, showing the leading articular sources of cervicogenic headache, the related nerves, and where needles are placed for diagnostic blocks of these structures. The red labels and needles point to target sites for diagnostic blocks." *AOJ,* Atlantooccipital joint; *C3 DMB,* C3 deep medial branch block; *C4mb,* medial branch of the C4 dorsal ramus; *dmb,* deep medial branch of the C3 dorsal ramus; *LAA IAB,* intra-articular block of the lateral atlantoaxial joint; *LAAJ,* lateral atlantoaxial joint; *ton,* third occipital nerve; *TONB,* third occipital nerve block; *ZJ,* zygapophysial joint. (Reprinted with permission from Elsevier. Bogduk N, Govind J. Cervicogenic headache: an assessment of the evidence on clinical diagnosis, invasive tests, and treatment. *Lancet Neurol* 2009;8:959–968.)



• **Figure 39.3** Fluoroscopic image showing the lateral view used for needle placement for the third occipital nerve and medial branch of C3 and C4 RFA. Note that the needle target for the third occipital nerve is at the middle of the C2–C3 joint. For C3–C4, the needle target is at the middle of the articular pillars.

• **Figure 39.4** Fluoroscopic image showing the anterior-posterior view used for needle placement during the third occipital nerve and medial branch of C3, C4, and C5 RFA.

It is not uncommon to have underlying myofascial pain and muscle spasms over the trapezius and cervical paraspinal muscles. Trigger point injections cause relaxation of muscle spasms, which may lead to pain relief,[11] and can help with the pain associated with myofascial pain triggers.

- Occipital nerve block[11]

The block of the greater occipital nerve in the occipital nerve entrapment can be effective in treating occipital neuralgia. The block can be performed using anatomic landmarks or ultrasound guidance. Local anesthetics can be injected with or without steroids. It can provide transient benefits in most patients, although some patients experience relief for an extended period of up to several months. If the block provides short-term relief, radiofrequency ablation using a pulsed technique or other techniques such as cryoablation can be considered for prolonged pain relief.

- Botulinum toxin[12]

Botulinum toxins can be injected into the pericranial and cervical muscles, which can potentially cause pain relief, although the Food and Drug Administration does not approve them. Further clinical studies are required to confirm its efficacy.

Surgical Treatment

Surgical intervention requires weighing the risk of worsening pain post-intervention, with the possible benefits of the procedure. There must be strong evidence of a treatable pathology on imaging and a history of pain refractory to all other treatment modalities.[12] Surgical procedures, such as neurectomy, dorsal rhizotomy, microvascular decompressing, nerve exploration and release, and joint fusion, can be considered a last resort, depending on the pathology suspected.

Efficacy of Non-pharmacologic Treatment

Generally, studies regarding the efficacy of non-pharmacologic treatment modalities have shown the greatest effect when the modes of treatment are combined. Further evidence suggests that control of cervicogenic headaches is considerable in those undergoing exercise and physical therapy programs.[13,14] Furthermore, in a randomized control trial conducted by Jull et al., long term reduction in cervicogenic headache frequency and intensity was shown to be statistically significant in those who underwent manipulative therapy and specific exercise.[15]

Efficacy of Pharmacologic Treatment and Interventional Procedures

At present, evidence of the efficacy of any pharmacologic treatment for cervicogenic headache is lacking. Therapeutic blocks of the occipital nerves have proven short term relief of symptoms, and repeated injections can lead to long term relief. Facet blocks were found to provide some acute pain relief but were less likely to have sustained benefits.[11] Overall, there is a paucity of randomized control studies that support the efficacy of interventional procedures for the treatment of cervicogenic headache.

Summary

Cervicogenic headache encompasses pain resulting from cervical spine disorders. This type of headache is more common in women and accounts for 25% of the headaches seen in chronic pain clinics. The pathogenesis of cervicogenic headaches can be explained by the overlap between the first three cervical nerves, the trigeminal nucleus, and the cervical plexus. Diagnosis can be made clinically using CHISG or HIS criteria or with relief of symptoms after a diagnostic block. History and physical examination are important for diagnosis, and more life-threatening causes should be ruled out. CT and MRI can be employed. However, this was not diagnostic. Imaging can be used to determine the presence of cervical disease. A temporal relationship is required to prove causation. Treatment can be non-pharmacologic, including massage, physical therapy, transcutaneous electrical nerve stimulation therapy, and psychotherapy. Interventional treatments such as radiofrequency ablation can be curative in patients who have complete pain relief after a diagnostic block. Surgical intervention, such as neurectomy and dorsal rhizotomy, requires weighing the risk of worsening pain post-intervention with the possible benefits of the procedure.

POST-MENINGEAL PUNCTURE HEADACHE

Louise Hillen, Deepti Agarwal

Post-Meningeal Puncture Headache

The first post-meningeal puncture headache (PMPH), also known as postdural puncture headache, was first described by August Bier in 1898 when he experienced a positional headache after undergoing a spinal anesthetic performed by his research assistant. He hypothesized that his headache was because of a loss of cerebrospinal fluid (CSF) during the spinal procedure.[16] PMPH is most commonly seen in obstetric patients following neuraxial procedures but can also be seen following interventional pain and

diagnostic lumbar puncture procedures. PMPH is a term used to describe an orthostatic bilateral headache following a meningeal puncture, and many argue that it should be termed as "meningeal puncture headache." The headache is always bilateral and is typically frontal or occipital in location.[17] Patients often present with neck stiffness, nausea, and vomiting. Other associated symptoms include vision changes (photophobia and diplopia) and auditory changes (tinnitus and hypoacusia).

Headache most commonly presents 24–48 h following a dural puncture and within 72 h in 90% of cases. However, it can occur 5–12 days after the dural puncture.[18,19] The headache generally resolves within seven days but, in rare cases, can persist for months after the initial complaint.[20] If the postural component of the headache is absent, other etiologies should be considered.[17] A PMPH can be severe and incapacitating and can greatly interfere with a parturient patient's ability to care for and bond with her newborn.[21] Among patients diagnosed with a PMPH, 39% experience at least one week of difficulty performing daily living activities.[22] PMPH can cause an increased incidence of chronic headaches, cranial nerve palsies, permanent disability, and reversible cerebral vasoconstriction syndrome.[17] Given the increase in healthcare costs and patient discomfort, prompt identification and treatment of PMPH is necessary.

Pathophysiology

Although the exact mechanism of PMPH is not fully understood, the onset of a headache is thought to be bimodal, resulting from leakage of CSF from the intrathecal space causing mechanical traction and from a reflexive cerebral vasodilation in accordance with the Monro-Kellie doctrine.[17] Both of which are caused by a disruption in the meninges that allows for leakage of CSF at a rate greater than CSF production. The average CSF volume in adults was 150 mL. It is constantly restored by the choroid plexus at a rate of 0.35 mL/min, creating 500 mL of CSF a day.[20] The absolute amount of CSF leakage is not necessarily correlated with the onset of a headache.[23] While some patients may develop a headache with small amounts of CSF leak, others may not develop a headache even with larger volumes of CSF loss. A loss of just 10% of CSF is thought to be sufficient to cause PMPH.[24]

The Monro-Kellie doctrine is a theory that the sum of the volumes of the brain, which includes CSF and intracranial blood, must remain constant. To maintain a constant intracranial volume, compensatory vasodilation of intracranial vessels occurs when CSF volume loss occurs. The increase in blood volume due to cerebral vasodilation activates the trigeminovascular system, leading to pain similar to that of migraine. The trigeminothalamic tract delivers signals to the thalamus and refers to pain to the ophthalmic branch and the first three cervical roots. Evidence of the Monro-Kellie doctrine is thickened meninges secondary to dural venous dilation observed on MRI in patients with PMPH.[25]

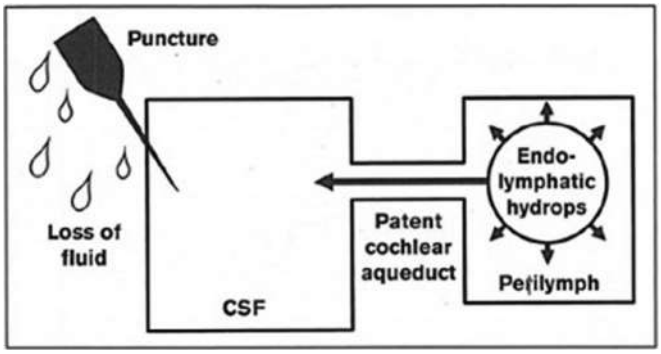
Secondary causes of PMPH are likely due to the relative CSF hypotension. CSF loss leads to a lower hydrostatic pressure, causing a loss of buoyant support and allowing the brain to sag while in the upright position.[26] The higher the level of the meningeal puncture, the less hydrostatic pressure at the puncture site. This explains why cervical meningeal punctures are much less associated with PMPH than lumbar punctures. Uncompensated CSF loss leads to a decrease in the subarachnoid pressure. The normal CSF opening pressure in the horizontal position is 70–180 mmH_20.[12] An opening pressure of 60 mmH_20, defined as CSF hypotension, is often present in PMPH but is not consistently correlated with the presence of symptoms.[27]

Although the absolute volume of CSF loss does not correlate with a PMPH, a sudden loss of CSF volume and a change in pressure between the inside and outside of the intracranial venous structures are thought to result in venous dilation.[28] Furthermore, a sudden loss of CSF results in a downward pull on pain-sensitive structures (dura, bridging veins, cranial nerves, venous sinus) when the patient is in an upright position.[28] This is exacerbated by a redistribution of CSF downward toward the spinal dural sac, worsening the stretch and tension on the meninges, intracranial vessels, and nerves. This theory is supported by radiographic evidence of downward displacement of intracranial structures following a PMPH.[25] Traction on the bridging veins can lead to a tear in the dura, potentially causing a subdural hemorrhage.[29] A cohort study of over 26 million deliveries suggests a small but statistically significant increased risk of diagnosis of intracranial subdural hematoma in obstetric patients with PMPH.[30]

CSF hypotension and the resulting traction often result in cranial nerve palsies (Table 39.3). The abducens nerve (CN VI) is most frequently affected because of its acute angulation near the point of fixation of the cranium and the petrous bone, resulting in increased traction.[31,32] Diplopia often occurs due to abducens nerve traction and subsequent paralysis of the lateral rectus muscle of the eye. Permanent vision damage is rare, and diplopia typically resolves within two weeks to eight months.[33] The facial nerve (CN VII) is also frequently affected and can result in paralysis of facial muscles, disruption of lacrimal and salivary gland function, and loss of taste in the anterior two-thirds of the tongue.[31] Changes in hearing can occur because of the effects on the vestibulocochlear nerve (CN VIII). A cochlear aqueduct connects the perilymphatic space to the CSF-filled subarachnoid space. CSF pressure changes are transmitted to the perilymphatic space (Fig. 39.5).[34] A loss of CSF pressure through a patent cochlear aqueduct can lead to perilymphatic hypotonia and endolymphatic hydrops, resulting in low-frequency hearing loss and tinnitus.[35] The ophthalmic branch

TABLE 39.3 Commonly Affected Cranial Nerves in Post-meningeal Puncture Headaches

Cranial Nerve	Symptomatology
Trigeminal Nerve (CN V) • Ophthalmic Branch (V1) • Maxillary Branch (V2) • Mandibular Branch (V3)	• Frontal pain • Sensory changes to all three branches, without motor involvement • Tongue numbness
Abducens Nerve (CN VI)	• Ocular abnormalities • Double vision • Deviated gaze because of lateral rectus muscle weakness • Photophobia
Facial Nerve (CN VII)	• Paralysis of the facial nerve • Loss of taste to anterior 2/3 of tongue • Interruption of lacrimal and salivary gland function
Vestibulocochlear (CN VIII)	• Changes in hearing • Low frequency hearing loss • Tinnitus
Vagus Nerve (CN X)	• Nausea and vomiting because of chemoreceptor triggering in the medulla • Occipital and posterior fossa pain



• **Figure 39.5** Mechanism of hearing loss and tinnitus after meningeal puncture. (From Michel, Olaf, and Tilman Brusis. Hearing loss as a sequel of lumbar puncture. *Ann Otol Rhinol Laryngol.* 1992;101(5):390–394.)

(V1) of the trigeminal nerve (CN V) innervates the bridging veins and dura and refers to pain in the frontal region. Vagus nerve (CN X) traction can also be responsible for nausea and vomiting due to stimulation of the chemoreceptor regions in the medulla. The vagus nerve also refers to pain in the posterior fossa and occipital regions. Traction of the upper cervical nerves can also manifest as shoulder stiffness and occipital and cervical pain. Rare case reports have suggested optic nerve (CN II) and trochlear nerve (CN IV) involvement (please refer to Table 39.3 for a summary).[31]

The Role of Arachnoid Matter in the Pathogenesis of CSF Leak

The dura mater is roughly 400 μm thick and comprises fibers distributed in a random organization of roughly 80 concentric layers called dural laminas.[36] The dural layer is elastic in nature compared with the more structured arachnoid membrane, and has the primary purpose of acting as a barrier to limit the escape of CSF fluid. Electron microscopy has demonstrated that tight junctions are present in the outer layer of the arachnoid, similar to that of the capillary endothelium of the brain, whereas the dura does not contain tight junctions.[37] This supports the concept that a puncture in the arachnoid mater, a typically impermeable layer that prevents the spread of CSF, rather than a puncture in the dura, is the primary cause of PMPH.

Dura Mater and Response to Trauma

Following neurosurgery, dura mater closure and healing are vital to prevent CSF leakage and infection. If the dural gaps are small, conservative management can be the treatment of choice. However, larger dural gaps necessitate direct repair or via the application of synthetic or biologic graft materials. It was first thought that fibroblastic proliferation from the edge of the dural tear facilitated dural closure.[38] In 1959 Keener showed that fibroblastic proliferation surrounding blood clots and tissue of the pia and arachnoid mater helped promote dural closure.[38] Therefore only minimal trauma to the dural layers and adjacent tissue would likely not promote substantial dural healing.

Diagnosis

The third edition of the International Classification of Headache Disorders defines a diagnosis of PMPH as a headache that occurs within five days of a dural puncture and resolves spontaneously within 14 days or with the closure of the epidural leak with an autologous epidural lumbar patch.[39] The period in which the headache develops is debatable and can occur within one–12 days of insult to the meninges. Headaches must fulfill the criteria that symptoms are attributed to low CSF pressure, which is an orthostatic headache accompanied by neck pain, changes in hearing, sunlight sensitivity, nausea, or vomiting.[39] The orthostatic nature of the headache means that symptoms significantly worsen with standing or sitting and improve after moving in a supine position. Prior editions of the International Classification of Headache Disorder criteria included a postural headache occurring within 15 min in the upright position and resolving within 15 min in the supine position. The headache improved once the CSF pressure returned to normal. Brain imaging may show brain sagging or pachymeningeal enhancement. Spine MRI may be notable for extradural CSF.[39]

It is important to rule out other causes of headaches. Further evaluation is needed if the headache is constant, unilateral, or presents with new-onset nausea or vomiting. Neurologic consultation and further diagnostic imaging are warranted in patients with altered mental status, seizures, or sensory/motor deficits. The differential diagnosis of a headache that develops or does not meet the classic diagnostic criteria of PMPH includes intracerebral hemorrhage, cerebral venous thrombosis, infection, eclampsia, caffeine withdrawal, and subdural hematoma.[40,41]

Incidence and Risk Factors

The incidence of PMPH ranges vastly from 1%–63%, and varies based on the patient characteristics, technique used, and needle size and design.[42] A trial by Vandam and Dripps in 1956 followed 10,098 spinal anesthetics and found an 11% incidence of PMPH, of which 0.4% were associated with ocular difficulties and 0.4% with auditory difficulties.[43] The greatest incidence of PMPH occurred in patients in the third and fourth decade of life and was twice as common in women (14%) than men (7%).[43] In a study of 27,064 obstetric patients undergoing a neuraxial procedure, 142 developed a post-dural puncture headache.[44] Eight of these were described as atypical, meaning the postural component of the headache did not exist despite other associated symptoms and improvement with an epidural blood patch (EBP).[44] Choi et al. found that the highest risk group of patients is the obstetric population, in which 1.7% of parturients will experience PMPH following spinal anesthesia with a 27-gauge Whitacre needle.[45] The incidence of accidental dural puncture with epidural placement is around 1.5%, with over half of these patients developing PMPH.[45]

Medicolegal analysis of outpatient procedures from 2009–2017 showed that interlaminar epidural injections at both the cervical and lumbar levels were most commonly associated with claims of unintentional dural puncture.[46] Among 10,000 fluoroscopic-guided interlaminar epidural injections, the incidence of inadvertent dural puncture was 0.5% overall, 1% in the cervical region, 1.3% in the thoracic region, and 0.8% in the lumbar region.[47] The incidence of PMPH in these patients was not followed.[47] The incidence of PMPH following intrathecal drug delivery systems is approximately 23%.[48] While most of these patients' symptoms were self-limited and resolved with conservative management, 21% of patients required an EBP or fibrin glue patch procedure.[48]

Patient risk factors for the development of PMPH include female sex, age (third to fourth decade of life), pregnancy, history of headaches, preexisting CSF hypotension, and low body mass index. Although the physiology resulting in the disparity among

genders is not fully understood, a large meta-analysis concluded that compared to males, nonpregnant females have double the risk of developing a PMPH.[49] Young age is also thought to be an independent risk factor for the development of a PMPH, possibly because the dura is more elastic and has a higher likelihood of maintaining a patent dural opening than the less elastic dura in older patients.[50] A medical history of PMPH and headaches prior to the procedure is also associated with an increased risk of PMPH after dural puncture.[51] Obesity is protective against the development of a PMPH because the increased epidural pressure decreases the gradient across the dural puncture, allowing less CSF to leak.[52] An increased abdominal pressure may also help seal a defect in the dura and decrease CSF loss.[52]

Modifiable risk factors for PMPH include the number of attempts and needle design, size, shape, and bevel direction. Spinal needles can be designed with cutting bevels, such as the Quincke-type, or as a pencil point, such as the Whitacre-type and Sprotte.[53] A systematic review of 25 randomized controlled trials comparing cutting and pencil point needles concluded that pencil point (non-cutting) needles had a much lower rate and incidence of PMPH and subsequent need for EBP.[54] The risk of PMPH following a puncture with a 20 to 22- gauge cutting needle is ~36%, compared to ~2% with a 22-gauge non-cutting needle.[55] The risk of PMPH is directly correlated to the diameter of the needle used, with smaller gauge needles having a lower incidence. Most unintentional dural punctures occur during epidural placement with a 17- or 18-gauge Tuohy cutting needle. Angle et al. found reduced CSF leakage with a 20-gauge Tuohy compared to a 17-gauge.[56] similarly, a cadaver study showed a six-fold greater mean CSF leak when using a 22-gauge needle compared to a 25-gauge needle.[57] Cutting needles have an increased rate of PMPH, likely because of its potential to cut dural fibers, whereas a pencil point blunt tip divides but does not disturb the continuity of the dural fibers.[57] Electron microscopy revealed that a blunt tip could cause an irregular hole in the dura, whereas a clean hole is produced by a cutting needle.[55] The irregular hole in the dura may promote an inflammatory reaction that promotes healing and hole closure.

Electron microscopy studies have shown that dural fibers are collagen and lack a specific orientation, whereas the arachnoid mater cells are oriented parallel to the long axis of the spinal cord. The orientation in which the bevel is directed compared to the dural fibers has been proposed to affect the amount of CSF leakage and subsequent headache risk. *In vitro* studies by Cruickshank and Thompson showed that fluid loss was not reduced when the bevel of the needle was aligned parallel to the longitudinal direction of the fibers. However, 22-gauge Whitacre point needles produced less fluid loss than a 22-gauge Quincke point needle inserted across the fibers, suggesting that the leakage rate was related to needle design, not to the alignment of a bevel point.[58] In contrast, a five study meta-analysis demonstrated that insertion of a beveled or cutting needle oriented parallel to the long axis of the spinal cord is associated with a statistically significant decrease in the incidence of PMPH than that inserted perpendicularly.[59] Norris et al. compared epidural catheter placement in two groups: one in which the bevel of the Tuohy was parallel to the dural fibers and one in which the Touhy was perpendicular to the long axis of the spinal cord. There was a similar rate of unintentional dural puncture. However, the intensity of PMPH was much lower in the parallel orientation group, requiring fewer EBPs.[60]

Proceduralist characteristics may also play a role in the development of PMPHs. There is a higher incidence of PMPH after a diagnostic dural puncture performed by a neurologist or neuroradiologist, likely because of the higher gauge needles required and possibly because of less experience in performing the procedure.[61] In a prospective study of 80 adult patients, the incidence of PMPH following a diagnostic lumbar puncture was 33%.[62] Diagnostic lumbar punctures often require a 20- or 22-gauge needle to measure opening pressure and obtain CSF over a brief period. If needles are less than 22 gauge, the collection of just 2 mL of CSF can take at least 6 min, and measuring the opening pressure can be very challenging.

Prevention

As mentioned before, PMPH prevention depends on needle characteristics and, probably, bevel orientation during dural puncture. Using the smallest pencil point needle parallel to the longitudinal access of the spinal cord will help decrease the incidence of PMPH. It is controversial whether the placement of an intrathecal catheter after an unintentional dural puncture during epidural placement can reduce the risk of PMPH. Many of the available studies are retrospective in design and cannot be randomized. Ayad et al. found a reduction in the incidence of PMPH from 81%–31% if an intrathecal catheter was placed but removed immediately after delivery, and an incidence of 3% if the catheter was left in for 24 h post accidental dural puncture.[63] In 173 patients who had an accidental dural puncture, 73 had an intrathecal catheter placed that remained in situ for 36–48 h, resulting in a 36% incidence of PMPH. This is compared to a 59% incidence in 99 patients who had an epidural catheter placed at a different level or just a single shot spinal administered through the Tuohy needle itself.[64] Furthermore, the severity of PMPH and requirement of analgesics was significantly less in the intrathecal catheter group.[64] A 2017 meta-analysis of over 1,000 patients in 13 studies showed a decreased risk for PMPH and need for an EBP in patients receiving an intrathecal catheter than a replacement epidural catheter group.[65]

A survey of North American obstetric anesthesiologists suggested that 75% would replace the catheter epidurally after an accidental dural puncture and 25% would place it intrathecally, even though 76% believed that leaving the intrathecal catheter in place for 24 h would reduce the incidence of PMPH.[66] The most important reason that an intrathecal catheter may not be placed following an inadvertent dural puncture is the safety of the intrathecal catheter. There is a high potential risk of misuse because of the lack of familiarity with intrathecal catheter dosage and usage. Although it may be beneficial to leave an intrathecal catheter in place for 24 h to reduce the incidence and severity of PMPH, it is often removed at most institutions because of safety concerns.

The use of a prophylactic epidural blood patch (PEBP) following an accidental dural puncture (ADP) is controversial because of the lack of strong literature. Some retrospective studies have shown that PEBP can decrease the severity, duration, or need for a therapeutic blood patch. A randomized, controlled, double-blinded study by Scavone et al. assessed the efficacy of PEBP in 64 parturients who had an unintentional dural puncture with a 17-gauge Tuohy.[67] After delivery, all patients had 20 mL of autologous blood drawn, which was either administered or not via a sham procedure. There was no difference between the two groups in the rate of headache, peak pain scores, or the need for a therapeutic blood patch, although the median duration of the headache was shorter in the PEBP group.[67] Other studies have shown that prophylactic epidural or intrathecal saline (typically 10cc) failed

to show a decreased need for a therapeutic blood patch.[68] An additional analysis of five studies involving 221 patients from the obstetric and surgical population showed insufficient evidence to recommend a PEBP.[69] Overall, PEBP does not appear to decrease the incidence of PMPH or eventual need for a therapeutic blood patch after an unintentional dural puncture.

Neuraxial morphine administration for prophylaxis following an unintentional dural puncture is controversial. In a randomized controlled trial by Al-Metwalli, a 3 mg dose of epidural morphine was administered immediately following an unintentional dural puncture and again at 24 h, demonstrating a decrease in PMPH from 48% to 12%.[70] However, a randomized, double-blind study by Peralta et al. showed that 150 μg of intrathecal morphine administered after delivery in patients with an ADP did not decrease the incidence or severity of PMPH discounting the prophylactic use of intrathecal morphine.[21] Furthermore, Brinser et al. demonstrated that both epidural and intrathecal administration of morphine following inadvertent dural puncture did not decrease the risk of PMPH.[71] It is important to recognize that neuraxial morphine is not without risks, including respiratory depression, nausea, vomiting, and itching. Caution must be taken when administering epidural morphine, especially after a dural puncture, since there may be translocation into the intrathecal space at unknown concentrations.

Recent attention has been given to the administration of cosyntropin, an adrenocorticotropic analog, following ADP for prophylaxis against PMPH. The mechanism by which adrenocorticotropic hormone (ACTH) could improve PMPH is not fully understood but is thought to be due to ACTH stimulation of aldosterone, which enhances salt and water retention, expands blood volume, and favors the closure of a dural tear. ACTH may also increase CSF production because of the active transport of sodium ions into CSF and possibly an increase in β-endorphins that modulate pain perception.[72] In a study of 95 patients who received 1 mg of cosyntropin following an ADP, the incidence of PMPH was halved from 69% with placebo to 33% with cosyntropin, and the need for an EBP was reduced from 30% to 11%.[73] Aside from rare hypersensitivity reactions, the risk associated with administering cosyntropin is low.

Treatment

Once the diagnosis of PMPH is established, treatment should be initiated. It is reasonable to start with conservative treatment options since 85% of PMPHs last less than five days and are rarely associated with significant morbidity.[74] Though recumbent bed rest may improve the symptoms of PMPH, a meta-analysis by Thoennissen et al. failed to show that recumbent bed rest reduced the incidence of PMPH more than immediate mobilization.[75] A survey of 1,024 anesthesiologists noted that aggressive hydration and bed rest were most commonly used as prophylactic measures to prevent PMPH following an inadvertent dural puncture. The same study concluded that the most frequently used treatment options were aggressive hydration, oral caffeine, oral non-opioid analgesics, and EBP procedures.[76] Though aggressive hydration is commonly recommended, there is no evidence to support it. While many physicians would encourage a patient to use conservative management for 24–48 h prior to recommending an EBP, some would argue that this can be particularly disabling if that patient is postoperative or in the postpartum period. Many pharmacologic agents have been studied for the treatment of PMPH. These include methylxanthines (caffeine and theophylline), serotonin agonists, anti-convulsant agents, adrenocorticotropic hormone, and corticosteroids.

Caffeine is a potent methylxanthine central nervous system stimulant that causes cerebral vasoconstriction. It is the most widely used pharmacologic treatment for PMPH. Caffeine can be administered at an oral dose of 300 mg or an intravenous dose of 500 mg caffeine sodium, equating to 250 mg caffeine.[77] While caffeine is considered safe in most patients, there have been reports of seizures associated with its use, and caution must be used in patients with a history of seizures. Careful use is also necessary for patients with hypertension, disorders of pregnancy-induced hypertension, anxiety, and arrhythmias. Sechzer showed that 75% of women receiving intravenous caffeine did have some temporary relief from their PMPH, supporting its use.[78] Jarvis et al. revealed that over 70% of women had improvement in their pain scores four h after intravenous caffeine infusion.[79] Additionally, 300 mg oral caffeine showed a decrease in pain scores at 4 h, but not at 24 h.[77] These studies ultimately show that the effects of caffeine are transient, and administration may need to be repeated. Caffeine administration does not appear to decrease the need for an eventual blood patch. Theophylline, another cerebral vasoconstrictor, has not been widely studied or supported by the literature.

Serotonin receptor agonists, such as sumatriptan, cause cerebral vasoconstriction and are often used to abort migraines. While there has been no evidence to support its use in the treatment of PMPH, a non-randomized study suggested that frovatriptan was useful in the prevention of PMPH in patients undergoing diagnostic lumbar punctures.[80] More studies are needed to evaluate serotonin receptor agonists in other patient populations.

Anti-convulsant agents such as gabapentin and pregabalin may be helpful in the treatment of PMPH. Pregabalin is a ligand of voltage-dependent calcium channels that reduces calcium influx at nerve terminals and attenuates the release of glutamate, substance P, and norepinephrine at the synapses. In a study of 40 patients experiencing a PMPH after spinal anesthesia or a lumbar puncture, half were assigned to receive 150 mg/day of oral pregabalin for three days, then 300 mg/day for two additional days, while the other half received placebo for the same length of time.[80] The pregabalin group had significantly lower pain scores after the second day of treatment and required less diclofenac for additional pain control.[81] An additional study of 42 patients showed that compared to the use of ergotamine and caffeine, patients taking gabapentin had significantly less pain, nausea, and vomiting following an ADP.[82] While these studies looking at pregabalin and gabapentin are promising, more studies are needed to demonstrate its efficacy.

Cortiosteroidogenic analogs (ACTH, cosyntropin, and tetracosactrin) have been studied for the treatment of PMPH. A prospective, randomized, double-blind study showed that a 1 mg single depot injection of the ACTH analog tetracosactrin did not decrease the severity of headache or the need for an EBP.[83] Further studies have shown that patients receiving an EBP following the development of PMPH had significant improvement in pain and function scores in patients receiving cosyntropin on day one of symptoms. However, cosyntropin showed similar efficacy to the blood patch group immediately after treatment and at days three and seven.[84] While these limited studies show some improvement with cosyntropin use, there is a question of its overall efficacy.
